Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication

To the Lisa Howes and Dougie MacIntires of our profession; those unnamed heroes whose never-ending desire to do what is right and good for animals and their owners—and their willingness to act on that desire—ensures that veterinary medicine remains among the most giving and most respected of professions.

Are not two sparrows sold for a cent? And yet not one of them will fall to the ground apart from your Father. But the very hairs of your head are all numbered. So do not fear; you are more valuable than many sparrows. Matthew: 10:29-31, New International Version

> A righteous man cares for the needs of his animal Prov: 12:10, New International Version

Acknowledgments

As with any textbook, there are many persons to thank for their contributing efforts. Included would be the contributing authors whose expertise was critical, and the editorial staff at Elsevier for their patience during this 10-year lapse in editions. Special thanks for direct help are extended to Mrs. Debbie Allgood who assisted with the task of typing and collating references. Harry Boothe (once again) read and re-read each chapter for editorial and content purposes, a fitting task for a detailed-oriented surgeon. More importantly, he constantly provided the encouragement to persevere in the completion of this second edition, despite cross-country moves, new jobs, children and the lesser important, but nonetheless never-ending distractions. I would woefully fail in my acknowledgments if I neglected to recognize my laboratory manager, Jameson Sofge, for his dayto-day willingness, flexibility, and readiness to help in any task that might reduce my distractions. I also thank the manager before him, Tiffany Finch, who accompanied me as I moved from Texas A&M University to Auburn and ensured the persistence of the Clinical Pharmacology Laboratory. The American College of Veterinary Clinical Pharmacology-including the newer, younger and remarkably motivated diplomates-are recognized for their continued efforts to expand the discipline and reveal its importance to the practice of veterinary medicine, whether to the veterinary patient or its owner. Finally and foremost, my thanks to our Lord for providing the motivation, materials, and support to finish what seemed to be a never-ending task.

Preface

Ten years have lapsed between the first and second editions of Small Animal Clinical Pharmacology and Therapeutics. An increased recognition of the importance and benefits of the human-companion animal bond by the profession has contributed to the remarkable changes that have occurred in the provision of health care to dogs and cats. Many private specialty practices now supersede academic veterinary teaching hospitals in terms of cases, clinicians, facilities, and diagnostic or therapeutic interventions. Corporate veterinary medicine has become an influential force in the provision of health care to dogs and cats. Electronic media and pharmacy services are simultaneously a blessing and a bane; discriminating between the two can be difficult. "Natural" products are increasingly perceived by consumers as the safer and preferred approach to prevention or treatment of diseases. The decade has seen a focus on public health in terms of antimicrobial resistance, bioterrorism, and translational medicine. Excitingly, an appreciation of the importance of naturally occurring diseases in dogs and cats as translational models for the same disease in humans has emerged in human and veterinary medicine, paving the way for integrated clinical research. The client's expectation of better care for their pet contributes to an urgency in the provision of quality care to our canine and feline patients. It has been accompanied by an explosion of information, scientific and otherwise, that must be used judiciously.

Among the goals of this second edition is the provision of information that will facilitate this judicious use. Pharmacology is directed physiology; as such, it is a dose away from toxicology (the dose *does* make the poison). With every therapeutic intervention we implement in our patient, our intent is to supersede signals that the patient's body has put in place to maintain normal physiology or correct pathophysiology. Each dose increases the risk of adversity as a result of therapeutic failure, medication error, or an adverse drug reaction. It is only with an accurate assessment of what we know, and a deep respect of and acknowledgement for what we don't know, that we should approach the use of drugs in our patients. Yet, today's veterinary curriculum often do not provide the education needed to promote judicious drug use, inadvertently promoting a more cavalier approach based on formulary-derived recipes rather than literature-based science. Today's pharmaceutical market provides fewer approved drugs, leading to increased use of drugs and preparations (e.g., compounded products) that are not approved for useand thus not scientifically studied-in the target species. Surveillance of adverse drug events or medication errors is paramount to safe drug use in the patient. Yet, the availability of such data to the veterinary profession is hampered by

limitations in practitioner reporting, user-friendly reporting sites, and the ability of regulatory or other agencies to analyze and to report the data to the profession in a timely and effective fashion. Accordingly, this edition continues to emphasize the basic principles of pharmacology, factors that impact plasma drug concentrations and the nuances of the individual patient that mandate an individualized approach to drug therapy. For newer drugs or therapeutic approaches in particular, the intent is to encourage judicious use through discussion of the physiology of the target organ, the pathophysiology of the target disease, and the clinical pharmacology of the drugs of interest. The second edition includes an increased emphasis on rational antimicrobial use, pharmacogenetics, and, in each chapter, expansion of tabular data that summarizes drug use and the addition of key points to emphasize major concepts.

Among the most time consuming efforts made toward improvement of the second edition is an assessment of the evidentiary basis for the therapeutic intent of each drug. This is manifested in part by a transition from a non-referenced to a reference-based textbook. Many time-honored therapeutic interventions are based on anecdotal evidence or standard of care expressed by experts; such information is difficult to reference. Indeed, dosing regimens offer an excellent example in that regimens for the same drug may vary widely. Multiple texts or formularies were consulted for dosing regimens provided in this table. For some dosing regimens, consensus could be determined; for others, an attempt was made to represent the diversity. The nature of scientific evidence is also diverse. For some therapeutic interventions, case reports are cited. For others, systematic reviews (often largely based on human data) are cited. However, the last decade has seen a marked increase in the report of clinical trials (not a sufficient number to allow meta-analyses), and an attempt has been made to identify and summarize the relevance of these studies to drug use in dogs or cats. Randomized, placebocontrolled (cross-over or parallel) blinded studies are the minimum criteria for a well-designed clinical trial attempting to demonstrate a treatment effect in sample populations. When possible, whether the study succeeded in minimizing bias and selecting a representative patient sample population is addressed. Among the more common assessments was the validity of statements regarding treatment effects. Most clinical trials are designed to minimize the risk of identifying a difference as real rather than from probability (a Type I error). However, failing to identify a true treatment effect (a Type II error) also is important, and it is this error (the power of the study) that is most negatively impacted by a small sample size. Readers and investigators tend to over-interpret

the failure of a study to demonstrate a significant difference. The assumption is made that such failure is evidence that a treatment does not have an effect, or worse, that treatments have equal effects. Accordingly, for many of the clinical trials reviewed in this text that did not demonstrate a treatment effect, the assessment includes a statement as to whether the investigators cited the power of the study to detect a significant difference. A related concern is the issue of *statistical* versus *clinical* differences among treatment groups. The commonly chosen p value of 0.05 is not sacrosanct; as clinicians, a p value of 0.1 (the probability that the different response between groups would occur despite no treatment effect is $\leq 10\%$ rather than $\leq 5\%$) may be just as relevant to our patient. On the other

hand, even a statistical difference may not justify a therapeutic intervention if the magnitude of differential response between the treatment groups is not clinically relevant.

This text focuses on evidenced-based therapeutic interventions. Among the limitations of texts such as these is the risk that important, clinically relevant information was potentially missed despite exhaustive data base reviews. Nonetheless, it is with pleasure, humility, and honor that I offer the updated second version of this text. My hope is that it provides helpful evidence-based assessment of therapeutic interventions that can be provided to the canine and feline patient through the practitioner.

OTHER CONSIDERATIONS

Dosing Based on Allometric Scaling and Body Surface Area Routes of Administration Oral Administration Parenteral Administration

The intent of drug therapy is to induce a desired pharmacologic response for a sufficiently long period of time while preventing adverse drug events (see Chapter 4). For most drugs the magnitude of pharmacologic response is proportionately related to the (log of) drug concentration at the tissue (receptor) site (Figure 1-1). Understanding the relationship among dose, drug concentration, and response requires an understanding of the pharmacodynamics (i.e., the science of drug action), or the physiologic and biochemical effects of a drug and their relationship to the drug's mechanism of actions. Most commonly, the response is measured in the animal but may also occur in a microbe or parasite.¹ Pharmacodynamics may be studied in vitro (isolated cells or tissue), ex vivo (isolated cells or tissues after exposure to the drug in the intact animal), or in vivo (exposure and study occurs in the whole animal). Pharmacodynamics ultimately should be integrated with the science of pharmacokinetics, that is drug movements through the body.

DOSE-RESPONSE RELATIONSHIP

Pharmacodynamic responses occur at many levels, ranging from single molecules to whole animals. Drugs induce their responses through a number of mechanisms, most of which involve direct or indirect interactions with cell macromolecules and generally proteins. Direct interactions with nonprotein molecules are less common, but examples include nucleic acids (e.g., cancer chemotherapeutic agents), metal chelating drugs, or antacids used to chemically neutralize gastric acid. Drug responses more commonly reflect the interaction of the drug, acting as a **ligand**, with **receptors** (Figure 1-2). A receptor most commonly is a large protein macromolecule (e.g., structural, enzymatic, carrier, or ion channel proteins) responsible for cellular signaling. Receptors may be located on or in the cell membrane, in the cytosol, or within an intracellular structure (i.e., nucleus). Physiologic functions of the body generally are regulated by multiple receptor-mediated mechanisms, each responding to different molecular stimuli. Examples of target receptor categories include hormones, neuromodulatory receptors, and neurotransmitters.

Interaction between a drug and its receptor generally results in activation (either directly or indirectly) of cellular biochemical processes (e.g., ion conductance, protein phosphorylation, or DNA transcription) by way of a transduction pathway that ultimately brings about the pharmacologic effect.¹ A time lag may be associated with transduction (Figure 1-2). Activation reflects the drug's mechanism of action, whereas the sequelae of the stimulation at the molecular, cellular, or tissue level reflect the drug's pharmacodynamic effects. Secondary intracellular messenger molecules are often activated by drug-receptor interaction; they subsequently set in motion a cascade of events that eventually causes the response. Among the most common receptors are transmembrane receptors linked to guanosine triphosphate-binding proteins (G proteins). These then activate second messenger systems such as adenylyl cyclase (e.g., beta-adrenoceptors), the cytosolic

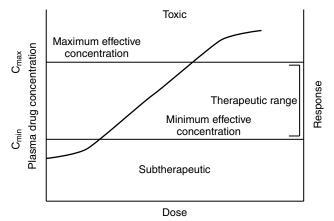

Figure 1-1 The relationship among log plasma or tissue drug concentration and dose and response generally can be considered linear within the concentrations used therapeutically. Ideally, plasma drug concentration will fall within the therapeutic range (between C_{max} and C_{min}) throughout most of the dosing interval. A representative concentration versus response curve generally yields a sigmoidal shape. At lower (20% response) and higher concentrations (>80% response), larger dose increases are required to stimulate a response. Therapeutic doses should target the linear portion of the curve, between 20% and 80% of the maximal effect. Above that point increasingly larger doses again are needed to generate a change in response, and the risk of toxicity increases, although the dosing interval may be prolonged for safe drugs.

inositol triphosphate pathway (e.g., alpha-adrenoceptors), or membrane-bound diacylglycerol (DAG).

Two properties describe drug-receptor interactions: affinity, or the capacity of a drug to bind to a receptor, and intrinsic efficacy (or activity), or the capacity of a drug to activate or inactivate a receptor. The latter is a complex relationship dependent on drug concentration, receptor activation, and cellular response. Affinity is usually mathematically defined as the reciprocal of the dissociation constant of the drug for the receptor.¹ A receptor often is characterized by multiple types (e.g., alpha- and beta-adrenergics; mu, kappa, and delta opioid receptors) and subtypes (e.g., alpha 1 and 2, beta 1, 2, or 3; mu 1 or 2). The selectivity of a drug action generally reflects the specificity of the drug for the target receptor binding. Drugs often target multiple receptors, although interactions may be concentration dependent or may result in blocking rather than activating specific receptors. Receptor characteristics (e.g., numbers and affinities) are influenced by both external and intracellular conditions. Tissues vary in receptor numbers and subtypes; indeed, proper physiologic responses are dependent on this variability. The relationship between a drug and pharmacologic response was at one time assumed to be directly proportional to the number of receptors occupied by the drug, with a maximal response reflecting 100% occupancy and activation (i.e., the drug receptor theory). However, the interactions are much more complex than that described by a simple linear relationship. Different kinetic relationships (linear, log-linear,

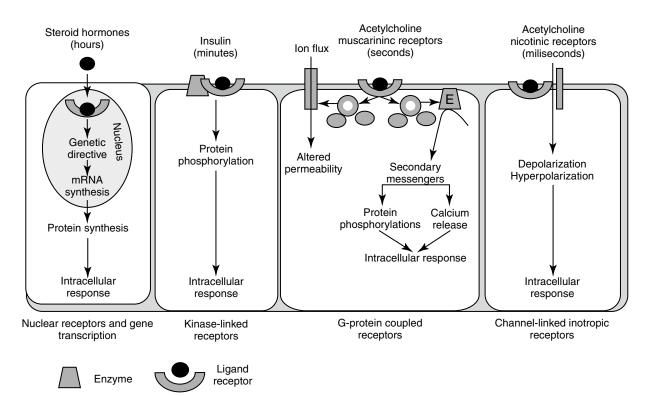

Figure 1-2 Examples of drug-receptor interactions at the cell membrane, cytosol or organelle site, and the secondary amplification cascades that ultimately result in the pharmacodynamic response.

polynomial), multiple activation states, (active, inactive, resting), cell amplification of the drug-receptor signal, and existence of spare receptors are some examples of the complexities that determine the relationship between drug concentration and response. The scientific description, examination, and ultimate prediction of drug-receptor interactions are often accomplished by generation of dose-response curves; the graphic representation most generally is represented by a sigmoidal curve (Figure 1-3; see also Fig. 1-1). The curve indicates that increasing drug concentration at the receptor site increases the number of bound receptors and thus drug effect. If concentration-response curves are plotted on a logarithmic (x) axis, the portion of the curve that lies between 20% and 80% of the maximal response is generally linear. This is the portion most relevant to therapeutic concentrations and thus encompasses the therapeutic range. Increasing a drug dose within this range generally results in a proportional increase in response. However, once the 80% mark is passed, as receptors become saturated, a much larger increase in concentration (dose) is necessary to increase response. Although this may increase the risk of adverse effects, for drugs which are safe, it may also prolong the dosing interval since the response will not change much as concentrations decline to the 80% level. At that point, drug concentration declines exponentially (generally first order), and response will also decline log-linearly with time (e.g., 50% decline with one half-life). Note that for some drugs (i.e., drugs that irreversibly interact with receptors, drugs with active metabolites,), response may not be related to plasma (tissue) drug concentrations.

The interaction of a drug with a receptor is similar to that between a substrate binding to the active site of an enzyme. As such, similar equations and parameters are used to describe the relationship between dose and response. The **effective dose** (ED) is the quantity of administered drug that will produce the 3

(desired) effects for which it is administered. The median effective dose (ED_{50}) is the dose that produces the desired effect in 50% of a population. However, dose is a less accurate descriptor of what is happening at the receptor than is effective concentration (EC). The affinity of the drug for the receptor is described by the (effective concentration) EC_{50} , the drug concentration that yields 50% of the maximal response (see Figure 1-3, A). The different actions of a drug, such as therapeutic and adverse effects, are often due to the drug binding to different receptors with different EC_{50} values. Ideally, the EC_{50} for an adverse event is higher than that of a therapeutic response. The ratio of adverse event EC_{50} to the therapeutic effect EC_{50} is the therapeutic index and provides some indication of drug safety in that the larger the index, the safer the drug. Efficacy and potency are two terms used to describe the relationship among drug, concentration, and response. Efficacy refers to the maximum effect (E_{max}) a drug can have (e = 1 indicates a full response), whereas **potency** is a comparative term that describes the concentration of two drugs necessary to induce the same magnitude of response. Generally, plots describing efficacy and potency are based on log 10 concentration versus percent response curve. (see Figure1-3, A). Drugs are considered equal in efficacy if they can cause the same magnitude of response; the more potent drug will cause an EC_{50} at a lower concentration. As such, the dose of a less potent drug may simply need to be increased to achieve the same effect of the more potent drug.

Drug-receptor interactions do not always yield the maximal response. Receptor interaction with a drug that acts as an **agonist** (generally, a structural analog of the targeted receptor) results in some level of activation. The occupation theory of drug-receptor interaction indicates that the magnitude of the response produced by an agonist is directly proportional to the number of receptors occupied.¹ Pharmacodynamic antagonism occurs when one drug inhibits the agonistic effects of another

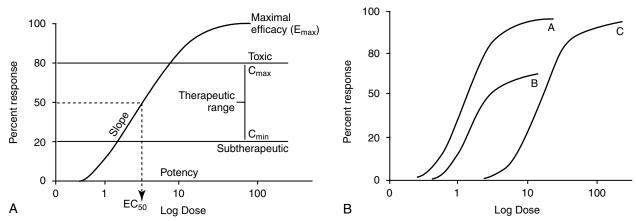

Figure 1-3 Drugs that are equally effective will cause the maximum response but may not be equally potent, i.e., they may not have the same relationship between dose (concentration) and response (**A**). Because drugs A and C result in the same maximum response (E_{max}), they are equally effective, whereas drug B is less effective (**B**). However, drug B is more potent than drug C, and drug A is more potent than both because the dose or concentration of A necessary to achieve a 50% maximum response (ED_{50} or EC_{50}) is less than that for B or C. A similar set of curves can be used to describe competitive and noncompetitive inhibition. A drug that noncompetitively inhibits another drug will prevent it from reaching its maximum effect, and thus decrease the E_{max} (plot B, with noncompetitive drug present, plot A without it). In contrast, a drug that competitively inhibits another drug will not alter its E_{max} , but will increase the concentration of the drug necessary to achieve it (plot C represents a drug with a competitor) present; plot A, drug without competitor).

through actions at the same pathway, although this does not have to occur at the receptor. Like an agonist, an antagonist interacts selectively with receptors, but it lacks intrinsic efficacy and thus is able to block or reduce the action of an agonist at the receptor. Drugs that target opioid receptors (at least three types, with mu receptors having at least two subtypes) offer an example of the different sequelae of drug-receptor interactions. The "full" agonist (e.g., fentanyl) results in the maximal effect (e.g., at mu receptors). A drug that acts as a "reversal" agent would reduce the effect of an exogenous agonist (e.g., naloxone reverses the effects of fentanyl) whereas a "blocking" drug antagonizes endogenous agonists (e.g., catecholamines targeted by beta- or alpha-blockers). Drugs might have dual agonist and antagonist properties at the same receptor (although to variable degrees in different tissues). Because the response is not maximal, they are referred to as partial (low-efficacy) agonists; buprenorphine is a partial agonist opioid at mu receptors. Drugs might also act as an agonist at some receptors and an antagonist at other receptors. Butorphanol is a mixed agonist/ antagonist (at kappa and mu receptors, respectively).

The relationship between an antagonist and receptor can be described as competitive or noncompetitive. Competition between compounds occurs at the same receptors and can be reversible or irreversible. Reversible antagonists easily dissociate from the receptor, whereas irreversible antagonists form a stable chemical bond with the receptor (e.g., in alkylation). If the interaction is reversible, an agonist present at sufficiently high concentrations can displace an antagonist. As such, reversal of the agonist or the response may require a higher dose (or a repeat dose) of the antagonist (see Figure 1-3, B). In contrast, an irreversible antagonist cannot be displaced from the receptor. As such, the cellular response can not occur until the receptor is replaced (duration dependent on rate of receptor turnover) and any remaining unbound antagonist has been removed from the body. The presence of a reversible competitive inhibitor will decrease the potency of a drug because a higher concentration will be necessary to induce the same pharmacologic response.

In contrast, the presence of an irreversible competitive inhibitor will decrease the efficacy of the drug by preventing the maximal possible response. In contrast to competitive antagonists, noncompetitive antagonists interact with receptors at a site different from the agonist-receptor interaction site. The interaction often involves a site in the transduction pathway between the receptor and the pharmacodynamic response.¹ Noncompetitive interactions are generally, but not always, reversible. Note that three other types of antagonism, in addition to pharmacodynamic, can occur between drugs: chemical antagonism results from a direct chemical interaction between two drugs (i.e., a weak acid and weak base), physiologic antagonism occurs when two drugs act in the same physiologic system but act on different receptors or pathways, and pharmacokinetic antagonism occurs when one drug alters the response to another drug through changes in disposition (see Chapter 2).

Pharmacodynamic responses are also influenced by the presence of drugs beyond activation. Receptor upregulation and downregulation is an adaptive mechanism that may affect clinical response. Sequelae may include but are not limited to tachyphylaxis, a rapidly decreasing response to a drug after administration of only a few doses; tolerance, a decreasing response to repeated constant doses of a drug that will necessitate a concentration and thus dose increase, if the response is to be maintained; and withdrawal, the syndrome of often painful physical and psychological symptoms that occurs when an addictive substance is discontinued.

The pharmacodynamic response to a drug ideally will occur with any given dose within a therapeutic range. The therapeutic range provides a target for the dosing regimen. It consists of a minimum effective plasma drug concentration (PDC) (**trough** or C_{min}), below which therapeutic failure is likely to occur, and a maximum effective PDC (peak or C_{max}), above which a type A adverse reaction (see Chapter 4) is more likely to occur (see Figures 1-1 and 1-3).^{2,3} Dosing regimens are composed of a dose (e.g., mg/kg) and an interval (e.g., every 8 hours) for each route. The dose of the regimen generally is designed to achieve and maintain PDC within the therapeutic range throughout most of the dosing interval. Thus targeted peak PDCs often approximate but do not exceed Cmax, whereas trough concentrations approximate but generally do not drop below C_{min}. However, a therapeutic range is a population statistic that describes the concentrations between which most animals will exhibit the (desired) pharmacodynamic response; each animal will respond (therapeutically or adversely) at a different point in the range. Although most animals will respond at some point within the range (the majority in the middle of the range), a small percentage will respond above or below the range. Therapeutic drug monitoring (see Chapter 5) is used to establish where in the therapeutic range the individual animal will respond; in other words, it will establish the patient's therapeutic range. Ideally, studies that determine the dosing regimen in a target species reflect integration of pharmacokinetic and pharmacodynamic studies in that species.⁴ Two primary components of a dosing regimen are dose interval. In general, dose, which ultimately determines PDC, is influenced primarily by the tissue that dilutes the drug (i.e., volume of distribution), whereas interval is influenced by elimination of the drug (i.e., half-life). Unfortunately, studies that describe the time course of a drug in animals are limited and, when available, generally focus on healthy rather than diseased animals. As such, clinicians are faced with individualizing dosing regimens in the patient according to the principles of clinical pharmacologythat is, the study of drugs⁵ and their behavior (disposition)⁶ in animals.

DETERMINANTS OF DRUG DISPOSITION

Mechanisms of Drug Movement

Drugs move through the body by two major mechanisms: bulk flow and passive diffusion. The cardiovascular system is the primary determinant of bulk flow; glomerular filtration is one of the more important specific examples. The chemical nature of the drug does not affect bulk flow. Most drugs are characterized by a molecular weight (MW) of 350 or less, ensuring movement of unbound drug between endothelial

5

cells despite the presence of protein filters in the endothelial gaps. Exceptions are made for those tissues whose capillaries are not fenestrated, because endothelial cell junctions are tight. Drug movement for these tissues must occur across cell membranes. Drugs can move through cells directly through the lipid layers of the cell (e.g., passive diffusion), through aqueous pores formed by aquaporins (proteins) that span the width of the membrane, by combination with transmembrane carrier proteins, and by pinocytosis. Of these, transmembrane (passive) diffusion and carrier-mediated movement are most important.

KEY POINT 1-1 Passive diffusion is the most common method by which compounds move through the body. It is most influenced by the concentration gradient of diffusible drug across the membrane to be diffused.

Passive diffusion occurs independent of any other mechanism of drug movement and requires no energy. Passive diffusion through cell membranes depends on a number of factors. The single most important factor is concentration of diffusible drug, which is most easily manipulated by increasing the dose. Additionally, host and drug factors will also influence the concentration of diffusible drug. Host determinants of passive diffusion are subject to change and include thickness of the membrane to be traversed (inversely proportional; e.g., edematous compared with normal tissues), surface area (directly proportional; e.g., small intestine versus stomach), environmental pH (see ionization), and temperature (directly proportional). In contrast, drug characteristics influencing passive diffusion are not subject to change, and thus cannot be easily manipulated. They largely influence lipid solubility of the drug.^{2,3} Lipid solubility is, in turn, influenced by a number of drug characteristics, including the inherent chemical structure of a drug, such as molecular weight (smaller molecules diffuse more easily) and partition coefficient (PC). The PC is an experimental measure of relative lipid solubility as influenced by the chemical structure of the drug. The ratio is determined by mixing the drug in a combination of water and an organic solvent (e.g., octanyl). The difference in drug concentration between the two solvents once mixing is complete reflects, in part, the inherent lipid versus water solubility of the drug. Measurement of the concentration of drug in each solvent generates an octanyl:water coefficient or PC, which might be useful for predicting the ability of a drug to pass through cell membranes. A ratio greater than 1 suggests greater distribution to the organic phase, indicating lipid solubility. For example, in regards to providing analgesia, fentanyl (PC of 717) is both more potent and more rapid acting, but shorter in duration, compared to morphine (PC of 0.7), presumably because it can move more rapidly through the blood-brain barrier (Figure 1-4). Benzene rings, carbon double bonds and methyl groups tend to make a drug more lipid soluble, whereas polar compounds such as amine or hydroxyl groups contribute to drug-water solubility.

In addition to lipid solubility, drug pKa and environmental (host) pH will also influence distribution of drug into body **KEY POINT 1-2** A drug will be more nonionized and more likely to diffuse into tissues when present in a "like" environment—that is, acidic drugs in an acidic environment.

compartments. The Henderson-Hasselbalch equation describes the pH partition theory (Figure 1-5). Assuming a drug is sufficiently lipid soluble to cross cell membranes, a steady-state equilibrium will be reached when the amount of drug moving from one area equals the amount moving in the opposite direction and the concentration of diffusible drug will be equivalent on either side of a membrane. However, in its ionized form, a drug is not diffusible, cannot traverse lipid membranes, and becomes trapped and thus "partitioned" by the pH in its surrounding environment. Although the concentration of the nonionized (diffusible) portion on each side of the membrane will be equal (assuming a steady state equilibrium is reached), the total concentration on either side may differ if the pH on either side of the membrane is different (Figure 1-5). The difference depends on the pKa of the drug and the environmental pH on either side of the membrane. Drugs will be trapped by ionization when present in an "unlike" environment. Drug pKa (the pH at which the drug is 50% ionized and 50% nonionized; ratio 1:1), and its behavior as a weak acid or base defines the degree of ionization. For a weak acid, as local pH decreases (becoming more "like"), the nonionized and thus diffusible proportion will increase. In contrast, for a weak acid, an increase in pH ("unlike") will increase the ionized proportion. The opposite is true for a weak base: increasing pH will increase the nonionized or diffusible proportion, whereas a pH decrease will increase the ionized, nondiffusible portion (Box 1-1).

Although less common, drug movements other than passive diffusion and bulk flow influence PDC. Carrier-mediated transport includes both facilitated diffusion (nonactive) or active transport. An example important transport system is the **P-glycoprotein** system, an MDR-1 gene product best known for imparting multidrug resistance to cancer cells (and to microbes).⁷ However, this transport system occurs in several tissues in the body, including renal tubular brush borders and bile canniculi (responsible for drug excretion from the body); the brain or other "sanctuaries" (responsible for keeping exogenous componds out of critical tissues); characterized by a bloodtissue barrier; and in portals of entry, including the lower gastrointestinal tract (reducing oral drug bioavailability).⁸ Pinocytosis is a rare drug movement exemplified by the uptake of vitamin B₁₂ in the ileum and aminoglycosides by renal tubular cells.

Plasma Drug Concentrations

Although response to a drug reflects concentrations at the tissue (or cellular level), because tissue samples cannot be collected easily, drug concentrations at the tissue site are approximated by measuring PDCs. After administration of a fixed dose of a drug, several drug movements act in concert to determine PDC (Figure 1-6).^{2,3,6,9} These movements largely, but not exclusively, depend on passive diffusion of the drug and include absorption (A) from the site of administration to

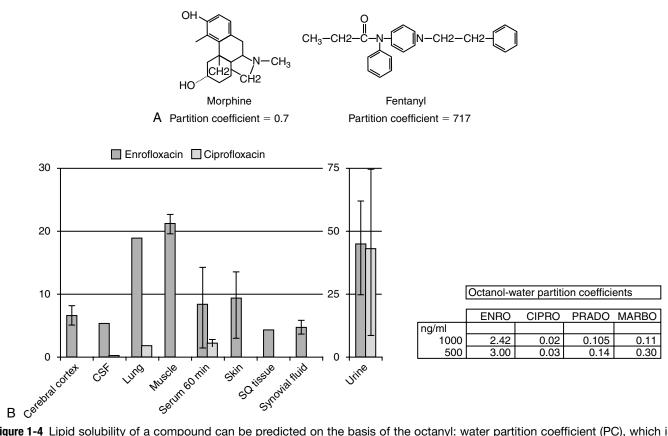

Figure 1-4 Lipid solubility of a compound can be predicted on the basis of the octanyl: water partition coefficient (PC), which in turn depends on chemical structure. **A**, Morphine and fentanyl both reach the central nervous system in sufficient quantity to provide analgesia. However, fentanyl is much more lipid soluble, as is supported by its octanyl:water partition coefficient of 717 compared with that of morphine (0.7). Fentanyl is much more potent and more rapid acting, but it also has a shorter duration of effect. **B**, The PC among the fluorinated quinolones suggests that enrofloxacin would have better tissue distribution than ciprofloxacin. This is supported by the relative concentrations of enrofloxacin versus ciprofloxacin in serum compared with tissues 60 minutes after administration of 20 mg/kg intravenous enrofloxacin in dogs. Although PC is an important determinant of lipid solubility, it may vary with surrounding pH. (ENRO, enrofloxacin; CIPRO, ciprofloxacin; PRADO, pradofloxacin; MARBO, marbofloxacin.)

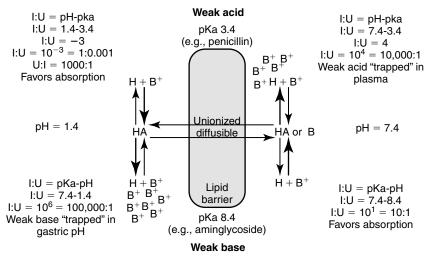

Figure 1-5 The Henderson-Hasselbalch equation and the pH partition hypothesis predict the behavior of an ionizable compound on the basis of its pKa and the ambient pH. A weak base (bottom) will be predominantly ionized in an acidic environment (i.e., gastric pH), and thus is likely to be trapped. It is less likely to be ionized in a higher pH and thus is more diffusible (i.e., plasma). In contrast, a weak acid (top) is likely to be nonionized in the acidic environment and thus is more likely than the weak base to move across the lipid membrane and be absorbed. However, in the plasma the higher pH will increase the proportion of ionized drug, limiting its diffusion from plasma into cells. (see Box 1-1.)

Box 1-1

The pH Partition Hypothesis

The pH partition hypothesis is the ratio of ionized:nonionized drug and is based on pH (of the environment) and pKa (of the drug) (see Figure 1-5). The proportion of ionized to unionized drug is described by the Henderson-Hasselbalch equation. For acids, the ratio (ionized:nonionized) is 10ⁿ, and for a weak base the ratio is 10⁻ⁿ. The ratio of the ionized:nonionized (I:U) drug can be useful for predicting movement between tissues. A drug is considered significantly ionized if the ratio (I:U) is greater than 100. Thus for a weak acid the drug is considered ionized in an environmental pH that is 2 or more higher than its $pK_a (pH - pKa = 2; 10^n = 10^2 = 100 I : 1 U)$ A weak base is considered ionized if the pH is or 2 or more below its pK_{a} . (pH – pKa = -2; 10⁻ⁿ = 10⁻⁽⁻²⁾ = 10² = 100). Ideally, for drug movement to occur by passive diffusion, the pH will be no more than 2 pH units above the pKa for the acid and no more than 2 pH units below the pKa for the base. The gastrointestinal tract (pH 6.0) offers an example of how pH partition influences drug movement. Orally administered aminoglycosides (weak bases with pKa approximating 7 to 9) are ionized at a ratio of approximately 1000:1 $(6 - 9 = -3, 10^{-n} = 10^{-(-3)}, = 10^3 = 1000:1$ [I:U]. Thus there is only one nonionized or diffusible ion for each 1000 ionized amikacin

molecules. The ionized molecules will be trapped and will not be absorbed, limiting absorption of this water-soluble drug. In contrast, the proportion of the ionized weak acid penicillin (pKa about 2) would be 0.0001:1 $(2 - 6=10^{-4})$; for every ionized molecule, 10,000 molecules would be nonionized (the inverse of 0.0001:1). As such, if other factors are supportive (e.g., the drug is not destroyed by the gastric acidity), penicillin should be well absorbed from the gastrointestinal tract. The urine is another site where pH partition may influence drug movement. Penicillin located in urine with a pH of 7 would be ionized at a ratio of 10,000:1 (10⁵), whereas the aminoglycoside would be ionized at a ratio of only 100:1. If the urine pH was 8, the ratio of I:U would be 10 for the aminoglycoside, which is not considered significant to preclude drug movement. In either pH the aminoglycoside would be more likely than the penicillin to be passively resorbed and to penetrate microbial membranes. Drug that is partitioned by ionization acts as a reservoir, replacing nonionized drug that may leave the other side of the membrane in an open system. Eventually, assuming the nonionized side remains "open," both sides of the membrane will eventually be depleted of drug.

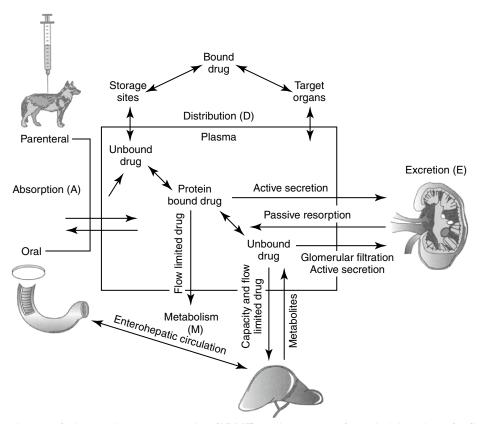

Figure 1-6 The determinants of plasma drug concentration (ADME) act in concert after administration of a fixed dose. The drug must first be absorbed, most commonly from the gastrointestinal tract (Absorption–A). Orally administered drug passes through the liver before reaching systemic circulation (not shown). Once in circulation, drug not bound to plasma proteins (free drug) is distributed into tissues (Distribution–D), where it can be bound to tissues or distributed back to circulation. Elimination of the drug from the body occurs by hepatic metabolism (Metabolism–M) and renal or biliary excretion (Excretion–E) of the drug or its metabolites. Drugs that are protein bound will not be filtered by the kidney or metabolized by the liver unless actively secreted in the kidneys and or characterized by flow-limitation in the liver. Excreted drugs can be passively reabsorbed by the kidney or following biliary excretion after deconjugation in the gastrointestinal drug (enterohepatic circulation). (Adapted from Ettinger SJ, Feldman EF, editors: *Textbook of veterinary internal medicine*, ed 5, Philadelphia, 2000, Saunders.)

systemic circulation, defined as the major vessels and wellperfused organs; distribution (D) of the drug from systemic circulation to tissues (target and nontarget) and back again; and elimination of the drug from the body by metabolism (M) and excretion (E). These drug movements are dynamic, occurring simultaneously, and their net effects determine PDC at any time during the dosing interval after administration of a fixed dose. Because passive diffusion is the major determinant of each drug movement, each in turn is influenced by a number of other factors. The impact of these factors on the drug movements and the time course of drug in the body as a result of these movements can be described or modeled mathematically, leading to the study of pharmacokinetics. Each drug movement is influenced by host and drug factors that may affect therapeutic success (see Chapter 2).

KEY POINT 1-3 Plasma drug concentrations at any point in time after administration of a dose reflect the combined effects of four dynamic drug movements: absorption, distribution, metabolism, and excretion.

Absorption

Bioavailability, extent, and rate of absorption. The percentage of an administered dose of drug that reaches systemic circulation and is thus able to induce a response is referred to as bioavailability (F).^{2,3,9,10} Bioavailability (see Pharmacokinetics section) is used to predict drug efficacy after different routes of administration or administration of different formulations of the same drug. Absolute bioavailability or extent of absorption is the actual bioavailability and can be determined only by comparing the appearance of the drug preparation to that after intravenous administration of the drug. In contrast, relative bioavailability of two different preparations or by two routes of administration of the same drug can be evaluated by comparing their area under the curve (AUC).¹⁰ The area under the concentration versus time curve (AUC) describes the entire time course of the drug. Because its magnitude depends on maximum drug concentration and rate of elimination, it is influenced by several drug movements, including absorption. The AUC is used to calculate several other pharmacokinetic parameters; clinically, it is useful for determining response to certain drugs, particularly antimicrobials.^{11,12}

KEY POINT 1-4 Absolute bioavailability of a drug preparation can be determined only by comparing its appearance to 100% availability, which occurs only after intravenous administration.

The greater the bioavailability, or extent of absorption of a drug, the greater the anticipated pharmacologic response. However, pharmacologic response of two different drug preparations or the same drug given by different routes may vary even if equally bioavailable; two products are considered bioequivalent only if neither their rate nor their extent of absorption differ. Differences in the rate of absorption (e.g., absorption half-life [see Pharmacokinetics section]) may cause different time to onset, as well as lower peak concentrations, although the duration of effect may be longer.

Factors impacting drug absorption are most profound for orally administered drugs. Factors impacting other routes are addressed under "Routes of Administration."

Oral absorption. Most orally administered drugs reach systemic circulation after absorption from the small intestine. The rate and extent of drug absorption in the gastrointestinal tract depend on a number of host factors, most of which affect passive diffusion (Figure 1-7).⁹ These include gastrointestinal pH, which favors absorption of weak acids; surface area, which favors absorption in the small intestine compared with the stomach; motility, which mixes the drug, the concentration of diffusible drug at the site of movement; permeability and thickness of the mucosal epithelium; and intestinal blood flow, which maintains the concentration gradient across the mucosal epithelium. The latter factor of blood flow is important only for drugs capable of rapid transfer across the epithelium.

In general, the intestinal surface area is so large that changes seldom are of sufficient magnitude to effect absorption (see Chapter 2). However, changing particle size of the drug preparation may cause differences in the rate or extent of absorption and markedly different bioequivalences. Drug preparations often are specifically designed to alter rates of absorption by manipulation of particle size.

Bioavailability of an orally administered drug also is influenced by factors after it passes into the gastrointestinal epithelium. Bioavailability is decreased if the drug is metabolized by intestinal epithelial cells, microbes, or by the liver. Additionally, enterocytes can decrease oral bioavailability of a drug by causing its efflux from enterocytes, in part because of the presence of active transport proteins located on enterocyte cell membranes.¹³

Transport membranes may act alone or in concert with one another; for some drugs, one transporter may predominate, but for others, none may. Identifying the role of each transporter protein is complicated and difficult to study. Several families have been identified. (1) Transporters located on the apical cell membrane include the family of organic anion-transporting polypeptides (OATPs); these proteins are also located in the liver, kidney, and brain and influence distribution and excretion. These proteins transport a large number of amphipathic drugs (e.g., digoxin, steroids) and endogenous compounds (e.g., steroids, thyroid hormones). (2) Proton-dependent oligopeptide transporters (POTs), driven by a proton gradient, are present in the kidney, brain, and the gastrointestinal tract, where their activity appears to increase from the duodenum to the ileum. Among the drugs influenced by these transporters are beta-lactam antimicrobials, ACE-inhibitors, and prodrugs of selected antivirals. (3) The family of ATP-binding cassette (ABC) superfamily of transporters includes the P-glycoproteins. These include multidrug resistance protein (MRP1) and a multispecific organic anion transporter (MOAT) also located in other tissues. An efflux transporter, P-glycoprotein is characterized by broad substrate specificity. Because it is abundant in enterocytes, it can profoundly decrease the oral bioavailability

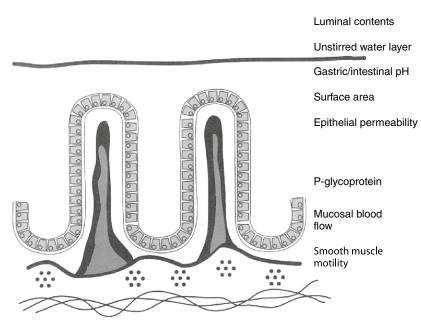

Figure 1-7 The determinants of oral drug absorption include local pH, the surface area to which the dissolved drug is presented, epithelial permeability, mucosal blood flow (particularly for drugs very rapidly absorbed), and smooth muscle motility. The drug must be diffusible, and thus must be in the dissolved state (to establish a concentration gradient). Most drugs are absorbed in the small intestine because of its larger surface area. The drug transport system, P-glycoprotein, decreases bioavailability through drug efflux from the intestinal epithelial cell.

of target drugs. It is associated and shares substrate specificity with selected cytochrome-P450 enzymes (most notably, CYP3A), which decreases drug that is not effluxed from the cell by the transporter (see Chapter 2).¹³

Hepatic metabolism also can profoundly affect the PDC of an orally administered drug. After gastrointestinal absorption, drugs enter the portal vein and then the liver (Figure 1-8). As such, an orally administered drug is exposed to hepatocytes before it enters the systemic circulation. Drugs characterized by a high hepatic extraction ratio (>70% extracted) are almost completely removed from the blood by hepatocytes during the first passage of blood through the liver. As a result, after oral administration, drugs that undergo first-pass metabolism may not reach systemic circulation in concentrations sufficiently high to cause a pharmacologic response. Despite good to excellent oral absorption, such drugs are characterized by poor bioavailability and are administered either parenterally (e.g., lidocaine) or in oral doses high enough to compensate for first-pass metabolism by the liver. Examples of drugs that are orally administered yet undergo significant hepatic firstpass metabolism include selected cardiac drugs (e.g., propranolol and other beta-blockers, diltiazem in some species, hydralazine, nitroglycerin), diazepam, and opioid analgesics. The negative effects of first-pass metabolism on pharmacologic response may be reduced if the drug metabolites (e.g., propranolol and diazepam) are also pharmacologically active.

Distribution

Once a drug reaches the systemic circulation, it must be distributed from the central (blood) compartment to peripheral tissues to impart a pharmacologic effect. Further, drug

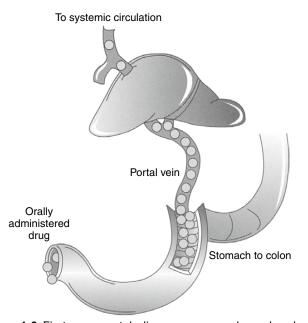

Figure 1-8 First-pass metabolism occurs as drug absorbed from the gastrointestinal tract (from the stomach to the lower colon) enters the portal vein and flows to the liver. Once in the liver, drugs that are characterized by a high extraction are removed rapidly from the blood before entering systemic circulation. Plasma concentrations of such drugs may not reach therapeutic concentrations unless the dose is increased to compensate for first-pass metabolism. The amount of drug removed on the first pass from the liver differs among species and ages and according to the presence or absence of disease. First-pass metabolism can be avoided by transmucosal absorption in the oral cavity, or rectal absorption.

in tissues will be distributed back into plasma so that it can be eliminated. The major factors that determine drug distribution to and from tissues include drug lipid solubility and its ability to penetrate cell membranes, the degree to which the drug is bound to plasma or tissue proteins, and regional (organ) blood flow. The presence of transport proteins (p-glycoprotein, OATPs, and POTs) also influence drug distribution, particularly in "sanctuary" tissues characterized by tissueblood barriers (e.g., brain, cerebrospinal fluid, placenta).¹³

Binding of lipid-soluble drugs to plasma proteins facilitates their circulation. Drug binding to proteins may influence several determinants of drug movement, including distribution.¹⁴ Weakly acidic drugs tend to bind to albumin, whereas weakly basic drugs tend to bind to α_1 -glycoproteins.¹⁵ The large molecular weight of protein precludes movement of bound drug from circulation into tissues. As such, the protein-bound drug is not pharmacologically active; cannot be filtered in the normal glomerulus, and for some drugs (i.e., capacity-limited, discussed later), cannot reach drug metabolizing enzymes in the hepatocyte (or other organ). Presumably, drugs that are highly protein bound may be more likely to be involved in adverse reactions early in the dosing regimen because displacement of only a small proportion of drug from the protein (e.g., due to competition with other protein-bound drugs or hypoalbuminemia) can increase the total amount of free, active drug (Figure 1-9).^{2,3} A drug is considered significantly

(highly) protein bound if 80% or more bound; for a drug bound less than 80%, displacing enough drug to significantly increase the unbound proportion is difficult. For example, displacement of only 1% of a drug that is 99% protein bound (e.g., nonsteroidal antiinflammatories) can double the concentration of pharmacologically active drug. In contrast, to double the pharmacologically active form of a drug that is only 80% bound (i.e., going from 20% to 40% unbound) would require displacement of 25% of the bound drug, which is clinically difficult to achieve. Yet even with highly protein-bound drugs, the clinical relevance of displacement and increased concentrations of unbound drug is questionable: in the face of normal renal and hepatic function, clearance of the freed drug by these organs will increase such that "extra" drug is rapidly removed.¹⁶ However, it is not clear that clearance will increase sufficiently in the face of organ dysfunction (e.g., renal or liver disease). Further, the package insert for Converia, which is highly protein bound, indicates that the plasma drug concentration of several other highly protein bound drugs increased with co-administration.

KEY POINT 1-6 If a protein-bound drug is displaced from its binding protein, the increase in concentration of free and thus active drug is likely to be short-lived as the free drug is cleared more rapidly in the normal animal, thus potentially offsetting any risk associated with increased concentration.

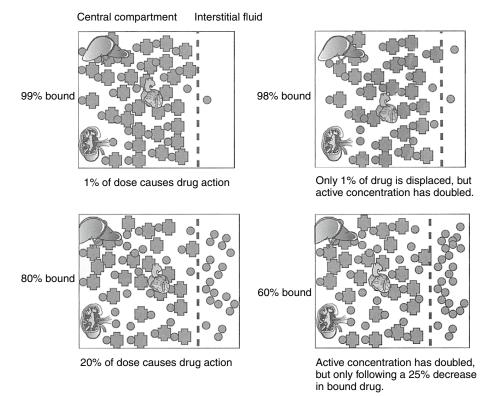

Figure 1-9 Displacement of drug from protein-binding sites becomes significant only if a drug is greater than 80% protein bound. Displacement of only 1% of a drug that is 99% protein bound doubles the pharmacologically active form of the drug (top two diagrams). For a drug that is 80% protein bound, however, 20% of the dose is responsible for pharmacologic actions. Displacement of 25% of the drug is necessary to double the pharmacologically active drug. However, because unbound drug will be cleared more rapidly (assuming normal organ function), displacement of highly bound drugs may not be clinically important.

In addition to its ability to reach target tissues and organs of elimination, distribution of a drug is important because of its influence on PDC and drug elimination. The amount of tissue to which a drug is distributed, often estimated by the theoretical parameter, volume of distribution (Vd) of the drug, directly but inversely influences PDC.^{2,3,17} Because it is theoretical, Vd is generally referred to as apparent Vd. The Vd of a drug also describes the ease with which the drug leaves the plasma. Simplistically, volume of distribution is also the volume to which a drug would have to be distributed if it were present throughout the body in the same concentration as that measured in the plasma after intravenous (IV) administration of a known dose. It can be exemplified by adding 5 g of dextrose (considered the dose) to each of two beakers containing a different but unknown volume of water. The dextrose is allowed to distribute equally throughout the beaker (no membranes are present in the beaker) and then the concentration is measured. If the concentration in beaker A is 5% (50 mg/mL or 5 g/100 mL), then the volume of water in the beaker must be 100 mL. If the concentration in beaker B is 2.5% (25 mg/mL or 25 g/100 mL), the volume must be 200 mL. The Vd in beaker A is twice that in beaker B. The Vd of a drug in an animal

is determined essentially the same way: a known dose is given intravenously to ensure that all the drug reaches the site being measured, the drug is allowed to distribute until equilibrium (or pseudo-equilibrium) is reached, and the peak drug concentration is determined. The Vd is then calculated by dividing the dose by the peak concentration (the y intercept, Co, A or B): Vd = Dose/Co (see the Pharmacokinetics section).

The PDC (and response to) a drug at a known dose varies inversely with Vd. Vd differences among species and ages (pediatric versus geriatric) can dramatically affect PDC (see Chapter 2). In addition, diseases associated with fluid retention or obesity are likely to increase the Vd of many drugs (and thus decrease PDC), whereas dehydration or weight loss is likely to decrease Vd and thus increase PDC (see Chapter 2). The impact depends upon whether the drug is distributed to total body water (i.e., a lipid-soluble drug) or extracellular fluid (i.e., a water-soluble drug). Because the distribution of a drug to peripheral tissues removes drugs from organs of drug clearance, Vd also directly and proportionately influences elimination half-life (Figure 1-10). Thus any factor that increases Vd will tend to decrease PDC but prolong the elimination half-life and thus the presence of the drug in the body.

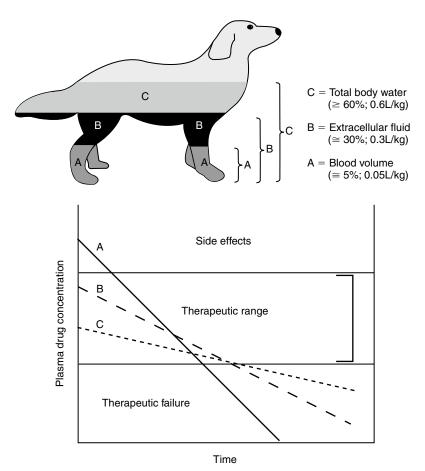

Figure 1-10 Despite its theoretical nature, the size of the apparent volume of distribution (Vd) may indicate the body compartment to which the drug is distributed. These include (A) the blood compartment (i.e., a drug tightly bound to plasma proteins), (B) extracellular fluid (e.g., a water-soluble drug), or (C) total body water (i.e., a liphophilic drug that penetrates cell membranes). Increasingly larger volumes represented by these compartment inversely affect plasma drug concentration (PDC) and the slope of the elimination (k_{el}) curve. This curve determines elimination half-life, which changes directly with Vd.

If a semipermeable membrane divided the beakers used to exemplify Vd into two compartments, distribution of the dextrose throughout each beaker would have taken longer than if the membrane were not present. At distribution equilibrium, (the amount of drug moving from one side equals the amount of drug moving from the other side. Further, at equilibrium, although the amount of drug passing between the two compartments is equal, membrane or fluid characteristics result in different concentrations of drug on each side of the membrane after equilibrium has been reached. Thus both the rate (i.e., distribution half-life) and extent of drug distribution may be affected by membranes. The body contains many membranes whose characteristics are sufficiently complex that multiple compartments may be formed. Extracellular and intracellular compartments (which together make up total body water) are major compartments to which drugs distribute. Most capillaries are fenestrated and present no barrier to passage of unbound drugs from plasma to interstitial fluid. Hence watersoluble drugs tend to be distributed to extracellular fluid (ECF; 20% to 30% of body weight) and thus are often characterized by a Vd of 0.1 to 0.3 L/kg. Lipid-soluble drugs tend to cross cell membranes and thus distribute into both ECF and intracellular fluid (ICF; i.e., total body water [TBW]) and as such, generally have a larger Vd (>0.6 L/kg). The Vd of highly protein-bound drugs reflects the plasma compartment, and as such is very small (0.05% of the body weight, or 0.05 L/kg). Such drugs may appear to distribute to their total volume almost instantaneously, resulting in a PDC versus time described by a single component, or a one compartment model (see the pharmacokinetics section). However, it is the Vd of the unbound or pharmacologically active drug that is more descriptive of the disposition and pharmacologic effects of a highly bound drug.

Capillaries of selected organs, including the brain, cerebrospinal fluid, eye, testis, and prostate, are not fenestrated, and drugs must diffuse through the capillary endothelium to penetrate these tissues.^{18,19} For treatment of such organs, lipid-soluble drugs (i.e., Vd >0.6 L/kg) are more likely than water-soluble drugs to penetrate the endothelial barrier and achieve therapeutic concentrations. However, simply because a drug has a Vd that equals or exceeds the volume of TBW does not assure lipid solubility nor does it guarantee sufficient tissue distribution. Drug distribution to various tissues differs with drug chemistry, and intracellular accumulation may occur for many reasons. Ion trapping was previously discussed; drugs also can bind to intracellular proteins (i.e., Na+ K+ ATPase of digoxin), bone (e.g., Ca²⁺ or Mg⁺ by tetracyclines) or other macromolecules (e.g., lysozymes by aminoglycosides). Bound drug is generally not active (unless binding occurs to target ligands), but bound drug may act as a reservoir for interstitial and plasma drug concentration (e.g., the antimicrobial cefovecin). Ion trapping or binding of a drug will remove it from plasma; as such, as PDC decreases, for any given dose, the Vd will increase. The Vd of a drug characterized by such multicompartments may result in a Vd that is greater than the volume of the animal (e.g., >1 L/kg). Such a drug exemplifies the theoretical nature of Vd in that it simply (mathematically) describes the amount of tissue that is diluting the drug if the **KEY POINT 1-5** Volume of distribution is used to calculate the dose by estimating the volume of tissue that will dilute the drug after its intravenous administration. It is theoretical because it provides no information regarding the site of distribution. However, it proportionately impacts plasma drug concentration (inversely) and elimination half-life (directly).

concentrations measured in plasma were the same throughout the body. Although Vd is a useful parameter, particularly for calculating drug dose, it should not be used to indicate where (i.e., ECF, ICF, TBW, or selected tissues) a drug has distributed. Further, because the rate and extent of drug distribution to tissues varies, the time to equilibrium also will vary. Calculations for Vd (and determining peak PDC) generally should not occur until distribution equilibrium has been reached.

The term **distribution equilibrium**, or steady-state equilibrium, is often used to refer to the state in which the amount of drug leaving plasma for tissues is equivalent to the amount of drug leaving tissues for plasma. The reality is that distribution equilibrium may not ever be achieved because drugs are characterized by an "open" system—that is, drug is continually being eliminated. Hence, the term *pseudoequilibrium* is more appropriate. Distribution equilibrium is less likely to be achieved for drugs with a short half-life, particularly when administered at a long dosing interval. Drugs that accumulate (given at a dosing interval that is shorter than the half-life; see later discussion) are more likely to reach a state of equilibrium between doses, although the actual concentrations may fluctuate between C_{max} and C_{min} during a dosing interval.

Documenting the extent to which a drug distributes to a specific site is difficult because techniques are required that allow collection of interstitial versus intracellular tissue. Measurement of drug in interstitial fluid or ICF might confirm the site of drug distribution. However, collecting a sample of sufficient size using methods that are not traumatic (and thus do not impact drug movement) is difficult. Several techniques have been developed to collect fluid representative of ECF. Examples include tissue cage models; "wick" methods; and more recently and perhaps most appropriately, the use of microfiltration systems that collect directly from ECF using a microprobe. A less representative method of reporting tissue concentrations is measurements of drug in homogenized tissues; this measures both extracellular and intracellular drug. Drugs bound (trapped) inside a cell (e.g., as a result of binding to proteins, or ionization) may markedly increase drug concentrations in homogenized tissue, but the drug may not be pharmacologically active or available to interstitial tissues. However, intracellular drug may act as a reservoir, providing continued input to interstitial fluid even as PDCs decline. Drug-void cells, on the other hand, will artificially dilute actual drug concentrations in the ECF.

Thiobarbiturates and propofol undergo a phenomenon of **redistribution**, relevant only for drugs for which an immediate effect can be realized (i.e., general anesthetics). After a rapid intravenous bolus administration of these drugs, they distribute first into a "central blood pool" composed of lowvolume, high-blood-flow organs such as the brain. Anesthetic

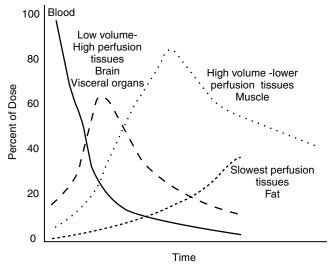

Figure 1-11 The phenomenon of redistribution involves the rapid distribution of drugs to a central blood pool composed of low-volume, high-blood-flow organs such as the brain followed by rapid redistribution to lean tissues. Further redistribution to fatty tissues further reduces plasma drug concentration and thus the pharmacologic effect. Sight hounds tend to have a prolonged recovery with these drugs because redistribution to the fat compartment is less. The effects of these drugs are also magnified in the presence of hypovolemic shock because a higher percentage of blood containing the drug flows to the brain and heart.

effects occur rapidly. However, the drug effect rapidly terminates, primarily because of redistribution from the brain to lean tissues such as muscle (Figure 1-11). Continued redistribution to fatty tissues further reduces PDC and thus the pharmacologic effect; sight hounds (which lack body fat) tend to have a prolonged recovery with these drugs. The effects of these drugs are also magnified in the presence of hypovolemic shock because a higher percentage of blood containing the drug flows to the brain and heart.

Drugs that distribute to TBW may take longer than distribution to ECF. Clinically, peak PDC (C_{max}) cannot be assessed until distribution has reached equilibrium (or pseudo-equilibrium). If PDCs are being monitored in a patient, blood samples for peak drug concentrations should not be collected until this time. For orally administered drugs, distribution occurs during absorption and sampling should occur after absorption is complete, generally within 1 to 2 hours after administration.

Metabolism

The rate at which a drug is excreted from the body is the final determinant of PDC. Most drugs are eliminated by hepatic metabolism, renal excretion, or both.^{2,3} Lipid-soluble drugs require conversion to a water-soluble form before they can be eliminated by the kidney; otherwise, their passive resorption in the renal tubules would preclude excretion. A single change in the molecular structure of a lipid-soluble drug to a more water-soluble form may reduce a half-life of weeks or months to only a few hours. Metabolism can occur in two

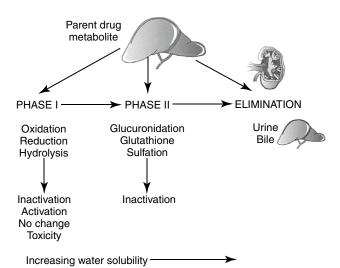

Figure 1-12 Hepatic metabolism can occur in one, two, or multiple phases. Phase I reactions are oxidative, most often accomplished by cytochrome-P450 (hepatic microsomal) enzymes. Phase I metabolites may be subjected to either phase I or phase II metabolism. Although phase I metabolites may be inactivated, they may also be the only active form of the drug (prodrugs). Metabolites may also exhibit similar, less, or more activity compared to the parent compound. Finally, they can also be an important source of drug-induced toxicity. Phase II metabolism generally inactivates the drug. The rate and extent of both phases of metabolism vary among spe-

cies, ages, and disease states.

phases (Figure 1-12). Drugs or their metabolites may undergo both phases or only phase II metabolism. In general, phase I metabolism chemically changes the drug so that it is more water soluble and thus more susceptible to phase II metabolism; phase II metabolism generally renders the drug sufficiently water soluble to be renally excreted. An exception is made for some phase II metabolites (e.g., selected acetylated compounds) that may not only remain reactive but also may be more lipid soluble than the conjugated metabolite.

KEY POINT 1-7 Perhaps more so than any other factor affecting drug disposition, drug metabolism is complicated by physiologic, pharmacologic, and pathologic factors.

The majority of drug metabolism occurs in the liver. However, the liver is not the only site of drug-metabolizing enzymes; other organs with substantial metabolic capacity attributable to CYP or other enzymes include the kidney and portals of entry (i.e., lungs, skin, and gastrointestinal tract). Most drugmetabolizing enzymes are located in the smooth endoplasmic reticulum (SER) of the hepatocyte; others are located in the cytosol of the cell. Those located in the SER generally consist of a protein (cytochrome) with an iron central core (pigmented like hemoglobin, hence "P") that, when bound to carbon monoxide, absorbs light at 450 nm; as such, the isozymes are referred to as *cytochrome P450 enzymes* (*CYP450* or simply *CYP*). When the liver is subjected to homogenization and special centrifugation procedures, the SER forms vesicles or microsomes that contain drug-metabolizing enzymes; hence these enzymes also are referred to as microsomal drugmetabolizing enzymes. These enzymes are actually an enzyme system that can be identified genetically as a superfamily containing several families of enzymes.²⁰⁻²³ Classification and nomenclature of CYP450 is based on gene sequence similarity. The importance of enzymes in humans and the proportion of drugs metabolized by the respective enzyme are 1A2 (13%), 2A6 (4%), 2B6 (1%), 2C (18%), 2D6 (1.5%), 2E1 (7%), and 3A4 (30%). All CYP-mediated drug metabolic reactions involve the addition of a single atom of oxygen onto the substrate; as such the CYP drug-metabolizing system is actually an electron-transport system, and oxygen radicals are generated during the metabolic process. Iron serves as a mechanism for separating molecules of oxygen; a lipid environment, (NADP reductase serves as the electron donor) and oxygen are required for CYP-catalyzed metabolism to occur. Not surprisingly, overlap among drug substrates for the different isozymes is among the reasons that isoenzyme activity can not be predictably extrapolated among species. Inducers and inhibitors differ in normal animals, among species, breeds, ages and gender, as well as tissue. Different concentrations of the various isoenzymes in tissues contribute to tissue specificities of some drug toxicities. The patterns of drug metabolism are complex, and the sequelae of the reactions variable. Drugs can be metabolized through several pathways, and metabolites often are further metabolized; metabolic pathways can also go backward to previous metabolites.

The major phase I drug-metabolizing reactions include oxidation (addition of oxygen across a carbon double bond [including on a benzene ring], addition of oxygen to a carbon chain, or deamination), hydrolysis (addition of water), and reduction (addition of hydrogen) (Figure 1-13).

The sequela of phase I metabolism commonly is drug inactivation (e.g., phenobarbital). However, phase I metabolites often are equally, more (i.e., primidone or prodrugs, which must be activated such as enalapril), or less (e.g., diazepam, cyclosporine) active than the parent compound. More problematic, phase I metabolites often are reactive

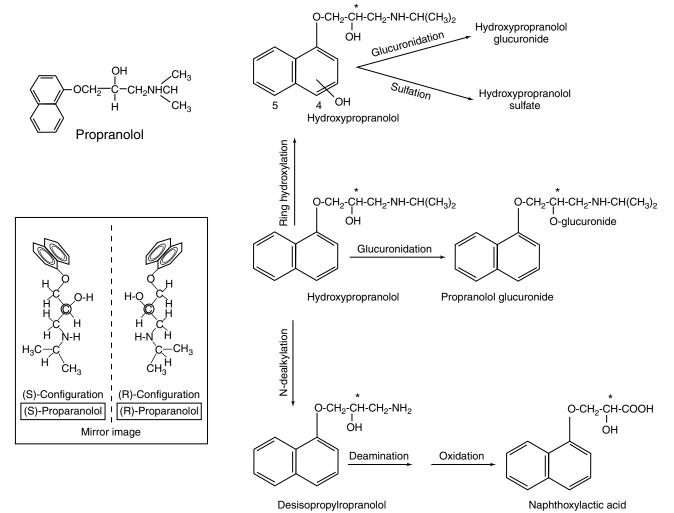

Figure 1-13 Propranolol offers an example of complex metabolism. Hepatic metabolism of propranolol follows multiple pathways, including both phase I (formation of hydroxyl propranolol) and phase II (glucuronidation). Propranolol contains a chiral carbon *(asterisk)* resulting in enantiomers *(inset)*. Each will potentially be metabolized by different pathways.

(e.g., oxygen radicals) and thus are more toxic (e.g., acetaminophen) than the parent compound (see Chapter 3).^{23,24} In such instances, phase II metabolism is critical to protecting the liver (or other metabolizing tissue) from metabolic products.

Phase II metabolism, also known as conjugation, occurs when a large water-soluble molecule is chemically added to either the parent drug or its phase I metabolite; this phase is often referred to as synthetic (see Figure 1-13). Generally, with the exception of glutathione transferase, phase II reactions require energy. As with phase I enzymes, families of enzymes catalyze each of the synthetic reactions. Glucuronidation is the most common phase II reaction; common substrates include OH and COOH functional groups (see Figure 1-13). The cat is deficient in some (but not all) glucuronide synthetic enzymes and as such does not eliminate phenols or carboxylic acids well (see Chapter 2). Glucuronide conjugates are eliminated in the urine and bile; degradation in the gastrointestinal tract and reabsorption of the substrate results in enterohepatic circulation. The glutathione transferase system targets electrophiles (compounds seeking electrons) and as such has several different roles in the body, including detoxification of radical metabolites. However, the enzyme can be rapidly depleted, which increases the risk of liver, red blood cell, or other tissue damage; n-acetylcysteine is a precursor for glutathione that can be used to replenish the system. Sulfonation targets hydroxyl groups and as such compensates somewhat for glucuronide deficiencies in cats. Acetylation is a less common synthetic reaction; sulfonamides are common substrates. The dog is a poor acetylator (see Chapter 2). With rare exceptions, phase II metabolites are inactive. The most common exception is with acetylation, which may result in formation of active metabolites (e.g., procainamide). Most hepatic drug metabolites are excreted in the urine, although some conjugated drugs undergo biliary excretion. Such drugs are potentially subject to enterohepatic circulation. Species (and no doubt breed) differences in both phase I and phase II metabolism are well recognized but insufficiently described (see Chapter 2).

Exogenous products are not the only substrates for drugmetabolizing enzymes. Many metabolic reactions are critical to formation or degradation of endogenous substances. Important noncytochrome metabolic enzymes include those that oxidize aldehydes or alcohols (esterases: e.g., acetylcholinesterases), monoamine oxidases (responsible for metabolism of endogenous catecholamines, dopamine, and related molecules) and dehydrogenases (alcohol and aldehyde) responsible for many endogenous reactions.

Factors that can affect hepatic drug metabolism include the amount and activity of drug-metabolizing enzymes and, if the drug is characterized by a high extraction ratio (>70%, a flow-limited drug), and hepatic blood flow. For flow-limited drugs, removal by drug-metabolizing enzymes is so rapid that the only limitation to the rate of elimination is blood flow. In contrast, extraction of capacity-limited drugs is slow. Protein binding directly decreases the clearance and thus rate of elimination of capacity-limited, but not flow-limited, drugs. Disease, drug interactions, and species differences can have a profound impact on drug metabolism and thus drug elimination (see Chapter 2).

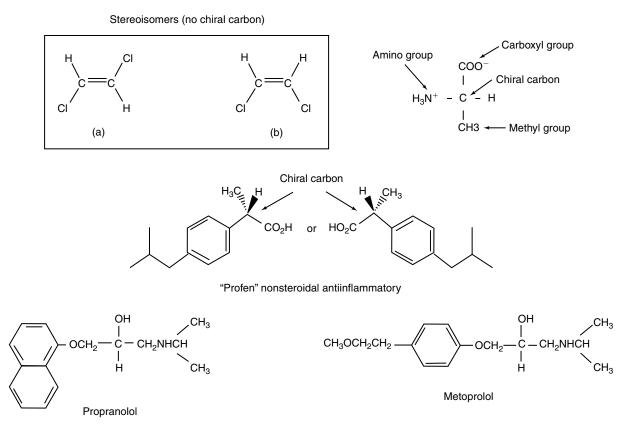

Enantiomers and Drug Disposition

Whenever a carbon atom has four different structures bonded to it, two different molecules can be formed. Stereoisomers are chemical compounds with the same molecular formula that differ only by the orientation of functional groups in space around the central atom (e.g., carbon). Enantiomers are stereoisomers that differ due to orientation of four different groups around a single carbon (or phosphorous or nitrogen) atom and are nonsuperimposable mirror images of one another (Figure 1-14). The center atom around which the asymmetry occurs is referred to as the chiral molecule. The enantiomers are differentiated as to either D (dextrorotatory) or L (levorotatory). More commonly, they are defined by the direction in which they rotate light. As such, they are "optical isomers": if one enantiomer rotates light to the left (S, or sinister [counterclockwise]), the other will rotate it to the right (R, rectus [clockwise]) the same number of degrees. The only physical difference between enantiomers is the direction in which they rotate light. However, although the physical characteristics of enantiomers are similar, the pharmacodynamics (including both potency and efficacy) and pharmacokinetics (all phases of disposition) may be profoundly different for each isomer. Most enantiomeric drugs are sold as racemic mixtures (generally 50:50), and administration of such drugs represents polypharmacy.²⁵ Further complicating enantiomer disposition is the potential for each enantiomer to be converted to the other after administration. Species differences are likely to be profound. Unfortunately, analysis of enantiomers in tissue samples is difficult: they are so physically similar that their physical separation and thus quantitation from one another is difficult. Examples of drugs that exist as enantiomers include selected anthelmintics, verapamil, ketamine, inhalant anesthetics (isoflurane), selected cardiac drugs (e.g., beta blockers, including propranolol [see Figure 1-13], albuterol, and others), and a number of nonsteroidal antiinflammatories (e.g., the profens [ketoprofen, carprofen]). Occasionally, the name of a drug indicates it is a sole isomer (e.g., levofloxacin is the L isomer of ofloxacin.)

Excretion

Renal excretion is the most important route of drug elimination for both parent (especially water soluble) drugs and their metabolites (Figure 1-15).^{2,3,26,27} Host factors that determine renal excretion include renal blood flow (including glomerular filtration rate), active tubular secretion, and tubular (generally passive) reabsorption. The kidney is also capable of metabolizing some drugs (e.g., imipenem), although this capacity is only occasionally of clinical importance.

Glomerular filtration is a passive process. Drugs enter the glomerulus by bulk flow, being excluded if too large (> 60,000 MW) as occurs for highly protein-bound drug if the glomerulus is healthy. In contrast, active transport of drugs in the proximal tubules is very efficient, rapid, and insensitive to protein binding. However, it is susceptible to competition among drugs. Separate active transport (p-glycoprotein,

Beta-blockers with multiple chiral carbons

Figure 1-14 Enantiomers are stereoisomers that exist as mirror images that are not superimposable because of the presence of a chiral carbon (*top*). Rotation of the four groups attached to the chiral carbon results in either S or R isomers (depending on the rotation of light by each molecule). Although they are similar in MW and chemistry, the body often responds to and handles enantiomers differently. Most products are manufactured as racemic (1:1). Some compounds contain more than one chiral compound, complicating disposition. Further, interconversion among species contributes to the complexities that characterize the pharmacokinetics and thus predictability of disposition of these compounds. Examples of compounds that exist as stereo-isomers include many nonsteroidal antiinflammatories (*middle*) or beta-blockers (*bottom*). Commercial products often contain mixtures of both enantiomers of a drug. However, some drugs are marketed as only the active enantiomer and are often named to indicate as such (e.g., "levo" as in levetiracetam or "dextro" as in dextromethorphan).

OATPs, POTs) systems exist for acid, basic, and neutral drugs. Probenecid has been used clinically to compete with and thus inhibit the renal excretion of other weakly acidic drugs such as expensive beta-lactam antimicrobials (e.g., penicillin historically and imipenem more recently), thus prolonging therapeutic PDC. Reabsorption of drugs from renal tubules into peritubular capillaries slows renal excretion. The extent to which a drug is reabsorbed depends on its lipid solubility and its ionization. Weakly acidic drugs are more likely to be reabsorbed in acidic urine but are trapped and excreted in alkaline urine. Urinary pH can be therapeutically altered such that the renal excretion rate of a drug can be modified, particularly in cases of overdose or toxicity. Drugs excreted in the urine that do not undergo passive reabsorption will be progressively concentrated in the renal tubule. Tubular cells may be exposed to higher concentrations of drugs, which may increase the risk of nephrotoxicity. Drug concentration in the urine can be of therapeutic benefit in some situations, such as bacterial cystitis. Most antibacterials excreted in the urine achieve concentrations that exceed plasma at least tenfold (see Chapter 6); for such drugs, culture

and susceptibility data and, in particular, minimum inhibitory concentrations based on PDC may underestimate efficacy if infection is limited to the urine.

In contrast to renal excretion, biliary excretion is very slow and much less clinically important. Drugs are eliminated in the bile by at least three active transport (p-glycoprotein) systems: one each for organic acids, organic bases, and organic neutral compounds. Characteristics that determine biliary excretion of drugs include chemical structure, polarity, and MW, with the latter being one of the major determinants (generally drugs >600 MW in size). Drugs excreted in the bile are in greater contact with the intestine and its flora compared with other drugs and are thus more likely to cause adverse reactions in the gastrointestinal tract. In addition, conjugated (phase II) drugs excreted by this route may undergo enterohepatic circulation (Figure 1-16) if intestinal bacteria unconjugate the drug or metabolite, allowing intestinal absorption to occur. Enterohepatic circulation prolongs drug elimination half-life and further exposes the gastrointestinal tract to drug.

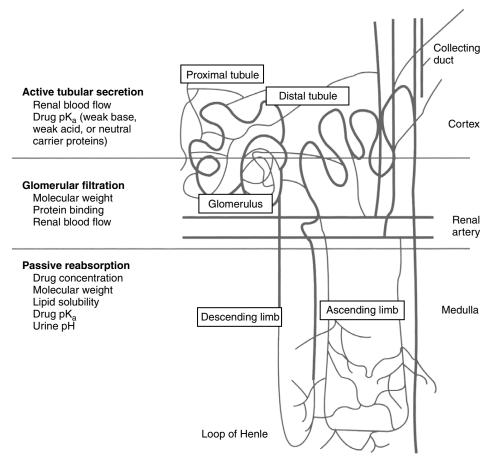

Figure 1-15 Renal excretion is the most common route of elimination of drugs and their metabolites. Three drug movements determine the rate of renal excretion. Active tubular secretion in the proximal tubule is a rapid process not limited by protein binding. Glomerular filtration is a passive process; protein-bound drugs cannot be filtered through the glomerulus. The rates of both active tubular secretion and glomerular filtration both depend on renal blood flow. Nonionized drugs that are sufficiently lipid soluble may be passively resorbed. Because urine drug concentration increases, passive resorption should also increase the concentration.

Elimination and Clearance

The combined effects of hepatic metabolism and renal and biliary excretion, as well as other routes of elimination not discussed (e.g., pulmonary, sweat), irreversibly remove or clear the drug from the body. Elimination refers to the disappearance of drug from plasma. Elimination half-life is among the more clinically relevant and the most often reported pharmacokinetic parameters. It is defined as the time necessary for plasma or blood concentrations to decline by 50%.²⁸ Elimination half-life, however, is also dependent on Vd. Along with the therapeutic range, the elimination halflife should be the basis for an appropriate dosing interval. The amount of fluctuation in drug concentrations during a chosen dosing interval depends on the elimination half-life of the drug. Further, drug elimination half-life determines the time to steady state when either a drug (or new dose) is begun or discontinued. For example, at one drug elimination half-life, 50% of the dose has been eliminated; by five drug elimination half-lives, more than 97% of the drug has been eliminated (Figure 1-17, Table 1-1, and Box 1-2). Finally, the elimination half-life, along with the dosing interval, also

determines the amount of drug that accumulates with each dose as steady-state equilibrium is reached (see the discussion of accumulation later in this chapter). This reflects firstorder elimination, which might be considered a protective mechanism to ensure rapid elimination of potentially toxic substances.

Clearance is a parameter often used to assess the excretory capacity and thus physical well-being of an organ. Plasma clearance (CL) is the volume of plasma irreversibly cleared of the drug per unit time and represents the sum total of organ clearance (Figure 1-18) ^{2,3,30,31} As such, it is the most important of the pharmacokinetic parameters.³² Clearance differs from elimination because it is a volume per unit time, not a rate constant (amount per unit time). If the drug is cleared exclusively by one organ (e.g., renal clearance of aminoglycosides or hepatic clearance of caffeine), then plasma CL also represents clearance of the specific organ and can be used to evaluate the function of the organ. With firstorder elimination, the volume of blood cleared per unit time by an organ is independent of PDC—that is, the same volume of blood will be irreversibly cleared of drug by an organ regardless of how much drug is in the blood. The exception occurs only if so much drug is present in the blood that the organ of clearance becomes saturated such that zero-order elimination emerges.

Although clearance is the reason that PDC ultimately declines (thus is physiologically independent of any other factor), pharmacokinetically it is obtained or calculated from the volume to which the drug is distributed (Vd) and the rate at which the drug is eliminated from the volume (k_{el} or half-life). Clearance can be calculated on the basis of compartmental modeling, or from AUC based on noncompartmental analysis (see the pharmacokinetics section). Despite its importance, practically, clearance is minimally useful in the design of dosing regimens other than through its impact on elimination half-life unless calculating a constant rate infusion. In contrast, half-life is the clinically useful estimate of how long a drug stays in the body. Yet, while half-life is the pharmacokinetic parameter measured directly from the PDC versus time curve, physiologically, it is a "hybrid" parameter in that it is affected by

both distribution (Vd) and clearance (CL) (Box 1-3). The more rapidly a drug is cleared by an organ, the shorter the drug halflife. However, if a drug is distributed to a large tissue volume, PDC will be lower. Thus, although clearance (which is concentration independent) does not change, the volume cleared per unit time contains less drug and elimination decreases. If the Vd is much smaller, PDC is higher, more drug is in the volume of blood that is cleared. (see Figure 1-10). As such, the rate of elimination decreases. Thus drug elimination half-life changes directly and proportionately with Vd but inversely and proportionately with CL. The clinical significance of the relationship among Vd, CL, and half-life is exemplified in a patient who has renal disease and eventually becomes dehydrated as a result of uncompensated chronic renal disease. Initially, as renal function declines, a smaller volume of blood goes through the kidney, which thus clears less blood. Drug elimination half-life decreases. However, as the patient becomes dehydrated, blood and ECF volume contracts, and the Vd decreases. As a result, PDC increases such that more drug is in each volume of blood

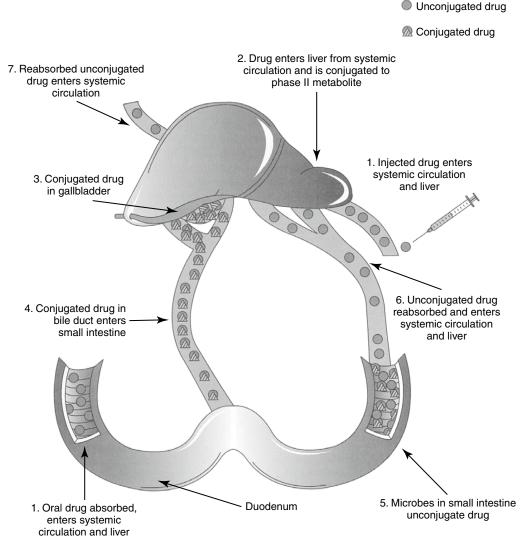

Figure 1-16 Enterohepatic circulation can prolong the elimination half-life of a drug. After oral or parenteral administration, the drug is conjugated in the liver and eliminated in the bile. The drug travels from the duodenum to the lower small intestine and colon. Bacterial degradation results in deconjugation of the drug, which can then be reabsorbed.

as it is cleared. Thus in the patient with both fluid volume contraction (half-life decreases) and compromised renal function (half-life increases), drug half-life may not change from normal even though renal function may be impaired. With volume replacement (i.e., fluid therapy), Vd will increase, causing

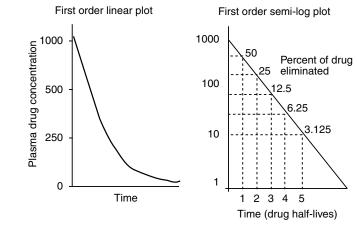

Figure 1-17 Drug elimination half-life can be derived from the plasma drug concentration versus time plot. Because most drugs are eliminated in a first order process (a constant fraction is eliminated per unit time), the amount of drug eliminated is concentration dependent. The relationship between concentration and time is linear when plotted on semilogarithmic paper but curvilinear when plotted on linear paper. The opposite is true for zero-order elimination (i.e., a constant amount is eliminated per unit time): The plot is linear on linear paper but curvilinear on semilogarithmic paper. For first-order elimination, if a line is drawn between two points (such as might be obtained from a peak and trough concentration), the line can be extrapolated to the y axis. The half-life is the time that elapses as plasma drug concentration decreases by half. Calculation of half-life is described in Box 1-3.

half-life to increase because less drug is now in the smaller volume that is being cleared.

FIXED DOSING REGIMENS

Dose

A fixed dosing regimen comprises a route, a dose, and an interval (or frequency)(see Box 1-3). The dose necessary to achieve a specified target PDC (e.g., C_{max}) following a single dose depends on the volume of tissue that will dilute the dose administered, estimated by Vd:2,3

$$Dose = [C_{max}] [Vd]$$

The dose of drug must be increased or decreased proportionately with changes in Vd to achieve the same target PDC

Box 1-2

Zero- Versus First-Order Elimination

The importance of first-order (constant fraction) versus zeroorder (constant amount; see Figure 1-17)²⁹ elimination can be appreciated best in the context of the elimination rate constant. Assume an animal has ingested several aspirin to the point that the plasma drug concentration has surpassed the therapeutic range of 100 to 500 mg/mL and has achieved the toxic concentration of 2000 mg/mL. The half-life of aspirin in the dog is about 9 hours. First-order elimination results in a concentration of 1000 ng/mL by 9 hours and 500 ng/mL at 18 hours. Thus by 18 hours, the drug is back into the therapeutic range, and by 36 hours, it approximates the low therapeutic range. For zeroorder elimination a constant amount is eliminated per unit time. For example, if 100 ng/mL of aspirin is eliminated every 9 hours, by the time 36 hours has elapsed, concentrations will have declined to only 1600 ng/mL.

	Concentrations					
FLUCTUATION				ACCUMULATION

Box **1-3**

Half-Life Calculation

Half-life of any drug movement can be determined in several ways. Half-life can be directly determined from a drug concentration versus time graph by measuring the distance on the X axis (time) that occurs as PDC (Y axis) decreases by 50% (see Figures 1-20 and 1-23). More often, half-lives for each component of a drug concentration versus time curve are determined from each slope, or rate constant, k_i: At one half-life $(t_2-t_1 = t_{1/2})$, the drug concentration declines by 50%. Thus at $t_{2-} t_1$, $C_1/C_2 = 2$. However, because drug concentrations (Y axis) are natural logs, C_1/C_2 becomes the natural log (ln) of 2 = 0.693. Thus the rate constant or slope of any line $k_i = 0.693/t_{1/2}$. Conversely, if the rate constant is known, $t_{1/2} = 0.693/k_i$. In the same manner, half-life also might be calculated from peak and trough concentrations collected from a patient (see Chapter 5). The slope, or k_i, is simply the rise/run, or $(C_1 - C_2)/(t_2 - t_1)$ where C is the concentration of sample 1 or 2 and t is the time that samples 1 and 2 were collected (see Figure 1-20). Because concentration is logarithmic, the actual equation becomes

$$K_i = \ln [C_1 / C_2] / t_2 - t_2$$

For example, if gentamicin samples collected at 2 hours and 12 hours after an intravenous dose were 10.5 and 2.0 mg/mL, respectively, the k_{el} for gentamicin in this animal would be 0.17 h⁻¹ and the elimination half-life would be calculated at 4.2 hours.

(or C_0 or C_{max})(see Figures 1-10 and 1-19). Often, the dose is not intended to reach C_{max} but rather C_{min} (e.g., phenobarbital) or midway between the two extremes of the therapeutic range. The concentration within a therapeutic range that is selected as the target depends on the drug efficacy and safety. The Vd of a drug is the sole determinant of PDC for single doses of an intravenously administered drug. With multiple dosing the relationship between elimination half-life and dosing interval also may influence PDC (see later discussion). For extravascular drugs, bioavailability also must be considered, with the dose inversely but proportionately influenced by bioavailability:

$$Dose = [C_{max}] [Vd] / F.$$

By definition, with intravenous administration, F= 1, or 100% bioavailability.

Interval

The relationship between elimination half-life and dosing interval determines the amount of fluctuation in PDC during a dosing interval. This relationship has several clinical implications (see Table 1-1 and Figures 1-20 and 1-21). The shorter the elimination half-life compared with the dosing interval, the greater the fluctuation. The dosing interval for a drug is based on the time (T_{max}) it takes for PDC to decline from the peak concentration achieved after dosing (C_{max}) to the lowest concentration that occurs during the

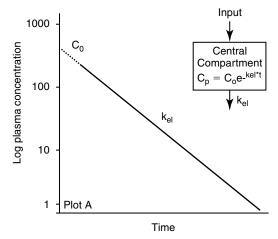

Figure 1-19 Plasma drug concentration (PDC) versus time curves after intravenous administration. This drug could be described by a one-compartment open model because it plots as a single straight line (one slope) on semilogarithmic paper. There is no initial distribution phase, and the volume of distribution is based on PDC extrapolated (*dotted line*) from the first concentration measured back to time zero (C₀). The equation for this single component curve would be $C_p = C_o e^{-kt}$ where C_p is the plasma drug concentration at any time and t and k are the elimination rate constants (slope) of the curve. Such behavior is unusual for a drug because it implies instantaneous distribution from plasma to tissues or failure to leave circulation. The latter might happen if a drug is very tightly bound to plasma proteins and total, rather than unbound drug, is measured.

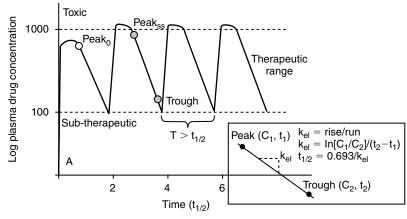

Figure 1-20 Plasma drug concentration versus time curves after multiple extravascular dosing for a drug that is administered at a dosing interval substantially longer than the elimination half-life. Such a drug is less likely to accumulate because most of the drug will be eliminated during a dosing interval. For such drugs equilibrium between tissue and plasma concentrations is never reached and steady state is not really relevant. The risk of toxicity and therapeutic failure is a potential concern with each dose, unless the dosing interval is shortened such that fluctuation during the dosing interval is minimized. For monitoring, a peak and trough concentration may be necessary. The *inset* demonstrates how the half-life of a drug might be calculated from drug concentrations measured at two time points after administration of a dose.

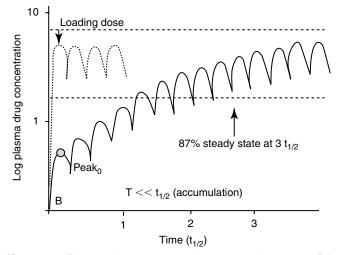

Figure 1-21 Plasma drug concentration versus time curves following multiple extravascular dosing for a drug that is administered at a dosing interval substantially shorter than the elimination half-life (see also Figure 1-16). The amount that the drug accumulates as steady state is reached determines the drug concentration at steady state and is based on the magnitude of difference between dosing interval (T) and drug half-life $(t_{1/2})$. Such a drug will accumulate because most of the drug from the previous dose is still in the body by the next dose. Although equilibrium may not be truly reached, steadystate (characterized by the same C_{max} and C_{min} at each dosing interval) occurs after three to five drug half-lives have elapsed after administration at the same dose, interval and route. For some drugs, if a rapid therapeutic response is desired, a loading dose can be given. Note, however, that steady state has not been reached and plasma drug concentration may increase or decrease as steady-state is reached if the maintenance dose is not correct. When monitoring is done for such drugs, generally a single sample collected at any time during the dosing interval is sufficient to reflect the whole dosing interval.

dosing interval (C_{min}) (see Figures 1-20 through 1-22). Thus the interval depends on the amount of fluctuation in PDC allowed during the dosing interval and the half-life of the drug, or its inverse ($0.693/t_{1/2}$), the elimination rate constant (k_{el}). If C_{min} for a drug is close to half of C_{max} , then approximately one drug half-life (i.e., $T_{max} = t_{1/2}$) can elapse before the next dose should be administered. A more appropriate interval can be calculated with k_{el} if C_{min} does not approximate half of C_{max} :

$$\Gamma_{\rm max} = [\ln C_{\rm max} / C_{\rm min}] / k_{\rm el}$$

The longer the elimination half-life of a drug, or the wider the difference between C_{max} and C_{min} , the longer the possible interval (or T_{max}) between doses. Understanding the relationship between dosing interval and elimination half-life can help determine which aspect of the dosing regimen (i.e., close or interval) should be changed when trying to improve drug response by either increasing PDCs or minimizing fluctuation during the interval. Through altered kinetics in the patient, two scenarios are offered.

The first scenario is dosing with a drug at an interval that is close to or longer than the drug elimination half-life. With this scenario, prolonging a dosing interval (e.g., for convenience) may allow drug concentrations to fluctuate excessively during the dosing interval and may result in either adverse events as C_{max} is approached with each dose or therapeutic failure as C_{min} is approached just before each subsequent dose. Note that wide fluctuation between C_{max} and C_{min} may not necessarily be undesirable. For example, if the drug is effective despite nondetectable drug concentrations, the interval can be longer than the half-life might dictate. Examples include concentration-dependent antimicrobials (e.g., aminoglycosides), drugs that accumulate in tissues (e.g., omeprazole), drugs such as diazepam whose metabolites are active (some with drug half-lives longer than that of the

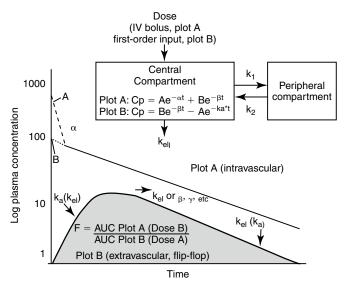

Figure 1-22 After intravenous administration, a drug distributed to peripheral tissues generally is characterized by at least two components or phases when plotted on semilogarithmic paper. According to compartmental modeling, the plasma drug concentration (PDC) declines in the first phase (component) due to both distribution into tissues and back and elimination (excretion) from the body. Once a distribution equilibrium (pseudo-equilibrium) has been reached, PDC decline is caused only by elimination (second phase or component of the curve). The two phases can be separated by stripping and residual analysis, or linear regression. The first (stripped and subsequently fitted) component of the curve (coarse dotted line) is understand to represent distribution, and the slope (α) is the distribution rate constant. The slope of the second phase of the curve is the elimination rate constant (k_{el}) . The equation for the curve represented by plot B (two components) can be used to determine the concentration of drug in plasma (or the tissue being sampled) at any time (t) by the equation: $C_{p} = Ae^{-\alpha t} + Be^{-\beta t}$. The volume of distribution (Vd) for this drug is ideally based on PDC after distribution, usually determined by extrapolating (fine dotted line) the terminal or elimination phase of the PDC versus time curve (B on plot A) yielding Vd area or Vd extrapolation. The Vd based on the extrapolated concentration for the first component of the line (A on Plot A) might be used to calculate the central volume (Vc) to which the drug is immediately distributed. The second PDC versus time curve (Plot B) reflects extravascular (e.g., oral) administration of the same dose of drug. The upswing of the PDC versus time curve reflects the simultaneous movements of absorption, distribution and elimination from the body, all occurring during first-order input (a constant fraction moves per unit time). As each movement reaches pseudoequilibrium (amount moving either way is the same), remaining movements that have not yet reached equilibrium emerge. Of the movements, elimination from the body will not reach equilibrium (open model) and as such, emerges as the terminal movement or component. The absorption rate constant (k_a) can be derived from the upswing of the curve but only after the elimination component of the curve has been mathematically stripped. Generally, the distribution phase of nonintravenous doses is masked by the absorptive phase. The equation of extravascular PDC versus time curves follows the general equation: $C_p = Be^{-\beta t} - Ae^{-ka t}$ where A is the extrapolated drug concentration from the

absorptive phase of the curve; it is subtracted from the overall equation because it represents the area that is "missing" from the curve as the drug is being absorbed. The elimination rate constant of a drug should be the same, regardless of the route of elimination. However, in some cases the rate of absorption is so slow that it limits the rate of elimination. As such, the absorption rate constant determines the slope of the terminal curve (i.e., ka and kel are "flip-flopped," as is demonstrated in the figure). A flip-flop model should be suspected if the elimination rate constant after extravascular administration is significantly less than that after IV administration. As such, a flip-flop model can be ascertained only if the drug is give intravenously. If IV administration is not done to affirm the terminal slope as kel, it should be reported as the disappearance rate constant, k_d. IV administration is also necessary to determine Vd,CL and absolute bioavailabilility (F) of a drug. (see Box 1-6.)

parent compound), and drugs whose effects are irreversible (e.g., receptors or enzymes are destroyed (e.g., aspirin and thromboxane synthetase).

On the other hand, if the drug is characterized by a narrow therapeutic window, fluctuation should be minimized and a shorter interval may be indicated. To add one half-life to the dosing interval, the dose must be doubled; however, to add subsequent half-lives, the dose must be doubled each time. Thus to add three half-lives to a dosing interval, the dose must be increased eightfold (2^3) (e.g., time dependent drugs or anticonvulsants). Some drug half-lives are short on the order of minutes (e.g., epinephrine). Constant rate infusion may be indicated if an intravenous preparation is available such that therapeutic concentrations can be maintained for a clinically relevant period while avoiding the negative consequences of undesirable fluctuations in PDC that might occur with convenient dosing intervals (see later discussion). Manufacturers have provided an alternative approach to maintenance of PDCs for drugs with a short half-life by formulating the drug in a preparation characterized by slowed absorption (e.g., extended release preparations) or (less commonly) distribution. However, even if absorption is prolonged, once the drug enters circulation, it's elimination half-life is the same. Absorption of a drug might be slowed by several methods. Examples of parenteral slow-release preparations include drug-esters (drug is released by esterases at the site of administration) or liposomal or other products that release drug as the product is degraded. Oral methods include extended- or delayed-release products consisting of capsules that degrade at different rates. Note, however, that absorption may be so slow that therapeutic concentrations are never reached. Many preparations used in animals have been formulated for humans, and the release kinetics may vary substantially in animals.. A less common mechanism of constant drug input is slow release from circulating plasma proteins for a drug that is highly protein bound (e.g., cefovecin).

A second scenario is a drug administered at an interval that is much shorter than the half-life. For such drugs, little drug may be eliminated during the dosing interval, and shortening the interval will be beneficial only if an additional dose is added (rather than dividing the same daily dose into more dosing periods). For example, assume the half-life of phenobarbital approximates an average of 72 hours. Dividing the dose into 8- rather than 12-hour intervals offers no advantage because 3 days must lapse for 50% of the drug to be eliminated. Indeed, a 24-hour dosing interval may be sufficient for most patients, unless induction of drug-metabolizing enzymes causes the half-life to markedly decrease (see Chapter 2). For drugs with very long half-lives, depending on the C_{max} and C_{min} of the drug, dosing intervals generally can be correspondingly long. However, a dosing interval that is too long might result in too much fluctuation in PDC during a dosing interval, which may be problematic for drugs characterized by a narrow therapeutic window. It also might lead to noncompliance if the owner forgets to medicate. In both situations the recommended dosing interval is often shorter than the drug elimination half-life. In such instances the drug will accumulate, and the concept of steady state and the potential need for a loading dose must be addressed (see below).

Accumulation

If a drug is administered at an interval that is approximately three half-lives, most (87.5%) of the drug will be eliminated between each dose. However, if the interval is shorter, some drug from the previous dose will still be present in the plasma when the next dose is given. Indeed, if the drug is administered at an interval that equals the half-life, 50% of the previous dose is still in the body when the next dose is given. Thus if each subsequent dose of drug is administered at an interval (T) that is equal to or shorter than the drug half-life, most of the previous dose is still in the body, and the drug accumulates with multiple doses (see Figures 1-17 and 1-21).^{2,3} Eventually, a steady state is reached such that the amount of drug administered with each dose equals the amount eliminated during the dosing interval. As with drug elimination, approximately three to five drug half-lives must elapse following a fixed dosing regimen before steady state is reached. Note that steady state is a relevant issue only for drugs that accumulate-that is, the drug is administered at a dosing interval that is shorter than the drug elimination half-life. The amount of accumulation can be described by the accumulation ratio (R), which describes the magnitude of the drug concentration following the first dose compared with that at steady state (Css); the ratio can be applied to C_{min} , C_{max} , or $C_{average}$ (R = Css/C^{1st}).

Just as the amount of fluctuation between C_{min} and C_{max} depends on the relationship between half-life and interval (i.e., for a drug dosed at an interval shorter than the half-life), the accumulation ratio also depends on the relationship between dose and interval, being logarithmically proportional to the difference between the two: $R = 1/1- e^{-kel^* T}$ where R = the accumulation ratio, T = the dosing interval and $k_{el} =$ the elimination rate constant (see Figure 1-21 and Tables 1-1 and 1-2). The dosing regimen of drugs that accumulate is generally designed so that drug concentrations will be in the therapeutic range at steady state. If the elimination half-life is equal to the dosing interval, although PDC will fluctuate

Table 1-2Rate of Drug Accumulation Based on the Length of the Dosing Interv (T) Compared with Elimination Half-Life (t1/2)			osing Interval
Dosing Interval (Hours)	Elimination Half-Life (Hours)	T: t _⊮ Ratio	Accumulation*
6	24	0.25	6.2
8	24	0.33	4.8
12	24	0.5	3.4
24	24	1	2
48	24	2	1.3
72	24	3	1.14
96	24	4	1.0

*Accumulation is the ratio of peak plasma drug concentration following the dose at steady state compared with that following the first dose (Cmax_{ss} : Cmax _{first dose}).

twofold between doses, the drug will also accumulate twofold (i.e., C_{max} at first dose: C_{max} at steady state = 2) as steady-state is reached. The greater the half-life compared with the dosing interval, the more the drug will accumulate (see Table 1-2). Using the example of phenobarbital, as drug is begun, the elimination half-life may approximate 72 hours ($k_{el}=0.693/72$ h). When the seventh dose is given 72 hours later, 50% of the first dose still remains. Based on a 72-hour half-life and 12-hour dosing interval, an accumulation ratio of 9 is expected. Thus if peak PDC following the first dose of 3.5 mg/kg was 2 µg/ mL, concentrations of 18 µg/mL would be expected at steady state 9 to 14 days later. Because drug concentrations fluctuate very little for drugs that accumulate, missed doses should present minimal risk of therapeutic failure. The missed dose can simply be given with the next dose. However, to change PDCs substantially, multiple doses (i.e., a "miniloading" dose) must be given. When monitoring, a single sample collected at any time during the dosing interval should accurately reflect PDC throughout the dosing interval because concentrations change minimally during the interval.

With a 21-day half-life in dogs, bromide offers an extreme example of accumulation when dosed once daily. At steady state, bromide concentrations will be 35 times what they were after the first dose. Likewise, during a 24-hour dosing interval, fluctuations in PDC will be so small that they should not be detectable. Levetiracetam, on the other hand, offers an example at the other end of the spectrum: With a 2-hour half-life, 87% of the drug may be eliminated during an 8-hour dosing interval. Missed doses may put the patient at risk for therapeutic failure, and monitoring might best include both a peak and trough sample. If only one sample can be collected, a trough sample might be sufficient because the drug is so safe. However, if side or adverse effects are of concern with the drug (e.g., clorazepate), both a peak and trough sample might be collected for drugs with a short half-life compared with the dosing interval.

Clinically, drugs that accumulate present another problem not encountered with drugs administered at an interval that precludes accumulation. Maximum therapeutic efficacy is not

realized until steady-state concentrations are reached, which may be an unacceptable time for some patients (e.g., epileptics receiving potassium bromide [KBr]) (see Figure 1-21). In such situations a loading dose can be administered with the intent of achieving therapeutic concentrations with a single dose or, in the case of bromide, several days of dosing. Note, however, that a loading dose **does not** achieve steady state. Steady state is achieved only after the drug is administered at the same dose for three to five drug half-lives. As such, although a properly calculated loading dose will result in PDCs immediately achieving the therapeutic range, the maintenance dose must be designed to maintain these concentrations. A loading dose should be considered only when therapeutic response depends on steady-state concentrations and the time to this point is unacceptable (i.e., three to five drug half-lives). The benefits of loading (i.e., a rapid response) should be weighed against the risk of adverse events that will be increased if the body does not have time to accommodate to high drug concentrations. Further, pet owners are not likely to understand the concept of loading and may either forget to modify or intentionally continue a loading dose, the latter because they wrongly assume that a higher dose can be tolerated longer.

A loading dose always is accompanied by a maintenance dose; the maintenance would be the same regardless of whether a loading dose is administered concurrently because it also is designed to achieve therapeutic concentrations at steady state. The maintenance dose should "match" the loading dose-that is, it should be designed to maintain what the loading dose achieved. The maintenance dose, not the loading dose, determines PDC at steady state: By the time steady state is reached (three to five half-lives), the loading dose will have been eliminated. However, at one half-life, while 50% of the loading dose will have been eliminated, 50% of steady-state concentrations will have been achieved. If the maintenance dose fails to maintain what the loading dose achieved, PDC will either decline (maintenance dose too small) or increase (dose too great) as steady state is achieved. Either miscalculation can lead to therapeutic failure. The greatest decrease (or increase) will occur during the first elimination half-life after loading is completed; as such, inappropriate patient response may occur at one half-life.

The loading dose is calculated according to the (apparent) Vd at steady state (Vd_{ss}) of the drug and the targeted PDC at steady state, C_{ss} (mg/mL). Thus for drugs with 100% bioavailability (e.g., intravenously administered drugs):

Loading dose (D_L; mg/kg) = Vd_{ss} × C_{ss}

The dose can be adjusted for less than 100% bioavailability by:

 $D_L = Vd_{ss} \times C_{ss} / F$ where F is the bioavailability (fraction of the drug absorbed)

Using bromide as an example, the minimum effective concentration (C_{min}) is 1 mg/mL (1 gm/L). With a Vd of 0.3 L/ kg, and near 100% oral bioavailability, a loading dose intended to achieve the minimum therapeutic range would be C_{min} * Vd/F or (0.3 l/kg) * (1 gm/L)/1 or 300 mg/kg. Because potassium bromide is only 69% bromide (potassium MW = 35; bromide MW = 79), the dose of potassium bromide necessary

Box 1-4

Calculation of a Constant-Rate Infusion for Fentanyl

In normal dogs, the volume of distribution (Vd) of fentanyl ranges from 4 to 10 L/kg and its $t_{1/2}$ ranged from 2.5 to 6 h. Using an average Vd or 7 L/kg and 3h as the $t_{1/2}$, then $k_{el} = 0.693/3 = 0..35$ hr⁻¹ and clearance (CL) becomes (0.173 hour⁻¹ * 7 L/kg) = 2.45 L/kg/h (2450 mL/kg/h to match units). To target C_{min} or 1 ng/mL (or 1 μ g/L) of fentanyl at steady state (9-15 hours), the rate of infusion (ROI or Ro) = ([1 ng/mL] * 2450 mL/kg/h) = 2450 ng/kg/h (2.45 μ g/kg/h) or 0.04 μ g/kg/min. If the half-life is 3 hours, steady-state concentrations should be reached in approximately 9 to 15 hours. Although analgesic relief may not require steady-state concentrations, safety of the constant-rate infusion cannot be fully assessed until steady state is reached. If the time to steady state is too long, 1 ng/mL (C_{min}) can be immediately reached by an administration of a loading dose (DL): DL = $C_{ss} * Vd = (5 L/kg * 1 \mu g/L)$ or 5 μ g/kg, which can be administered as an intravenous bolus.

to achieve 1 mg/mL is 300 mg/kg/0.69 = 433 (rounded up to 450 mg/kg). Note that he loading dose of bromide that targets 1 mg/ml at steady-state is much higher than the daily maintenance dose (approximately 30 mg/kg per day) that would achieve 1 mg/mL at steady state (approximately 2.5 months of dosing). The difference between the loading dose of a drug and its maintenance dose reflects the difference between the elimination half-life and the dosing interval. Simplistically, the loading dose should reflect all the doses that would be given as the drug reaches steady state, less the amount eliminated during that same time period. The longer the elimination half-life, the larger the loading dose compared to the maintenance dose.

Constant-rate infusion (CRI) offers an example of a drug that is administered at an interval that is much shorter than the half-life (Box 1-4). For CRI the rate is infinitely small. The rate of infusion (ROI or k_0) should result in an input that equals the output. Output will be described by (total body) clearance (CL; ml/kg/hr) of the drug: ROI (mg/kg/h) = $CL \times C_{ss}$ (see pharmacokinetics section). Because clearance, in turn, reflects the volume of blood from which drug is eliminated per unit time (CL = Vd * k_{el}), then ROI = Css * Vd * k_{el} . Further, because k_{el} can be calculated from half-life, then ROI = Css * Vd * $(0.693/t_{1/2})$. When calculating CRI, care must be taken to ensure that units are converted such that they match. Note that increasing the ROI will increase the total concentration achieved at steady state but will not increase or decrease the time to steady state. As with any other dosing scheme, steady state will not be achieved with a CRI until three to five elimination half-lives have elapsed, which may be unacceptably long. As such, a loading dose may be indicated when administering a CRI if patient response time is too long. Note, however, that a sufficient clinical response may occur well before maximum drug concentrations are achieved at steady-state. Likewise, the time for drug concentrations to decline after a CRI is discontinued will be based on the same elimination rate constant: Three to five drug half-lives must elapse before the drug is eliminated from the body, although clinical response may resolve well before all the drug is entirely eliminated.

Extrapolation of dosing regimens among species for drugs that accumulate is more difficult than for drugs that do not. For drugs that do not accumulate, dose is largely based on Vd and, if not administered intravenously, bioavailability (which can be difficult to extrapolate among species). However, for drugs that accumulate, if the drug is given in multiple doses, both Vd and elimination half-life must be taken into account for intravenous drugs, along with bioavailability for nonintravenous drugs.

PHARMACOKINETICS

The quantitative description of drug movements in the body is referred to as pharmacokinetics. Pharmacokinetic modeling is used to predict the behavior of a drug in the body. Generally, the drug of interest is given at the desired route of administration as a single dose, and drug concentrations are collected over time, preferably for at least three elimination half-lives to ensure that all phases of drug movement are identified. For bioavailability studies, the drug should be given intravenously (100%) as well as by the route of interest, ideally using a randomized crossover paired design. For drugs intended for multiple dosing, particularly chronically, pharmacokinetic analysis also should take place across the intended duration of therapy to detect changes in drug disposition over time. Several methods of pharmacokinetic modeling are used to study drug movements; the most common described in the veterinary literature are either compartmental or noncompartmental analysis; population pharmacokinetics represents an emerging variation.^{2,3,9,33} Boxes 1-3 to 1-6 provide some useful pharmacokinetic equations.

Compartmental Analysis

Compartments

Plotting of PDC versus time data on semilogarithmic paper linearizes the data for most drugs because drug movements follow first-order kinetics-that is, a constant fraction rather than a constant amount (zero order) of drug moves (is absorbed, distributed, or excreted) per unit time. For firstorder behavior, the amount of drug per unit time varies with the concentration of drug, whereas with zero-order elimination (as might occur when metabolism enzymes are saturated), the amount eliminated per unit time is concentration independent. Theoretically, after administration, each movement to which the drug is subjected occurs at a different rate: absorption and distribution are generally faster than elimination. Each movement results in a change in the slope of the curve, with each slope thus reflecting a different drug movement or combination of movements. Intravenous drug administration yields a PDC versus time curve that begins with the highest PDC (see Figures 1-19 and 1-22).

After intravenous administration (no absorption), data described by a single component (i.e., only one slope or rate; see Figure 1-19) is interpreted to indicate that only one compartment or drug movement occurs, which is elimination from the body (excretion Such a behavior might describe a drug whose distribution is either instantaneous (or occurs

before the first sample is collected) or is limited to plasma (i.e., highly protein bound drug). The model is described as a one-compartment open (meaning drug can move into or out of compartments) model. More commonly, two drug movements characterize the time course of the drug in the body (see Figure 1-22, plot A). For such drugs, PDCs initially decline because of the combined effects of two drug movements: distribution to (and from) tissues and excretion (elimination) from the body. Because distribution is generally more rapid, elimination emerges after distribution equilibrium (pseudoequilibrium) is reached (i.e., the amount of drug moving into tissue equals the amount of drug leaving the tissue). Beyond that point, less drug is leaving the plasma because changes in PDC reflect only one drug movement, excretion (elimination from the body). The elimination is slower (the slope is flatter). Data for such drugs is characterized as a two-compartment open model.^{2,3,9} More than two compartments may emerge as drug behavior is modeled. Drugs also can be bound to peripheral tissues. For such drugs the time to distribution to well perfused tissues may reach equilibrium more rapidly than to the deeper peripheral tissues, and the PDC versus time curves may be composed of three or more components: the terminal component presumably reflecting elimination from the body, the next component potentially reflecting distribution to a "deep" compartment, and the initial component reflecting distribution to "peripheral" compartments.

If a drug is given via an extravascular route (e.g., orally, intramuscularly, subcutaneously), the initial change in PDC is characterized by an increase (see Figure 1-22, plot B; nonintravenous). Once absorption is complete, drug concentrations decline as elimination becomes the primary drug movement (see Figure 1-22, plot B; nonintravenous). Because absorption generally is slower than distribution, the latter is often "masked" by the absorptive phase and can not be mathematically determined. Thus, extravascular administration may be characterized only by two drug movements, absorption and elimination (one compartment open model with first order input). It is important to note that the assignment of each component or compartment of the PDC versus curve to a specific drug movement is theoretical. While conceptually, this approach to modeling makes sense, other models also can describe the data without compartmentalization (e.g., physiologic).

Mathematical Description

In order to pharmacokinetically describe or model drug behavior, thus allowing prediction of drug concentrations at any time, the time course of drug movements is reduced to one equation that best describes, or "fits" the data. If the data are best described by multiple compartments, each component should be described uniquely in the equation. Thus to distinguish the rate constant and Y intercept of one movement from those of another, each slope must be separated or "stripped" from the combined curve. Each component of PDC can be manually separated from the previous component. To do so, the terminal-most component is first extrapolated to the Y axis, and the "predicted" Y values on that line are subtracted from the "actual" data on the PDC versus time curve. The residuals (predicted) are plotted at the same time points, and a new line is drawn to represent the next (proximal) component of the curve. The process is repeated for each component until the initial component has been identified. The process of residual analysis is tedious; as such, computergenerated programs generally strip the data and identify the components. Each component that results from stripping is then subjected to linear regression to determine the equation that best describes each component of the time versus PDC relationship. Thus, one of the disadvantages of compartmental analysis is that predicted data, rather than actual data, may be the basis for determining pharmacokinetic parameters. This does not represent a problem unless the predicted data are not a good "fit"; poorly fitting data will contribute to the variability of the data. Scientific papers that describe the pharmacokinetics of a drug on the basis of compartmental analysis should provide an assessment (e.g., sum of residuals) of how well the actual data fit the "best" predictive line resulting from linear regression, thus providing an indication of the relevance of the predicted parameters to actual parameters. The advantage of compartmental analysis is that each component may reflect a different drug movement (absorption, distribution, or elimination), thus elucidating drug behavior. However, no matter how good the fit, the labeling of a component of the curve with a drug movement is theoretical and may not actually reflect what occurs in the body. Further, the labeling of each of the components of the curve with a drug movement, although routinely done, is theoretical: modeling does not assure the first component is distribution, the next elimination, etc.

Once separated, each component of the PDC versus time curve is described by a Y intercept (Co if one compartment [see Figure 1-19], A and B if two compartments [see Figure 1-22, plot A], or A, B, and C for three compartments, and so forth) and a rate constant (k_{el} for one compartment or α , β , or y, and so forth, for multiple compartments). The Y intercept for each component is determined by extrapolation of the line of each component (beginning with the terminalmost) back to the Y axis. For a one-compartment model, the extrapolated Y intercept is generally referred to as Co to indicate plasma drug concentrations at time 0. For multiple components each succeeding component is not extrapolated until that portion of the line has been stripped from the distal component. The units of PDC as extrapolated to Y are weight/volume (i.e., µg/mL, mg/mL, mg/L, and so on). The rate constant (or slope) describes the percentage change per unit time for each component. The rate constant of the terminal-most component is generally referred to as k_{el} but also referred to as β if a two-component curve, γ with three components, and so on. Alternatively, the slopes or rate constant may simply be referred to as λ (lambda; i.e., λ_1 , λ_2 , λ_z , etc with λ_z being the terminal component) as a reminder that assignment of movements is theoretical. The units of rate constants are the inverse of time (time⁻¹, e.g., min⁻¹). The rate constant of the initial component of the curve following intravenous administration is generally referred to as α and the distribution rate constant.

Box 1-5

Parameters for Compartmental Analysis

Plasma drug concentrations (Cp), at any time (t) after administration. For open model, after intravenous administration:

One compartment: Cp = Coe^{-kt} (Figure 1-19)

Two compartment: $Cp = Ae^{-\alpha t} + Be^{-\beta t}$ (Figure 1-22)

Three compartment: $Cp = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$.

For first order input (extravascular): $Cp = Be^{-kel^*t} - Ae^{-ka^*t}$

Area under the curve (AUC): One compartment: AUC = A/ α ; (or Co/ k_{el}). Two compartment: AUC = A/ α + B/ β : three compartment: AUC = A/ α + B/ β + C/ γ . Units for AUC are reflected in its determinants: plasma drug concentrations represented by the respective Y intercepts Co, A B, C, and so on, reported in weight/ volume (e.g., mg/L or µg/mL), and the respective rate constants (α , β , γ , and so on for intravenous administration and k_a for the absorptive phase of extravascular administration; reported in inverse time or time⁻¹[e.g., min⁻¹]).

Area under the moment curve (AUMC): A/α^2 for one compartment; $A/\alpha^2 + B/\beta^2$ for a two-compartment model, and so on).

(Apparent) Volume of Distributions (Vd): Vc (volume of the central compartment), Vd_B, Vd area, and Vd_{ss}; > Vd_B > Vd area > Vd_{ss} > Vc.): Units of volume/mass (e.g., L/kg) reflect the dose (generally mg/kg) and extrapolated drug concentration (C_0 or B). The Vd of a drug can be determined only after intravenous administration because bioavailability = 100 %; if F is known, Vd can be calculated substituting D * F for D in each of the equations.

One compartment: Vd = Dose/Co

Two compartment: $V_c = Dose/A$

Vd $_{\rm B}$ = Dose/B (Figure 1-22, Figure 1-23)

Vd area = Dose/(AUC $\star \beta$)

Vdss: $(D \times AUMC)/AUC^2$

Dose (D) (units generally mass/mass, e.g., mg/kg):

Intravenous administration: D = Co * Vd Extravascular administration: D = Co * Vd/F

Clearance (CL): The CL of a drug represents the fraction of the Vd of a drug that is cleared per unit time (k_{el}) . Thus if the Vd and k_{el} (or half-life) of a drug are known, the CL of the drug can also be determined: CL = Vd • k_{el} Because CL is calculated from Vd, it can be determined only after intravenous administration of a drug (unless F is known).

Volume or weight units must match for all calculations.

Once the Y intercept and slope of each curve is identified, the PDC versus time curve, regardless of the number of components, can be described by the following basic equation: $(Cp) = Coe^{-kt}$, where Cp is the plasma drug concentration at any time, t; Co is the instantaneous plasma drug concentration (before distribution or elimination have occurred, extrapolated from the appropriate component of the curve), and k is the respective elimination rate constant (slope of the line). This equation is simply the semilogarithmic (because movements are first order) version of the equation for a line, Y= mx + B where Y is the concentration (Cp) at any time X (t), m is the (logarithmic) slope of the line (e^{-k}), and B is the Y intercept (Co) (Box 1-5).

A similar approach to modeling is taken for extravascular data, which must be described by at least two components. The slope of the upswing of the PDC versus time curve (once stripped from the distribution or elimination components of the curve) describes the absorption rate constant, designated k_a ; the Y intercept must be determined after all other components of the curve are stripped (see Figure 1-22). For extravascular administration, the model would be referred to as a one-compartment open model with first-order input, indicating that the rate of absorption, like the rate of elimination, is first order. If the decline in PDC after the absorptive phase revealed two slopes, the model would be two compartments, with the first compartment or component possibly representing distribution that was slower than absorption. For some drugs (including extended- or delayed-release preparations), the rate of absorption is slower than the rate of elimination. For such drugs, absorption is reflected in the terminal-most, rather than initial, component of the PDC versus time curve and the elimination rate constant for such drugs is determined from the upswing of the PDC versus time curve. Such drugs are generally said to follow a "flip-flop" model and can be identified only after intravenous administration because it is only through this route that the effects of absorption are removed from the terminal component of the curve (see Figure 1-22). Drugs exhibiting a flip-flop behavior are characterized by a terminal rate constant following intravenous administration that is statistically shorter than the terminal rate constant measured after non-IV administration.

Area under the Curve (AUC)

Once the equation of the PDC versus time curve of a drug has been established, a number of parameters can be determined to further describe or explore drug behavior (see Box 1-5). Among the more important parameters generated from pharmacokinetic analysis is the AUC, a parameter that indicates duration and extent of exposure of a drug after administration of a specific dose. Following compartmental analysis, AUC is calculated by dividing the Y intercept of each slope by the rate constant of the slope; for multiple compartments the terms are additive. Thus, for a one-compartment model, AUC = A/α ; (or Co/ k_{el}); for a two-compartment model, AUC = A/α + B/β , and so on (see Figure 1-22). The units for AUC are reflected in its determinants: PDC (Co, A, B, and so on) of mg/mL (or weight/volume) and a rate constant (inverse time or time⁻¹: min⁻¹). An example would be an AUC of 546 mg * min/mL.

AUC is used to calculate several other parameters important to the description of drug behavior. Area under the moment curve (**AUMC**: A/α^2 for one-compartment model, $A/\alpha^2 + B/\beta^2$ for a two-compartment model, and so on) is a parameter with little physiologic relevance, but it is used to calculate other parameters. Among the more important parameters based on AUC is bioavailability, the percentage of a drug that reaches systemic circulation. Absolute bioavailability is determined by measuring the AUC after nonintravenous administration (see shaded area of plot B in Figure 1-22) and comparing it with the AUC measured after intravenous administration (100% absorption), with differences in doses adjusted for as needed. Rather than presented as a percentage, bioavailability is often presented as a ratio (F) and, as such, is unit-less. If the AUC for both curves is equal, bioavailability is 100% (F = 1) (Box 1-6).

Box 1-6

Bioavailability Calculation

Bioavailability (F, unitless) is the percentage of a drug that reaches systemic circulation. **Absolute** bioavailability is determined by measuring the area under the curve (AUC) after nonintravenous administration and comparing it with the AUC measured after intravenous administration (100% absorption), with differences in doses adjusted for as needed (see Figure 1-22): $F = [AUC_X] * [Dose_{IV}] / [AUC_{IV}] * [Dose_X]$, where X is the nonintravenous route of administration (Figure 1-22). **Relative** bioavailability can be compared between different nonintravenous routes in the same manner.

Rate Constants and Half-lives

Generally, because each component of the curve is associated with a specific drug movement, the half-life is also associated with that movement (e.g., absorption, distribution, or elimination [disappearance] half-lives), each referring to the time necessary for 50% of the respective drug movement to be complete (or reach equilibrium). Of the drug movements, elimination from the body is generally the slowest. As such, the elimination half-life is represented by the slope of the terminal, or final component, of the PDC versus time curve. However, this assignment can only be confirmed with IV administration since the terminal component of non-IV administration may reflect absorption (i.e., a flip-flop model). If an intravenous dose is not studied, the terminal component may be referred to as a disappearance rate constant or half-life. The distribution half-life is generally calculated from the initial component of the curve (generally referred to as α) following intravenous administration; the distribution component of the curve is often masked with oral administration. Absorption half-life is derived from the k_a unless a flip-flop model has been identified. Note that the faster the absorption half-life, the higher C_{max} and shorter T_{max}, the time to the maximum concentration. Because half-life is calculated from the inverse of k_{el} ($t_{1/2}$ $= 0.693/k_{el}$) (see Box 1-4), half-life from a sample population cannot be normally distributed. As such, reports providing descriptive statistics should be reported as harmonic mean (derived from averaging the inverse of each half-life, [1/HL + 1/HL...] and reinversing the mean) and pseudo standard deviation is generally reported.

Volume of Distribution

The dose of a drug is based on the target concentration and the volume of tissue to which the drug appears to be distributed. The actual volume of tissue distribution cannot be calculated. However, the Vd is a theoretical volume to which the drug is distributed (or the volume of tissue that dilutes a drug), assuming that the drug concentration throughout the body is the same as that measured in plasma. Because this is unlikely, and because it is mathematically derived, the Vd of a drug is referred to as *apparent*. The Vd of a drug is calculated by administering a known dose intravenously and dividing it by the maximum PDC that occurs after the drug is distributed but before any elimination occurs: Vd = Dose/PDC (Co) (Figure 1-23). Because dose is generally in milligrams per kilogram and C_0 (or B) is generally milligrams per milliliter (the same as grams per liter), Vd is generally reported as liters per kilogram. The Vd of a drug can be determined only after intravenous administration in order to ensure that all drug reaches systemic circulation (i.e., bioavailability = 100 %). Occasionally, if a drug is not given intravenously, scientific articles or drug package inserts might report Vd/F, indicating the Vd corrected for bioavailability that is less than 100% (F<1). However, the clinical relevance of this parameter largely depends on knowledge of bioavailability.

The Vd of a drug is primarily used to calculate the dose of the drug (see Box 1-5). Three different Vds are reported in the literature. Because the PDC cannot be measured immediately (before distribution and elimination influence the curve), the PDC used to determine Vd must be derived after the terminal component is extrapolated to the Y intercept (see Figure 1-22). If the plasma elimination curve yields only one component (e.g., distribution from plasma does not occur or is instantaneous), PDC is extrapolated to time 0 or C_0 , yielding the volume of the central compartment (Vc). This volume can be used to determine the initial concentration of a drug (e.g., to assess potential toxicity) or to estimate plasma volume. However, for many drugs distribution is not instantaneous and the PDC versus time curve is multicomponent. To remove the effects of elimination that occur during distribution, the terminal component of the PDC is then extrapolated to the Y axis. Generally referred to as B if the model is two-compartment, this PDC theoretically reflects peak PDC after distribution has reached equilibrium (pseudo-equilibrium) but prior to elimination. The Vd after distribution has reached pseudoequilibrium then becomes Vd = Dose/B, often referred to as

Vd area, Vd extrapolated, or *Vd*β. For multicomponent curves, Vc can still be determined using the extrapolated initial component of the curve using A (or C₀): Vc = Dose/C₀ or Dose/A (see Figure 1-22).^{2,3,12,30,34,35} Because Vd area is influenced by clearance (it is based on extrapolation of the terminal elimination curve), it tends to overestimate the true volume. It is useful to predict the amount of drug that remains to be excreted at any time point during elimination.¹⁷ The third Vd is that which occurs at steady state, when equilibrium has been reached (Vdss). True equilibrium can be reached only if clearance does not occur, or if input equals output, as might occur with CRI.¹⁷ As such, Vdss is independent of clearance and more accurately reflects the true volume diluting the drug. (see Box 1-5).

The Vd, although a calculated parameter, is used to calculate clearance, which is the physiologic action that is responsible for the elimination of drug (see Box 1-5). As with Vd, CL/F may be reported in studies for which an intravenous drug was not administered. However, this is not a clinically relevant parameter unless bioavailability has been demonstrated to be 100% for the animals in the study in question or unless bioavailability is known. Although generally calculated, clearance can be measured. However, collection requires repeated sample of the tissue into which drug is cleared. Plasma clearance of a drug that is cleared exclusively through the urine can be determined by sequentially sampling urine rather than plasma or, as with creatinine clearance, collecting a volume of urine into which the drug has cleared and plasma samples containing the drug at the beginning and end of the sampling time. Determining clearance of a drug excreted in the bile would require biliary catheterization.

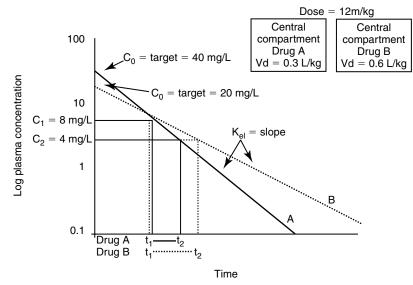

Figure 1-23 Changes in volume of distribution (Vd) affect plasma drug concentration and the slope of the elimination (k_{el}) curve that determines elimination half-life. The former is impacted because movement of drug into tissues removes it from plasma and thus organs of elimination. Plot A represents PDC versus time following administration of a dose of drug in an animal with a Vd that is half of that represented in plot B (compartment size increased in the latter). Note that the slope of the plasma elimination curves for animal B is flatter. As such, elimination half-life also will be longer. Drug half-life can be determined by measuring the time ($t_2 - t_1$) necessary for PDC to decrease drop 50% (C_1 to C_2).

All models are, by definition, incorrect. Thus, a disadvantage of compartmental analysis is that data (particularly poor fitting data) is forced to fit the "best" equation that mathematically describes the data (Box 1-7). The more variable the data, the more inaccurate compartmental analysis is because the greater the deviation of actual data from predicted data. Noncompartmental analysis often is used in lieu of compartmental analysis, particularly if rate constants are not necessary to describe the behavior of a drug in the body. Further, no attempt is made to relate noncompartmental pharmacokinetic parameters with physiologic processes, thus reducing confusion or bias that might occur with interpretation. For noncompartmental analysis the primary parameter determined is

Box 1-7

Parameters for Noncompartmental Analysis

Mean residence time: MRT = AUC/AUMC (area under the curve/ area under the moment curve)

Clearance (intravenous only): CL = dose/AUC

Extravascular: CL and volume of distribution (Vd) must be corrected for bioavailability by multiplying by D * F. For extravascular administration, mean absorption time (MAT) describes the absorptive phase of the drug movement; however, it can be determined only if the drug is also studied intravenously (MAT = MRT_{EV}- MRT_{IV} where EV = extravascular).

Vd at steady state (intravenous only): Vd_{ss} = Vdss: (D × AUMC)/ AUC² (* Extravascular: Vdss: (D * F x AUMC)/AUC²) Volume or weight units must match for all calculations.

(From Martinez MN: Special series: use of pharmacokinetics in veterinary medicine, Article II: volume, clearance, and half-life, *J Am Vet Med Assoc* 213:1122-1127, 1998.)

AUC. This parameter can be determined in a variety of ways, but the most common (for noncompartmental analysis) is the trapezoidal method (Figure 1-24).^{33,34} For this method a series of sequential trapezoids are drawn, each defined by a line drawn between two subsequent data points in the PDC versus time curve. The remainder of the trapezoid is determined by dropping the lines from each data point on the line to the X axis. The area for each trapezoid is determined, and areas are summed to generate AUC. The last trapezoid can end at either the last actual time point measured or be extrapolated "to infinity" based on the slope of the terminal component of the data. As with compartmental analysis, the elimination rate constant (terminal component of the curve) and thus half-life is based on the best-fit analysis. However, all other remaining parameters are based on AUC. As such, mean residence time, MRT, is a comparable, more physiologically descriptive and thus preferred parameter to elimination half-life. Based on AUC, MRT describes the average time a molecule is in the body (or the time necessary for 63.2% of a drug to be eliminated). The difference between MRT after intravenous versus extravascular administration is the mean absorption time, MAT, providing a noncompartmental method for assessment of the absorptive phase of the drug.

Alternative Pharmacokinetics

Pharmacokinetic studies generally are implemented in a sample population of the target species by administration of a dose via the intended route and subsequent intermittent collection of tissues (generally blood, representing the central compartment, but occasionally specific tissues representing peripheral/ compartments), that are subjected to quantitative analysis of the drug and or its metabolites. The number of animals and samples from each animal must be sufficient for accurate

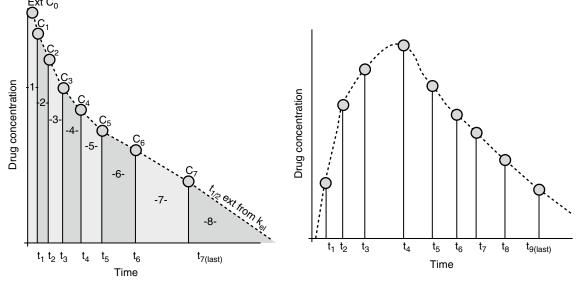

Figure 1-24 For noncompartmental analysis the area under the curve is determined by adding the area calculated for the trapezoids formed by two adjacent data points. If AUC is determined to infinity, the terminal component is based on the slope of the terminal time points as determined by linear regression. The advantage of noncompartmental analysis is that actual data points are used rather than predicted data. As with compartmental analysis, the more data points, the more accurately the data is likely to represent the actual time course.

description of the time course of drug concentrations in the sampled tissue. The more the data points, the better the data represents the population. The approval process for animal drugs does not necessarily require pharmacokinetic modeling of drugs; if required, generally the studies are performed in normal animals. Pharmacokinetics for human drugs are performed in humans, with studies involving dogs most often focusing on toxicity. Data often are available only through Freedom of Information Act publications. Population pharmacokinetics study the sources of variability in drug concentrations among patients, and as such the science takes advantage of multiple studies that differ in study design or subjects. Further, population pharmacokinetics can take advantage of data collected in patients, which generally is restricted because of ethical considerations that might limit the study to small sample numbers.³⁵ With limitations, a pharmacokinetic profile of a drug might also be generated for the individual patient using this approach (Chapter 5).

OTHER CONSIDERATIONS

Dosing Based on Allometric Scaling and Body Surface Area

Allometry refers to the phenomenon of changes in shape that result from changes in size. Allometric scaling attempts to predict a change in physiologic response based on a change in another physiologic parameter. Over 34 anatomic, physiologic (including heart rate, blood volume, and glomerular filtration), and biochemical parameters correlate with body weight across species; not surprisingly, body weight has been extensively examined as a method of allometrically scaling for species differences in physiologic processes. Using the allometric equation $Y = a W^b$, many physiologic parameters (Y) do appear to be predicted by weight (W) adjusted with an allometric exponent (b) of 0.67 to 1. The usefulness of adjusting doses on the basis of body weight scaled according to body surface area (BSA = $10 - W^{2/3}$) was initially realized in children receiving drugs characterized by a narrow therapeutic index.^{37,38}

As with children, the simplest method of dosing based on body weight, tends to underdose small animals and overdose larger animals, and the use of BSA should improve accuracy of dosing. Because animals differ so much in body shape as well as size, the equation can be further normalized by the addition of the shape constant K: BSA = K \cdot 10 – W^{2/3}. The formula is most commonly applied to cancer chemotherapeutic drugs, with the supposition that large-breed dogs would benefit most (thus preventing the relative overdosing they received compared with smaller dogs). However, because the incidence of adverse reactions to cancer chemotherapeutic drugs increased in smaller dogs compared with larger dogs using this approach, the method needs to be reassessed. Several observations made by Price and associates³⁶ help support the need to re-examine the application of the method to all animals. First, studies have suggested that the mass exponent used to correct weight (²/₃ or 0.67) is incorrect. Other studies have shown that the exponent may vary as a function of age. This and other factors suggest that a range of mass exponents should be applied to

animals within the same species. Second, although studies have shown that the allometric scaling of doses does help normalize doses among species, normalization using the same shape constant (K) within species has not been documented. Although a single K may be appropriate for the domestic cat, marked differences should be expected for the dog. Indeed, previous literature reveals that a number of shape constants have been used in dogs, ranging from 9.9 to 12.3 (Appendix 2), with the smaller value being applied to smaller or more compact dogs. It may be necessary to apply different constants to growing animals.

Using allometric scaling based on body weight or BSA, even adjusted for body shape, as a method of predicting dose (which incorporates both pharmacodynamics and pharmacokinetics) is likely to be difficult; many aspects of drug disposition seemingly are not related to BSA or body weight. These include protein binding; effects of pH on drug movement; actions of p-glycoprotein (i.e., active tubular secretion in renal tubular cells); differences in the composition of body compartments; and, most dramatically, differences in the rate, extent, and type of drug-metabolizing enzymes among the species. One study evaluated the allometric relationship between body weight and drug elimination half-life. Because half-life is equally affected by Vd and clearance, it serves as a good parameter to assess the overall relationship. Not surprisingly, those drugs whose half-lives are most likely to be predicted by allometric scaling tended to be minimally protein bound, characterized by a Vd indicative of distribution to ECF and excreted renally in the unchanged but also undergoing flow-limited hepatic extraction;³⁸ many antimicrobials meet these criteria. Half-life tended to be less correlated allometrically with body weight for drugs that were highly protein bound, distributed to specialized body compartments, or metabolized by the liver in a capacity-limited fashion.37,38 Additional studies are needed to identify the most appropriate factors to be used to allometrically scale dosing regimens. To date, use of weight adjusted to BSA appears to be the most reasonable method for smaller animals.

Routes of Administration

Choice of the route and technique of administration is generally based on several factors, including the physicochemical properties of the drug, formulation to be used, therapeutic indication, pathophysiology of the disease, and the target species. The manufacturer's recommendations should always be followed carefully unless it is explicitly known that a proposed deviation will not adversely alter the activity or kinetic fate of the principal ingredients. Note that regardless of the dosage form used, it is imperative to have an appreciation of the makeup of the pharmaceutical formulation, the factors that may alter the efficacy of the product, and the best way to derive optimal therapeutic benefit from the agent without jeopardizing its bioavailability or pharmacologic action.

KEY POINT 1-8 The route of administration might influence the rate and extent of absorption but should not influence distribution or clearance. As such, elimination half-life should not differ.

Oral Administration

The United States Pharmacopeia provides an excellent source of currently accepted dosing forms.³⁸ Common oral dosage forms include tablets, capsules, boluses, powders, granules, syrups, solutions, suspensions, and pastes. Oral bioavailability of oral dosing forms may profoundly differ. Other specialized delivery systems are also available, including enteric-coated tablets and sustained-action or controlled-release preparations. However, if designed for human use, their behavior in animals may be substantially different, particularly if orally administered. The advantages of oral dosing are that it is usually convenient and safe, sterility is not a requirement, and the danger of acute drug reaction is not as great as with intravenous administration. The disadvantages include a slower onset of action and unpredictability and inconsistency of absorption, including the sequela of exposing the drug to the unstable gastrointestinal tract. Additionally, dosing may be difficult in fractious animals, poor technique or dysphagia may lead to intratracheal delivery and subsequent bronchopneumonia, and inactivation may occur within the gastrointestinal tract. Some drugs may cause esophageal damage, particularly in cats.

Parenteral Administration

The most common parenteral dosage form is a stable aqueous solution. Less frequently, the active components may be dissolved in an inert vegetable oil, which delays absorption. Other kinds of prolonged-release preparations include subcutaneous implants of solid dosage forms and relatively insoluble salts and esters as suspensions in various vehicles. It is important to appreciate the basic differences between these and standard pharmaceutical preparations. First, accidental intravenous administration can lead to serious and even fatal effects related to microembolism. Second, persistent drug residues in racing or other show animals may have ethical and legal ramifications. The stability of solutions intended for parenteral administration often is delicate, depending on pH, temperature, and the presence of stabilizers, solubilizers, and preservatives. Indiscriminate mixing of such products for the sake of convenience (e.g., single versus multiple injections) should be avoided unless proof exists that the formulations are physically and chemically compatible. Several novel approaches for the parenteral delivery of drugs are being developed, including microspheres, microcapsules, liposomes, microsponges, resealed carrier erythrocytes, and projectile biodegradable missiles. Additionally, monoclonal antibodies have been used to carry highly selective, bound drugs to specific target tissues or even cells. Implantable controlled-release drug delivery systems include pellets (composed of various polymeric forms) and silicone capsules. Several implantable devices also have been introduced that permit constant systemic delivery of a drug within the body; these include osmotically or propellantdriven pumps and mini pumps. The advent of nanotechnology is likely to markedly improve drug delivery to targeted tissues. Liposomes are the earliest example of drug delivery systems based on nanotechnology; more current products include polymer-drug conjugates.

The most frequently used parenteral routes are intravenous (IV), intramuscular (IM), and subcutaneous (SC). Common but less frequently used routes include epidural, intradermal, intratracheal, and intraperitoneal (IP). Occasional routes of injection include intraarterial, intramedullary, intrathecal, intrathoracic, subarachnoid, intracardiac, subconjunctival, and intratesticular. Intralesional injection is a way of attaining high concentrations of a drug at the target site. In all cases solutions for injection must be sterile, techniques must be aseptic, and the dose must be accurate; a painful reaction is a possibility. For the IV route, aqueous solutions are preferable, which lead immediately to predictably high blood levels with a rapid onset of action. Irritating and nonisotonic solutions can be injected intravenously if done slowly and carefully. Usually, but not always, drugs given intravenously can be given intramuscularly or subcutaneously, but injection may be painful (e.g., arginine vehicles, or other basic or acidic solutions). Further, IM absorption of some IV drugs (e.g., diazepam) is not predictable. The IM route can be used for aqueous or oleaginous suspensions, solutions, and other depot preparations. Absorption occurs either hematogenously or by way of lymphatics and usually is fairly rapid except in the case of long-acting preparations. The addition of esters can variably prolong absorption depending on the rate of hydrolysis. Acetate salts are more slowly hydrolyzed than succinate salts (e.g., glucocorticoids); benzathine salts are more slowly hydrolyzed than procaine salts (e.g., penicillin). Moderately irritating preparations can be injected intramuscularly, but tissue reaction and necrosis may become evident with time. The duration of drug action is longer than for IV injection but most often is slightly shorter than for SC administration; however, this is not always predictable. A disadvantage of the IM route is the possibility of improper deposition in nerves, blood vessels, fat, or between muscle bundles in connective tissue sheaths. The advantages of the SC route are similar to those of the IM route, although irritant preparations and oily vehicles should be avoided due to possible undesirable reactions. The rate of absorption from SC injection sites may be unpredictable and depends on several factors. The most important of these is blood flow, and the presence of vasoconstrictors or vasodilators can substantially alter rates of absorption. Usually, the rate of absorption is slightly slower than from IM sites.

Miscellaneous Parenteral Routes

The other parenteral routes of administration are generally used for the following purposes: epidural and subarachnoid for spinal analgesia and myelography; intradermal testing for hypersensitivity and for vaccination; intratracheal treatment of respiratory tract infections; intraarterial with simultaneous venous constriction, with the latter causing high concentrations of drug in the dependent area for a short time (occasionally necessary in cancer chemotherapy and special radiographic or other imaging techniques); intramedullary (blood transfusion or fluid therapy directly into the bone marrow) when other routes are awkward, as in neonates; intrathecal (cisterna magna) for treatment of meningoencephalitis and myelography; intrathoracic (intrapleural or intrapulmonary and); and intracardiac for emergencies, especially cardiac arrest.

Inhalation (pulmonary route). Gases, volatile agents, and fine particles usually are rapidly absorbed from the airways and alveoli into the pulmonary circulation. Delivery into the respiratory passages is done by standard anesthetic machines in the case of inhalation anesthetics or by vaporization or nebulization for the local delivery of expectorants, bronchodilators, and antiinfective agents. Drugs in the gaseous state readily reach the alveolar surfaces, whereas only particles less than 2 μm (produced by nebulization) are inspired into the terminal ducts and alveoli. Particles less than 5 µm may reach the respiratory bronchioles, and those 5 to 10 µm in size may reach the upper respiratory tract and larger airways. Because the depth of airway penetration is influenced by depth of respiration (directly) and respiratory rate (inversely) as well as the tortuosity of the airways, aerosolization generally should not be the sole route of administration of drugs in animals. Aqueous solutions of antibacterial drugs intended for injection may be delivered intratracheally. Absorption of drugs may occur after topical administration in the respiratory tract.

Topical administration (local application). Drugs can be applied topically to the skin and its adnexa or to a variety of mucous membranes. The routes that may be used include sublingual, intranasal, intravaginal, intrauterine, intracystic, rectal, preputial, ocular, and aural. Many dosage forms have been developed to deliver active principles to the site of application to produce local effects. However, in many instances absorption into the systemic circulation also occurs. A wide variety of preparations are available for dermal application, including ointments, creams, pastes, dusting powders, lotions, sprays, liniments, and poultices. Systemic effects may occur as a result of the animal licking at the applied medication or due to percutaneous drug absorption, which often occurs, especially when the skin is damaged or inflamed (e.g., burns, ulcers, wounds, dermatitis). Absorption through the skin can also be enhanced by occlusive dressings, inunction, or the use of dimethyl sulfoxide (DMSO) as a carrier. Several drugs are deliberately applied to the skin with the anticipation of systemic effects after transdermal absorption—for example, transdermal gels, ectoparasiticides available as "pour-on" formulations, nitroglycerin ointment, and scopolamine in a transdermal patch device as well as iontophoresis devices. Of these the pluroniclecithin transdermal gels, which are generated through compounding pharmacies, appear to be minimally effective for all but a few drugs and their use is not recommended unless specifically supported by scientific studies.

Transmucosal administration. Transmucosal or buccal drug administration represents a variation of oral administration (see previous discussion of topical administration). Drugs are given by mouth with the intent of absorption occurring through the mucosa of the mouth. A major advantage of this route of administration is avoidance of first-pass metabolism, which occurs with drugs that are swallowed. Convenience may be an additional reason. In contrast to the skin, mucosal tissues do not contain a stratum corneum, and therefore drugs are not presented with a significant barrier to movement into vascular tissues. Several methods of transmucosal delivery have been studied in dogs, including transmucosal gels (often with carboxymethylcellulose as the carrier), sprays, and patches. Among the difficulties associated with transmucosal administration in animals is maintaining contact time between drug and surface.

Factors Affecting Drug Disposition

Dawn Merton Boothe

Chapter Outline

PHYSIOLOGIC FACTORS	PATHOLOGIC FACTORS
Age-Induced Differences	Renal Disease
Pregnancy and Lacation	Hepatic Disease
Roles of Species and Breed Differences in Drug	Cardiac Disease
Disposition	Thyroid and Other Diseases
Role of Species Differences in Target	PHARMACOLOGIC FACTORS
Tissues	Pharmaceutical Drug Interactions
Miscellaneous	Intravenous Preparations
RECOMMENDATIONS REGARDING	Oral Preparations
EXTRAPOLATION OF DOSING REGIMENS	Topical Preparations
Drug Information Sources	Compounded Preparations
Water-Soluble Drugs	Pharmacokinetic Drug Interactions
Lipid-Soluble Drugs	Pharmacodynamic Drug Interactions

Ideally, fixed dosing regimens are based on scientific studies performed with the drug of interest in the target species. Often, however, the dose for a drug used in dogs or cats is extrapolated from other species, especially humans to dogs and humans or dogs to cats, rather than based on scientific studies. For those drugs backed by scientific evidence, sample numbers are often too small, resulting in marked variability in the pharmacokinetic parameters. Further, as in human medicine, animals in which pharmacokinetic studies are performed are generally healthy and may not represent the state of disease in the animals treated with the drug. A number of factors can alter plasma drug concentrations (PDCs) in the patient due to changes in drug disposition, thereby increasing the risk of therapeutic failure. Many of these can be anticipated, allowing for adjustments in the dosing regimen. In addition to the disposition of a drug, these factors might also alter patient response to the drug. These factors might be categorized as physiologic factors such as species and age; pathologic factors, particularly cardiac, renal, or hepatic disease; and pharmacologic factors that occur when one drug alters the kinetics or response to another drug (Box 2-1).

PHYSIOLOGIC FACTORS

Age-Induced Differences

Drug Disposition in the Geriatric Animal

This discussion focuses on some of the clinically important changes that are likely to alter response to drug therapy in geriatric patients (Table 2-1) and on actions that can be implemented to compensate or reduce the sequelae of these changes.

 nimal

 clinically important

 ns that can be imple

 elae of these changes.

Age is associated with changes both in pharmacokinetics (gerontokinetics) and pharmacodynamics, with changes generally compared with those of the young adult.¹⁻³ Data in animals are limited, but in general, disposition pattern changes described for humans appear to extrapolate adequately to dogs and cats.⁴ Geriatric animals are at a greater risk for therapeutic failure because of normal aging changes in physiology, an increased incidence of disease, and the likelihood of polypharmacy in response to disease; moreover, a decrease in normal organ protective mechanisms may increase the risk of adverse events. The age at which body functions shift from a period of growth to a period of decay (16 to 18 years in humans) has not been established in dogs and cats. The age probably differs among canine breeds. Aging is accompanied by permanent loss of up to 30% of body cells, with a parallel loss in oxygen consumption. Body composition changes, as do regional blood flow rates. Physiologic functions generally decline steadily with increasing age. In humans basal metabolic rate decreases by 0.4% per year²; according to the National Research Council,⁵ energy requirements of dogs decrease as they age. Changes among the body systems can influence all four drug movements.

KEY POINT 2-1 As the geriatric animal ages, organ mass reduces in size and function by approximately 25%, resulting in corresponding changes in drug disposition.

Cardiovascular. As animals age, cardiac output decreases and circulation transit time increases. In humans cardiac output decreases by about 1% per year for a total decline of 30% to

40% in the aged. Regional and organ blood flow rates similarly decrease.² The net effect of these changes depends on the state of disease but can influence each drug movement. Absorption, metabolism, and excretion are likely to decrease, whereas distribution may increase or decrease depending on the state of vascular responses or fluid retention.^{2,6,7} As cardiac function decreases, secondary compensatory responses can lead to further risks of adverse reaction.⁷ Blood flow is preferably redistributed to the brain and heart, increasing the risk of toxicity of drugs toxic to these tissues.

Central and peripheral nervous systems. As the geriatric patient ages, brain weight and peripheral fiber numbers decrease. Connective tissue infiltrates peripherally.² Oxygen consumption and cerebral blood flow decrease. In addition, decreased amounts of selected neurotransmitters have been documented. Morita and coworkers⁸ reported alterations in the blood-brain barrier in elderly dogs.

Respiratory. In human geriatric patients, residual lung volume decreases by 50% with accompanying decreases in vital capacity, arterial oxygen pressure (PO₂), and maximum oxygen uptake. In addition, the central response to hypoxia and hypercapnia, such as that induced by opioid analgesics, decreases.² Anesthetic or other sedating agents must be used more cautiously.

Gastrointestinal. As animals age, deglutition decreases as a result of decreased salivation and pharyngeal and esophageal motility. Gastric function is characterized by atrophy of the mucosa with a reduction of hydrochloric acid secretion and a subsequent increase in gastric pH. Gastrointestinal motility is generally reduced. The intestinal macrovilli and microvilli also atrophy, increasing the risk of bacterial overgrowth. These sequelae tend to reduce the absorption and thus the PDC of orally administered drugs. Changes in gastrointestinal function (including reduction of gastroprotective effects) may also predispose the geriatric patient to adverse effects induced by toxic drugs such as chemotherapeutic agents and nonsteroidal antiinflammatory drug (NSAID) analgesics. The latter should be used with caution; the clinician should anticipate and be prepared to treat toxicities. Digestibility of key nutrients, such as fat, tends to decrease in elderly cats.9 As with humans, the intestinal microbiota population shifts in elderly dogs and cats, with lactobacilli decreasing and clostridia increasing in dogs¹⁰ and bifidobacteria decreasing in cats.¹¹ In addition to response to antimicrobials, these changes might influence enterohepatic circulation of bile acids and thus, potentially, some drugs.12

Hepatic. Changes in hepatic function are important to the geriatric animal because of the liver's role in the metabolism of drugs.¹³ Hepatocyte number and function decrease, as do hepatic and splanchnic blood flow, hepatic oxidation, and cytochrome P450 content (the primary drug-metabolizing enzyme). Both flow-limited and capacity-limited drugs are affected. For example, hepatic clearance of both opioid analgesics (which are characterized by first-pass metabolism; i.e., flow limited) and nonsteroidal analgesics (eliminated principally by hepatic metabolism; i.e., capacity limited) is decreased in geriatric patients. Increased response of human geriatric patients to opioid analgesics-they require 60% to 75% less drug than younger patients do-has been attributed to changes in drug elimination.^{14,15} Changes in hepatic function, oxygenation, and nutrition may also predispose the liver to drug-induced hepatotoxicity. Because of reduced hepatic function, the geriatric patient may be less able to generate endogenous hepatoprotectant agents, increasing the risk of drug-induced hepatotoxicity (Chapter 4).

Urinary. As renal blood flow decreases, the glomerular filtration rate and active secretory capacity of the nephron unit progressively decrease with age. Both result in a similar decline in renal clearance. Renal excretion is the major route of elimination of many drugs. Changes in renal clearance tend to prolong the elimination and thus increase PDCs in the geriatric patient. Changes in renal function also render the geriatric patient more susceptible to adverse drug reactions such as those induced by aminoglycosides, angiotensin-converting enzyme inhibitors, and NSAID analgesics.

Body weight and composition. Changes in body composition may be among the most complex in the geriatric animal. Like humans, dogs tend to lose lean body mass and accumulate body fat as they age (Figure 2-1).¹⁶ In male humans, fat increases from approximately 18% in young adults up to 50% in the aged.² Increased proportion of body

	Absorption	Distribution	Metabolism	Excretion
Geriatric				
	Decreased gastric motility prolongs time to peak effect	Increased fat mass and decreased lean body weight results in decreased distribu- tion, higher concentration, and shorter half-life of water- soluble drugs	Decreased hepatic mass and drug metabolizing enzymes (phases I and II)	Decreased GFR, decreased renal clearance
	Increased risk of bacterial overgrowth	Increased body fat increasing distribution and prolonging half-life of lipid-soluble drugs	Decreased hepatic blood flow, decreased clearance of flow-limited drugs, increased absorption of drugs that undergo first-pass metabolism	Decreased renal clearance and longer half-life
	Generally decreased absorption	Decreased protein binding compensated for by clearance of free compound (?)	Decreased hepatic clearance and prolonged half-life	Decreased renal protection
	Decreased gastroprotection	Increased distribution to heart and brain as cardiac function declines	Decreased hepatoprotection	
		Decreased distribution of water-soluble drugs resulting in increased drug concentra- tions, shorter half-life	Higher plasma drug concentra- tion	
Pediatric				
≤ 12 weeks	Increased absorption for first 24 hours (during colostrum absorption)	Increased volume of distri- bution, reduced plasma concentrations	Decreased phase I metabolism, being absent for first weeks and reaching adult levels at 3 to 4 months	Decreased renal clearance until 2 to 3 months
	Decreased acidity leading to decreased absorption of weak acids	Greater proportion of extracel- lular fluid reducing plasma concentrations of water- soluble compounds	Increased bioavailability of drugs that normally undergo first-pass metabolism	Prolonged half-life
	Decreased rate (not extent) of absorption of most drugs	Longer half-life	Decreased response to com- pounds that must be metabolized to active state	
	Milk possibly binding to luminal contents	Decreased distribution of com- pounds that accumulate in fat	Decreased peripheral metabo- lism of compounds	
	Reduced absorption of fat-soluble drugs	Decreased protein binding pos- sibly increasing distribution		
		Increased blood flow to brain and heart		
		Increased permeability of		

Table 2-1 The Impact of Age-Related Differences in Physiology on Xenobiotic Disposition

GFR, Glomerular filtration rate.

fat is accompanied by a decrease in total body water and cell mass. Although extracellular fluid does not change in total amount, the relative proportion of total body water that it makes up increases. Thus the proportion of intracellular to extracellular fluid decreases. The sequelae of these changes depend on the drug. As distribution of water-soluble drugs decreases with total body water, PDCs tend to increase. The distribution of lipid-soluble drugs increases as the proportion of body fat increases, however, which tends to decrease PDCs unless the patient is dosed on a mg/kg basis. The impact of aging on body composition in dogs varies with breeds. For example, in one study body fat increased with age in Great Danes but not Labrador Retrievers or Papillons,¹⁷ although this did occur within 1 year of death in

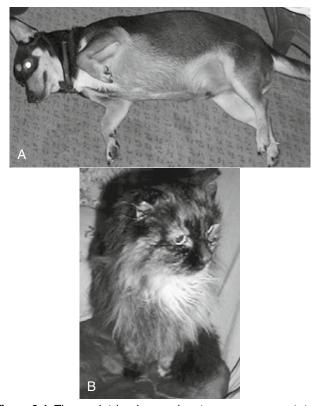

Figure 2-1 The geriatric dog and cats may represent two extremes in regard to the impact of aging on disposition. Body mass frequently increases in dogs (**A**) but decreases in geriatric cats (**B**). Mass loss in cat reflects lean tissue and fat. In contrast to the geriatric animal, adult cats, like dogs, may be characterized by marked differences in body composition, as is exemplified by the obese cat or dog. Water-soluble drugs generally do not distribute to fat, and dosing of water-soluble drug on the basis of total body weight may result in overdose. Dosing on lean body weight is more prudent. Distribution of a lipid-soluble drug to the fat compartment, on the other hand, may increase the volume of distribution, decreasing drug concentrations. For such animals dosing on total body weight (per kg) is more reasonable.

elderly Labrador Retrievers in another study.¹⁶ Although middle-aged cats tend to be overweight, geriatric cats often become thin.⁹ Thus PDCs of water-soluble compounds might be expected to be higher in older animals compared with those of young adults, even if dosing on an mg/kg body weight basis, whereas for lipid soluble drugs, dosing on an mg/kg body weight basis might compensate for potential changes in plasma concentrations.

Serum albumin. Although total serum plasma protein content probably remains the same in the geriatric animal, the proportion represented by albumin decreases and that by gamma globulins increases. Changes in serum albumin can be clinically important to patients receiving highly protein-bound drugs, such as NSAIDs. Decreased albumin can result in a greater proportion of free drug: Most NSAIDs are close to 99% protein bound. A decrease of only 1% (i.e., 99% to 98% binding) doubles the concentration of a pharmacologically active drug. The sequelae of increased PDC may be offset by a compensatory increased clearance, because only unbound drugs are generally conducive to hepatic or renal clearance. However, this balance might be minimized if organs of clearance are negatively affected.

Receptor sensitivity and pharmacodynamics. Geriatric patients respond differently to some drugs, which suggests that tissue receptor sensitivity to the drugs is altered. Changes in receptor number or responsiveness have been implicated but not documented.^{2,3} Physiologic changes such as altered neurotransmission or intracellular constituents have also been suggested. For example, geriatric patients are less likely to perceive, appreciate, or express pain. Thus the need for analgesic therapy is often not detected. In addition, geriatric patients are less able to respond to many analgesic drugs.

Disease. Aged animals are more likely to be suffering from diseases that affect not only drug disposition but also tissue receptivity to drugs and organ protection.¹⁵ The immune system of the geriatric patient is not as effective as that of the adult,¹⁸ leading to the use of bactericidal antimicrobials and minimizing the use of immunosuppressive drugs. In addition, the geriatric patient is more likely to be receiving multiple drugs, which increases the likelihood of drug interactions. Finally, diseases of selected organs may predispose these organs to drug-induced toxicity.

Drug Disposition in the Pediatric Animal

With regard to dogs and cats, *pediatric* generally refers to the first 12 weeks of life.¹⁹ Important developmental changes occurring within this time spectrum, however, justify further staging into neonatal (0 to 2 weeks), infant (>2 to 6 weeks), and pediatric (>6 to 12 weeks) periods of growth. Changes associated with each of these periods cause accompanying changes in drug disposition, thus rendering the pediatric patient more susceptible to drug-induced adverse reactions. All four determinants of drug disposition (i.e., absorption, distribution, metabolism, and excretion) undergo dramatic changes as the neonate matures (see Table 2-1).^{20,21} However, the clinical significance of these sequelae varies.

KEY POINT 2-2 Drug clearance generally does not reach adult capacity until approximately 3 months of age.

Absorption. Young kittens have decreased energy, carbohydrate, and organic matter digestibility compared with kittens older than 19 weeks of age.²² However, because the surface area of the small intestine is large, even in neonates, the extent of drug absorption probably does not clinically differ between normal pediatric and adult animals. The rate of absorption tends to be slower in pediatric animals, however, probably because of decreased gastric emptying and irregular intestinal peristalsis. As a result, peak PDCs may be lower in pediatric patients. The decreased rate of absorption might actually

protect against toxic drug concentrations.^{23,24} However, protection may not be present before absorption of colostrum. During this period the permeability of the intestinal mucosa is increased, leading to increased rate and extent of drug absorption. Occasionally, drugs that normally are not absorbed from the gastrointestinal tract (e.g., aminoglycosides, carbenicillin, and other acid-sensitive beta-lactams and enteric sulfonamides) can reach systemic circulation. Intestinal permeability decreases rapidly after the ingestion of colostrum,^{24,25} possibly because of the endogenous release of hydrocortisone or adrenocorticotropic hormone. Exogenous supplementation of either of these hormones by the 24-hour prepartum mother prevents increased permeability and colostrum absorption in the neonate.

A number of other factors may alter small intestinal drug absorption in pediatric patients. Gastric pH is neutral in the newborn; adult levels are not reached until sometime after birth, depending on the species.^{23,25} Increased gastric pH (achlorhydria) may decrease the absorption of many drugs that require disintegration and dissolution or are ionized in a less acidic environment (e.g., weak acids such as penicillins). Milk diets can reduce drug absorption by either decreasing gastric emptying or directly interacting with drugs (e.g., milk can impair absorption of tetracyclines). The "unstirred water layer" adjacent to the surface area of the mucosal cells is thicker in the neonate than in the older pediatric patient and may limit the rate of absorption of some drugs. As biliary function matures, the absorption of fat-soluble drugs (e.g., griseofulvin and fat-soluble vitamins) increases. Microbial colonization of the gastrointestinal tract may alter response to antimicrobial drugs, extrahepatic metabolism, or enterohepatic circulation.26,27

Absorption from the rectal mucosa is rapid. Rectal administration of drugs or fluids can be used for pediatric patients when venous catheterization is difficult, to reduce complications associated with intravenous administration (e.g., sedation, anesthesia), or when oral administration is undesirable (e.g., antiemetics). Several pediatric drugs intended for systemic effects are available as rectal suppositories. Limited data from studies of human infants indicate that peak plasma concentrations after rectal administration may be higher than those obtained by other routes.²⁶

Absorption of drugs administered parenterally to pediatric animals also varies from that of adults. The rate of absorption after intramuscular administration changes with age as muscle mass and its accompanying blood flow increase and as vasomotor responses mature.²⁶ Because muscle mass is small, subcutaneous administration is frequently preferred for pediatric patients. Again, variability in subcutaneous absorption rates can be anticipated with age. Less fat but greater water may result in faster absorption compared with that in adults.²⁸ Environmental temperature probably influences subcutaneous absorption, particularly in newborns whose thermoregulatory mechanism functions poorly. Cold environments are likely to reduce subcutaneous drug absorption if the neonate is not kept warm. The same is true for patients in a state of hypothermia. Intraperitoneal administration can be a lifesaving route of blood and fluid administration, particularly for the newborn with inaccessible central veins. Isotonic fluids are rapidly absorbed, and up to 70% of red blood cells are absorbed in 48 to 72 hours.²⁹ Blood and fluids can also be administered into the medullary cavity of large bones.^{30,31}

Absorption of volatile anesthetics from the pediatric respiratory tract is rapid because minute ventilation is greater.¹⁹ Thus young animals are more sensitive to the effects of gas anesthetics. Although not a common route of drug administration, percutaneous absorption of drugs is likely to be greater in pediatric patients. Percutaneous absorption is directly related to skin hydration, which is greatest in neonates. Topical administration of potentially toxic lipid-soluble drugs (e.g., hexachlorophene and organophosphates) is not recommended.

Distribution. The most important factors contributing to differences in drug distribution in pediatric patients are differences in body fluid compartments and drug binding to serum proteins. Body fluid compartments undergo profound changes with the growth of the neonate. Both the percentage of total body water and the ratio of compartmental volumes change with maturation. The percentage of total body water decreases with age, but the decrease is more substantial in the extracellular versus the intracellular compartment (see Table 2-1; Figure 2-2).³² Daily fluid requirements are greater in neonatal and pediatric patients, in part because a larger proportion of their body weight is represented by body water (see Figure 2-2). The sequelae of these body compartment differences depend on the normal distribution of the drug. Most water-soluble drugs are distributed to extracellular fluids. In pediatric patients the volume to which these drugs is distributed is therefore higher than in adults; PDCs correspondingly decrease. Thus it may be necessary to increase doses to prevent therapeutic failure. A different pattern might be expected for lipid-soluble drugs because they tend to be distributed to total body water. Such drugs should be dosed according to body weight (e.g., mg/kg). Although decreased PDCs resulting from increased distribution may protect the pediatric patient from potentially toxic drug concentrations,³³ a poor therapeutic response may result from failure to generate therapeutic drug concentrations of water-soluble drugs. The disposition of several antimicrobials in neonatal animals has been reviewed by Baggott,³⁴ with differences in disposition generally found to be similar to those described for humans. Ampicillin is characterized by volumes that are larger in puppies and kittens (threefold to fourfold higher) compared with adults, resulting in clinically significant lower drug concentrations.^{35,36} Distribution of enrofloxacin, a lipid-soluble drug, is somewhat unpredictable and age dependent in kittens, being smaller at 2 to 4 weeks but greater at 4 to 6 weeks.³⁷ Changes in the half-life of each drug parallel changes in distribution. Because many drugs are distributed to a larger volume in pediatric patients, a longer half-life should be anticipated, and it may be necessary to prolong the dosing interval. However, for enrofloxacin in kittens this effect was balanced by increased clearance at 6 weeks.37

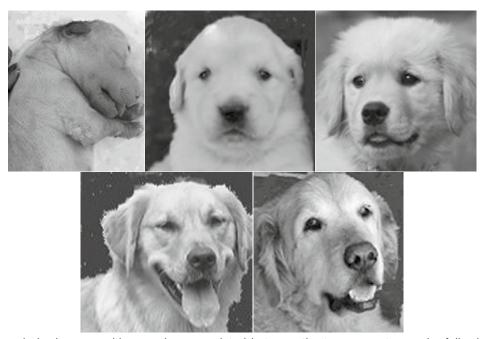

Figure 2-2 Differences in body composition can be appreciated between the two age extremes by following changes as the animal ages. The extracellular compartment and total body water of dogs and cats is greatest in the neonate and gradually decreases toward adult proportions as the animal ages. Increased extracellular fluid and increased total body water result in larger volumes of distribution of most drugs in neonates or pediatric animals, which may decrease plasma drug concentrations and prolong half-life. As the adult ages, fluid content declines, especially in the geriatric cat. The impact of these changes might be greater on water-soluble drugs because the extracellular component represents a greater proportion of total body water in the young animal.

Because the proportion of body fat is smaller in pediatric patients, the distribution of lipid-soluble drugs that accumulate in fat (e.g., organophosphates, chlorinated hydrocarbons, ultrashort thiobarbiturates) may be proportionately decreased. Although drug half-life would decrease, PDCs may become toxic. Many lipid-soluble drugs have a high affinity for and are bound by plasma proteins, thus facilitating their movement through the body. Binding, however, limits their distribution to tissues. Predicting the distribution of highly protein-bound drugs is complicated in the pediatric patient. Serum concentrations of both serum albumin, the protein to which most drugs are bound, and α_1 glycoproteins (to which basic drugs preferentially bind) are decreased in pediatric patients.³⁸ Protein binding of drugs may also be reduced because of differences in albumin structure or because drugs compete with endogenous substrates (e.g., bilirubin) for binding sites.^{24,39} As drugs are displaced, the concentration of free, pharmacologically active drugs and the risk of adverse reactions increases. These changes are significant, however, only if the drug is highly (i.e., >80%) protein bound and characterized by a small therapeutic index. Although the concentration of free drug increases, that of total drug in the plasma tends to decrease because unbound drug is free to distribute into tissue.³⁹ Consequently, drug half-life may increase, and longer dosing intervals may be indicated for potentially toxic drugs. Increased clearance of unbound drug may ultimately normalize a half-life that has been lengthened by an increased volume of distribution.

Differences in regional organ blood flow might cause clinically important changes in drug disposition in pediatric animals. Differences in renal blood flow have been documented^{40,41} and result in clinically important differences in drug excretion. Blood flow to vessel-rich tissues of the body (i.e., heart and brain) is greater and faster;¹⁹ the pediatric patient is thus more susceptible to drug-induced cardiac and central nervous system (CNS) toxicity. The potential for CNS toxicity is further increased because the blood-brain barrier is poorly developed immediately after birth. Increased permeability protects the neonatal brain from a deficiency of nutritional fuels in stressful states (e.g., hypoglycemia, hypoxia, acidosis) by allowing the movement of oxidizable substrates such as lactate into brain cells.⁴² The status of efflux proteins is not yet established. Drugs normally incapable of reaching the adult brain are, however, also able to reach brain cells, which are very susceptible to their effects, thus increasing the risk of CNS toxicity.43,44

Metabolism. Drug elimination, including both hepatic metabolism and renal excretion, is limited in neonatal and pediatric patients. Thus many drugs administered to the young animal are characterized by decreased clearance.^{20,24} In contrast to human infants, hepatic metabolism of drugs is incompetent in the near-term and neonatal puppy.⁴⁵⁻⁴⁷ Both phase I (e.g., oxidative) and phase II (e.g., glucuronidation) reactions are reduced. The various pathways of metabolism mature at different rates. Phase I activity may not occur in the neonatal puppy and may not be evident until day 9 if it does. Activity appears to progressively increase after day 25,

not reaching adult levels until 135 days postpartum.⁴⁶ Drug metabolism in pediatric patients, however, is quite complex. For example, Ecobichon and coworkers⁴⁸ found that in Beagle puppies, phase I metabolites decreased with age, and for phase II metabolism, glucuronidation was the most predominant, with sulfonation decreasing as puppies got older.

Generally, decreased hepatic drug metabolism is reflected as decreased plasma clearance, increased plasma half-life, and potentially toxic PDCs. Dose reduction, dose prolongation of intervals, or both may be indicated for some drugs. Oral bioavailability of drugs characterized by significant first-pass metabolism in adults (e.g., propranolol) is probably greater in puppies and kittens. Response to prodrugs (e.g., primidone; prednisone; enalapril; and, potentially, methylprednisolone) may be reduced because of decreased formation of active drug products. Pediatric hepatic drug-metabolizing enzymes do appear to be inducible by phenobarbital and other drugs. Nonhepatic drug-metabolizing enzymes also appear to be decreased in pediatric patients. For example, pediatric lower plasma cholinesterase can result in increased sensitivity to organophosphates, succinylcholine, and procaine.

Excretion. Reduced renal excretion, characteristic of the pediatric puppy, results in decreased clearance of renally excreted parent drugs and products of phase II drug metabolism. Although the number of glomeruli remains constant throughout pediatric development, both glomerular filtration and renal tubular function progressively increase.^{41,49} Adult values may not be reached until approximately 2.5 months of age. In contrast to glomerular filtration and secretion, renal tubular reabsorption in puppies appears to be similar to that in adults as long as body fluids and electrolytes are maintained.^{50,51} The sequelae of developmental changes in pediatric renal function include decreased clearance and prolonged half-life of drugs (primarily water soluble) excreted by the kidneys. Such a pattern has been shown for several drugs. Compared with current recommendations for adults, pediatric patients may require a higher dose (owing to increased volume of distribution) and longer intervals (owing to increased distribution and decreased clearance) for gentamicin administration. More important, modifications should be anticipated in the gentamicin dosing regimen of unhealthy puppies because they are likely to be affected by conditions that increase the potential for gentamicin-induced nephrotoxicity (e.g., dehydration). However, underdeveloped glomeruli may actually protect the pediatric patient from aminoglycoside-induced nephrotoxicity.²¹ Further investigations are needed to establish safe yet effective doses of gentamicin for the neonatal puppy or kitten.

Specific Drug Therapy for the Pediatric Patient

Fluid therapy. Pediatric patients are predisposed to dehydration because extracellular fluid is increased, renal capacity to conserve water is decreased, the ratio of surface area to body weight is large, and fluid loss through immature skin is greater.⁵² Fluids can be administered by several routes. Crystalloids administered rectally should be isotonic; rapid rectal absorption of hyperosmolar solutions can lead to life-threatening hyperosmolarity. Subcutaneous administration may be an acceptable route if small volumes of isotonic fluids are administered in patients with normal hydration. Intraosseous fluid administration is an acceptable route of administration if a central vein is not accessible.⁵³ Oral rehydration is recommended as the preferred therapy for dehydration caused by diarrhea in human pediatric patients.⁵⁴

Antimicrobial therapy. As for adults, an appreciation of the chemotherapeutic triangle (i.e., relationship among host, drug, and microorganism) is necessary for the appropriate use of antimicrobials with pediatric patients. Several antimicrobials are not recommended for pediatric patients. These include chloramphenicol, tetracyclines, doxycycline, and other drugs that undergo enterohepatic circulation (e.g., clindamycin) and thus are more likely to disrupt the normal colonization of the alimentary tract in pediatric patients.

Beta-lactam antibiotics are generally the drugs of choice for pediatric patients whenever possible. Although drug half-lives are likely to be prolonged, they tend to be safe because they are characterized by a wide therapeutic index. Higher doses may be necessary to achieve desired peak PDCs because their distribution is greater. The time interval of administration can be prolonged to compensate for the longer half-life. Therapeutic drug monitoring should be used to improve the safety and efficacy of aminoglycosides whenever possible. Higher doses and longer intervals may be necessary to achieve recommended peak and trough concentrations. Amikacin, which is potentially less nephrotoxic (and more effective against Pseudomonas spp.) than gentamicin, might be preferred. Quinolones are very effective and, for most patients, safe antimicrobials. They are characterized by excellent tissue distribution. However, these drugs are not appropriate for large-breed pediatric animals because they can cause destructive lesions in the cartilage of long bones. Thus the author does not recommend these drugs as first choice for any pediatric patient. The use of disease-modifying agents containing glucosamine should be encouraged in any animal in which cartilage is growing (or repairing). The combination of a sulfonamide with trimethoprim or ormetroprim tends to be safe and effective for kittens and puppies. Oral tetracyclines should be avoided in nursing animals and before tooth extraction. Therapeutic indications for lincosamides and macrolides are limited for pediatric patients. Because both groups of drugs undergo extensive biliary secretion and enterohepatic circulation, they should not be used as first-choice antimicrobials. An exception should be made for Mycoplasma infections for which tylosin is the drug of choice. Metronidazole is the drug of choice for Giardia infections in dogs and cats, and it is often used for the treatment of anaerobic infections. Decreased clearance and prolonged half-life should be anticipated in kittens and puppies; lower doses and longer intervals may be necessary to prevent CNS toxicity. Enrofloxacin is one of the few drugs that has been studied well in neonatal to pediatric kittens.³⁷ After oral administration, bioavailability of enrofloxacin (5 mg/kg) was at least 33% at 2 weeks of age, increasing to 50% at 4 and 70% at 6 and 8 weeks of age. Following intravenous and subcutaneous administration, the area under the curve compared to adult cats varied with the age of the kittens and route of administration. Neonates (younger than 2 weeks of age) presented as most "different," with area under the curve at least twofold higher than that of any other age (4, 6, or 8 weeks), although elimination half-life was similar among the groups studied. In general, volume of distribution (Vd) was greater (up to twofold) at 4 and 6 weeks compared with the younger age groups and adults, indicating the need for a higher dose; because clearance was faster as well, elimination half-life was actually shorter than with adults.

Sedation, anesthesia, and analgesia. Opioid agonists are the preferred sedative, premedicant, or analgesic of some veterinary clinicians for pediatric patients.¹⁹ Although associated with marked cardiac and respiratory depression, the effects of opioid agonists are largely reversible with opioid antagonists. Bradycardia can be prevented in older pediatric patients by premedication with atropine or glycopyrrolate. Whereas the duration of fentanyl analgesia (nontransdermal patch) is generally too short to justify its use for adult patients, some clinicians prefer it for short-term intraoperative analgesia for pediatric patients because it minimally affects the cardiovascular system. Ketamine can be administered subcutaneously, intramuscularly, or intravenously for the restraint and immobilization of young cats. Response to ultrashort barbiturates such as thiopental and methohexital or similar agents (e.g., propofol) should be exaggerated in young animals because of decreased body fat and hepatic clearance. Dilution to a 1% to 2% solution is indicated to prevent over-administration.

Complications associated with intravenous administration can be reduced by rectal administration of either thiopental or methohexital in human pediatric patients. As a class the benzodiazepines can probably be used safely in pediatric patients. Elimination occurs primarily by hepatic metabolism and is likely to be slower in pediatric patients. Benzodiazepines are, however, characterized by a wide therapeutic index. Midazolam, the newest member of this group, is more potent, has a faster onset of action, and is more rapidly eliminated than diazepam. Although not approved for use in human pediatric patients, it has been used in this age group successfully to induce sedation.55 Inhalant anesthetics are preferred for maintenance anesthesia in veterinary pediatric patients. Halothane, methoxyflurane, enflurane, and isoflurane, and to a lesser degree, sevoflurane have been used. Hypotension is a complication of all gas anesthetics, however, and variable patient response necessitates close monitoring.

Pregnancy and Lacation

Maternal–Fetal–Placental Unit

Even the most simple pharmacokinetic representation of the maternal–fetal system is complex, being composed of at least three compartments: maternal, placental, and fetal. The pharmacokinetics of each compartment is determined, in turn, by its own rate of absorption, distribution, metabolism, and elimination.⁵⁶⁻⁵⁸ Pregnancy is further complicated by its dynamic

nature, with dramatic changes in placental and fetal growth and in the physiology of the pregnant animal. All pharmacokinetic processes change in concert with the progression of pregnancy.

KEY POINT 2-3 Assuming that most drugs administered to the pregnant or lactating bitch or queen will reach the offspring is prudent. Water-soluble drugs should be chosen when possible if therapy is necessary.

The placenta transfers nutrients and oxygen from the mother to the fetus and facilitates waste removal from the fetus. However, the placenta also has a number of metabolic functions, among them the synthesis of hormones, peptides, and steroids that are vital for a successful pregnancy. The placenta also presents a barrier to drug distribution from maternal blood into the fetus. Transporter proteins (e.g., P-glycoprotein [P-gp]) on both the maternal and fetal side influence drug movement; placental phase I and II drugmetabolizing enzymes also have been identified throughout gestation in the human placenta. Thus far, CYP1A1, 2E1, 3A4, 3A5, 3A7, and 4B1 and uridine diphosphate glucuronosyltransferases have been detected in the term human placenta. However, these barriers to drug movement from the mother to fetus presented by the placenta are not impenetrable. Extrapolation of data among species regarding maternal to fetal transfer of compounds is complicated by differences in placentation.⁵⁹ Humans and rats have the least number of layers. However, the endotheliochorial placentation of carnivores differs from hemochorial placentation of humans only by the presence of maternal endothelium, and it is likely that this single fenestrated layer does not present a significantly greater barrier.⁶⁰ The idea of absolute placental selectivity has been replaced with the realization that any drug administered to a pregnant animal might prudently be anticipated to cross the placenta, regardless of the degree of intimacy between fetal and placental membranes.^{56,57,61} The route of administration is also likely to determine the amount of placental transfer: Routes that result in higher plasma peak concentrations (i.e., intravenously, as an intravenous infusion, and in multiple doses) are likely to expose the fetus to higher drug concentrations. Further, a "depot phenomenon" described in the human placenta reflects the accumulation of selected lipid-soluble xenobiotics in the placenta, with the placenta possibly serving as a storage site.61

The primary mechanism of drug movement is passive diffusion, with the amount of transfer dependent on physiochemical properties; less commonly, active transporters and facilitated diffusion contribute to drug movement.⁶¹ Although many factors determine the rate and extent of drug transfer across the placenta, the lipid solubility of the drug and a steep maternal–fetal drug concentration gradient are probably the most important.⁵⁷ In general, nonionized compounds with high lipid solubility cross rapidly, whereas drugs with little lipid solubility cross slowly. Impermeability of the placenta to polar compounds, which generally do not penetrate cell membranes, has been described as relative rather than absolute.⁵⁷ A number of drugs that are polar at physiologic pH can cross the placenta rapidly.⁵⁷ Molecular weight influences drug movement, with those below 500 Dalton more likely and those above 1000 less likely to transfer. Protein binding precludes drug movement, whereas differences in fetal and maternal blood pH increase the accumulation of weak bases in fetal blood (humans).

Fetus and Neonate

Unique differences in drug disposition predispose the near-term fetus and neonate to adverse drug reactions. The pharmacologic principles that address risk of fetal exposure to potential teratogens have been reviewed.^{61,62} The drug approval process generally precludes availability of those compounds with a demonstrated risk, but premarket assessment does not necessarily occur in dogs or cats. The responses of the fetus and newborn to individual drugs, however, vary. Differences in responses reflect, in part, differences in placental kinetics of drugs. The fetus is most sensitive to adverse effects particularly in the first trimester. The risk is positively correlated with the duration of pregnancy, with the risk greater in shorter pregnancies (e.g., dogs and cats) because this period represents a longer proportion of the pregnancy.⁶³

Current efforts in human neonatology are concerned with the characterization of the pharmacokinetic differences between drugs in the near-term fetus. Differences in drug disposition compared with that of both pediatric animals and adults can lead to adverse reactions in the near-term fetus receiving drugs through the placenta. The amount of fetal protein is generally less in the neonate, which is, in turn, less than that in the adult.^{56,57} Thus higher concentrations of unbound and pharmacologically active drugs can be anticipated. It is not clear if increased concentrations of unbound drug will be compensated for by increased clearance, as will occur in the adult animal. Perhaps more important are anatomic peculiarities of fetal circulation. Because the fetal liver and lungs are largely bypassed, blood reaching the heart and brain contain essentially the same concentration of drugs as present in the umbilical vein. Although fetal metabolism of drugs can contribute to the ultimate elimination of drugs in the human neonate, the amount of drug-metabolizing enzymes present in near-term animals is negligible.57

Although drugs administered to pregnant animals may be detectable in the fetus, they may not produce clinically important effects. Examples of drugs that have been shown to reach detectable and potentially clinically important concentrations in the fetus include salicylates and other NSAIDs, anticonvulsants (phenytoin and diazepam), local anesthetics such as lidocaine, gentamicin (in some species), and narcotic analgesics. In human infants the ratio of maternal to fetal concentration of beta-lactams approximates 1.⁶⁴ Because predicting the effects of a drug crossing the placenta is difficult, drug selection for the mother should be based, in part, on anticipated safety to the near-term fetus.

Maternal

The effects of pregnancy can alter all phases of disposition in the mother. Gastrointestinal motility and gastric acid secretion decrease and may lead to decreased drug absorption. Distribution may be influenced by decreased serum albumin, and increased Vd of drugs, resulting in lower PDCs. However, drug clearance may be more rapid as cardiac output, renal blood flow, and glomerular filtration rate increase. High progesterone concentrations may induce hepatic microsomal enzymes and increase drug metabolism.⁶⁵

Lactation

As is the fetus, the nursing animal is an inadvertent recipient of drugs administered to the mother. Most of the pertinent information in the veterinary literature is concerned with excretion of drugs in the milk of food animals; there appears to be no information regarding small animals. Studies of humans indicate that drugs diffuse into the milk from maternal circulation. Low-molecular-weight (<200), un-ionized, highly lipid-soluble drugs that are minimally protein bound diffuse into the lactating mammary gland rapidly, whereas water-soluble drugs diffuse more slowly.⁶⁶ The pK_a of a drug largely determines its concentration in milk. Animal milk tends to be acidic compared with plasma pH. Consequently, although a drug may be nonionized in the plasma and thus more likely to diffuse into milk, it may become ionized and nondiffusible once in the milk. Such "ion trapping" can concentrate drugs in milk. The ratio of drugs in milk to plasma is predictable, being greater for weak bases and weak acids whose pK_as differ from the pH of milk by 2 pH units (+2 for acids and -2 for bases).⁶⁷ Generally, the amount of drugs excreted in milk is less than 2% of the maternal dose.⁶⁶ Greater concentrations can be expected, however, if a drug is administered to the mother intravenously, as an intravenous infusion, or in multiple doses.

Not all drugs ingested with milk during nursing will be absorbed from the gastrointestinal tract of the nursing animal. For example, milk may decrease the absorption of some drugs, whereas the pharmacokinetic properties of other drugs (i.e., aminoglycosides) preclude their absorption except in the very young. Not all drugs, however, must be absorbed to cause clinically important adverse effects. For example, antimicrobials can sometimes alter the developing flora of the pediatric alimentary tract.^{27,68} Thus it is prudent to refrain from administering potentially toxic drugs to the lactating bitch or queen.

Sex

Pregnancy and lactation are obvious differences between the sexes that affect the disposition of and response to drugs. However, sex differences are relevant without the influence of active reproduction. The impact of sex on drug disposition is not well characterized in human or other animal medicine. In general, female humans, compared with male humans, are characterized by reduced smooth muscle motility, greater body fat, greater content and fluctuation in plasma volume and increased organ blood flow, xenobiotic metabolism (increased CYP3A4, others not clear), and transporter protein activity.^{69,70} It should be anticipated that sex differences are likely to be complex, as has been demonstrated for CYP enzymes in cats.⁷¹ Female cats were characterized by greater CYP2D and lower CYP3A compared with males.

Roles of Species and Breed Differences in Drug Disposition

Differences among species in the kinetics and response to drugs are profound; Riviere⁷² has offered a review in animals. Few studies have compared disposition among species, and when reported, data are generally oriented toward human medicine, with the intent to identify the (laboratory) animal most predictive of human drug disposition. Presumably, species that are physiologically similar tend to have similar drug disposition patterns, and the same dosing regimen can often be used for a particular drug.⁷³ However, pharmacokinetic data (Vd, clearance, and mean residence time) after intravenous administration have been compared among humans, monkeys, dogs, and rats for over 100 molecules (including many drugs).74 Correlations between chemical structures of the compounds with pharmacokinetics allowed two categories of compounds to be identified: those characterized by high clearance, for which mathematical models would allow general extrapolation of data from one species to another, and those whose characteristics yielded incorrect extrapolations. Although the authors concluded that such an approach might be useful for extrapolation, more to the point is the reality that drugs may not be extrapolatable even with the most sophisticated of mathematical models. The combination of computation analysis of the molecular characteristics of each compound with in vivo pharmacokinetic data might ultimately be helpful in identifying the most appropriate species for predicting pharmacokinetic behavior of a particular molecule in another species. Thus caution needs to continue when extrapolating information from humans to the dog, and dog to cat. Likewise, pharmacodynamic responses may be profound.

Absorption

Gastric pH profiles have been described for the dog in anticipation of extrapolation to humans.⁷⁵ Dogs are described as poor gastric acid secretors, compared with humans as good secretors, with gastric pH fluctuating in dogs from 2.7 to 8.3 (mean 6.8). The shorter gastrointestinal tract of dogs compared with that of humans, results in a transit time (111 minutes) that is 50% of that of humans, although this may be offset by taller villi and greater bile salt concentrations. Accordingly, differences in absorption might be expected between dogs and humans in the oral absorption of drugs, particularly for enteric-coated or altered-release products.75 Different affinities for P-gps have been demonstrated among humans, nonhuman primates, and Beagle dogs.⁷⁶ In dogs absorption of some hydrophilic compounds is more similar to that in rats, whereas absorption of others is more similar to that found in humans.⁷⁷ Another retrospective comparison between dogs and humans in the oral bioavailability of 43 drugs found

close to 50% to be completely absorbed in both species. For the remaining drugs, 12 were absorbed more rapidly and to a greater (15% to 200%) extent.78 However, the extent of absorption for drugs not well absorbed correlated poorly between the two species. In general, if the drug was well absorbed in humans, it tended to be well absorbed in dogs. Both lipid- and water-soluble drugs appear to be better absorbed in dogs, the latter suggesting more paracellular transport. The rate and magnitude of drug absorption for many drugs may be similar between dogs and cats, regardless of the route of administration. However, extrapolations must be done with caution, as is exemplified with ciprofloxacin, whose oral bioavailability in the dog is 40% (compared to 80% or better in humans) but 0% to 20% (the latter more likely with multiple dosing) in cats.79,80 Another example is prednisone. An exception also may need to be made for slow-release preparations; rates and extent of absorption do vary among species. Dye81,82 has demonstrated not only differences in bioavailability in cats versus dogs but also differences in pharmacokinetics related to morning versus evening dosing. Because slow-release preparations used in human patients are designed to maintain therapeutic concentrations in humans, absorption kinetics of these products can be profoundly different in the dog and cat. Use of such drugs should be based on clinical studies of these preparations in dogs and cats.

Distribution

Because most determinants of xenobiotic distribution are largely affected by cardiac output, regional blood flow, and xenobiotic chemistry, distribution differences among species might be predictable through allometric scaling.⁸³ However, they must also take into account differences in transport proteins. Differences in drug distribution can result in important differences in drug response. Blood volume of the cat (70 mL/ kg) is less than that of the dog (90 mL/kg); PDCs of drugs whose distribution is confined to the plasma compartment may therefore differ between the species. The same amount of drug (on a per-kilogram basis) is diluted less in cats because the plasma volume is smaller. Thus drug concentrations after administration of a mg/kg dose might initially be higher in cats than in dogs. Organs that are well perfused (i.e., heart, brain) may be more susceptible to toxicity. Cats are approximately the same size as the smaller dog breeds. Thus doses determined for medium-size to large-size dogs may not be appropriate for the cat because the smaller animals have a greater body surface area. In larger animals body water makes up a larger proportion of body weight, which tends to dilute the drug. A higher dose may be needed for larger animals. Because the drug halflife may be longer (owing to increased distribution), however, the dosing interval may need to be longer.

Differences in plasma protein-binding characteristics (particularly albumin) may alter the distribution of drugs that are highly protein bound. The degree to which various drugs are protein bound varies dramatically among the species, although the clinical implication is not clear. Although the elimination characteristics of many drugs have been established for cats, few studies have determined the extent of protein binding.

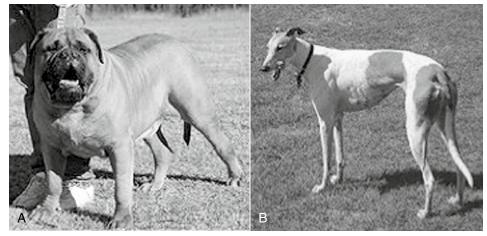

Figure 2-3 Differences in breeds may affect body composition (A) as well as other aspects of drug disposition. The sight hounds, represented by the Greyhound (B) is at risk for selected adverse drug events, in part because of a larger lean body mass compared with fat. Drugs that normally accumulate in fat may achieve higher drug concentrations in such breeds.

The interaction between disease and species should be considered when considering species differences in drug distribution. For example, the unhealthy cat does not maintain hydration as well as the dog; fluid imbalances resulting from dehydration or edema alter drug distribution. The obese cat can represent a "sink" for drugs that are lipid soluble, thus lowering PDCs potentially to submaximal levels if the dose is not appropriately increased. Weight loss in a hyperthyroid cat can have the opposite effect.

Sight hounds (e.g., Salukis, Greyhounds; Figure 2-3) offer an example of potential breed differences in drug distribution. Their lean body weight provides little fat tissue for drug distribution. As a result, they are more susceptible to overdosing with drugs that redistribute, such as thiobarbiturates.

Distribution is influenced by the multidrug transport protein P-gp. Polymorphism has been demonstrated in the Collie, yielding differences in P-gp content. Two P-gp transporting proteins are encoded by ABCB1 (previously MDR1 or PGY1) and MDR3 (also named MDR2 and PGY3); only the MDR1 gene product is thought to significantly influence drug metabolism. P-gp acts as an efflux pump by translocating drugs from the intracellular to extracellular compartments (Table 2-2) (see Chapter 3). The protein transports a large number of drugs that are chemically divergent; further, these drugs are associated with a specific CYP450 responsible for metabolism of the drugs that have been transported. Polymorphism of the MDR1 gene and P-gp have been reported in humans and are associated with altered drug disposition and thus susceptibility to adverse drug events. Interestingly, polymorphism also has been associated with an increased risk of certain illnesses (e.g., refractory seizures, Parkinson's disease, inflammatory bowel disease biliary mucoceole in dogs*). Polymorphism reflecting a mutation deletion of MDR1 that causes nonfunctional P-gp has been documented in Collie and related workingbreed dogs. The incidence of the deletion is impressively high: in the U.S., in one study, 35% of Collies were homozygous and another 42% heterozygous for the mutation deletion.⁸⁴ A

*Personal communications, K. Mealey, Washington State University.

similarly high incidence was found in dogs in France: 20% of Collies and related breeds were found to be homozygous for the normal allele, 32% heterozygous for the deletion (carrier), and 48% homozygous for the mutant allele (affected dogs).⁸⁵ The impact of the mutation on drug safety in afflicted animals can be profound (see Chapter 3). Substrate specificity for P-pg appears to be similar among species, suggesting that human data can be used to predict which drugs might be more likely to cause adverse effects in these breeds.⁸⁶ However, protein type and amount may vary among species and breed.

Metabolism

Human polymorphisms in CYP metabolic enzymes have been associated with therapeutic failure resulting from extremely rapid metabolism of a drug and toxic effects caused by decreased metabolism.⁸⁷ Species extrapolation among the CYP450 appears to be predictable in order of most to least: 2E1 (reasonably predictable) greater than 1A1, 1A2, and 4A (cautiously predictable) greater than 2D and 3A greater than 2A, 2B, and 2C (major caution with extrapolation).88 Studies attempting to identify similarities between dog and human CYP activity suggest general extrapolation between the species is not prudent.87 Although significant differences among species were not detected among rodents, rabbits, and dogs for CYP2E1, 3A2, and 4A1, comparison of animal CYP activity with human found only 2D6 to be most similar to dog.89 Other enzymes present in dogs are CYP1A, 2C, and 2D families and subfamilies (Table 2-3).90

KEY POINT 2-4 The genetic basis for differences in drug transport and metabolism limits extrapolation of dosing regimens among species, and potentially, breeds. How-ever, understanding of these polymorphisms is increasing our ability to predict increased risks associated with drug administration in some breeds.

Species differences have been documented in the handling of racemic isomers of selected drugs. Inversion (from one isomer to the other) patterns differ and are likely to result in

in sight hounds reflect both differences in drug distribution (to lean versus fat compartments; see Chapter 1) as well as differences in metabolism. Cytochrome-mediated clearance of several anesthetic agents is less in Greyhounds compared with other (nonsight hound) dogs; documented drugs include thiopental, thiamylal, and methohexital. Clearance of propofol by Greyhounds is three times less than that by Beagles. Ketoconazole plasma concentrations were twofold higher than expected in Greyhounds in one study.93 Further, Greyhound disposition of celecoxib, a cyclooxygenase-1 protective NSAID, indicates that breed differences may predispose this breed to adverse drug reactions. Polymorphism also has been described for CYP2C isoenzymes, again in Beagles94 and possibly Greyhounds.95 Polymorphism in celecoxib metabolism was attributed to CYP2D15, for which three canine variants were found.96 In a study of 242 Beagles receiving celecoxib, approximately 50% were considered efficient metabolizers and 50% poor metabolizers, with bioavailability and maximum PDC in the latter group almost twofold higher. The impact of species differences in pharmacokinetic and pharmacodynamic considerations of enantiomers has been described.91,97 For example, for many NSAIDs the S-isomer has a much greater affinity for cyclooxygenase-2, but the proportion of the S isomer varies among species. Further, species differ in their ability to interconvert S and R isomers.⁹⁷ For example, chiral inversion has been described for ketoprofen in cats.98

Other polymorphisms that have been described include thiopurine methyltransferase (TPMT), which is one of several enzymes responsible for the metabolism of the active metabolite of the prodrug azathioprine; polymorphisms resulting in

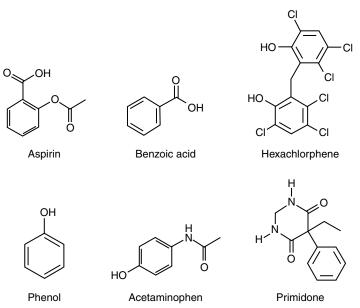

Figure 2-4 Examples of drugs (many containing phenols) whose metabolism in cats is slower owing to deficiencies in drug phase I and phase II drug-metabolizing enzymes.

deficiencies in humans have been associated with an increase in the toxic bone marrow effects of the drug. Differences in dogs have been demonstrated as well: Kidd⁹⁹ and coworkers have demonstrated that Giant Schnauzers have significantly less and Alaskan Malamutes significantly more TPMT compared with other canine breeds.

The most significant and best-characterized differences in drug disposition between the dog and cat probably result from differences in drug metabolism. Identification of phase I enzymes and their specific drug substrates is difficult, and few species differences have been described in the cat or dog. However, a recent review of CYP450 activity-based substrate metabolism in cats suggests that cats have very low activity of CYP2C, but activity of CYP2D and CYP3A approximates that of dogs or humans, depending on sex.⁷⁷ Deficiencies in demethylation and hydroxylation have been described in the cat and may be responsible for different patterns of prodrug activation (e.g., primidone; see Chapter 27) or adverse reactions to selected drugs (i.e., chloramphenicol).¹⁰⁰ Deficiencies in phase I demethylation and hydroxylation as well as phase II glucuronidation lead to much slower elimination of phenols and aromatic acids and amines in the cat compared with other species (Figure 2-4).^{101,102} The described reaction of cats to diazepam may represent differences in the metabolites produced, as may the susceptibility of the feline liver to metabolite-induced damage.¹⁰³ Polymorphisms in drugmetabolizing enzymes have also been described in cats, which have at least three variants of CYP2E,104, although breeds were not cited.104

Deficiencies in phase II metabolism have long been recognized in cats. The deficiency reflects extremely low concentrations of some glucuronyl transferases. Thus many drugs excreted as glucuronide conjugates in other species are characterized by a prolonged clearance rate and half-life in the cat. Toxic levels may accumulate much more quickly in the cat, and exaggerated pharmacologic responses or toxicities occur more easily (Figure 2-4). Dosing regimens must be modified for such drugs by either decreasing the dose (especially for drugs whose dosing interval is shorter than the elimination half-life) or prolonging the dosing interval. The prototypic example is aspirin, whose half-life approximates 36 hours in cats compared with 8 hours in dogs. To prevent toxicity in the cat, aspirin is dosed every 48 to 72 hours, compared with twice daily in dogs.

Not all drugs that are conjugated with glucuronide are predisposed to toxicity in the cat. This is true for several reasons. First, the cat is deficient only in certain families of glucuronyl transferase. Cats can conjugate and excrete endogenous substrates such as bilirubin, thyroxine, and steroid hormones as well as other species. Metabolism of a variety of exogenous drugs, however, particularly phenols and aromatic acids and amines, occurs at a much slower rate in the cat than in other species.^{101,102} The degrees of deficiency and potential toxicity depend on the drug substrate. For example, some phenolic compounds are sufficiently conjugated, whereas others are not. Second, glucuronide-conjugated drugs characterized by a wide safety margin are associated with few adverse reactions even if accumulation occurs. Finally, in the absence of glucuronide, drugs may be sufficiently metabolized by an alternative pathway. Some sulfates may be particularly well developed in the cat, and many drugs that are excreted as glucuronideconjugates by the dog may be excreted as sulfated compounds by the cat. Other sulfate-conjugating systems, however, appear to be easily saturated in the cat. Unfortunately, alternate pathways of drug metabolism may also contribute to the toxicity of some drugs because they may involve phase I enzymes that catalyze the formation of toxic metabolites. Thus drugs shunted to another pathway in the cat may be very toxic to the cat but minimally toxic in other species. Deficiencies in both glucuronide and (potentially) glutathione transferase may also might be realized by these systems and further contributing to toxicity. Acetaminophen is an excellent example of the potential sequelae of phase II deficiences in the cat (See Chapter 4). Because glucuronide is deficient, excessive acetaminophen is shunted to phase I enzymes, which produce toxic oxygen radicals. More metabolites are produced than can be handled, and the glutathione-scavenging system of feline erythrocytes and hepatocytes is overwhelmed, resulting in life-threatening methemoglobinemia and (potentially) hepatic necrosis. The rationale for cimetidine treatment can be understood in the context of the role of phase I metabolism, as well as that of *N*-acetylcysteine, a glutathione precursor.

Not all deficiences in metabolism occur in the cat. Although acetylation is not a common route of elimination for xenobiotics, it is an enzyme system whose deficiency in the dog is clinically relevant (e.g., procainamide). For example, the antiarrhythmic procainamide is acetylated in humans to an active metabolite. Procainamide is less potent than its acetylated metabolite and the canine dose for procainamide is considerably higher than that in humans on a mg/kg basis in order to achieve an equivalent pharmacologic response (see Chapter 14, Cardiac). A second example might be sulfonamide elimination. Sulfonamides are detoxified by N-acetylation in humans. In the face of deficient acetylation, shunting of the xenobiotic to an alternative pathway in dogs, with the production of the cytotoxic metabolite hydroxylamine, may be one mechanism of sulfonamide toxicity in dogs, although alternative mechanisms are likely to be responsible.¹⁰⁵

Renal Excretion

In contrast to hepatic metabolism, differences in renal excretion between the dog and cat do not appear to be profoundly important to drug disposition. Glomerular filtration and active tubular secretion parallel cardiac output and thus should be predictable among species based on allometric scaling.⁸³ The glomerular filtration rate of cats (2.5 to 3.5 mL/min/kg) is less than that of dogs (3 to 5 mL/min/kg), suggesting that renal clearance of drugs may be faster in dogs. Although this is true of inulin, differences have not been established for most drugs. Renal disease profoundly alters the rate of drug excretion in all species. In general, serum creatinine concentrations can be used to modify the dose (decrease in proportion) or interval (prolong in proportion to abnormality). The modification should be applied only to that portion of the drug eliminated by the kidney. Note that fluid imbalances in renal disease can also alter drug distribution. Finally, differences in active transport and passive resorption-the latter influenced by differences in urinary pH-may result in differential excretion among species. However, because urine tends to be acidic in both dogs and cats, differences in the latter may not be profound.

Role of Species Differences in Target Tissues

It is difficult to predict differences in drug reaction that can be ascribed to differences in target tissues because very little is known about cats. Differences in response to selected drugs (e.g., opioids, insulin, chlorinated hydrocarbons) are known to be or are thought to be reflections of differences in tissues; however, often these differences turn out to be pharmacokinetic differences reflecting decreased or increased PDCs of active (including toxic) compounds rather than differences at the receptor level.

Feline erythrocytes (hemoglobin) appear to be more susceptible to oxidation and thus to methemoglobinemia. Drugs reported to cause methemoglobinemia in the cat include urinary antiseptics containing methylene blue¹⁰⁶ or azodyes, acetaminophen^{101,107,108} and related compounds, benzocaine,¹⁰⁹ and propylthiouracil.¹¹⁰ Several mechanisms have been postulated to explain the potential increased sensitivity of cats to methemoglobin formation. Lower concentrations or activities of the intracellular repair enzyme methemoglobin reductase have been postulated but not confirmed.111,112 Faster metabolism of specific drugs to toxic metabolites that overwhelm scavenging systems has already been discussed as a likely cause for some drugs, particularly those whose elimination is shunted to alternate (toxic) pathways (i.e., acetaminophen).¹⁰⁷ Differences in the structure of feline hemoglobin have also been postulated. Feline hemoglobin contains up to 20 sulfhydryl groups compared with a maximum of four in other species. Sulfhydryl groups tend to be reactive and thus are susceptible to interaction with reactive parent drugs or metabolites. Thus more sulfhydryl groups would need to be maintained in a reduced state in cats.¹¹³ Other unique considerations for the cat might include its propensity for drug-induced retinal damage; hepatic lipidosis associated with anorexia; and, potentially, an increased risk of nephrotoxicity.

Canine breed differences in response to drugs may also reflect pharmacodynamic responses. For example, brachycephalic breeds (e.g., Boxers) are more susceptible to cardiac arrhythmias (sinoatrial block) caused by acepromazine.

Miscellaneous

Differences in circadian rhythm (i.e., diurnal versus nocturnal) play a role in some differences between the dog and cat. Aminoglycosides are less likely to cause toxicity if administered during active periods. This also has been established for theophylline, for which clearance occurs more rapidly at night in the dog compared with early morning in cats. Dosing of glucocorticoids at night has been recommended for cats in order to mimic endogenous release patterns. The clinical significance of these differences has not been determined.

RECOMMENDATIONS REGARDING EXTRAPOLATION OF DOSING REGIMENS

Drug Information Sources

Extrapolation of doses of human drugs to dogs and cats and from dogs to cats should be based on a knowledge of the clinical pharmacology of the drug to be administered and on the physiologic differences of the target species. The safer the drug, the safer the extrapolation. Numerous resources are available for human drug information (e.g., *Facts and Comparisons, USP Pharmacopeia*, the package insert from the product, *Physicians' Desk Reference*)¹¹⁴ to determine the safety and the determinants of disposition of a new drug. The veterinary literature and clinicians with expertise in the field, including diplomates of the American College of Veterinary Clinical Pharmacology, are additional sources.

Note that every drug that has been approved for use in humans has been studied in dogs. The studies generally have focused on *safety*, however, not efficacy. The information regarding safety (often including pertinent pharmacokinetic data, such as volume of distribution, bioavailability, and drug elimination half-life) may be obtainable through a Freedom of Information Act request, which would be processed by the Food and Drug Administration.¹¹⁵

Extrapolation of dosing regimens should be limited to relatively healthy animals, if possible, to avoid the effects of disease on drug disposition. Likewise, extrapolation to geriatric and pediatric patients is discouraged. Administration by the oral route is generally safer (although gastric irritation may be more likely). Oral administration is less preferred if the drug undergoes first-pass metabolism, however, because this can vary dramatically among animals. A 50% change in first-pass metabolism may double the pharmacologically active dose in a patient. Intravenous administration is not recommended; when it is absolutely necessary, the drug should be administered slowly (over 5 to 10 minutes or more). Drugs with long half-lives (>12 hours) should generally be avoided. If a drug is administered at an interval that is less than the drug halflife, accumulation should be anticipated and accounted for in the dosing extrapolation. Note that maximal adverse effects may not appear until accumulation is complete at steady state. Also, a drug half-life can change (as a result of disease or drug interactions). Thus a drug that initially did not accumulate (and whose dose is based primarily on volume of distribution) may begin to accumulate as disease worsens. Unless the drug can be monitored, a change in drug half-life will be missed. In such instances a dosage reduction is again indicated. On the other hand, as a patient improves, response to therapy may again change disposition, perhaps leading to therapeutic failure. The veterinarian should be prepared to treat adverse effects if they occur. If the drug half-life is long, the time necessary for abatement of the adverse reaction will also be long. In general, extrapolation of lipid-soluble drugs is discouraged because of the risk of too many species differences.

Water-Soluble Drugs

As a general rule, extrapolation of doses for drugs that are water soluble is more appropriate because these drugs are distributed to extracellular fluids (normalizing Vd) (Box 2-2); protein binding is likely to be negligible; and hepatic metabolism is minimized. Drug Vd and renal elimination may be similar among species, and the interval used for such drugs can often be extrapolated among species. The dose administered, however, probably should be reduced to compensate for differences in blood volume among animals. Increased doses are indicated for pediatric patients and for patients with edema; decreased doses are indicated for geriatric and dehydrated patients.

KEY POINT 2-5 Extrapolation of dosing regimens among species is often safer with water-soluble drugs compared with lipid-soluble drugs because disposition tends to be much simpler.

Lipid-Soluble Drugs

Lipid-soluble drugs tend to be distributed to total body water and beyond, leading to a greater risk of differences among species. They are more likely to be highly protein bound, leading to a risk of differences in tissue distribution and in the proportion of pharmacologically active drug. In contrast to water-soluble drugs, lipid-soluble drugs are more likely to require hepatic metabolism (Box 2-3). In general, the clinician should anticipate a longer half-life in cats for drugs that undergo phase I metabolism in other species. Note that species differences in phase I metabolism can be very profound. If acetylation is a major phase II route of elimination, it is likely that the drug may be metabolized faster in cats than in dogs. If phase I metabolism and glucuronidation is the major route of elimination, a longer half-life should be anticipated in cats. Although glucuronidation does not necessarily indicate that elimination of the drug will be slower in cats, until an appropriate study has established the kinetics of the drug in cats, its use is discouraged. An exception

Box 2-2

General Characteristics of Water-Soluble Drugs

- Distributed to extracellular fluid
- Characterized by a volume of distribution ≤0.3 L/kg
- · Minimally protein bound
- · Undergo minimal to no metabolism
- Associated with fewer drug interactions
- · Less likely to be allergenic
- · Less likely to be hepatotoxic
- · Tend to be renally excreted
- · Often characterized by a short elimination half-life
- May not accumulate and thus reach steady state

Box **2-3**

General Characteristics of Lipid-Soluble Drugs

- Distributed to total body water
- · May be accumulated or stored
- Characterized by a volume of distribution ≥0.6 L/kg
- · More likely to be significantly protein bound
- · Generally metabolized before renal excretion
- More likely to interact with other drugs
- · More likely to be associated with hepatotoxicity
- More likely to be allergenic
- · Often characterized by a long elimination half-life
- May accumulate and thus be characterized by a time lag to steady state

might be made if the drug can be monitored or the drug is characterized by a wide therapeutic window. Altered-release preparations are not recommended because rates of absorption among the species can be dramatic. Finally, it might be necessary to refrain from administering preparations containing propylene glycol and other unknown carriers because of adverse reactions in cats.

All Drugs

Drugs with large (>2 L/kg) Vds are not recommended because accumulation or tissue binding of the drug may occur. These factors are likely to vary among species. Prodrugs, drugs for which active metabolites contribute significant activity and slow-release drugs are not appropriate because the amount of active drug is not predictable among the species. Body surface area should be used whenever possible to determine doses of toxic drugs. Drug disposition may change as the animal improves, particularly if a disease that affects drug disposition (i.e., cardiac, renal, hepatic) is being treated. Changes in dosing regimen may again be indicated. Finally, the veterinarian should be aware of the laws regulating the use of drugs labeled for use in humans.

PATHOLOGIC FACTORS

The diseased patient is more likely to react adversely to a drug. Although such reactions occasionally reflect disease-induced differences in receptor number or sensitivity, most often they reflect differences in drug disposition. The dosage regimens recommended for a pharmaceutical preparation generally are based on controlled studies in the normal, healthy animal. However, drugs are most frequently administered to the diseased patient. Pathophysiologic changes in most body systems can alter all phases of drug disposition, predisposing the patient to adverse drug reactions (Table 2-4). The sequelae of disease on drug disposition often but not always leads to increased PDCs and thus to a greater potential for adverse drug reactions. Occasionally, however, PDCs are lower than

Pharmacokinetic Changes	Impact	Sequelae
Liver disease	Decreased hepatic blood flow	Increased oral bioavailability, decreased clearance of highly extracted compounds
	Decreased phase I enzymes	Decreased hepatic clearance (longer half-life)
	Decreased phase II enzymes	Decreased hepatic clearance (longer half-life)
		Decreased hepatoprotection (increased risk of hepatoxicity
	Decreased albumin	Increased concentration of free drug (may not be cleared more rapidly in presence of liver disease)
	Ascites	Decreased distribution of water-soluble drugs, higher drug concentrations, shorter half-life
	Decreased production of phase II enzymes	Decreased cytoprotection
Renal disease	Decreased cytoprotection	Increased risk of xenobiotic-induced nephrotoxicity
	Decreased autoregulation	Increased risk of xenobiotic-induced nephrotoxicity
	Decreased body mass (dehydration)	Decreased volume of distribution (higher xenobiotic concentration, shorter half-life)
	Increased fluid retention	Increased distribution of drugs, decreased concentration, longer half-life
	Decreased renal blood flow	Decreased renal clearance (longer half-life)
	Tubular disease	Decreased concentration of drug, decreased efficacy of urinary antibiotics, decreased clearance
	Glomerular disease	Increased risk of xenobiotic-induced nephrotoxicity
		Deceased protein-binding (increased fraction of unbound xenobiotic)
		Increased clearance of unbound fraction of highly protein-bound xenobiotics
Cardiac disease	Decreased renal blood flow	See renal disease
	Decreased hepatic blood flow	See hepatic disease
	Decreased regional blood flow	Decreased organ delivery (higher concentrations delivered to brain and heart)
Gastrointestinal disease	Decreased cytoprotection	Increased risk of gastrointestinal toxicity
	Altered permeability	Altered absorption
	Altered gastrointestinal motility	Decreased rate of absorption
	Altered P-glycoprotein	Altered absorption

anticipated (e.g., increased Vd, decreased oral bioavailability), and therapeutic failure may occur. Diseases most likely to contribute to adverse drug reactions are those affecting the kidneys, liver, and heart. Less significant effects accompany gastrointestinal, pulmonary, endocrine, and metabolic disorders. Pathologic responses that generate clinical signs of disease also may be associated with changes in drug disposition. For example, following oral administration, amoxicillin area under the curve increased in dogs rendered febrile by administration of endotoxin.¹¹⁶ The cause of the increase was not clear but may have reflected increased absorption caused by lipopolysaccharide reduction of gastrointestinal transit time or fever-induced increased absorption or endotoxin-induced decreased renal clearance. The sequelae of hypovolemia affects multiple aspects of drug disposition. Because blood flow to the brain and heart are maintained, drug that might have been distributed to peripheral organs is distributed to these two organs, increasing their risk of toxicity while simultaneously limiting clearance by organs of excretion. Drug distribution to peripheral organs will then increase with successful management.

Renal Disease

Drug toxicity in renal failure may result either from increased sensitivity to the drug owing to uremia-induced alterations in tissue receptors or from decreased or increased PDCs caused by disease-induced changes in pharmacokinetics. Changes induced by renal disease have been best characterized (see Table 2-4).¹¹⁷⁻¹²⁰

Renal blood flow is often profoundly decreased in patients with renal disease. Changes in glomerular filtration and tubular secretion tend to parallel changes in renal blood flow. The effects of changes in renal blood flow (usually decreased) on drug excretion are most profound if renal extraction of the drug is high (e.g., penicillins, sulfates, glucuronide conjugates) but are less significant for drugs that are slowly extracted (e.g., aminoglycosides, diuretics, digoxin).

Glomerular filtration of drugs and other compounds is also adversely affected in renal disease independent of changes in renal blood flow. The determinants of glomerular filtration include protein binding, glomerular integrity, and the number of functional (filtering) nephrons. The molecular size of the drug is also important because drugs with a molecular weight greater than approximately 70,000 usually cannot be filtered. Drugs that are tightly protein bound (such as NSAIDs) are not filtered until they are displaced from the protein. Factors that tend to displace such drugs from protein-binding sites may increase the rate of drug excretion in renal disease and include hypoalbuminemia, competition for protein-binding sites owing to accumulation of uremic toxins, or changes in the conformation and thus binding affinity of the protein (e.g., albumin). Changes in protein binding that have been measured in renal disease include decreased binding of acidic drugs (e.g., furosemide, NSAIDs, selected penicillins and anticonvulsants) and normal or increased binding of basic drugs owing to increased concentrations of inflammatory proteins (e.g., propranolol, diazepam, prazosin). The impact of increased clearance of otherwise protein-bound drug may be offset by the increase in plasma concentration of the free drug displaced from the protein, thus increasing elimination of unbound drug.

Although changes in active tubular reabsorption that may accompany renal disease probably do not profoundly influence the rate of drug excretion, changes in active tubular secretion can be significant. Active tubular secretion occurs in the pars recta (straight segment) of the proximal tubule. A transport system exists for a variety of organic acids (e.g., penicillins, cephalosporins, NSAIDs, sulfonamides, several diuretics) as well as bases (e.g., cimetidine, procainamide, some morphine derivatives). Distal nephron active transport may also be important for some drugs (e.g., digoxin). Excretion of these drugs is most likely to be decreased in the presence of renal disease because of decreased nephron mass, decreased renal blood flow, and decreased tubular function.

In addition to these changes, renal disease can also alter drug disposition because of changes in electrolyte, acid-base, and fluid balance. Changes in electrolytes and acid-base balance may also be important in altering receptor sensitivity to drugs, such as those affecting the cardiovascular system (e.g., hyperkalemia and its effects on responses to digitalis, quinidine, and procainamide).

KEY POINT 2-6 Serum creatinine is a reasonable indicator of the impact of renal disease on renal drug clearance.

For drugs whose elimination depends on renal function and whose clearance is known to be decreased in renal disease (Box 2-4), dosing regimens can be appropriately altered to reduce the incidence of adverse reactions.¹¹⁹ Either serum creatinine or creatinine clearance is generally used to estimate glomerular filtration rate; however, because of its ease of measurement, serum creatinine is most commonly used. Decreases in the renal elimination of a renally excreted drug

Box 2-4

Changes in Clearance

Aminoglycosides Beta-lactams Digoxin Sulfates Furosemide tend to parallel increases in serum creatinine, and dosing regimens can be altered by either lengthening the dosing interval or decreasing the dose by a proportional decrease in creatinine clearance or the increase in serum creatinine (Box 2-5).

The parameter of the dosing regimen that should be altered depends on the drug. Lengthening the interval results in wider swings in PDCs during a single dosing interval and thus may not be desirable for time-dependent antimicrobial therapy but would be acceptable for concentration-dependent drugs or lengthening the interval also should be avoided for anticonvulsant or cardioactive drugs that depend on maintenance of a minimum drug concentration within a specified therapeutic range. Thus decreasing the dose may be more appropriate for these drugs. For drugs with a long elimination half-life or drugs whose effects persist in the absence of detectable drug (e.g., selected antimicrobials [e.g., concentration-dependent], glucocorticoids, nonsteroidal agents), however, it may be more appropriate to prolong the interval. Aminoglycosides previously were dosed at 12-hour intervals. Because their efficacy depends on a high PDC, yet safety is based on allowing PDCs to fall below a recommended trough concentration, prolonging the interval (i.e., from 12 to 18 or 24 hours) was more appropriate than lowering the dose in patients with renal disease sufficient to alter creatinine clearance. However, aminoglycosides are currently administered at 24-hour dosing intervals, precluding the need to prolong intervals in some renal disease patients. For other drugs whose toxicity is related to peak drug concentrations, the dose might be decreased by 50%, or the interval prolonged one half-life. Few clinical studies have addressed the impact of renal disease on the clearance of drugs in dogs or cats. Experimentally induced renal disease sufficient to cause serum creatinine to increase to $145 \pm 122 \mu mole/L$ in dogs caused a slight decrease in renal clearance but no clinically significant change in elimination half-life of marbofloxacin.¹²¹

Hepatic Disease

The efficiency of hepatic elimination is determined by hepatic clearance and the hepatic extraction ratio of the drug.¹²²⁻¹²⁵ Both, in turn, depend on hepatic blood flow; the extent of drug protein binding; and intrinsic hepatic clearance, which itself consists of hepatic uptake (the rate-limiting step of hepatic clearance), intracellular transport, metabolism, and (if applicable) biliary elimination. Drugs that are eliminated by the liver can be categorized according to their rate of

Box 2-5

Dosing Regimens for Drugs Dependent on Renal Function

New dose = old dose × pt CrCl/normal CrCl or × normal Cr/pt Cr New interval = old interval × normal CrCl/pt CrCl or × pt Cr/ normal Cr

pt = patient, Cr =creatinine, and CrCl = creatinine clearance For example, a patient has a serum creatinine level of 2.5 mg/dL

(normal is 1.2), a dosing interval for a drug given every 12 hours would be prolonged to every 24 hours, or the dose of 2 mg/kg could be reduced to 1 mg/kg. extraction.¹²⁶ Flow-limited drugs (e.g., lidocaine, propranolol, verapamil) are so rapidly extracted by the liver that their rate of elimination depends only on the rate at which it is delivered to the liver (e.g., hepatic blood flow). Such drugs are insensitive to changes in hepatic metabolism but are very sensitive to changes in hepatic blood flow. *Capacity-limited* drugs (e.g., diazepam, prednisolone, phenylbutazone, phenytoin, theophylline, cimetidine, and antipyrine) are extracted slowly by the liver, and their elimination depends on hepatic blood flow. The elimination of such drugs is affected by changes in hepatic metabolism but not by changes in hepatic blood flow. Some drugs are intermediate, being partially dependent on hepatic blood flow and hepatic metabolism.^{123,126}

Protein binding can affect the elimination of some capacity-limited drugs because only unbound drug can be extracted by the liver. Flow-limited drugs tend to be *binding insensitive* in that hepatic extraction is so fast that binding to proteins does not alter their rate of elimination. Some capacity-limited drugs are not significantly protein bound and thus are also binding insensitive (e.g., antipyrine). In contrast, some capacity-limited drugs are *binding sensitive* (e.g., theophylline, phenytoin) because their slow rate of extraction can be increased by decreasing or increasing, respectively, protein binding.¹²⁷

The effects of hepatic disease on drug disposition are very complex, particularly for drugs that are affected by changes in hepatic blood flow, hepatic metabolism, and protein binding (Box 2-6).^{123,126} Each of these parameters may be altered in various ways in patients with liver disease. Hepatic blood flow is generally reduced in chronic liver disease because of formation of portosystemic shunts and intrahepatic shunting. Drug delivery bypasses many functional hepatocytes that would otherwise clear the drug. Plasma and tissue drug concentrations are markedly higher when dosing regimens are not appropriately altered. This is particularly important for highly extracted drugs when they are administered orally. The dose of such drugs (e.g., propranolol, verapamil, prazosin, morphine derivatives) in the presence of normal hepatic blood flow is based on decreased bioavailability owing to first-pass extraction: a large percentage of the drug does not reach systemic circulation because it is removed from portal blood by the liver the first time it passes through the liver. Decreased hepatic blood flow and intrahepatic shunting of blood can markedly increase systemic bioavailability of such drugs (Figure 2-5).128 Studies in human patients with liver disease suggest that the intrinsic metabolism of highly extracted drugs also is reduced in patients with liver disease. In human patients with liver disease, the dose of many highly extracted drugs is reduced by 50%; such an approach is probably reasonable for the veterinary patient.

The effect of liver disease on poorly extracted (capacitylimited) drugs is more difficult to predict, particularly for drugs that are highly protein bound. Generally, hepatic metabolism is reduced in patients with liver disease. Disease is generally quite profound, however, by the time changes in drug disposition become evident. The severity of disease is manifested as a decrease in serum albumin and blood urea nitrogen levels. This has been shown by studies that have measured the clearance of

antipyrine and caffeine, which are capacity-limited, bindingsensitive and binding-insensitive drugs, respectively, in dogs with experimentally induced liver disease.^{129,130}

KEY POINT 2-7 If liver disease has impacted serum albumin or blood urea nitrogen, ensuring that drug metabolism is also impacted is prudent.

Because elimination of these drugs depends entirely on hepatic metabolism, their clearance might be used as a hepatic function test. Because their elimination does not necessarily correlate with the elimination of other drugs that also depend on hepatic clearance, however, they are not used to predict changes in dosing regimens for the patient with liver disease. Recommendations regarding dosing regimens for drugs not highly extracted by the liver thus are difficult to make for the patient with liver disease, in part because there is no simple test that will assess or quantitate hepatic function.^{125,129-133} In general, clearance of capacity-limited drugs is probably not impaired in patients whose serum albumin and blood urea nitrogen levels are within normal limits. Common sense dictates, however, that discretion be used when administering potentially toxic drugs that depend on hepatic clearance for elimination.

Diseases of the biliary tract alter the disposition of drugs eliminated through the bile. This route of elimination is

Figure 2-5 Portosystemic shunting affects drug disposition at multiple sites. Clearance of flow-limited drugs will be decreased in proportion to the fraction of blood shunted around the liver. Capacity-limited drugs may also be decreased if hepatic mass is sufficiently reduced. Accumulation of fluid in response to sodium retention may be profound, particularly in the abdomen. Albumin may be decreased, increasing the fraction of unbound drug, which may not be cleared as rapidly in the presence of disease.

complex, however, with drugs being eliminated in feces and undergoing enterohepatic circulation. Characterizing these changes is difficult without catheterization of the biliary duct, and recommendations are very difficult to offer. Cholestasis decreases the content or activity of cytochrome P450 drugmetabolizing enzymes and thus can affect the elimination of drugs that are not secreted in bile.^{134,135} In general, doses of drugs eliminated principally in the bile should be reduced, particularly if the drug is characterized by a narrow therapeutic window. Examples include selected antimicrobials (doxycycline and clindamycin), digitoxin, and naproxen.

The effects that changes in protein binding may have on hepatic drug clearance contribute to the unpredictable nature of liver disease-induced changes in drug disposition.^{127,136,137} Decreased protein binding of drugs that may accompany liver disease (i.e., caused by decreased synthesis of albumin, competition for binding sites by endogenous compounds, or changes in conformation of the binding site) may increase hepatic clearance and thus compensate for reduced hepatic metabolism, although the ability of the diseased liver to compensate is not clear. Increased rather than decreased binding may occur particularly for basic drugs (e.g., lidocaine) as a result of increased production of acute-phase proteins, which may have the effect of decreasing clearance. Changes in protein binding will also affect drug distribution. Protein binding decreases the amount of drug that distributes to peripheral tissues. Drug distribution in the patient with liver disease

Figure 2-6 Disease can affect body composition. The ascitic compartment in an animal with liver or other disease can represent up to 30% or more of body weight. If this compartment is not one to which a drug distributes and the animal is dosed on the basis of total body weight, plasma drug concentrations may be more than 30% higher than expected. If the drug is distributed to the ascitic compartment, prolonged distribution from the compartment back to plasma may result in a longer elimination half-life.

will be further complicated by the effects of fluid, electrolyte, and acid–base imbalances, which are also likely to occur. For example, an ascitic compartment may lead to overdosing if a patient is not dosed on the basis of lean body weight and the drug does not distribute to the ascitic compartment, which may constitute up to 30% of body weight (Figure 2-6).

Cardiac Disease

Cardiac disease profoundly affects drug disposition (see Table 2-4). Primary or compensatory disturbances that lead to altered drug disposition include renal sodium and water retention, increased pulmonary and systemic venous pressures, and increased sympathetic nervous system output.⁶ Sodium and water retention can cause profound changes in drug distribution owing to changes in the sizes of body compartments. In addition, increased sympathetic outflow results in redistribution of blood flow such that the heart and brain receive a higher proportion of blood and thus are exposed to more drug. Because other tissues, particularly skeletal muscle, represent a large volume to which drug is normally distributed, reduced distribution of drug to these tissues results in even higher PDCs in blood going to the heart and brain. Thus the heart and brain are more susceptible to toxicity. CNS and cardiac toxicities to lidocaine and cardiac toxicity to digoxin have been described in some patients with cardiac disease; these toxicities have been attributed to blood redistribution, which accompanies cardiac failure.

KEY POINT 2-8 Cardiac disease can affect every aspect of drug disposition. Variability may be greater as the patient responds or fails to respond to therapy.

As cardiac output decreases, reduced blood flow to the kidney and liver will have profound effects on clearance of drugs through either of these organs. Reduced blood flow reflects, in part, redistribution mediated by sympathetic output. As cardiac disease progresses, however, decreases in blood flow to both the liver and kidneys parallel decreases in cardiac output. The effects of decreased hepatic blood flow on drug elimination depend on the drug; as with liver disease, hepatic clearance of flow-limited drugs may be profoundly decreased. In the kidney, sympathetically mediated intrarenal redistribution of blood from cortical to juxtaglomerular tubules increases the likelihood of tubular reabsorption, which prolongs drug half-life.

Tissue hypoxia and decreased delivery of nutrients to the kidney and liver also contribute to decreased clearance by these organs. The metabolic capacity of the liver is reduced; thus clearance of capacity-limited drugs is impaired. Similarly, renal tubular function is impaired.

Drug absorption may be impaired in the patient with cardiac disease. This is particularly true for parenterally administered drugs. The rate of absorption is more likely to be affected than the extent of absorption; hence peak concentrations may be less, although the extent of drug absorption may not be affected. Redistribution of blood away from skeletal muscle and skin decreases the rate of drug absorption after intramuscular and subcutaneous injections. Autonomic disturbances, consisting of increased sympathetic activity and decreased autonomic tone, tissue hypoxia, and mucosal edema may decrease both the rate and the extent of gastrointestinal absorption. Decreased blood flow to the intestinal villus may decrease absorption of drugs that are normally very rapidly absorbed from the gastrointestinal tract. Finally, the effects of cardiac disease on hepatic clearance of flow-limited drugs and thus on systemic bioavailability of orally administered drugs must be considered.

Several recommendations can be made for administering drugs to the patient with cardiac disease (Box 2-7):

- 1. Critical drugs should be administered intravenously because absorption from all other routes is limited.
- 2. Drugs that are toxic (particularly to the brain and heart) should not be rapidly administered intravenously (i.e., administer over 10 to 30 minutes).
- 3. High drug concentrations resulting from redistribution should be compensated for by decreasing loading doses.
- 4. Maintenance doses of selected drugs cleared by the liver, kidney, or both should probably be lowered, although predicting which drugs and how much is difficult. Therapeutic monitoring should be used to guide alteration of dosing regimens whenever possible.

Thyroid and Other Diseases

Both hyperthyroidism and hypothyroidism can profoundly affect drug disposition, although the manner is unpredictable.¹³⁸ The effects thus far involve metabolism. In human patients with hyperthyroidism, the activities of some cytochrome P450 enzymes (e.g., hydroxylation) are increased, whereas those of others (e.g., N-demethylation) are decreased. In rats in which hyperthyroid disease had been induced, enzymes that act as cofactors were increased. Thyroidectomized animals have a general decrease in drug metabolism, although the sequelae are not always predictable. The effects of thyroid disease on drug disposition also depend on sex, with male rats having a general decrease in cytochrome P450 enzymes. The clinical sequelae of changes in drug disposition induced by thyroid disease are not well described in scientific studies, although several examples are provided in the

Box 2-7

Examples of Drugs Characterized by Changes in Drug Disposition in Patients with Cardiac Disease

Decreased Volume of Distribution Lidocaine Procainamide Quinidine Theophylline

Decreased Clearance

Lidocaine Prazosin Procainamide Quinidine Theophylline Digoxin*

*Clearance of digoxin is affected by other drugs used to treat cardiac disease. (From Benowitz NL: Effects of cardiac disease on pharmacokinetics: pathophysiologic considerations. In Benet LZ, Massoud N, Gambertoglio JG, editors: *Pharmacokinetic basis for drug treatment*, New York, 1984, Raven Press, pp 89-104.) human literature. Digoxin doses necessary to induce a clinical response are in general increased for patients with hyperthyroidism, whereas smaller doses than normal are needed for patients with hypothyroidism. Interestingly, propranolol clearance is decreased in cats with hyperthyroidism.¹³⁹

Diseases of other body systems can also dramatically alter drug disposition. For example, gastrointestinal disease (e.g., chronic inflammatory bowel disease) alters absorption of orally administered drugs.¹⁴⁰ Diseases of any system may alter the response of that system to a drug. Nutrition also can alter drug-metabolizing enzymes. The effects of disease, regardless of the system, on drug absorption, distribution, metabolism, and excretion are very complex, often subtle, and very difficult to predict. Finally, as therapy becomes successful and the clinical signs of disease resolve, the sequelae of disease on drug disposition also resolve. Therapy once again may need to be adjusted as the animal responds.

PHARMACOLOGIC FACTORS

Drug interactions occur whenever the action of one drug is modified by the presence of another, concurrently administered drug. The incidence of interactions increases with the number of drugs included in the preparation and with the duration of treatment.¹⁴¹ As such, the critical care patient may be particularly at risk; indeed, 81% of patients in a small animal intensive care unit were at risk for clinically relevant drug interactions in one study. The risk was greater in dogs with disease of the abdominal cavity and cats with cardiovascular disease.¹⁴² Drug interactions should be expected to have a potentially profound impact on animals. In human medicine more than 50% of recent drug withdrawals in the United States have occurred because of serious drug-drug interactions, which underscores the increasing recognition of the role of interactions in adversity.¹⁴³ The author is aware of several instances of euthanasia in patients resulting from drug interactions that were not recognized until significant pathology had occurred.

The route of administration can influence the type of drug interaction. Drug interactions are not limited to interactions with active drug ingredients but may also involve interactions with additives or excipients. Interactions may occur among drugs, herbs, botanicals, and endogenous nutraceutical preparations and with foods (i.e., drug–diet interactions (Table 2-5). Interactions may also occur with containers in which the drug is stored or through which it is administered and the environment in which the drug is stored. Drug interactions can be categorized according to the phase of drug administration in which they occur: pharmaceutical, pharmacokinetic, or pharmacodynamic.

KEY POINT 2-9 The risk of drug interactions increases with the number of drugs the patient is simultaneously receiving. The negative sequealae of the interactions is likely to be greater when complicated by the presence of physiologic and pathologic factors.

Pharmaceutical Drug Interactions

Pharmaceutical drug interactions occur before the drug is absorbed and may occur before administration (Figure 2-7). Interactions can occur between two drugs or between a drug and a carrier (solvent), a receptacle (including intravenous tubing), or the environment in which it is administered (e.g., gastric environment).¹⁴⁴ In human medicine pharmaceutical interactions most frequently result from the addition of drugs to intravenous fluid preparations. In veterinary medicine they are most likely to occur in the critical care environment, where intravenous administration and multiple drug administration are common, or after inappropriate compounding of drugs. Drug incompatibilities can change the chemical or physical nature of a drug (Figure 2-8). Incompatible reactions can reflect degradation caused by changes in pH, binding by drugs with different charges, or other molecular interactions; changes in temperature; or exposure to ultraviolet radiation.145 Incompatibilities may occur both with (approved) finished dosing forms or compounded preparations. A number of sources can be used to minimize the risk of drug interactions involving admixtures of drugs.146-150

Intravenous Preparations

A number of interactions involve drugs intended for injection (Table 2-6). Drugs that are unstable generally have a short shelf life when in solution. Reconstituted parenteral solutions

should always be labeled with the new expiration date and used with strict adherence to the product label instructions after reconstitution. If directed by the label, refrigeration or freezing can prolong the shelf life. It is risky, however, to assume that cold storage will prolong the shelf life of the drug unless efficacy has been documented at the intended conditions. Freezing can increase the degradation (e.g., ampicillin), crystallization (e.g., heparin, dobutamine, furosemide), or precipitation (e.g., insulin) of drugs. Refreezing of a previously frozen and defrosted solution increases the risk of efficacy loss. Often, if specifically queried, the manufacturer of the product can provide specifit information regarding drug stability in conditions beyond those stated on the label. The proper reconstituting fluid should be used to prevent inactivation of drugs. For example, amphotericin B should be diluted only with 5% dextrose because precipitates will otherwise form; whole blood or packed red blood cells should be diluted only with 0.9% saline to prevent damage to infused cells.

Changing the pH of a solution by improperly diluting it or mixing it with another drug can be risky. The release of some insulins is pH dependent. Diluting insulin with a solution other than that provided by the manufacturer may change the pH and thus the rate of insulin release. The pH of a solution may be needed to keep the active drug dissolved or stable; changing the pH may result in precipitation or loss of stability. For example, acid-labile drugs (e.g., penicillins) can be

Drug	Supplement	Side Effect
Alprazolam	Kava	Enhanced effect
Anesthetics, sedatives	St. John's wort, valerian, kava	Increased CNS effects
Antiplatelet/anticoagulants	Garlic, ginger, ginkgo, chamomile, feverfew, bromelain, dang gui	Prolonged bleeding time
Antiviral	Garlic (allium)	Decreased effect because of CYP3A4 and P-glycoprotein induction
Cardiac stimulants	Ephedra, ginseng	Increased risk of cardiac arrhythmias
Chlorpropamide	Garlic (allium)	Hypoglycemia
CNS stimulants	Ephedra, yohimbine, guarana, ginseng, caffeine	Increased CNS stimulation
Cyclosporine	St. John's wort	Decreased effect because of CYP3A4 and P-glycoprotein induction
Digoxin	St. John's wort	Decreased effect because of P-glycoprotein induction
Diuretics	Senna, licorice	Electrolyte disturbances
Hypoglycemics	Ginseng, bilberry, dandelion, garlic, bitter melon	Hypoglycemia
Immunosuppressants	Echinacea, astragalus	Antagonizes immunosuppressive effects
Loperamide	St. John's wort	Inhibition of monoamine oxidase (enhanced effect)
Oral drugs	Senna	Decreased absorption
Propranolol	Piperine	Enhanced effect (CYP inhibition)
Selective serotonin reuptake inhibitors	St. John's wort, SAMe, silamaryn	Increased risk of side effects, serotonergic crisis
Theophylline	St. John's wort	Decreased effect because of CYP3A4 and P-glycoprotein induction
Theophylline	Piperine	Enhanced effect (CYP inhibition)
Thiazide diuretics	Ginkgo	Decreased clearance (enhanced effect)

CNS, Central nervous system; SAMe, S-adenosylmethionine.

destroyed in a low-pH solution. Drugs prepared as an acid salt (e.g., lidocaine hydrogen chloride) or in acidic solutions (i.e., sodium heparin) should not be combined with alkaline solutions (i.e., sodium bicarbonate).

Drugs can bind to and inactivate one another, often because of ionic attractions. Calcium in solutions causes precipitation when combined with solutions containing carbonates (e.g., sodium bicarbonate). Heparin is incompatible with several drugs, such as aminoglycoside and beta-lactam antibiotics. Thus saline rather than heparin should be used whenever possible to maintain patency of catheters through which drugs are administered. When present in sufficiently high concentrations, penicillins inactivate aminoglycosides. In fact, ticarcillin can be used therapeutically to bind gentamicin in cases of overdose. Although plasma concentrations after therapeutic dosing of either drug probably do not achieve concentrations necessary to inactivate aminoglycosides, in the critical care situation, and as a once-daily dosing regimen of aminoglycosides becomes more generally acceptable, the risk of aminoglycoside (or a fluorinated quinolone) antimicrobial inactivation by a penicillin may become greater.

Often, a pharmaceutical drug interaction involving intravenous solutions can be detected by a visual change in the appearance of the drugs. Discoloration, cloudiness, and formation of precipitate generally are indications of an interaction, and with some exceptions use of the drug should be reconsidered. Not all interactions will result in a physical change of the appearance, however. Likewise, the change in physical appearance of a drug combination does not necessarily indicate that the activity of the drug has been changed. For example, diazepam has been mixed with other preanesthetics with no observable change in drug efficacy, despite a

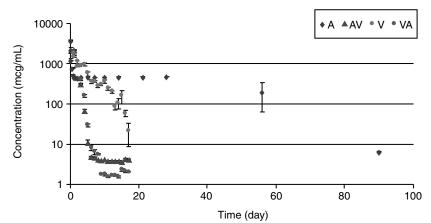

Figure 2-7 An example of a drug interaction is exemplified by drug efflux from calcium hydroxyapatite (plaster of Paris) beads. Individually, amikacin or vancomycin is characterized by an initial rapid release, followed by slow release from the beads over several weeks. However, when both drugs are mixed in the beads, efflux of both amikacin and vancomycin is much more rapid, being nearly complete in 1 to several days.

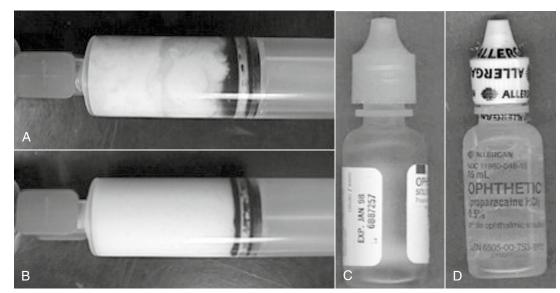

Figure 2-8 Examples of chemical changes in drugs. Transdermal gels are thermoreversible, liquefying at refrigerated temperatures (A) and solidifying at room temperature (B). Discoloration, shown here for an ophthalmic product (C and D) and steroid.

Table 2-6 Examples of	of Drug Interactions in Solution			
Drug or Drug Class	Incompatible Drugs	Other Risks		
Amino acid solutions	Many drugs			
Aminoglycosides	Semisynthetic beta-lactams, heparin, many others; check manufacturer's label	Adsorbs to glass; use plastic for monitoring		
Aminophylline	Should not be mixed with other drugs			
Amphotericin B	Use only 5% dextrose (or manufacturer suggests sterile water).	Light exposure		
Ampicillin sodium	Selected diluents and drugs; check manufacturer's label			
Atropine sulfate	Bicarbonate, methicillin, promazine, warfarin, others			
Beta-lactams				
Cephalosporins	Many drugs, depending on specific antimicrobial; check manufacturer's label	eck Check manufacturer's recommendations regarding stability upon reconstruction		
Penicillins	As for cephalosporins; aminoglycosides			
Bicarbonate	Many drugs			
Buprenorphine	Should not be mixed with dimenhydrinate, pentobarbital			
Butorphanol	Should not be mixed with diazepam			
Blood, red blood cells	Any intravenous solution except 0.9% saline			
Calcium-containing solutions	Many drugs			
Calcium disodium EDTA	Should not be mixed with many drugs, including dextrose, metal salts			
Chloramphenicol	Many drugs			
Carbenicillin disodium	Should not be mixed with many drugs			
Cefazolin	Should not be mixed with any other drug			
Cephalothin	Should not be mixed with any other drug			
Diazepam	Cloudiness when mixed with many other drugs indicates precipitation, which will include drug; potency may be reduced.	Adsorbs to intravenous tubing and plastic containers		
		Protect from light.		
Digitoxin (not digoxin)	Calcium, epinephrine, vitamin B complex			
Diphenhydramine	Furosemide, methylprednisolone, pentobarbital			
Dobutamine	Alkaline solutions	Check manufacturer's label regarding discoloration.		
Doxorubicin	Bicarbonate, heparin, insulin, others	Avoid prolonged contact with aluminum.		
Doxycycline	Selected drugs, including lidocaine, heparin, isoproterenol, vitamin B complex			
Epinephrine	Calcium-containing solutions, ampicillin, other penicillins, pentobarbital, prochlorperazine, others			
Erythromycin	Several drugs, including selected cephalosporins, chloram- phenicol, heparin, tetracyclines, and vitamin B complex			
Flunixin meglumine	Most solutions			
Furosemide	Acidic solutions cause hydrolysis; precipitates when com- bined with many drugs	Yellow discoloration; protect from light		
Gentamicin	Many drugs, including dopamine, furosemide, heparin (see also beta-lactams, amphotericin B)			
Glycopyrrolate	Alkaline solutions	Strongly acidic solution		
	Should not be diluted with saline or bicarbonate for intrave- nous infusion			
	Other drugs			
Heparin	Many drugs	Strongly acidic solution		
		Slightly yellow discoloration is acceptable.		
Hydrocortisone sodium esters	Acid pH causes hydrolysis.	Use proper dilution volume to prevent precipitation.		
	Incompatible with many selected drugs			

Drug or Drug Class	Incompatible Drugs	Other Risks
Imipenem		Do not freeze.
Insulin	Check package label regarding diluents and refrigeration need and mixing lente insulin kinetics; incompatible with many drugs	Binds to intravenous tubing, selected type of glass, and plastics
Iron dextran	Oxytetracycyline, sulfonamides	
Kanamycin	See gentamicin, aminoglycosides	
Ketamine	Barbiturates, diazepam	
Lidocaine	Alkaline solutions	Loss of drug when stored in polyvinyl chloride bags (adsorption to polyvinyl chloride)
Magnesium sulfate	Many drugs, including calcium-containing drugs, sodium bicarbonate, tetracyclines, others	
Mannitol	Blood, strongly acidic, or alkaline solutions	Crystallization of high (25%) concentra- tions in glass containers generally can be redistributed by warming; crystal- lization in plastic solutions is difficult to resolve
Methylprednisolone sodium succinate	Normosol-R, Normosol-M, selected drugs	Do not dilute with a volume that is too small; precipitation may occur other- wise.
Metronidazole		Reconstituted lyophilized product is very acidic and must be buffered with bicarbonate. Ready-to-use product requires no additional handling. It is light sensitive; however, discoloration induced by light is not accompanied by loss of potency. Do not freeze.
Metoclopramide	Beta-lactams, erythromycin, sodium bicarbonate	Protect from light.
Morphine	Many drugs	
Multiple vitamin	Bicarbonate, selected cephalosporins, aminophylline, others	Decreased potency as been documented; complexes 8 hours after dilution.
Nitrofurantoin	Many drugs	
Oxyglobin	Vitamin K (see phytonadione)	Removal from foil wrap exposes hemo- globin to oxidation, with subsequent formation of methemoglobinemia (indi cated by brown discoloration).
Oxytetracycline	See tetracycline	
Oxytocin	Do not mix with any other drug.	Refrigerate at <25° C; do not freeze.
Penicillin G	See also beta-lactams	Rapidly inactivates in pH <6-7 or >8
	Polyethylene glycol	
	Prochlorperazine, pentobarbital, sulfadiazine	
	Others	
Pentobarbital	Acid pH	Prepared as extremely alkaline solution
	Many drugs	
Phenobarbital	Many drugs, especially acidic solutions	
Phenylephrine	Penicillin, pentobarbital, phenobarbital, phenytoin, sodium bicarbonate	
Phenytoin	Do not mix with any other drug or intravenous solution.	
Phytonadione	Do not mix with ascorbic acid, barbiturates, phenytoin.	
Potassium chloride	Do not mix with amphotericin B.	
Pralidoxime chloride (2PAM)	Reconstitute with sterile water only; do not mix with any other drug.	

Table 2-6 Examples of Drug Interactions in Solution—cont'd

Drug or Drug Class	Incompatible Drugs	Other Risks
Procaine	Many solutions, especially alkaline	
Procainamide	Dextrose	Light yellow (but not amber) discoloration acceptable
Prochlorperazine	Many drugs; do not mix in same syringe	
Promazine	Many drugs	
Promethazine	Selected drugs	
Protein hydrolysate	Many drugs	
Propofol	Do not mix with any other drugs.	
Propranolol	Rapidly decomposes in alkaline solution	
Ringer's lactate	Alcohol in 5% dextrose, epinephrine, oxytetracycline, sodium bicarbonate, sulfadiazine	
Sodium bicarbonate	Many drugs; check package insert	
Sodium iodide	Several drugs	
Sulfonamides, sodium salts	Many drugs	
Tetracycline	Highly acidic solution may render this incompatible with many drugs.	Dark solution indicates decomposition; discoloration in multiple electrolyte solution does not indicate potency loss.
Thiopental	Many drugs	
Vancomycin	Selected drugs	
Vitamin B complex	Magnesium sulfate, erythromycin, selected others	
Warfarin	Many drugs	

Table O C

cloudy discoloration. Whereas a pink discoloration of dopamine indicates inactivation, discoloration of dobutamine does not preclude efficacy if the drug is used within 24 hours. Slight yellow discoloration of procainamide is acceptable; dark discoloration indicates a loss of efficacy.

Several drugs can bind to receptacles. For example, lipidsoluble drugs (e.g., diazepam) can bind to plastic containers; insulin binds to selected glasses and to many plastics, including polyethylene and polyvinyl; aminoglycosides bind to glass. Binding to catheters and intravenous lines can be minimized by flushing each new system with a sufficient volume of solution (50 mL) before drug administration. Drugs packaged in brown bottles (e.g., diazepam, furosemide) are somewhat protected as such from ultraviolet light, and protection should be continued if they are transferred to another vial.

Oral Preparations

Oral preparations may involve drug-diet or drug-drug interactions (see Box 2-7 and Tables 2-5 and 2-6). Many drugs bind luminal contents (drug-diet interactions; Table 2-7), and oral absorption is impaired.¹⁵¹ Food can alter splanchnic blood flow, gastric motility (and thus mixing and drug dissolution as well as gastric emptying), and gastric secretions. Changes in gastric secretions can alter gastric pH, which can change the percentage of ionized and thus diffusible drug. The net effect of food on drug absorption depends on the pK_a of the drug, whether the drug is labile to the effects of pH and enzymes, and the site of absorption of the drug (i.e., stomach versus intestine).¹⁵¹ The sequelae may affect either the rate or

extent of drug absorption. The effect of food on the rate of drug absorption is most important for drugs with a narrow therapeutic window and for drugs with a steep dose-response curve, for which a small change in PDC can cause profound differences in response to the drug. Predicting drug-diet interactions on the basis of chemical structure should be done cautiously. Whereas food will impair the oral absorption of most tetracyclines, doxycycline is minimally affected. Food reduces the absorption of ampicillin but not amoxicillin;¹⁵² food prolongs the time to peak plasma concentrations of cefadroxil (and increases time above the minimum inhibitory concentration) but has no impact on the absorption of cephalexin.¹⁵³ Oral absorption of selected drugs is enhanced rather than decreased in the presence of food (see Table 2-2). Interactions between drugs and foods were recently well reviewed using a body-systems approach.154

Drug-drug interactions (see Table 2-7) in the lumen include, but are not limited to, changes in the diffusibility, dissolution rate, and particle size of orally administered drugs. Drug-drug interactions in the gastrointestinal tract can inactivate or prevent absorption of drugs. Sucralfate, cimetidine, aluminum hydroxide, and attapulgite (previously Kaopectate®) are examples of drugs that bind to and prevent the absorption of many drugs. Other drugs alter the rate of absorption by altering gastric motility (see Table 2-4; see also the discussion of pharmacokinetic interactions later in this chapter). To minimize these effects, none of these drugs should be given simultaneously with another orally administered drug.

Interaction	Example Drugs				
Binding to luminal contents	Tetracyclines (except doxycycline), fluorinated quinolones, antacids, sucralfate,				
Absorption					
Gastric motility	Metoclopramide, anticholinergics, erythromycin				
Gastric pH	Antisecretory drugs, antacids				
Competition for transport proteins	See Table 2-2				
Inhibition or induction of drug metabolizing enzymes	See Table 2-7				
Increased splanchnic blood flow (nutrients)					
Distribution					
Competition for transport proteins in circulation	See Table 2-2				
Competition for transport proteins in tissues	See Table 2-2				
Altered regional blood flow	Fluid therapy, ACE inhibitors, other cardioactive drugs, phenothiazines				
Metabolism					
Competition for transport proteins	See Table 2-2				
Induction of phase I enzymes (CYP 450)	See Table 2-8				
Inhibition of phase I enzymes (CYP 450)	See Table 2-8				
Increased phase II enzymes (glutathione)	See Table 2-8				
Excretion					
Competition for transport proteins	See Box 2-8				
Altered renal blood flow	Cardioactive drugs, NSAIDs, amphotericin B, aminoglycosides				
Altered urinary pH	See Box 2-9				

NSAIDs, Nonsteroidal antiinflammatory drugs.

Topical Preparations

Pharmaceutical interactions in topical preparations may occur between drugs or between drugs and the vehicle in which they are carried.^{155,156} Both the rate and extent of drug absorption can be affected adversely. For example, macromolecular additives may bind chemically with the active drug. Methyl, ethyl, hydroxyethyl, and carboxymethyl cellulose frequently form complexes with drugs that can lead to drug precipitation. Vehicles are often selected because of their effect on drug absorption. For example, retardant vehicles (e.g., polyethylene glycol 300) interact with the drug, decreasing its absorption, whereas dimethyl sulfoxide (DMSO) is well recognized for its ability to enhance absorption of many topically applied drugs. The pluronic-lecithin vehicle of PLO gels (PLO) designed for transdermal drug delivery is thermoreversible, meaning they are semisolid at room temperature but become liquefied when refrigerated (see Figure 2-8).

The concentration of drug available for skin penetration depends on its dissolution in the vehicle. Drugs must generally dissolve in an aqueous layer of fluids that collects under the ointment base before percutaneous absorption can occur. Few drugs (and particularly water-soluble drugs) are sufficiently soluble to be dissolved in petrolatum bases; most drugs mixed in such bases are present as particles. Because few particles are located at the vehicle–skin interface, and dissolution is very slow for the particles, drugs in such preparations are likely to be ineffective. As such, lipid-soluble drugs tend to be better absorbed, particularly when prepared in lipid vehicles. Because only dissolved drug can move, the solubility of a drug in the vehicle is an important determinant of drug movement into the skin. However, a drug that has too great an affinity for the vehicle also may not be well absorbed simply because it will not leave the vehicle.¹⁵⁶

Compounded Preparations

Many U.S. pharmacies now cater specifically to veterinarians and thus are prepared to address special problems in drug therapy through compounding. As important as compounding can be to the safe and effective administration of drugs to animals, compounded products present more risks of therapeutic failure than encountered with approved drugs.^{157,158} Among the risks are the potential failure of the drug at the pharmaceutical phase because of interactions among the active or inactive ingredients. These risks are addressed in more depth in Chapter 4.

Pharmacokinetic Drug Interactions

Drug interactions that occur inside the body may lead to life-threatening adversities because of either therapeutic failure or increased side effects. Pharmacokinetic interactions occur when one drug alters the disposition of another drug.¹⁵⁹ Each stage of disposition of a drug—absorption, distribution, metabolism, or elimination—can be altered by another drug. The majority of drug interactions leading to serious adverse events in humans reflect pharmacokinetic interactions, involving either transport proteins or drug-metabolizing enzymes.¹⁴³ Identifying the role of drug interactions in causing adverse effects is difficult; large numbers of patients generally must be studied to identify even common interactions. Predictions of drug-diet or drug-drug interactions might be facilitated by evaluation of chemistry, but caution is necessary.¹⁵⁴ Models that predict drug interactions are complicated by complex interactions (e.g., species, disease, and multiple drug interactions).¹⁶⁰ Identification of drug interactions involving dietary supplements is handicapped by the lack of a mandated surveillance mechanism; information in human medicine generally is obtained through reviews, case reports, or case series or based on open, uncontrolled studies.¹⁶¹ Evidence-based information in veterinary medicine is even further limited. Several human-medicine reviews have described interactions between drugs and botanicals or herbs161 and foods.154 Mechanisms are often difficult to identify, in part because of broad substrate specificity. Some examples of drug-drug or drug-supplement interactions follow.

Absorption

Absorption of one drug may be hindered as a result of changes in the drug's passage through biological phases and changes in local pH; the integrity of biological membranes; regional blood flow; and, in the case of orally administered drugs, gastrointestinal motility. Each of these changes can be induced by a concurrently administered drug. Examples include the impact of an antisecretory drug on the ratio of un-ionized (diffusible) to ionized (nondiffusible) drugs. For weakly acidic drugs, a decrease in the ratio may decrease oral absorption; for weakly basic drugs, the opposite may occur. Sucralfate and cimetidine are examples of drugs that bind to and prevent the absorption of other drugs. Likewise, tetracycline and enrofloxacin are bound by divalent or trivalent cations that might be found in antacids (see Table 2-4). Finally, drugs that alter gastric motility might alter the rate of oral drug absorption. Most drugs are absorbed from the small intestine. Administration of anticholinergics decreases gastric emptying, allowing a longer time to elapse before a drug moves to the small intestine. Although extent of absorption may not be affected, peak PDCs may be lower. Metoclopramide probably has an opposite effect. In contrast to gastric motility, increasing motility of the small intestine is unlikely to alter the oral absorption of drugs because the surface area is so large that it is difficult to manipulate. However, a few drugs alter drug absorption by causing malabsorption or changing gastric blood flow (see Table 2-4). Phenytoin and phenobarbital have been associated with decreased oral absorption of vitamins.

KEY POINT 2-10 The role of drug induction and inhibition on drug transporter proteins such as P-glycoprotein is only now being delineated, but can be particularly profound for drug absorption and distribution.

Drug interactions that have an impact on absorption may also reflect altered metabolism and/or uptake in the enterocyte or liver. Drugs entering enterocytes are subject to metabolism by CYP3A, efflux mediated by P-gp, or passage into

portal system and exposure to metabolic activities of the liver. Cytochrome P450 3A is the most predominant drug-metabolizing enzyme in the intestinal cell and mediates biotransformation of more than half of all drugs currently available (for humans).¹⁶² Transporters such as the multidrug export pump P-gp, facilitate either drug absorption or efflux from the enterocyte, and drugs may act as substrates or inhibit or compete at these proteins (see Table 2-2). Both proteins (CYP 3A and P-gp) share drug substrates, and interplay between metabolic enzymes and transporters appears to confound the disposition of many orally administered drugs (Table 2-8; see also Table 2-2). Poor oral bioavailability may reflect a coordinated action of intestinal drug-metabolizing enzymes and efflux transporters. Experimentally, drug efflux by intestinal P-gp is known to prevent absorption and thus decrease the bioavailability of many CYP3A4 substrates. The interaction between P-gp and CYP3A4 at the apical intestinal membrane increases drug metabolism of those drugs that are absorbed.¹⁶³ In contrast, selected drug interactions also involve inhibition of the P-gp, resulting in increased oral bioavailability. Fooddrug interactions most commonly occur in the gastrointestinal tract154 and reflect therapeutic failure owing to reduced bioavailability of the drug. Less commonly, increased drug concentrations reflect altered appetite or gastrointestinal acidity. Those most commonly identified drug-diet (nutrient or supplement) interactions involve altered drug pharmacokinetics caused by interference with either P-gp or xenobiotic metabolizing enzymes (see the section on metabolism). Of the potential drug-nutrient interactions affecting absorption, competition among substrates for transport proteins have probably been the best described.^{143,164} For example, flavenoids (found in grapefruits) are inhibitors of several P-gp substrates, which increases the risk of diet-diet or diet-drug interactions during both absorption and distribution.¹⁶⁴

Distribution

Pharmacokinetic drug interactions that alter drug distribution from the central compartment to peripheral tissues usually result from competition for protein-binding sites between two or more concurrently administered drugs. Because protein binding is reversible, the drug with the highest affinity for protein (usually albumin) displaces the drug with less affinity (Box 2-8). If a highly (>80%) protein-bound drug is displaced by only a small fraction, the amount of unbound, pharmacologically active drug markedly increases, and the risk of toxicity is initially increased. Because NSAIDs are generally more than 90% protein bound, even slight displacement of the drug from its binding sites can initially result in concentrations that might increase the risk of adverse effects. Increased hepatic or renal clearance of the unbound drug tend to balance displacement of bound to unbound drug such that PDCs of free unbound drug only minimally increase (see Chapter 1).¹⁶⁵ However, according to its package insert, co-administration of cefovecin with other highly protein bound drugs increases the concentration of the latter. It is not clear whether increased clearance of unbound drug will be sufficient in the presence of hepatic (or renal) disease. Most drug interactions involving

Box 2-8

Highly (>80%) Protein-Bound Drugs

Weak Acids (Albumin) Nonsteroidal antiinflammatories Coumarin derivatives Antimicrobials Doxycycline Minocycline Cefovecin Anticonvulsants Valproic acid Phenytoin Diazepam Furosemide Weak Bases (a Glycoproteins) Several cardiac drugs Propranolol Lidocaine (some species)

Tricyclic antidepressants

protein binding reflect competition for albumin-binding sites because albumin is the most common binding protein, particularly for weak acids. Lipoproteins; globulins (increased with acute-phase protein increase); and, to a lesser extent, albumin bind weak bases (e.g., bupivacaine, lidocaine) (see Box 2-8).

Use of drugs that alter drug distribution to peripheral organs can alter drug delivery to the organs. For example, the use of afterload reducers may increase renal blood flow; renal clearance of drugs may also increase. Use of glucocorticoids before volume replacement in a hypovolemic patient may enhance peripheral vasoconstriction, reducing tissue distribution of other drugs. Rarely, drug interactions occur at the tissue site. For example, drugs can compete with each other at tissue-binding sites. Quinidine increases digoxin toxicity because it displaces digoxin from cardiac tissues; in contrast, hypokalemia facilitates binding of digoxin to cardiac tissue, thus enhancing digoxin cardiotoxicity.

Because P-gp is located on the cell membrane of many organs, this transporting protein can influence tissue distribution of drug. The most notable example is its presence in the blood-brain barrier, where it serves to efflux many drugs that are able to penetrate the barrier. Genetic deficiency of this protein has been associated with an increased risk of CNS toxicity in certain breeds its role in drug interactions should be anticipated (see Chapter 4 and later discussion). Drug–nutrient interactions resulting in competition for transport proteins may also affect distribution of drugs.^{143,164}

Metabolism

Pharmacokinetic drug interactions frequently alter the metabolism of a concurrently administered drug (see Table 2-4).¹⁶⁶⁻¹⁷⁰ When administering a drug metabolized by the liver, it is wise to anticipate a drug interaction if a second drug also metabolized by the liver is added to therapy. Most of the interactions result from modulation of hepatic (phase I) drug-metabolizing enzymes (see Table 2-8).

KEY POINT 2-11 Interactions at the level of drug-metabolizing enzymes are among the most dangerous, yet their predictability is complicated by the large number of enzymes, the lack of substrate specificities, and polymorphisms among animals.

Induction of drug-metabolizing enzymes should be considered as a protective mechanism that facilitates excretion of potentially toxic compounds. However, induction is a double-edged sword: although the elimination of a potentially toxic drug increases, so does potential formation of toxic or carcinogenic metabolites. Most CYP enzymes are inducible, with response to inducers varying within and among species, age, and gender. Human CYP known to be influenced by inducers include CYP 1A1/2, 2A6, 2C9, 2C19, 2E1, and 3A4 (see Table 2-8). Inducers generally act as substrates for the induced enzymes, and induction generally is dose dependent.¹⁷¹ Inducers often induce more than one CYP and may significantly increase the activity of an enzyme that otherwise (constitutively) is either absent or present only in very low concentrations. Induction is accompanied by an increase in the transcription and thus intracellular concentration of the induced enzyme. Maximal induction of transcription generally requires 10 to 12 hours of exposure to a drug. Although transcription may return to baseline 18 to 24 hours (depending on dose) after the inducer is discontinued, the

impact of the inducer may persist. The duration of the effect varies with the rate of enzyme degradation, which normally results in half-lives that range from 8 to 30 hours. Although not common, induction also may reflect a decrease in the rate of CYP degradation—that is, a prolongation of enzyme half-life.¹⁷²

Barbiturates are recognized inducers of CYP; indeed, the observation that "tolerance" to hypnotics developed in dogs chronically exposed to barbiturates led to the recognition of the phenomenon of induction.¹⁷² Phenobarbital is one of the most potent microsomal enzyme inducers known and can enhance the hepatotoxicity of other hepatotoxic drugs. Likewise, it increases the formation of and response to prodrugs and decreases the effects of itself and other drugs metabolized by the liver as clearance of these drugs is increased.^{73,173,141} The CYP2B9 family, responsible for metabolism of a large number of drugs in rodents, is induced by phenobarbital. Therapeutic doses of phenobarbital have been associated with induction of CYPIA activity, as well as alpha-glycoproteins in dogs.¹⁷⁴ The clinical impact of this effect is demonstrated in epileptic dogs treated with phenobarbital: initial concentrations may decrease within several months of therapy despite no dose change. Interestingly, oral pentobarbital also increases the amount of CYP2C present in the intestinal tract of dogs when administered at doses consistent with that consumed by dogs fed commercial dog foods prepared from animals euthanized by pentobarbital (10 to 60 μ g/gm). The impact on the metabolism of selected subtrates varies and is greatest for higher doses, but changes are also present at low doses, suggesting a potential clinical impact on therapeutic drugs.171

Drug interactions that reflect inhibition of drug-metabolizing enzymes may be at greater risk in causing serious adverse events. A number of inhibitors of CYP enzymes have been identified. As with inducers, the extent of inhibition is dose dependent,^{172,175} with inhibitors often acting as substrates at the inhibited enzyme, and either characterized by broad enzyme interaction, being inhibitory for a number of different CYPs, or acting selectively for a single enzyme (see Table 2-8).¹⁷² Currently, three types of drug-metabolizing enzyme inhibitors have been described: reversible, quasireversible, and irreversible, with reversible inhibitors being the most commonly involved in drug-drug interactions. Reversible inhibition is transient, resolving when therapy with the inhibitor is discontinued. Like induction, reversible inhibition appears to be dose dependent.¹⁷⁵ Reversible inhibition most commonly reflects interactions that are competitive or noncompetitive. Competitive inhibition is exemplified by a drug that blocks access to the catalytic site of the enzyme of another structurally similar drug. The drug may or may not be a substrate for the enzyme. Noncompetitive inhibition occurs when substrate binding occurs at a different site but nonetheless changes the catalytic activity of the enzyme such that it is inactivated.¹⁷²

Generally, clearance of a concurrently administered drug metabolized by the liver is prolonged in the presence of inhibitors, increasing the potential for toxicity or for an exaggerated pharmacologic response. Additionally, prodrugs (e.g., enalapril, primidone) are less likely to be activated. Chloramphenicol, cimetidine, and imidazole antifungal drugs are examples of potent microsomal enzyme inhibitors.73,173,141 Co-administration with potentially toxic drugs that are also metabolized by the liver should be done cautiously. Fluorinated quinolones such as enrofloxacin and marbofloxacin can increase theophylline plasma concentrations to toxic levels, presumably because of impaired hepatic clearance of theophylline.¹⁷⁶ Ketoconazole inhibits cytochrome P450 enzymes, including CYP3A4 in the dog.177 However, it does not necessarily clinically affect all drugs metabolized by the liver. For example, morphine clearance was not changed in Greyhounds treated with an average of 12.7 mg/kg ketaconazole per day.93 Although area under the curve was greater in the presence of morphine, the change was neither statistically nor clinically significant. This may reflect, however, the flow-limited nature of morphine clearance or, potentially, breed differences in drug metabolism. Other imidazoles (fluconazole and, to a lesser degree, itraconazole) also have broad enzyme inhibitory activity (see chapter 9).

Drug-induced inhibition of drug metabolism can be used for therapeutic benefit. Both cyclosporine and ketaconazole are substrates and inhibitors of both P-gp and CYP3A. As such, the combined use of the drugs may result in marked prolongation of the half-life of either drug. Ketoconazole has been used to increase blood drug concentrations of cyclosporine (owing to both inhibition of drug-metabolizing enzymes and competition with P-gp) in dogs.¹⁷⁸ A twofold increase in expected PDCs may occur, as indicated by a 50% dose reduction in Beagles¹⁷⁹ or a twofold increase in C_{max} in Greyhounds.⁹³ Indeed, the impact may be greater in some dogs: our laboratory has documented an elimination half-life of over 150 hours in dogs simultaneously receiving ketoconazole, yielding concentrations that exceed 4500 ng/mL. In cats, cyclosporine (4 mg/kg orally) concentrations can be expected to increase approximately twofold when administered with ketoconazole (10 mg/kg).180 The macrolides also have broad inhibitory effects. The inhibitory effect of erythromycin may reflect inhibition of CYP3A macrolides, which appear to inhibit cyclosporine clearance. Again, in our laboratory azithromycin co-administration was associated with marked prolongation of cyclosporine half-life in a cat, leading to cyclosporine concentrations that exceeded 4500 ng/mL (therapeutic range 800-1400 ng/ mL). The effect of cimetidine, another drug-metabolizing inhibitor with broad substrate specificity, is variable, ranging from no significant effect in Beagles (n=10; 15 mg/kg cimetidine every 8 hours for 8 days and 5 mg/kg once daily for cyclosporine) to 50% decrease in clearance in humans.¹⁸¹ Cimetidine-induced enzyme inhibition, however, has been used to prevent metabolism of acetaminophen in humans and cats into potentially lethal toxic metabolites.^{182,183} Cilastatin inhibits renal tubular drug metabolism of imipenem; the net effect may prolong the half-life of imipenem, but hepatotoxicity or renal toxicity resulting from metabolites might also be reduced (see Chapter 4). Nutrition, sex, age, and other factors can influence the way drug-metabolizing enzymes respond to drugs. Alcohol and 4-methylpyrazole competitively inhibit alcohol dehydrogenase, the drug-metabolizing enzyme that converts ethylene glycol to its lethal metabolite.

Although less common, drug clearance may also be affected by drugs that change hepatic blood flow, solely due to substrate delivery, not a limitation on metabolic rate. This interaction is significant, however, only for drugs that are characterized by extensive and rapid hepatic clearance (e.g., propanol, lidocaine) and probably is not clinically relevant.

Among the most commonly identified drug-diet (nutrient or supplement) interactions that alter drug pharmacokinetics are those reflecting drug metabolism, particularly CYP3A4.¹⁵⁴ Several dietary supplements are known to interact with drugs.¹⁶¹ These include, but are not limited to, St. John's wort (induction of CYP3A4, particularly intestinal), echinacea (induction and inhibition of intestinal CYP), ginkgo biloba (induction of CYP219A), and grapefruit (inhibition of CYP3A4 and inhibition of P-gp).

Excretion

Pharmacokinetic drug interactions may alter urinary excretion because of changes in glomerular filtration, competition between the drug for active tubular secretion, or both (Box 2-9). Competition for carrier proteins responsible for active tubular secretion usually involves acidic drugs. Probenecid is still occasionally used to prolong the elimination of an expensive penicillin because it competes with the penicillin for a carrier protein. Renal excretion may also be affected by drugs that alter urinary pH and tubular reabsorption. Changes in urinary pH conducive to formation of a greater proportion of un-ionized drug (e.g., an acidic urinary pH and an acidic drug) encourage tubular reabsorption of a drug, thus decreasing its clearance and prolonging its elimination half-life (Box 2-10).73,173,141 For example, overdosing of some drugs (e.g., aminoglycoside or strychnine poisoning) can be treated by hastening elimination with urinary acidifiers.

Box **2-9**

Examples of Drugs That Compete for Renal Tubular Secretion

Anions (Acidic Drugs) Penicillins Cephalosporins Probenecid Sulfonamides Aspirin Furosemide Nonsteroidal anti-inflammatories Phase II metabolites (gluconic acids, glycine, and sulfate conjugates)

Cations (Basic Drugs) Procainamide Dopamine Trimethoprim Several opioid agents

Pharmacodynamic Drug Interactions

Pharmacodynamic drug interactions occur when one drug alters the chemical or physiologic response to another drug (see Table 2-6). Pharmacodynamic interactions may increase response to a drug in an additive or synergistic fashion at the same receptor (e.g., the permissive effect of glucocorticoids on alpha-adrenergic receptors; phenobarbital and clorazepate at gamma-aminobutyric receptors), at an intracellular site (e.g., epinephrine and theophylline in bronchial smooth muscle), or at different sites but with the same physiologic reaction (e.g., hypokalemia induced by cardiac glycosides and diuretics; many interactions of antimicrobials). Pharmacodynamic interactions may also decrease the response of some drugs owing to competitive antagonism at the same receptor site (e.g., atropine and anticholinesterases or atropine and metoclopramide) or antagonistic responses mediated at distant but physiologically related sites. Antagonistic pharmacodynamic interactions have been used therapeutically: oxymorphone or other mu agonistic effects are reversed with naloxone, xylazine and other chemical sedatives are reversed with tolazoline or yohimbine, and medatomidine is reversed with antipamazole.

KEY POINT 2-12 Pharmacodynamic interactions can be either detrimental or beneficial.

The most familiar pharmacodynamic interactions are probably those that act in an additive or synergistic manner to augment response to a drug. Augmentation can occur through different mechanisms of action (i.e., controlling vomiting by combining a drug active at the chemoreceptor triggering zone with a drug that acts peripherally, controlling seizures by combining phenobarbital with bromide, controlling tachycardia by combining diltiazem with digoxin or atenolol). Less commonly, augmentation may occur through similar actions at a receptor site; more often, drugs will compete with one another at the same receptor, thus resulting in antagonism. Unfortunately, often forgotten is the fact that augmentation of the desired pharmacologic response may be accompanied by augmentation of an undesirable adverse drug event (ADE). For

Box **2-10** Examples of Drugs Capable of Changing Urine pH Urinary Acidifiers

Ascorbic acid Methionine Sodium acid phosphate Ammonium chloride

Urinary Alkalinizers

Sodium bicarbonate, citrate, and acetate Carbonic anhydrase inhibitors

example, drugs that impair renal prostaglandin synthesis (e.g., NSAIDs, angiotensin-converting enzyme inhibitors, aminoglycosides) should be used in combination cautiously because their combination increases the risk of renal failure. Likewise, ulcerogenic drugs (NSAIDs, glucocorticoids) enhance the risk of gastrointestinal ulceration when used in combination.

Pharmacodynamic interactions may decrease the response to a drug because of competitive antagonism at the same receptor site. Most commonly, these actions are desirable and are frequently the target of combined drug therapy: atropine to treat organophosphate toxicity, reversal agents for opioids and anesthetic agents. Antagonistic pharmacodynamic responses can also occur through different receptor sites or different mechanisms. The combination of a bacteriostatic antimicrobial (one that slows the growth of an organism) with a bactericidal antimicrobial (one whose efficacy depends on rapid growth) might be considered as an example. Also, the prokinetic effects of cisapride and metoclopramide are prevented by anticholinergics; calcium-containing solutions should not be combined with blood or blood components because the loss of anticoagulant effects increases the risk of microthrombi formation in the transfused blood.

Hu¹⁶¹ has reviewed pharmacodynamic interactions between drugs and herbs or botanicals. These can be clinically significant, as is exemplified for selected organosulfur components of garlic, which act as anticoagulants. Increased bleeding times have been documented in patients taking garlic supplements and subsequently treated with warfarin compared with increases with warfarin alone.

Pharmacogenetics

Katrina A. Mealey

Chapter Outline

PHARMACOGENETICS OF DRUG ABSORPTION PHARMACOGENETICS OF DRUG DISTRIBUTION PHARMACOGENETICS OF DRUG METABOLISM PHARMACOGENETICS OF DRUG EXCRETION PHARMACOGENETICS OF DRUG RECEPTORS

The goal of drug therapy is to produce a specific pharmacologic effect in a patient without producing adverse effects. Unfortunately, this goal is not fully realized for every veterinary patient. If the same drug were administered to 10 patients with a particular disease, each may respond differently with respect to both drug efficacy and the likelihood of an adverse reaction. This variation in response to drug therapy can be caused by a number of patient factors, including the patient's age, health or disease status, species, gender, and breed. In many instances, however, these factors cannot fully explain the degree of interpatient variation observed. Pharmacogenetics, the study of genetic determinants of response to drug therapy, is likely the ultimate way to establish the right drug and dose for each patient, thereby optimizing efficacy and minimizing toxicity. Despite the fact that this branch of pharmacology is still in its infancy as a science, a number of important discoveries have already contributed to improved pharmacotherapy in human and veterinary patients.

Genetic variation can affect both the pharmacokinetics (i.e., drug absorption, distribution, metabolism, and excretion) and pharmacodynamics (i.e., interaction with drug transporters and receptors) of pharmaceutical agents (Figure 3-1). Currently, the greatest body of knowledge with regard to pharmacogenetics involves genetic variation in drug metabolism. Indeed, the concept of pharmacogenetics originated in the 1950s as a result of the observation in human beings that two populations of individuals existed with respect to their ability to metabolize succinylcholine, followed by the realization that this trait was inherited.¹ Approximately 1 in 3500 Caucasian subjects is homozygous for a mutation in the butyrylcholinesterase gene.² Because this gene is responsible for hydrolysis and inactivation of succinylcholine, patients who have the mutation experience prolonged muscle paralysis and apnea. At the time, molecular biological techniques had not yet been discovered, so the field of pharmacogenetics was initially based purely on phenotypic observations.

Modern pharmacogenetics has progressed rapidly from those initial phenotypic observations. It currently involves identifying both the phenotype and the genetic variation, or PHARMACOGENETICS AND HYPERSENSITIVITY REACTIONS PHARMACOGENETICS IN CLINICAL PRACTICE FUTURE DIRECTIONS

polymorphism, responsible for it. Furthermore, the pharmacogenetic traits that were first identified were monogenic that is, they involved a polymorphism at a single gene. It is presently known that myriad genes may be involved in determining a particular drug's disposition, which increases the complexity of pharmacogenetics. Pharmacogenetics now involves systematic searches to identify functionally significant variations in DNA sequences in genes that affect drug disposition. Sequencing of the human, canine, and now feline genome should facilitate the progress of pharmacogenetics toward individualized drug therapy.

It is important to note that individualization of drug therapy encompasses two distinct, yet equally important, clinical implications. First is the ability to predict those patients at high risk for developing drug toxicity. These patients may have a polymorphism in a drug-metabolizing enzyme that results in low clearance rates for the drug. For such patients a lower drug dose or alternative drug should be administered. Second is the ability to predict those patients that are most likely to benefit from a particular drug because of appropriate receptor interactions. Patients with polymorphisms in drug receptors may be poor responders to certain pharmaceutical agents because of inappropriate drug-receptor interactions. Rather than using a trial-and-error approach to drug therapy, a veterinarian could select the drug most likely to produce the desired pharmacologic response in a particular patient, decreasing the amount of time in that the patient's disease state is poorly controlled.

Described in this chapter will be several recent discoveries in pharmacogenetics and examples of pharmacogenetically based differences in drug absorption, distribution, metabolism, excretion, and drug–receptor interactions. The role of these discoveries in clinical veterinary medicine will also be presented.

PHARMACOGENETICS OF DRUG ABSORPTION

Until recently, systemic bioavailability of orally administered drugs was considered to be a function of physicochemical characteristics of the drug and subsequent hepatic metabolism. A

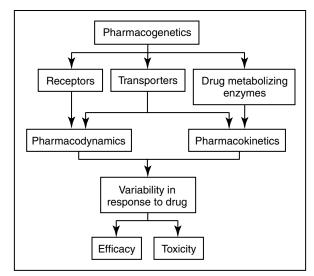

Figure 3-1 Pharmacogenetics can alter both drug efficacy and the likelihood of toxicity. Polymorphisms in drug receptors contribute to variable pharmacodynamics, and polymorphisms in drug-metabolizing enzymes contribute to variable pharmacokinetics. Interestingly, polymorphisms in drug transporters can contribute to variation in pharmacodynamics and/ or pharmacokinetics, depending on the particular drug transporter involved.

number of other factors have recently been shown to affect the ability of a drug to be absorbed into the systemic circulation after oral administration. Intestinal phase I drug metabolism and active drug extrusion by efflux transporters are now considered to be among the most important determinants of oral drug bioavailability. Consequently, polymorphisms in intestinal drug-metabolizing enzymes and drug transporters should dramatically affect oral drug absorption.

In humans CYP 3A enzymes are expressed at higher levels in mature villus tip enterocytes than in hepatocytes.³ Because intestinal villi make up such a large surface area, there is a high likelihood that absorbed drug will interact with intestinal CYP 3A enzyme, facilitating substantial first-pass metabolism. Interpatient variability in intestinal CYP 3A levels has been studied in a small sample of human patients. Elevenfold variations in CYP 3A protein content and sixfold variation in enzymatic activity were identified, suggesting that CYP 3A polymorphisms exist in the human population.⁴

Intestinal drug metabolism is thought to be important in veterinary patients also, but relatively little is known with regard to interpatient variability in enzyme activity. In dogs tissue distribution (specifically liver and duodenum) of *CYP3A12* and *CYP3A26* mRNA has been investigated by the author. Overall, expression of *CYP3A* mRNA was greater in liver than in duodenum, but the relative contributions of the two canine *CYP3A* isoforms differed. Hepatic expression of *CYP3A26* was greater than *CYP3A12* in all dogs, with *CYP3A26* making up 75.2% of the hepatic CYP3A pool. Conversely, duodenal expression of *CYP3A12* was greater than *CYP3A26* in all dogs, with *CYP3A12* composing 99.8% of the duodenal *CYP3A* pool.⁵ Additionally, there was a large amount of interindividual variability among dogs. Further research is needed in this area to determine whether genetic differences account for the variation in expression of this important drugmetabolizing enzyme in hepatic and intestinal tissue among dog breeds and/or individual dogs.

Drug transporters are also known to play an important role in drug absorption. Many drug transporters have been identified in people, but the most well-characterized drug transporter is P-glycoprotein (P-gp), the product of the MDR1 (ABCB1) gene. The potential impact of transporter pharmacogenetics on drug pharmacokinetics is dramatically illustrated by P-gp. P-gp is a transmembrane protein that was first described in highly resistant tumor cell lines.⁶ Tumor cells expressing P-gp were cross-resistant to various anticancer agents (anthracyclines, vinca alkaloids, taxanes, and others). P-gp has since been shown to act as an ATP-dependent pump that exports drugs from cells. P-gp is also expressed in normal mammalian tissues, where it appears to function in a protective capacity. P-gp is expressed on bile canaliculi, renal tubular epithelial cells, the placenta, brain capillary endothelial cells, and at the luminal border of intestinal epithelial cells.⁷ At these locations P-gp pumps transported drugs either out of the body (into the bile, urine, or intestinal lumen) or away from protected sites (brain tissue, fetus).

KEY POINT 3-1 Intestinal and hepatic drug transporters and cytochrome P450 enzymes contribute to variability in oral drug absorption.

The significant role intestinal P-gp can play in determining oral drug bioavailability has been demonstrated in rodent studies. In *mdr*1(-/-) knockout mice, oral bioavailability of many P-gp substrate drugs (vinblastine, taxol, digoxin, loperamide, ivermectin, cyclosporine A, others) are substantially greater than in wild-type mice.^{8,9} Similarly, MDR1 polymorphisms in humans have been shown to result in altered oral bioavailability of P-gp substrate drugs. Studies have shown that oral bioavailability of digoxin, a P-gp substrate, is greater in subjects with the 3435TT MDR1 genotype compared with those with the MDR1 3435CC genotype.¹⁰ Similarly, the P-gp substrate phenytoin has been shown to have lower oral bioavailability in subjects with the MDR1 3435 CC genotype.¹¹

P-gp has been fairly well characterized in dogs. Tissue distribution of P-gp in dogs is similar to that in people,¹² and it has been shown to contribute to chemotherapeutic drug resistance in vitro and in vivo.¹³⁻¹⁵ Although its role in determining oral drug bioavailability is not well characterized, there is some evidence that P-gp is important. Bioavailability of the anticancer agent (and P-gp substrate) docetaxel was increased seventeenfold when co-administered with a P-gp inhibitor.

The MDR1 polymorphism in dogs consists of a four basepair deletion mutation. This deletion results in a shift of the reading frame that generates several premature stop codons.¹⁶ Because protein synthesis is terminated before even 10% of the protein product is synthesized, dogs with two mutant alleles exhibit a P-gp null phenotype, similar to mdr1 (-/-) knockout mice. Affected dogs include many herding breeds. For example, roughly 75% of Collies in the United States, France, and Australia have at least one mutant allele.¹⁷ Other affected herding breeds, albeit affected at a lower frequency, include Old English Sheepdogs, Australian Shepherds, Shetland Sheepdogs, English Shepherd Dogs, Border Collies, German Shepherd Dogs, Silken Windhounds, McNab Shepherds, and Longhaired Whippets.¹⁸

One group of investigators describe a modest effect of the MDR1 deletion mutation on oral drug availability.¹⁹ Three P-gp substrate drugs (fexofenadine, loperamide, and quinidine) were simultaneously administered to two groups of dogs, dogs homozygous for the MDR1 deletion mutation (MDR1 mut/mut) and MDR1 wild-type dogs (MDR1 WT/WT). Statistically, there were no differences in area under the curve for any drug between the two groups. Plasma concentrations of fexofenadine were significantly higher at two time points in MDR1(mut/mut) dogs than in MDR1(WT/WT) dogs.¹⁹ The investigators suggest that P-gp limits intestinal absorption of fexofenadine, an antihistamine (H₁), in dogs.

PHARMACOGENETICS OF DRUG DISTRIBUTION

Drug distribution, the delivery of drugs from the systemic circulation to tissues, can be dramatically affected by pharmacogenetics. The drug transporter P-gp serves as an important barrier to the distribution of substrate drugs to selected tissues. For example, P-gp is a component of the blood-brain barrier, the blood-testes barrier, and the placenta. Therefore distribution of P-gp substrate drugs to these tissues is greatly enhanced in MDR1(mut/mut) dogs. MDR1(mut/mut) dogs experience adverse neurologic effects after a single dose of ivermectin (120 µg/kg). Heterozygous [MDR1(WT/mut)] or MDR1(WT/WT) dogs are not sensitive to ivermectin neurotoxicity at the 120 µg/kg dose, but MDR1(WT/mut) animals may experience neurotoxicity at ivermectin doses greater than 120 µg/kg, particularly if daily doses are administered (i.e., protocols for treatment of demodectic mange). Affected dogs also appear to have increased susceptibility to neurologic adverse effects of other avermectins, including milbemycin, selamectin (Revolution package insert), and moxidectin.²⁰ Interestingly, a retrospective study conducted by a national veterinary poison center reported that Collies were overrepresented in canine cases of loperamide-induced neurotoxicity.²¹ Many Collies displayed signs of neurologic toxicity after administration of routinely recommended doses of the antidiarrheal agent loperamide (Imodium). Loperamide is an opioid that is generally devoid of central nervous system activity because it is excluded from the brain by P-gp.^{22,23} Loperamide neurotoxicity was recently reported in a Collie that had received a routine dose (0.14 mg/kg orally).²⁴ The dog in this report had the MDR1(mutant/mutant) genotype. MDR1 (WT/WT) dogs do not exhibit neurologic signs after receiving even higher doses of loperamide, indicating that P-gp plays a key role in modulating distribution of substrates such as loperamide to canine brain tissue. The images in Figure 3-2 illustrate the role of P-gp in the blood-brain barrier of dogs.

KEY POINT 3-2 Dogs with the ABCB1-1∆ mutation experience greater brain penetration of drugs that are substrates for P-glycoprotein.

Less information is available regarding P-gp and the bloodbrain barrier in cats. The author has received anecdotal reports of ivermectin toxicity in cats after standard doses, but whether the underlying cause is a result of altered P-gp expression or function is not currently known.

Distribution of some drugs to the testis and fetus may also be limited by P-gp. In human patients, this creates a problem for treating certain diseases. For example, the testes and brain are considered to be a sanctuary site for the human immunodeficiency virus (HIV).²⁵ Because HIV-1 protease inhibitors are substrates for P-gp, the virus can remain viable in these sanctuary sites, hampering effective therapy. Similarly, therapeutic concentrations of certain chemotherapeutic agents may not be achievable for testicular cancers because of active efflux by P-gp.²⁶ The effect of placental P-gp on distribution of drugs to the fetus is an area of active research in human medicine.²⁷ Understanding the role of pregnancy-associated hormones in regulating P-gp expression and function is one possible key in developing strategies to deliver drugs to the mother with minimal fetal risk.

PHARMACOGENETICS OF DRUG METABOLISM

Pharmacogenetic variation can affect both phase I and phase II metabolic enzyme activity. The pseudocholinesterase mutation serves as an example of how pharmacogenetic variation can result in dramatic differences in drug response among patients. Patients with a normal pseudocholinesterase genotype metabolize succinylcholine and recover from neuromuscular blockade rapidly, whereas those with the mutant genotype undergo sustained neuromuscular blockade that has resulted in prolonged apnea and the necessity for mechanical ventilation. A number of polymorphisms have been described in human CYP450 enzymes, many of these resulting in profound variations in clinical response. For example, CYP2D6 is a highly variable P450 pathway in humans with individuals ranging from undetectable activity (found in 6% to 10% of Caucasians) to "ultrarapid" activity (found in 3% to 10% of Europeans and 30% of one black population).²⁸ The ultrarapid phenotype is due to a unique gene duplication. Drugs that are substrates for CY2D6 in people include beta-receptor antagonists (propranolol, timolol, metoprolol), antiarrhythmics (quinidine, flecainide), antidepressants (amitriptyline, clomipramine, fluoxetine, imipramine), neuroleptics, and certain opioid derivatives. Depending on the patient's CYP2D6 genotype, the "typical" dose of a substrate drug may need to be decreased (poor metabolizers require 1/10 of the standard dose of nortriptyline to avoid toxicity) or increased (ultrarapid metabolizers require 5 times the standard dose to achieve therapeutic concentrations).

Relatively few polymorphisms in drug-metabolizing enzymes have been described in veterinary patients, although

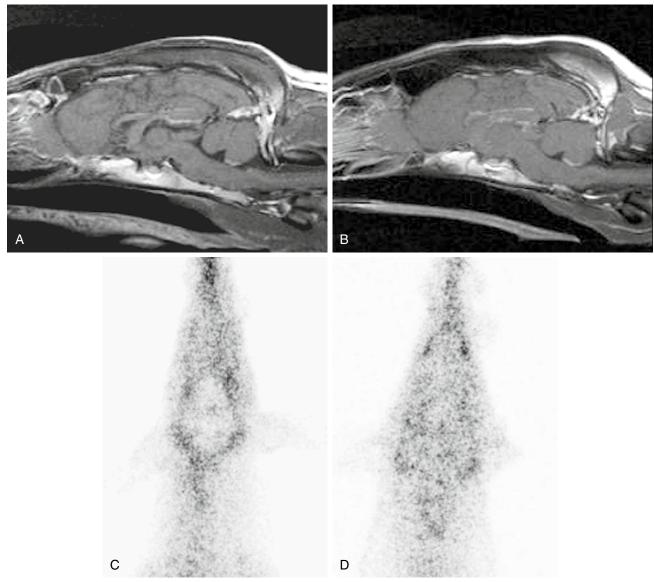

Figure 3-2 Sagittal T1-weighted post gadolinium administration magnetic resonance images displaying normal brain anatomy, tissue signal characteristics, and contrast enhancement of an MDR1 WT/WT dog (**A**) and an MDR1 mut/mut dog (**B**) showing no differences between dogs of these two genotypes. Conversely^{99m}Tc-MIBI nuclear scintigraphic neuroimaging of the brain after ^{99m}Tc-MIBI administration demonstrates the role of P-glycoprotein at the blood–brain barrier. Representative ^{99m}Tc-MIBI nuclear scintigraphic images show diminished activity in the brain compared with surrounding tissue of an MDR1 WT/WT dog (**C**) but similar activity in the brain compared with surrounding tissue of an MDR1 WT/WT dog (**C**) but similar activity in the brain compared with surrounding tissue of an MDR1 mut/mut dog (**D**). (From Mealey KL, Greene S, Bagley R, et al: P-glycoprotein contributes to the blood–brain, but not blood–cerebrospinal fluid, barrier in a spontaneous canine p-glycoprotein knockout model, *Drug Metab Dispos* 36(6):1073-1079, 2008.)

this is likely to change insofar as research in this area is currently in progress. However, variation in metabolism of some drugs has been documented in dogs. CYP2B11 has been shown to have at least a fourteenfold variation in activity in mixed-breed dogs.²⁹ Greyhounds have been shown to have particularly low CYP2B11 activity, which results in sustained plasma concentrations of propofol, and delayed recovery compared with mixed-breed dogs.³⁰ The specific genetic alteration responsible for reduced CYP2B11 in Greyhounds compared with other canine breeds has not been determined. There is some evidence to suggest that CYP 2D15 may also be polymorphic in dogs. The nonsteroidal antiinflammatory drug celecoxib is metabolized to a large degree by CYP2D15. Clearance of celecoxib in Beagles is polymorphic, with about half the population being extensive metabolizers and the remainder being poor metabolizers.³¹ Celecoxib has a 1.5- to 2-hour half-life in extensive metabolizers and a 5-hour halflife in poor metabolizers. One pharmacogenetic variant that has been identified in the canine CYP2D15 gene, a deletion of exon 3, results in undetectable celecoxib metabolism. The frequency and breed distribution of this polymorphism has not yet been determined. However, it is likely to have clinical significance for other drugs that are CYP2D15 substrates, including dextromethorphan, imipramine, and others.

KEY POINT 3-3 Polymorphisms in drug-metabolizing enzymes can dramatically affect drug efficacy and toxicity.

Variability in gene copy number is a phenomenon that has recently been explored in dogs.³² Among the genes that have been demonstrated to exist in copy number variant regions in canine DNA are CYP3A12 and CYP1A. Furthermore, there appear to be breed-specific copy number variants for some dog breeds. Thus variability in gene copy number may be another source of genetic variation in drug response involving phase I enzymes.

With respect to phase II metabolic enzymes, a pan-species defect in UDP-glucuronyl transferase exists in cats. Although this is not a true example of pharmacogenetics, it serves as an example of genetic variation among species, rather than within a species, that significantly affects drug disposition. Because cats have a pseudogene, rather than a functional glucuronyltransferase gene, aceptaminophen and other drugs are not conjugated with glucuronide as they are in other species. Another pan-species phase II metabolic defect occurs in dogs. N-acetyltransferase is the enzyme responsible for metabolizing sulfonamides, procainamide, hydralazine, and other drugs. Both N-acetyltransferase genes are absent in dogs, increasing the risk for hypersensitivity reactions and adverse effect from these drugs relative to other species.³³

A true pharmacogenetic variation exists for the thiopurine methyltrasferase (TPMT) enzyme. TPMT is a phase II enzyme that is responsible for metabolizing azathioprine and its active metabolites to their inactive forms. A ninefold range in TPMT activity exists in dogs, and activity level appears to be related to breed. Giant Schnauzers had lower TPMT activity, and Alaskan Malamutes had high TPMT activity.³⁴ Decreased TPMT activity has been documented to be associated with increased susceptibility to azathioprine-induced bone marrow suppression.

PHARMACOGENETICS OF DRUG EXCRETION

Drugs are eliminated from the body either unchanged or as metabolites. Renal and biliary excretion are the most important pathways of drug elimination, but excretion may occur by other routes as well. As noted previously, P-gp is expressed on renal tubular cells and biliary canalicular cells, suggesting that it may play a role in drug excretion. Concurrent administration of a P-gp-inhibitor decreases the biliary and renal clearance of doxorubicin in rats.³⁵ In a separate study, biliary and renal excretion of digoxin and vincristine were increased in rats after treatment with a P-gp inhibitor.³⁶ Further research is necessary to fully define the role of P-gp in regulating renal and biliary drug excretion in veterinary patients. However, altered biliary or renal excretion may play a role in the apparent increased sensitivity of herding breeds to chemotherapeutic drugs that are P-gp substrates. For example, MDR1(mut/ mut) and MDR1(WT/mut) dogs are significantly more likely to develop hematologic toxicity, specifically neutropenia and thrombocytopenia after treatment with vincristine

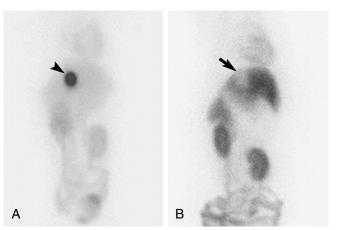

Figure 3-3 Images of the abdomen of dogs positioned in ventral recumbency on a gamma camera. Images were acquired 2 hours after intravenous injection of ^{99m}Tc-MIBI to an MDR1 WT/WT dog **(A)** and to an MDR1 mut/mut dog *(b)*. Intense uptake of ^{99m}Tc-MIBI in the gallbladder *(arrowhead)* is present in *(a)*. A void of activity in the location of the gallbladder *(arrow)* is present in **(B)**. (From Coelho JC, Tucker R, Mattoon J et al: Biliary excretion of technetium-99m-sestamibi in wildtype dogs and in dogs with intrinsic (ABCB1-1 Δ mutation) and extrinsic (ketoconazole treated) P-glycoprotein deficiency, *J Vet Pharm Ther* 32:417-421, 2009.)

than ABCB1-1 Δ wild-type dogs. However, these dogs tolerate cyclophosphamide at full doses.^{37,38} In dogs vincristine is eliminated primarily through biliary excretion of parent drug with some urinary excretion of parent drug and metabolites.³⁹ The enzyme family responsible for metabolizing vincristine in dogs has not been identified. Biliary excretion of vincristine in other species is highly dependent on the P-gp–mediated drug transport.³⁶ The images in Figure 3-3 illustrate the role of P-gp in the biliary excretion of substrate drugs in dogs.

KEY POINT 3-4 Biliary excretion of P-glycoprotein substrate drugs is significantly decreased in dogs with the ABCB1-1 Δ mutation compared with ABCB1 wild-type dogs.

PHARMACOGENETICS OF DRUG RECEPTORS

A relatively new and important area of pharmacogenetics research involves polymorphisms in genes encoding drug receptors and effector proteins. In human patients polymorphisms have been described in angiotensin-converting enzyme, beta-2 adrenergic receptors, the dopamine receptor, the estrogen receptor, and others.⁴⁰ In vitro functional studies suggest that these polymorphisms have functional significance. A polymorphism in the canine dopamine receptor D4 gene has been described, but its clinical implications are not yet understood.⁴¹

KEY POINT 3-5 Genetic variation in drug-metabolizing enzymes, drug transporters, and drug receptors can have a substantial impact on drug safety and efficacy.

PHARMACOGENETICS AND HYPERSENSITIVITY REACTIONS

Pharmacogenetic differences in metabolic pathways not only can affect type A adverse drug reactions (predictable; generally correlating with plasma drug concentration) but can also affect type B adverse drug reactions (idiosyncratic). Idiosyncratic toxicity to sulfonamides is similar in dogs and humans and can be characterized by fever, arthropathy, blood dyscrasias (neutropenia, thrombocytopenia, or hemolytic anemia), hepatopathy consisting of cholestasis or necrosis, skin eruptions, uveitis, or keratoconjunctivitis sicca.42 In humans slow acetylation by NAT2 has been shown to be a risk factor for sulfonamide hypersensitivity reactions. It has been proposed that the alternative metabolic pathway in these individuals produces reactive metabolites.⁴³ Covalent binding of reactive metabolites of these drugs to cell macromolecules results in cytotoxicity and immune response to neoantigens. Ongoing research in one veterinary pharmacology laboratory (Department of Medical Sciences, School of Veterinary Medicine, University of Wisconsin-Madison; latrepanier@svm.vetmed. wisc.edu) is under way to characterize dogs with possible idiosyncratic sulfonamide reactions, using several methodologies, including enzyme-linked immunosorbent assay (ELISA) for antidrug antibodies, immunoblotting for antibodies directed against liver proteins, flow cytometry for drug-dependent antiplatelet antibodies, and in vitro cytotoxicity assays.

PHARMACOGENETICS IN CLINICAL PRACTICE

Scientific interest in the field of human pharmacogenetics has increased each year in parallel with the knowledge of the human genome. However, interest in this field from physicians has lagged significantly behind, presumably because relatively few significant clinical consequences can be correlated to the vast number of pharmacogenetic mutations described in the literature. There are two main reasons for this discrepancy. Up to this point, polymorphisms described in human patients either have had low allelic frequencies or the clinical relevance of a particular polymorphism was not significant. For example, a highly clinically relevant polymorphism in the human TPMT gene has been described. TMPT metabolic activity in affected patients is essentially absent, so these patients experience severe neutropenia after a "normal" dose of azathioprine. Because this TPMP polymorphism affects approximately 0.3% of the Caucasian population, pharmacogenetic testing is not routinely performed in clinical practice.⁴⁴ Conversely, the allelic frequency of a genetic polymorphism of the human MDR1 gene has been shown to be associated with lower levels of P-gp expression in the duodenum and other tissues. Although the allelic frequency of this particular MDR1 polymorphism is relatively high (>10%), it does not appear to have an important and predictable clinical impact on drug disposition. The vast majority of pharmacogenetics in human medicine is carried out for research purposes and is not performed in clinical medical practice.

In veterinary medicine, however, a commercial veterinary pharmacogenetics laboratory (Veterinary Clinical Pharmacology Laboratory, Washington State University, Pullman, WA; www.vetmed.wsu.edu/vcpl) is currently performing canine MDR1 genotyping for veterinarians, breeders, and owners in the United States. Such testing is available in Europe and Australia as well. The primary reasons that commercial pharmacogenetic testing is readily available for canine patients and not for human patients are because the MDR1 mutation in dogs has a very high allelic frequency (55% in Collies, 42% in Longhaired Whippets, and roughly 20% in Australian Shepherds), and because the polymorphism is highly predictive for serious adverse drug events, not just for ivermectin, but for chemotherapeutic drugs,³⁸ other antiparasitics,⁴⁵ loperamide,²⁴ and other drugs.⁴⁶ Box 3-1 contains a partial list of drugs that are substrates for P-gp.

KEY POINT 3-6 Pharmacogenetic testing of canine patients for the ABCB1-1 Δ mutation can be used to prevent adverse drug reactions.

FUTURE DIRECTIONS

The field of pharmacogenetics, particularly in veterinary medicine, is still in its infancy. However, we have an ever-increasing arsenal of molecular tools that can be used to expand our knowledge of pharmacogenetics. Furthermore, with the recent completion of the canine and feline genome projects and the ongoing elucidation of their data, we may soon know the sequences of virtually all genes encoding drug-metabolizing enzymes, drug transporters, drug receptors, and other drug targets. With this information the traditional pharmacogenetics approach (phenotype to genotype) will likely give way to a pharmacogenomics approach (genotype to phenotype). In other words, genetic variation identified in a specific gene will be investigated to determine if it results in a variation in pharmacologic response. The convergence of these advances has the potential to individualize drug therapy for many veterinary patients.

DEFINITIONS AND PREDISPOSING FACTORS

An adverse drug event (ADE) is any harm caused by a therapeutic or preventive (or diagnostic) intervention (Figure 4-1). The evolution of the definition in human medicine during the past decade has led to further subdivision into medication errors and adverse drug reactions (ADRs).¹ Medication errors are ADEs that result from a mistake made by the caregiver, including but not necessarily limited to administration of the wrong drug, dose, interval, or route to the wrong patient. Thus, ADEs are iatrogenic in origin. A potential subcategory of medication errors might be failure to modify a dosing regimen for recognized patient, drug, or disease factors that lead to inappropriately low or high drug concentrations at the site of action.

In contrast to medication errors, an ADR is a noxious and unintended response to a drug or other medication that occurs at a dose given with the goal of achieving the intended effect of the medication. As such, the term *ADR* implies a reaction that might cause serious harm to the patient and reflects a patient response to the inherent properties of the drug. An ADR may reflect a pharmacodynamic response or a pharmacokinetic effect. An ADR should be contrasted with the term *side effect*, which refers to an effect other than the intended effect that does not cause harm. A side effect may not be undesirable and may, in fact, be desirable or inconsequential to the health of the patient. For the purposes of this discussion, the term ADE will be used to refer to ADR with or without an iatrogenic basis. Adverse drug reactions can be further classified as either type A (type I) or type B (type II).²⁻⁴ Type A ("augmented") adverse events generally result from drug concentrations at the site (generally estimated by plasma drug concentrations [PDCs] that either exceed the maximum or drop below the minimum therapeutic range (see Chapter 1). If the clinician is familiar with the drug and the patient, type A reactions are largely predictable and, as such, avoidable. Like type A, side effects are also generally predictable and dose dependent and for the purposes of discussion, will be included with type A adverse events in this chapter.

Generally, type A reactions are manifested as an exaggerated but normal or expected pharmacologic response to the drug (see Figure 4-1).⁵ This response may be the desired response (e.g., bradycardia in a patient receiving propranolol to slow a sinus tachycardia) but also may reflect an unwanted, secondary response resulting from the drug's pharmacologic effects (e.g., bronchospasms induced by the beta-blockade effects of propranolol) (Figure 4-2). Some drugs also cause adverse events unrelated to their pharmacologic response. These reactions usually reflect damage to target cells and are referred to in this chapter as cytotoxic adverse reactions. Cytotoxic adverse reactions are exemplified by nephrotoxicity induced by aminoglycosides (Figure 4-3) or hepatic necrosis or methemoglobinemia induced by acetaminophen. Often, it is the metabolite of the drug rather than the drug itself that causes cytotoxicity (see Chapter 2). In such cases, drugs that induce metabolism, particularly in the liver

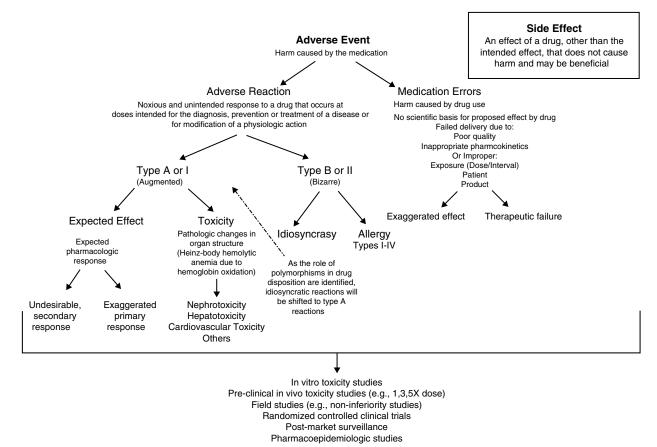

Figure 4-1 Flow chart delineating the definitions of adverse drug events (ADEs), including medication errors and adverse drug reactions (ADRs). ADEs can result in either an exaggerated response or failed response. In contrast to ADR, which implies harm to the patient, side effects do not cause harm and in some cases, may be beneficial. The risk of toxicity or ADR is assessed at several points before and during the approval process, with postmarket surveillance being perhaps the most comprehensive.

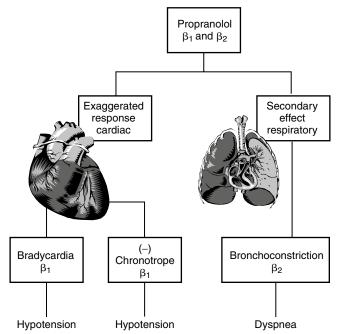

Figure 4-2 Type A drug reactions resulting from overdose. Propranolol offers an example of a type A adverse reaction that reflects both an exaggerated primary response (bradycardia, decreased contractility) and an undesirable secondary response (bronchospasm).

(e.g., phenobarbital, phenytoin; Figure 4-4), may increase the risk of toxicity, whereas drugs that decrease metabolism may reduce the risk of toxicity (e.g., cimetidine).⁶⁻⁸ Cytotoxic drug reactions might be treated with drugs that scavenge radical metabolites (i.e., *N*-acetylcysteine, a glutathione precursor).

In contrast to type A events, type B ("bizarre") events are not dose or concentration dependent. As a result, these reactions are not predictable and are largely unavoidable. They occur only in a small percentage of the population receiving the drug; in human medicine they account for approximately 6% to 12% of all ADRs.9 Generally, their incidence-indeed their existence-often is not documented until the drug is in wide use. In addition, because their cause is not well understood, treatment is generally limited to symptomatic therapy. Examples of type B adverse reactions include drug allergies or idiosyncrasies. Many of the idiosyncrasies eventually may be shown to be genetically or otherwise based (e.g., polymorphisms in transport or drug-metabolizing proteins [ivermectin toxicity of Collie-related breeds]), but the cause has yet to be identified and thus the reaction cannot be predicted. As with type A events, type B events may occur in response to the parent drug or its metabolite. This chapter will focus on allergies as type B ADRs.

This chapter discusses the mechanisms and clinical signs of the adverse events caused by selected drugs and methods by

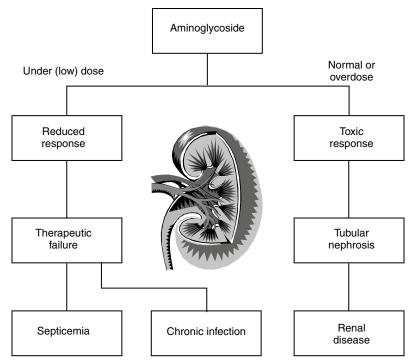

Figure 4-3 Underdose and cytotoxic response. An aminoglycoside such as gentamicin can cause two examples of a type A adverse reaction/therapeutic failure, meaning effective antimicrobial concentrations are not achieved, and a cytotoxic reaction, manifested as nephrotoxicity in response to persistent (rather than very high) plasma drug concentrations.

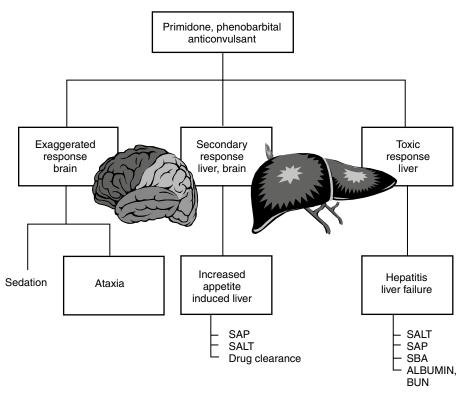

Figure 4-4 Exaggerated and cytotoxic responses. Anticonvulsants metabolized by the liver exemplify a type A adverse reaction manifested as cytotoxicity (hepatic disease). These drugs also can cause an exaggerated (but expected) response (sedation) as well as a secondary undesirable response or side effect that is not necessarily considered severe or life threatening (increased appetite, polyuria, and polydypsia). *BUN*, Blood urea nitrogen; *SALT*, serum alanine aminotransferase; *SAP*, serum alkaline phosphatase; *SBA*, serum bile acid.

which the events might be avoided or treated. Adverse events or side effects that result from the expected pharmacologic action of a drug (e.g., exaggerated pharmacologic effect) are also discussed with each drug in subsequent chapters and generally are not emphasized here. This chapter focuses more on type A than type B events because they are recognized more commonly. The list of drugs included is by no means complete but represents those drugs most commonly recognized, as well as the addition of some that are often overlooked. ADEs are also addressed in chapters that address the use of the drug.

The impact of ADEs on the monetary and health costs in human medicine were assessed in the late 1990s. The implementation of a voluntary, anonymous reporting system has facilitated medication error reporting in human medicine and thus enabled a more accurate assessment of their impact.¹⁰ The majority (66%) of medical errors occurred during transfer of patient care within hospitals, and another 19% occurred on discharge. In a human intensive care unit (ICU) environment, 1 out of every 5 doses of medication was associated with an ADE as a result of medication errors. The veterinary profession has yet to implement a mechanism whereby ADEs due to medication errors can be assessed. Yet needs are equally applicable to veterinary medicine.¹⁰

Organs most susceptible to type A drug events usually are those subjected to the greatest exposure or concentration of the drug. Thus the organs with the greatest blood flow and those organs capable of drug concentration, such as the liver and kidney, are the most vulnerable to systemic drugs. Highly metabolically active organs are also more likely to manifest toxic effects for two reasons. First, such organs depend on the presence of energy, and anything that impairs acquisition of energy (including blood flow) can lead to malfunction. Second, if the metabolic activity includes metabolism of compounds, the production of potentially reactive metabolites can increase the likelihood of cytotoxicity if these metabolites interact with cellular structures. In contrast to Type A ADEs, the organs most susceptible to damage by type B reactions tend to be the organs that contain tissues that act as haptens for drug-induced allergy (e.g., skin, blood-forming units) or tissues that filter and trap immune complexes (e.g., glomerulus, joints). Organs containing a preponderance of mast cells also are more likely to manifest immune-mediated reactions (i.e., "shock organs"; see the section on allergic reactions). A summary of compounds causing predominantly type A drug reactions and, when available, their antidotes, can be found in Appendix 5. A variety of factors can influence the likelihood of adverse, and particularly toxic, reactions.⁶⁻⁸ Factors that predispose a patient to the development of type A adverse events are discussed in Chapter 2.

Not all adverse reactions are clinically evident. Sometimes the reaction is not detectable unless actively sought. For example, clinical laboratory tests may detect a drug-induced hepatotoxicity (e.g., increased serum alanine transferase activity) that is otherwise clinically silent. Many drugs can directly interfere with or indirectly influence clinical laboratory tests, including endocrine function testing (discussed later).¹¹ Organ predisposition to drug-induced toxicity may show diurnal variations. For example, both aminoglycosides and cisplatin¹² exhibit increased renal toxicity in humans when administered in the evening as opposed to in the morning. For the amino-glycosides, safety in the morning has been attributed, in part, to the increase in glomerular filtration rate that occurs in the morning;¹³ an increased sensitivity to interleukin-6–induced inflammation has been suggested for cisplatin.

PRINCIPLES OF TOXICOLOGY RELEVANT TO PHARMACOLOGY

Terminology of Toxicity and Safety Assessment

Toxicology refers to the study of poisons and their effect on living organisms.¹⁴ A *poison* is any substance that is injurious to animals; the term is synonymous with toxic substance, toxic chemical, and toxicant. It is important to note that any drug can become a poison ("the dose makes the poison"), and the toxic response to the poison tends to correlate with the dose (or duration). Toxic response refers to the effects manifested by an organism in response to a toxic substance. Toxicity describes the quantitative amount or dose of a poison that produces a toxic response or effect. Acute toxicity generally results from a single dose or exposure or multiple doses in a 24-hour period. Most acute toxicants rapidly interfere with critical cellular processes. Subacute and subchronic toxicity occurs after 1 week to 1 month of exposure. Chronic toxicity occurs after 3 or more months of exposure.¹⁴ These latter terms are generally applied to humans, but the relative duration of exposure applies equally to animals. Toxic chemicals can act *directly* by injuring the cells with which they come in contact or *indirectly* by injuring a group of cells that subsequently precipitate injury to others. Alternatively, toxins can act indirectly by interfering with a physiologic process on which a group of cells are vitally dependent. Toxins can act systemically (the majority), locally, or a combination of the two.¹⁵

An indicator of the assessment of toxicity is the LD_{50} , or the dose per unit weight of a chemical that kills 50% of animals receiving it (the median lethal dose) (Figure 4-5). The LD_{50} is both drug and species specific. The lethal dose of a drug can be compared with the dose necessary to induce the desired pharmacodynamic response (effective dose, or ED) in a targeted percent of the sample population (see Chapter 1). The ED₅₀ is the dose expected to induce the response in 50% of the population; its more useful companion indicator is the EC_{50} , which describes the concentration at which 50% of individuals respond, thus removing the effects of drug absorption and distribution from consideration. Like the LD₅₀, ED₅₀ and EC₅₀ are generally based on single dosing and do not take into account duration of exposure. The therapeutic index offers a measure of the relative safety of a drug by comparing the dose producing toxicity to that causing the desired effect, or the ratio of the LD_{50} to ED_{50} (see Figure 4-5). A related term is margin of safety which is the ratio minimal lethal dose (LD_{01}) and the dose associated with the greatest efficacy (ED₉₉). Caution is recommended if the margin of safety (MOS) is less than 1. Alternatively, rather than measure lethality as the adverse event, the concentration necessary to cause a specific adverse event can

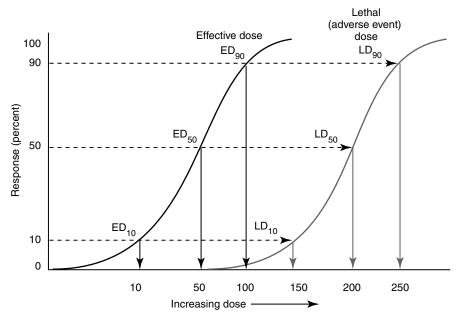

Figure 4-5 The dose necessary to cause the response in 50% of animals tested is referred to as either the *lethal dose*₅₀ (dose necessary to cause death; LD_{50} or 200 mg/kg) *or effective dose*₅₀ (dose necessary to cause targeted pharmacodynamic response; ED_{50} or 50 mg/kg), respectively. However, to induce the pharmacodynamic response of interest in the target species would require a dose of 50 mg/kg. The therapeutic index for this hypothetical drug would be the LD_{50}/ED_{50} or 200/50 = 4.

be measured and used to calculate the therapeutic index. A second set of terms by which the safety of a compound might be assessed are the lowest observed adverse effect level (LOAEL) and no observed (adverse) effect level (NOEL, or NOAEL). The LOAEL is the lowest concentration of drug associated with observed adverse effects. The NOAEL is defined as the greatest concentration of a compound that causes no detectable adverse effect. When compared with anticipated drug intake, it provides an alternative margin of safety. The absence of these effects can be used to help verify the NOAEL. The NOAEL generally is based on chronic exposure and thus may be more relevant for drugs administered at more than a single dose. NOELs and LOELs (no or lowest observed effect level, respectively) differ in that they may not indicate an adverse effect, but in fact may address a beneficial effect. All four terms are important to risk assessment which addresses exposure and the adverse outcomes that might be associated with exposure (see later discussion).

Other toxicologic terms relevant to drugs include *terato-gen*, which is a compound that causes abnormal fetal development. It is important to note that teratogenicity is not the only form of toxicity that may occur in utero; any toxic effect that occurs in the adult is likely to occur in the developing fetus as well. *Carcinogenesis* refers to the ability of a compound, or a *carcinogen*, to cause cancer. Cancer cells are cells that have been able to avoid the sophisticated mechanisms that control normal growth, development, and division. Induction of cancer by a compound involves many variables, including duration, dose, and frequency of exposure. Generally, carcinogens take 20 years or more to induce cancer, and the cause-and-effect relationship between the compound and the cancer often is not recognized.^{15,16} Although some compounds can

directly interact with DNA, leading to a cancerous cell, most compounds must first be converted to a reactive metabolite to covalently bond with DNA. Damage may still be avoided if DNA repair occurs before cell division. Cellular damage increases the stimulus for division of adjacent cells, leading to a new cell type with new genotypic and phenotypic properties that can then be transformed to a malignant cell under the correct conditions. A number of compounds are recognized to be *initiating agents*, targeting molecular DNA, whereas others are considered *promoters*, acting to increase the incidence of cancer or decrease the latency period without interacting with DNA. These latter compounds must be administered repeatedly and after the initial insult. Endogenous compounds such as growth factors or hormones may act as promoters.¹⁵

Many compounds can induce cancer in laboratory animals when they are exposed to extremely high (supratherapeutic) doses for prolonged periods of time. Rarely do these compounds cause cancer in humans, and it is even more unlikely that they will do so in companion animals, in part because the life expectancy of companion animals generally is too short to allow emergence of cancer. Lifestyle changes that increase the risk of drug or toxicant-induced cancer in humans are likely to have the same effect in animals as well. These include but are not limited to exposure to cigarette smoke, exposure to charcoal-cooked food, chronic consumption of alcohol (unlikely in animals), and consumption of foods, many of which contain possible carcinogens.

Two mechanisms by which drugs can cause cell death are apoptosis and necrosis, each with distinct morphologic and biochemical characteristics. Apoptosis is an active process characterized by cell shrinkage, nuclear and cytoplasmic condensation, chromatin fragmentation, and phagocytosis. In contrast, necrosis is a passive process resulting in inflammation associated with cellular and organelle swelling, rupture of the plasma membrane, and spilling of cellular contents into the extracellular milieu.¹⁷ Because apoptosis is an active process, sufficient intracellular energy must be maintained; depletion of adenosine triphosphate (ATP) may cause an apoptopic process to become a necrotic process. Not surprisingly, mitochondria appear to play a role in apoptosis. A number of toxicants cause their effects by disrupting mitochondria function and thus ATP production. However, several drugs appear to exert their toxicologic effect through induction of apoptosis (e.g., digoxin, selected chemotherapeutic agents).¹⁷

Genetic diversity is increasingly being identified as a cause for individual variation in response to toxins and drugs, leading to the fields of toxicogenetics and pharmacogenetics, respectively.^{5,16,18} The role of polymorphic cytochrome P450s as a cause of interindividual differences in xenobiotic metabolism and drug toxicity is fairly well established. In humans polymorphism occurs less commonly in those cytochrome P450s responsible for carcinogen activation (CYP1A1 and 2, CYP1B1, CYP2E1, and CYP3A4) compared with those that are primarily responsible for drug metabolism (CYP2C9, CYP2C19, CYP2D6, and CYP3A4). Polymorphisms in drug-metabolizing enzymes have been associated with drug hypersensitivities.⁶ All hepatic drug-metabolizing P450s are polymorphic with the clinically most important polymorphism in humans occurring with CYP2C9, CYP2C19, and CYP2D6.¹⁹ Polymorphisms in cytochrome P450s of animals is now being elucidated but may play a role in adversities in certain breeds (e.g., Beagles, Greyhounds). In addition, polymorphism in P-glycoprotein (P-gp) is a well-established reason for susceptibility to adverse drug events for selected drugs in Collie-related breeds (see Chapter 2).

Postmarket Surveillance

The approval process for human-marketed drugs is designed to identify adverse reactions at several stages preclinical phase (short- and long-term animal testing): through phase III (extended clinical trials) and continuing into phase IV, which includes a mandated postmarket surveillance. However, the drug approval process for animals is not as regimented (see Figure 4-1). The requirements by the Food and Drug Administration's Center for Veterinary Medicine tend to vary with the drug undergoing approval (See Appendix 1).²⁰ In general, directed toxicity studies that are implemented during the approval process involve a small number (e.g., 2 to 30 but most commonly 4 of each sex) of study animals receiving the drug under conditions of exaggerated use-that is, doses (e.g., 1, 3, $5 \times$ the highest labeled dose,) and durations (e.g., $3 \times$) of several magnitudes greater than the anticipated approved intended use. Field trials implemented during the approval process are performed in the approved species, generally as controlled (placebo or positive), randomized clinical trials, under conditions of intended use. Such studies generally involve a much larger sample population (e.g., hundreds of animals) than the directed toxicity studies. However, although toxicity studies do predict a number of adverse events that occur in the target

species,²¹ neither directed toxicity nor field studies are likely to involve a sample size sufficiently large to allow detection of many adverse events that occur in a very small proportion of patients (e.g., 1 in 1000 or more). Detection of such an adverse event is likely to require thousands of subjects. Further, directed studies are generally performed in a sample population of generally healthy animals unaffected by the complexities of host, drug, and disease factors associated with drug use in the target population (see Chapter 2). As such, postmarket surveillance studies and pharmacoepidemiologic studies (which focus on subgroups of target species) are particularly important to the safety assessment of approved drugs used in animal patients.²¹ For the same reason, if an ADE is suspected as a result of drug therapy, the importance of reporting it (or suspicion of it) cannot be overemphasized. Note that safety assessment of human-marketed drugs are studied in dogs but with an emphasis on human rather than animal safety. Although all approved human-marketed drugs are likely to have been studied in dogs during the preclinical phase, most of this information is not generally available unless specifically requested through Freedom of Information Act mechanisms. If an ADE is suspected, it first should be reported to the manufacturer; by law, animal drug pharmaceutical companies must report adverse events reported in animals to the Food and Drug Administration (FDA). The veterinary profession, probably more so than the human-medicine community, is less likely to report adverse event perhaps because the mechanism by which the information is forwarded to the veterinary health care provider is limited in both scope and distribution. In contrast to drugs, adverse event reporting for animal dietary supplements is entirely voluntary, with no obvious mechanism for reports to be collected, assessed, or returned to the veterinary profession.

It is only through postmarket surveillance that more clinically relevant assessments of drug safety can emerge, and subtle differences in the safety of different drugs might become apparent. Assessments include hazard or risk assessment, which express the probability of harm under conditions expected with use of the drug. Hazard is the potential to cause harm-that is, the inherent toxic nature of the compound. Risk is the likelihood that harm will occur. As such, it takes into account both hazard and exposure-that is, the amount of the toxin ingested and thus dose and duration.²² Risk-benefit analysis compares the risk associated with the use of a product and its potential benefits.²³ As such, a risk/benefit ratio addresses the acceptability of an adverse reaction by taking into account the importance, frequency, and duration of therapeutic benefit and the adverse reaction. Risk-benefit analysis generally is based on postmarket use of a product and a mechanism of surveillance that detects and assesses adverse events.²⁴

Among the difficulties in assessing risk through postmarket surveillance is the attribution of the adversity to the drug. Information submitted in an ADE report is limited, and care must be taken to not assume a cause–effect relationship The FDA's Center for Veterinary Medicine has recently reviewed its ADE reporting program.²⁵ It defines an ADE as an undesired or lack of desired response to a drug, medical device, or (in food animals) medicated feed. As such, a distinction is not made between adverse events associated with medication errors and those associated with inherent properties of the drug. In its 2004 report, the FDA indicates that a 6-point scoring system evaluates drug reactions submitted from manufacturers, pet owners, or veterinarians. Information collected includes previous experience with the drug (i.e., historical evidence of adversities from the label information or previously submitted reports), timing of the event in relation to dosing, alternative causes, the role of overdose, and effects of dechallenge or rechallenge. Plans for improved submission include a web-based submission process.

The FDA website (http://www.fda.gov/AnimalVeterinary/ SafetyHealth/ProductSafetyInformation/ucm055375.htm; accessed May 2010) can be reviewed for yearly and cumulative adverse event reports that have been reported in animals. Unfortunately, at the time of publication, the reports provide no evidence of frequency of occurrence, other than a ranking. This decision was made in part because of the inability of the FDA to standardize the number of adverse events by the number of doses administered (or units sold).

Predicting Drug Safety

Woodward²¹ has demonstrated that, to some degree, studies implemented during the approval process tend to predict adversities that emerge in target species, but with marked limitations. Guengerich²⁶ has discussed the role of predictive toxicology based on drug chemistry in assessing clinical safety of drugs. Toxicities are likely to be predictive if the drug is characterized by a high level of intrinsic toxicity; for such drugs chemistry may often predict toxicity. Toxicity is less predictable, although still reasonably so if metabolism plays a role, but is much less predictable if the toxicity is idiosyncratic (i.e., type B or II).

IDIOSYNCRATIC REACTIONS: ALLERGIC DRUG EVENTS

The clinical manifestations of idiosyncratic ADRs vary with the type of reaction and the body system targeted. Generally, for allergies, previous exposure to the drug must occur regardless of the type of reaction, or therapy must have been sufficiently long (i.e., at 10 to 14 days for some drugs) for an allergic response to develop. However, exceptions appear to exist, as is exemplified by allergy-based reactions to sulfonamides, which may occur in as early as 5 days (see Chapter 7). Drugs generally are too small in molecular size (<1000 D) to be sufficiently antigenic. As such, drugs that induce an allergic response generally act as haptens, covalently combining with a body tissue that then also becomes antigenic. As a result, the allergic response may be directed toward the drug or tissue.⁹ The hapten hypothesis is controversial because only a small percentage of persons develop a reaction, possibly because of a failure to develop tolerance. Failed tolerance may occur at one or more proposed sites. First, the role of metabolism in the formation of chemically reactive metabolites as the initial step in mediating idiosyncratic drug responses (including allergies) is increasingly supported by scientific studies. Those

individuals that produce more metabolites appear to be more likely to fail to develop immune tolerance to a drug.⁹ For the same reason, the dose of antigen exposure may determine the type of response. The role of CYP enzymes in idiosyncratic reactions (whether or not allergy based) is increasingly being recognized. Second, the metabolite must bind with an appropriate ligand, one with a high epitope density sufficient to induce an immune response. Third, an allergic response to a drug requires activity of an antigen-processing cell. As such, it may be more likely in the presence of inflammation, such as might be the case with a viral or bacterial infection or after stress or traumatic damage. Molecular signals that activate immune cells may also be more prevalent in the face of large concentrations of reactive metabolites because of their ability to induce oxidative stress.9 Fourth, other factors that may determine emergence of an allergic response (i.e., failed tolerance) may include failed downregulation of regulatory factors. A balance toward protective t-helper (Th1 or 2) response may preclude emergence of an allergic response; a loss of balance may facilitate it. Accordingly, both genetic predisposition and environmental factors contribute to emergent drug allergies.9

KEY POINT 4-1 Drug allergies:

- 1. require previous exposure or treatment for 5 to 12 days.
- 2. generally involve metabolism to a reactive chemical, which serves as a hapten.
- 3. often involve binding of the hapten to a highly epitopic protein.
- 4. are facilitated by inflammation (e.g., infection).
- 5. might be manifested as types I through IV.

Type I allergic reactions (immediate or anaphylactic) are IgE mediated and result from the release of chemical mediators (e.g., histamine, serotonin, eicosanoids) from tissue mast cells or basophils. The reaction occurs within minutes after drug administration regardless of the dose administered (Figure 4-6). Clinical manifestations generally include nausea, vomiting, circulatory collapse, tachycardia, pulmonary edema, and neurologic signs. Urticaria and angioedema may also be evident. Clinical signs may be species dependent, depending on the shock organ of the species. The shock organ generally is the organ in which mast cells occur in greater numbers. In the dog the shock organs tend to be the liver and gastrointestinal tract; in the cat the shock organ generally is the lung, with fulminating pulmonary edema being a clinical manifestation.

The exact antigen that causes anaphylaxis may not be known. For example, even though anaphylaxis in microfilaremic dogs after administration of microfilaricides is well documented, the specific antigen released by the effect of the drug is not known.²⁷ When given to microfilaremic dogs, both dimethylcarbamazine and ivermectin can induce shock manifested as peripheral vascular collapse, dyspnea, bloody diarrhea, and other clinical signs and laboratory test results consistent with anaphylaxis.

Treatment of drug-induced anaphylaxis is directed toward prevention of the physiologic response to mediator release (i.e., epinephrine and antihistamines) and prevention of further histamine release (e.g., epinephrine and glucocorticoids;

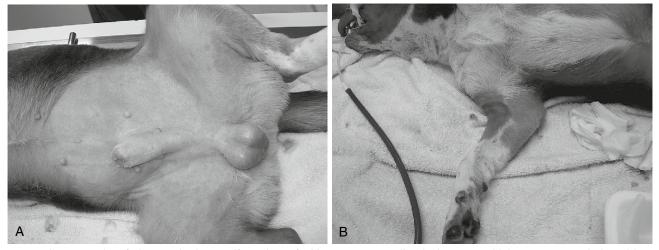

Figure 4-6 An example of dermatologic manifestation of either a type 1 allergic hypersensitivity or an anaphylactoid reaction. **A**, The former would involve antigen formation; **B**, whereas the latter would reflect a direct drug-induced histamine release from cutaneous mast cells. Skin lesions appeared 15 minutes after the puppy (undergoing an elective castration) received a preanesthetic dose of hydromorphone. (Courtesy Harry W. Boothe.)

possibly antihistamines). Ideally, antihistamines might also include the newer classes that may decrease mast cell degranulation as well as block H₁ receptors associated with histaminemediated shock. Interestingly, and perhaps disconcertingly, glucocorticoids themselves have been associated with anaphylactic reactions (see Chapter 30).²⁸ Supportive therapy is also indicated. Prophylactic pretreatment in cases of anticipated anaphylaxis helps decrease the manifestations of anaphylaxis by decreasing the mast cell response. Drugs associated with type I allergic reaction in humans include penicillins, angiotensin-converting enzyme inhibitors (particularly in the first 3 weeks of therapy), nonsteroidal antiinflammatories drugs (NSAIDs), and opioids. However, the latter drugs may actually be more associated with an anaphylactic-like reaction, also referred to as an *anaphylactoid reaction*.

An anaphylactoid reaction is very similar to anaphylaxis but differs in that it is not mediated by an antigen-IgE response and thus is not allergic or immune mediated. Rather, selected drugs or compounds cause direct mast cell degranulation. Generally, these drugs are cationic (basic) and include opioids (particularly morphine [see Figure 4-6], polymyxin, radiographic contrast agents, thiacetarsamide, and amphotericin B). Hyperosmolar solutions such as mannitol can also cause direct mast cell degranulation. Adverse response to rapid intravenous administration of enrofloxacin, which is both hyperosmolar and basic, may represent an anaphlylactoid response or may simply reflect (in cats) stimulation of the chemoreceptor trigger zone. However, ciprofloxacin has been associated with an allergic response in humans,²⁹ and the author is aware of at least one dog treated with ciprofloxacin for which the adverse reaction met the World Health Organization category of "probable" ADR. Anaphylactoid reactions tend to be related to dose. As such, administration of a small test dose may help the clinician determine the likelihood of occurrence. Response is probably more likely with intravenous administration. In addition to the prophylactic measures

for anaphylaxis, decreasing the rate of drug administration may help reduce the risk of the adverse response.

Type II reactions (cytotoxic) occur as antibody-bound blood cells become lysed and are removed from circulation. Lysis results from direct binding by either IgG or IgM. Complement may or may not be activated. Either stem cells in the bone marrow or mature circulating cells may be targeted. Targeting red blood cells, leukocytes, and platelets results in, respectively, hemolytic anemia, agranulocytosis and leukopenia, thrombocytopenia, or any combination thereof.

Type III drug reactions (immune complex disease, or serum sickness) are induced by antigen-antibody complexes involving either IgG or IgM and complement activation. Circulating antigen-antibody complexes may be filtered by and lodged in the vasculature of a number of organs, including the kidney, central nervous system (CNS), or peripheral vasculature. Clinical signs generally refer to the predominant organ affected but also include fever and lymphadenopathy. The Arthus reaction is a variation of the type III reaction and is manifested as swelling and pain at the site of drug administration. Among drug reactions in veterinary medicine, the potentiated sulfonamides are probably the most well-recognized cause of type III immune-mediated drug reaction.³⁰ Type IV drug reactions (delayed hypersensitivity, cell mediated) reflect cellular response at the site of the antigen. Lymphocytes and macrophages infiltrate the site and cause mediator release that perpetuates the inflammatory response.

The list of drugs that cause each type of drug-induced allergy is long and probably will remain incomplete. Although some drugs are more likely to cause a specific type of allergic reaction, any drug that causes allergy probably can cause any type of allergy, affecting any body system. Eventually, studies of structure–chemistry relationship involving metabolites and assessment of the immune system's response might allow identification of the patient at risk of developing an allergic response. Diagnosing an allergic (or any adverse) drug reaction can be Drug-induced allergy can be life threatening. Vasculitis and serum sickness are more likely to become life threatening when the kidney, liver, gastrointestinal tract, and nervous system become involved. Angioedema is life threatening if mucosal edema threatens ventilation.

Among the drugs recognized to be associated with drug allergies in dogs are the sulfonamides. Many medications contain a sulfonamide (a sulfur dioxide [SO₂] and nitrogen [N] moiety), including sulfonamide antimicrobials (derivatives of sulfanilamide in which the sulfonamide is attached to an aryl amine; e.g., sulfamethoxazole, sulfadiazine, sulfadimethoxine), "coxib" cyclooxygenase-1-sparing NSAIDs (e.g., deracoxib, firacoxib), carbonic anhydrase inhibitors (e.g., acetazolamide), diuretics (e.g., hydrochlorothiazide, chlorthalidone, furosemide), uricosurics (e.g., probenecid), drugs to treat inflammatory bowel disease (e.g., sulfasalazine), sulfonylureas (e.g., glyburide, glipizide), and selected anticonvulsants (e.g., zonisamide).³¹ However, it is likely that a metabolite associated with the nitrogen moiety is responsible for the reaction, with reactions being limited to molecules containing an aryl-amine (both the sulfur and an amine moiety are attached directly to a benzene ring; sulfonylarylamine), a structure limited to sulfonamide antimicrobials. The underlying pathophysiology, clinical manifestations, and other aspects of the response have been well described^{32,33} and are reviewed in Chapter 7.

ADVERSE DRUG EVENTS BY BODY SYSTEMS

Drugs causing adverse events in the various body systems are listed in tabular form in the respective sections on body systems. Discussion of the adverse reaction also can be found in the appropriate chapter. When available, treatments are offered, including tabular presentation (see Appendix 5).

Liver

The liver is vulnerable to drug-induced toxicity for several reasons (Box 4-1).³⁴⁻³⁷ The potential for hepatotoxicity can be enhanced by dietary imbalance (high fat, low protein), presence of disease concurrent with administration of drugs that alter hepatic drug-metabolizing enzymes or hepatic blood flow,³⁷ and age.³⁸

Drug-induced and chemical-induced liver injury have been classified into two categories.^{34,35,37} Type I toxins, or intrinsic hepatotoxins, cause type A adverse events, which are predictable, dose and time dependent and occur in most, if not all, subjects exposed to appropriate doses of the substance. Any drug metabolized by the liver probably can cause some degree of type I hepatic disease simply by the production of phase I

metabolites, which as a general rule tend to be toxic because of their reactivity. The longer the drug is used and the higher the dose, the more likely the ADE will occur. Type II, or idiosyncratic hepatotoxins, cause type B events, which are unpredictable and dose and time independent (consistent with Type B). Their occurrence is sporadic and not reproducible.

Drug-induced hepatotoxicity (Box 4-2) is associated with a wide range of histologic changes, from acute, reversible, and

Box 4-1

Hepatic Drug-Induced Toxicity

The liver is vulnerable to drug-induced toxicity for several reasons:

- 1. It receives a large portion of the cardiac output and thus is exposed to large amounts of drug.
- 2. The liver is a portal of entry and is exposed to the greatest concentrations of orally administered drugs.
- 3. The liver is the major site of metabolite formation. Thus the liver not only concentrates parent drugs but also is exposed to the greatest concentrations of their toxic metabolites.
- 4. The liver is a site of drug and metabolite excretion.
- 5. The liver is a highly metabolic organ and is susceptible to toxicities that induce hypoxia, interactions with enzymes, or loss of energy substrates.

Box **4-2**

Examples of Drugs or Drug Classes Associated with Hepatotoxicity*[†]

Acetaminophen Anabolic steroids Deoxycholic acid Diazepam (cats) Glucocorticoids Griseofulvin (cats) Halothane Isoniazid Ketoconazole Mebendazole Megestrole acetate (cats) Melarsomine Methotrexate Methoxyflurane Mibolerone Nonsteroidal antiinflammatories (including Cox-1-sparing drugs) Oxibendazole Phenobarbital Phenytoin Rifampin[‡] Primidone Sulfonamides Thiacetarsamide

^{*}Many other drugs that are metabolized by the liver are potentially hepatotoxic because of the production of phase I reactive metabolites.

[†]Microscopic lesions tend to be centrolobular in location, associated with necrosis, but otherwise nonspecific for most drugs.

[‡]In the author's experience, marked increase in serum alkaline phosphatase may occur but is not necessarily associated with hepatic dysfunction.

clinically benign lesions to those that cause fatal massive necrosis, chronic hepatitis, or malignancy.^{34,35} Some drugs characteristically cause only a single lesion, whereas others cause multiple lesions. The lesions caused by any drug are rarely specific for that drug but can be caused by a variety of drugs or other disorders, often limiting the potential usefulness of biopsy (Figure 4-7).

Frequently, drug-induced hepatic injury is limited to select regions or zones (e.g., central, middle, or peripheral) in the lobule.^{34,35} Various histologic lesions associated with drug hepatotoxicity have been described.^{34,35} *Zonal necrosis* usually results from type I or predictable toxins. The production of toxic metabolites may be an important cause of zonal necrosis because drug-metabolizing enzymes predominate in zones most likely to develop necrosis. In most cases of acute injury, the process is either fatal or completely resolved. If exposure is chronic or recurring, however, the lesions may persist and progress, depending on the dose, agent, and health of the

patient. *Lipid accumulation*, usually of triglycerides, may be associated with either minimal alteration of hepatic function or with both clinical and laboratory manifestations of liver dysfunction.

Nonspecific hepatitis is seldom associated with serious or progressive hepatic decompensation or failure and is fully reversible after discontinuation of the drug. *Chronic hepatitis* usually requires continued exposure and is not the result of self-perpetuation of an acute lesion. In general, prompt and complete resolution of this lesion can occur after timely discontinuation of therapy with the inciting drug. *Cirrhosis* generally requires prolonged or repeated exposure to the toxin. *Silent cirrhosis* is a term used to describe the gradual evolution of liver disease to cirrhosis without any clinical illness. Although methotrexate is among the most implicated drugs in humans, it is likely that many drugs that cause progressive liver disease do so "silently" for a long time.

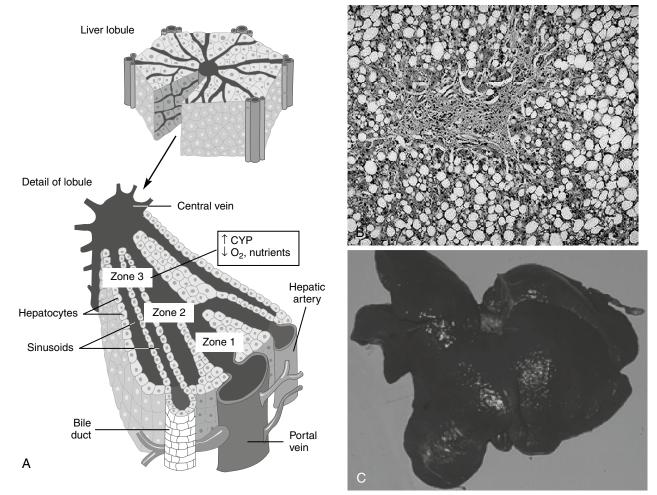

Figure 4-7 A, Drug-induced liver disease is generally nonspecific in presentation. Among the more frequent lesions are necrosis, particularly centrolobular, because hepatocytes in this region (zone 3) contain the most drug-metabolizing enzymes (i.e., production of toxic metabolites) yet receive the least oxygen. Hemorrhage and vacuolization are also common lesions. **B,** In the persistent presence of the toxin (including drug), the liver will continue to progress to irreversible changes, including the deposition of fibrous tissue as part of the cirrhotic process. **C,** A liver from a dog that died as a result of end-stage liver disease associated with phenobarbital concentrations above 50 μg/mL for 2 months. Clinical pathologic findings progressed from normal to indicative of end-stage disease within a 3-month period. (**A** from Cunningham CC, Van Horn CG: Energy availability and alcohol-related liver pathology, *Alcohol Res Health* 27(4):281-299, 2003.)

Drug-induced *cholestasis* is not well understood. Drugs can target bile ducts or canaliculi, causing primarily cholestasis without hepatocellular disease. When accompanied by an inflammatory infiltrate, systemic illness usually occurs, whereas cholestasis without inflammation is associated with no or very mild clinical signs. Recovery usually occurs after discontinuation of drug therapy.^{34,35} Drugs can also affect primarily sinusoidal or endothelial cells, causing primarily *fibrosis* or *veno-occlusive disease*. Veno-occlusive disease tends to be predictable and is most commonly associated in people taking anticancer drugs. An immune basis has been recognized for some drugs causing clinical signs consistent with chronic active hepatitis.

Treatment of drug-induced liver disease is primarily supportive. Because reactive metabolites often either cause or exacerbate disease, however, use of compounds that help prevent metabolite damage to the liver should be considered. Specific examples include *N*-acetylcysteine, a precursor to intracellular glutathione; ascorbic acid, another type of oxygen radical scavenger; *S*-adenosylmethionine (SAMe), a compound that contributes to a number of methylation reactions in the body; and the herbal agent silymarin (see Chapter 19). Care must be taken to ensure that the duration of treatment exceeds the duration of activity of the toxicant, as has been demonstrated for *N*-acetylcysteine for treatment of acetaminophen toxicity.³⁹

Hepatotoxic Drugs

Inhalant Anesthetics

Adverse events to inhalant anesthetics are unusual in veterinary medicine,^{40,41} in part because duration of anesthetic exposure is limited. Historically, methoxyflurane administration in dogs has occasionally been associated with acute centrilobular necrosis accompanied by a mixed inflammatory infiltrate. Halothane-associated hepatic injury in the dog has not been confirmed, although a clinical case report has described acute hepatic necrosis after its use. In humans the degree and incidence of halothane-induced liver damage do not appear to correlate with the duration or number of exposures and therefore has been suggested to reflect an idiosyncratic hypersensitivity.

Mebendazole and Oxibendazole

The bendazole anthelmintics have been associated with liver pathology. Acute centrilobular hepatic necrosis and fatal fulminating hepatitis have been reported in dogs after the clinical and experimental administration of the anthelmintics mebendazole and oxibendazole.^{42,43} Clinical signs were evident in as few as 2 days or as many as 10 to 14 days after administration. Although mebendazole was originally thought to be an intrinsic hepatotoxin, other studies suggest that it produces an idiosyncratic reaction.

Sulfonamides. Sulfonamide antimicrobials are associated with toxicity of multiple organs, including the liver.^{30,32,33,44} Sulfonamides do not appear to differ in their likelihood of causing toxicity. In one report that supports an idiosyncratic reaction, the duration of therapy before hepatotoxicity

developed ranged from 4 to 30 days, and the dose ranged from 18 to 53 mg/kg every 12 hours.⁴⁴ The mechanism of sulfonamide toxicity is discussed in more depth in Chapter 7.

Thiacetarsamide and Melarsomine. Thiacetarsamide (caparsolate) is associated with hepatic injury in humans and animals. Chronic exposures in humans are more likely to cause clinically significant hepatic disease. Hepatotoxicity is, however, a common complication of acute administration of thiacetarsamide for heartworm disease in dogs, although residual effects after therapy is completed are not expected (see Chapter 14). In normal animals melarsomine causes less hepatotoxicity and renal toxicity than thiacetarsamide.⁴⁵

Bile Acids. Bile acids are hepatotoxic, and they contribute to the development of hepatitis in patients with cholestasis, regardless of the origin. Bile acids are also used therapeutically as choleretics. Among the bile acids present endogenously and used therapeutically, however, those that are lipid soluble (e.g., deoxycholic acid) are more hepatotoxic than those that are water soluble (e.g., ursodeoxycholic acid). Ursodeoxycholic acid rather than deoxycholic acid should be used for therapy. Bile acid therapy should be discontinued in the event of cholecystectomy.

Xylitol. The sugar alcohol xylitol is associated with lifethreatening hypoglycemia and hepatic necrosis in dogs. Most cases, reported by the American Society for Prevention of Cruelty to Animals (ASPCA) Poison Control Center, reflect over ingestion of products containing xylitol as a sweetener (a small to average cookie may contain approximately 4 g xylitol). In contrast to humans, xylitol induces a ten-fold increase in insulin secretion in dogs compared to an equivalent amount of glucose. The result is a precipitous drop in serum glucose within 30 to 60 minutes after ingestion of as little as 100 mg/kg. Onset of hypoglycemia may be offset for 12 hr if xylitol-containing gum is ingested. Lethargy, ataxia, collapse, and seizures may occur. Clinical pathology may also reveal hypokalemia as potassium moves into the cell with glucose, and hypophosphatemia as a result of insulin's effects on cell permeability.^{45a,b} The impact on cats is not clear. More recently, hepatic necrosis has been reported in dogs ingesting xylitol. Enzyme increases within 12 to 24 hours after ingestion of 500 mg/kg or more are followed by clinical signs and sequelae, including coagulopathies consistent with acute hepatopathy. Hyper- rather than hypophosphatemia associated with acute hepatopathy may be a poor prognostic indicator. Sorbitol does not appear to be associated with toxicity in dogs.

Kidney

Like the liver, the kidney is vulnerable to drug-induced toxicity for several reasons (Boxes 4-3 and 4-4).⁴⁶ Specific cellular or subcellular sites of nephrotoxins frequently are not known. Usually, a toxin affects more than one type of renal tissue because of the high drug concentrations to which the kidney is exposed. The glomerulus is susceptible to direct nephrotoxicity as well as to indirect toxicity such as that caused by immunologic injury.⁴⁶ Many nephrotoxins cause predominantly proximal tubular damage. This is expected in part because blood flow is greatest in the renal cortex, where

Box 4-3

Acyclovir Aminoglycosides Amphotericin B Angiotensin-converting enzyme inhibitors Bacitracin Carboplatin Cephaloridine Cisplatin Colistin Cyclosporine (humans) Foscarnet Ganciclovir and other antiviral drugs Iodine radiologic contrast agents (intravenous) Methoxyflurane Nonsteroidal antiinflammatory drugs Polymyxin B Sulfonamides Tetracyclines Thiacetarsamide Vancomycin (in combination with other nephrotoxic drugs)

Box 4-4

Renal Drug-Induced Toxicity

The kidney is vulnerable to drug-induced toxicity for several reasons:

- 1. Renal blood flow accounts for 25% of cardiac output, exposing the kidneys to large amounts of blood-borne drugs.
- 2. Reabsorption of salt and water in the proximal tubules results in progressive concentration of drugs in the glomerular filtrate.
- 3. Passive drug reabsorption exposes the tubules to even greater concentrations of drug.
- 4. The kidney contains drug-metabolizing enzymes, thus increasing its exposure to potentially toxic metabolites.
- 5. The kidney is sensitive to extrarenal factors (e.g., those that induce ischemia or dehydration) that can predispose the kidney to or exacerbate drug-induced renal damage .

the proximal tubules are located. Variations in proximal tubular susceptibility to toxins may reflect different tubular functions.^{46,47}

A study in human medicine focused on the use of nephrotoxic drugs in the critical care patient.⁴⁸ Reductions in renal blood flow associated with hemodynamic responses to a myriad of illnesses predisposes the ICU patient to acute renal failure which occurs in 6% of human ICU patients. Prolonged use of vasopressors increases the risk of renal hypoxia. Additionally, of note, the use of low-dose dopamine ($\leq 3 \mu g/kg/min$) as a nephroprotectant, particularly in patients with acute renal failure (representing at least 6% of ICU patients) was discouraged. Although renal vasodilation and urine flow increase, outcome does not improve, and the increased risk of cardiac or other adversities balances any potential nephroprotection.⁴⁸ NSAIDs were cited as a particular risk in ICU patients; newer drugs that target COX-2 do not appear to offer an advantage in regard to nephrotoxicity. Nephrotoxicity induced by NSAIDs in the critical care environment occurs rapidly and is manifested as a rapid increase in serum creatinine. If an NSAID must be used in the ICU patient, one with a short half-life is recommended, and use of other nephroactive drugs (those that alter renal blood flow) are discouraged.⁴⁸ The ICU patient also is at increased risk for aminoglycoside toxicity, with urine enzymes the earliest indicator. Clinical evidence of nephrotoxicity occurs within 5 to 10 days of therapy; once-daily (or less frequent) therapy reduces the risk. Likewise, amphotericin B often is associated with acute renal dysfunction. Sodiumcontaining fluids and lipid-based products are recommended in the patient at risk. The use of nacetylcysteine to protect the kidney should be considered for selected drugs.

Nephrotoxic Drugs

Most nephrotoxic drugs are discussed in relevant chapters. *Methoxyflurane* causes a dose-dependent, high-output nephrotoxicity in humans. Toxicity appears to be the result of oxalate metabolites and inorganic fluoride. Oxalate metabolites crystallize in and obstruct the tubules, whereas inorganic fluoride produces tubular necrosis.⁴² Veterinary reports of methoxyflurane-induced nephrotoxicity are rare, probably because veterinary patients are at a reduced risk of develop-ing nephrotoxicity because exposure (surgery) times are much shorter than in humans.⁴⁹

Trivalent *arsenicals* such as thiacetarsamide denature proteins by binding to sulfhydryl groups. The glomerulus is often the first site of arsenical-induced nephrotoxicity, but proximal tubule damage predominates, probably because of the large number of enzymes that are denatured in this region.⁴⁶ Initial proteinuria is followed by tubular necrosis and degeneration.

Gastrointestinal

Stomatitis may progress to ulcerations with several drugs, particularly antineoplastic agents. Those most likely to cause stomatitis are listed in Table 4-1. A number of drugs are sufficiently caustic that ulcerations occur if the drug remains in contact with the mucosa (see Table 4-1). A number of drugs, including doxycycline and other drugs administered orally as a tablet have been associated with local mucosal damage and subsequent esophageal strictures in cats (see Chapter 19).

Although not an ADE, several drugs can cause tooth discoloration. Among the most recognized are tetracyclines, which chelate to calcium of either dentin or enamel, resulting in a yellow to brown discoloration. Oxytetracycline causes the least discoloration. The effect occurs during tooth development and is one reason that tetracyclines should not be administered to pregnant animals. The time that must lapse postpartum is not clear in animals. (It is up to 8 years of age in children.) Minocycline can cause discoloration despite animal age, probably as a result of chelation of iron resulting in insoluble complexes. Oral iron solutions can cause transient superficial discoloration of teeth, which can be removed. Other compounds associated with tooth discoloration in humans include isoproterenol, ciprofloxacin (a greenish-yellow discoloration when used in

Table 4-1 Examples of Dr	ugs Associated with	Gastrointestinal Toxicity				
Ulceration/Erosions	Xerostomia		Gingival Hyperplasia	Taste disturbance	Miscellaneous	
Antineoplastic drugs	Anticholinergic-like drugs	Omeprazole (gastric)	Omeprazole (gastric)	ACE inhibitors	Angioedema	Drugs associated with allergic response (many)

infants), and chlorhexidine (reversible yellowish-brown stains when used as a mouth rinse for more than several days).

Xerostomia (dry mouth) has been associated with anticholinergics and drugs with anticholinergic-like effects (see Table 4-1), as well as other drugs. Taste change is more discernible in humans and is caused by a number of drugs, including several antimicrobials (see Table 4-1).

Most orally administered drugs are probably capable of causing nausea or vomiting simply as a result of irritation or stimulation of the gastrointestinal tract mucosa. Erythromycin, for example, is a prokinetic agent and, as such, may cause upset in up to 50% of animals taking the drug. A patient with disease of the gastrointestinal tract is predisposed to these side effects. Many intravenous drugs also cause nausea or vomiting, particularly if given rapidly because of stimulation of the chemoreceptor-triggering zone. A number of drugs are recognized for their tendency to stimulate this zone regardless of the route of administration. Examples include digoxin, anticancer drugs, and most opioids.

Gingival hyperplasia has been reported for several drugs, including phenytoin and (in humans) calcium or sodium channel blockers.⁵⁰ The risk of its emergence might be reduced with good dental hygiene; in dogs it responded to metronidazole therapy.⁵¹ Gingival hyperplasia is a recognized side effect of cyclosporine administration in dogs and cats (package insert, Atopica); 31% of the dogs developed gingival hyperplasia and gingivitis, which responded to metronidazole and spiramycin.51 However, the more common effect of drugs on the oral mucosa is erosion. A number of drugs cause direct erosion with prolonged contact, especially in the feline esophagus (Table 4-1). Any drug that is antianabolic or inhibits cellular division is potentially toxic to the gastrointestinal tract by impairing the rapid turnover of epithelial cells in the mucosa (see Table 4-1). Tetracyclines and chloramphenicol are antianabolic, although long-term administration is necessary before these drugs affect the gastrointestinal tract.

Anticancer chemotherapeutic drugs best exemplify drugs that decrease epithelial cell turnover. Among the drugs most commonly causing gastrointestinal disease in veterinary medicine are the NSAIDs. These drugs inhibit prostaglandins, which in the gastrointestinal tract mucosa serve to inhibit gastric acid secretion, stimulate bicarbonate and mucus production and epithelialization, and increase blood flow. Among the NSAIDs most likely to cause gastrointestinal tract ulceration are aspirin, which also directly irritates the gastrointestinal tract mucosa, and ibuprofen, whose therapeutic range in the dog appears to be higher than the toxic range. Selected antimicrobials alter the microflora of the gastrointestinal tract and can subsequently cause diarrhea. Achlorhydria induced by a number of drugs can lead to gastrointestinal upset by changing microflora.

Torpet⁵⁰ has reviewed oral side effects of cardiovascular drugs in humans. The list of possible lesions is impressive, as are the number of drugs associated with lesions, which suggests that the oral mucosa (at least in humans) is sensitive to the effects of many drugs. Lesions include taste disturbances (diuretics, angiotensin-converting enzyme inhibitors),

xerostomia (e.g., alpha-agonists and beta or calcium channel blockers, angiotensin-converting enzyme inhibitors), gingival overgrowth (calcium and sodium channel blockers) and ulcerations, as well as a number of syndromes associated with cutaneous lesions indicative of drug allergies, including angioedema (many).

Nervous System

Because of the brain's role in integrating the body, toxic injury to one of its areas can result in manifestations from another site. Likewise, drugs that cause injury to other systems can result in CNS damage caused by metabolic changes (e.g., hypoglycemia, hypoxia). The high metabolic rate of neurons and their marked need for nutritional support render this system more susceptible than others to damage.¹⁵ Neurons are uniquely dependent on the cell body to provide support for the dendrites and axons; the axon, which is devoid of metabolic function, depends on axonal transport for supplies to meet its metabolic needs. Drugs or chemicals that interfere with axonal transport ultimately lead to axonal atrophy.¹⁵ The CNS is also uniquely lacking in effective regenerative capacity. Lesions of CNS damage therefore persist, leading to additive effects after subsequent exposures to a toxic compound, as well as delayed manifestations when neuronal reserve can no longer compensate for the abnormalities. Some toxicities may not occur until age-related attrition of neurons causes decompensation, thus prolonging the time between cause and effect and decreasing the likelihood that the relationship between exposure and neurotoxicity will be recognized.15

The blood-brain and blood-CSF barriers limit the incidence of adverse events in the CNS. Increased permeability of this barrier, however, such as might occur in pediatrics or disease, predisposes animals to CNS events. All CNS-active drugs are likely to cause CNS signs if the dose is too high. Drugs that can induce seizures in epileptic patients, and should therefore be avoided, include butyrophenones, metoclopramide, tricyclic antidepressants, and reportedly (although little literature supports this fact) glucocorticoids (Table 4-2). The impact of phenothiazines on seizure activity is less clear (see Chapter 27). A number of antimicrobials can cause seizures. The fluorinated quinolones have received some attention for their possible CNS side effects and, in particular, potentiation of seizures. The mechanism of action appears to be inhibition of gammaaminobutyric acid-receptor interactions and may (although this has not yet been proven) be facilitated by the presence of NSAIDs.⁵² High doses are therefore discouraged, particularly in predisposed patients. Several other antimicrobials are associated with CNS toxicity in people.⁵³ These include the beta-lactams, with imipenem and cefazolin being the most epileptogenic (see Table 4-2). Metronidazole also is associated with CNS adverse effects. Clinical signs of metronidazole toxicity in the dog include ataxia, nystagmus, and stumbling. Signs may not occur for 7 to 12 days after therapy is begun (see Chapter 7). Seizures may take up to 2 weeks to resolve; therapy is supportive. Signs may be more dramatic in the cat, including seizures and blindness. Toxicity has been reported at doses as low as 30 mg/kg every 24 hours.⁵⁴ Seizures respond

wi	amples of Drugs Associated th Adverse Drug Reactions in the
Ce	entral Nervous System
Drug	Manifestation
Beta-lactams (cefazolin)	Hyperexcitability, depression, aggression, seizures
Amitraz	Sedation, ataxia, muscle weakness
Aminoglycosides	Neuromuscular blockade
Antidepressants	Hyperexcitability, depression, aggression, seizures, ataxia
Antihistamines	Sedation, excitement
Benzyl alcohol	Hypersynthesis, ataxia, aggression, depres- sion, coma (cat)
Beta-lactams (cefazolin and imipenem)	Lowered seizure threshold, ataxia
Bismuth	Lethargy, somnolence
Butyrophenones	Lowered seizure threshold
Enrofloxacin	Seizures, exacerbated by coadministration of NSAIDs; dizziness
Erythromycin	Seizures, others
Glucocorticoids	Lowered seizure threshold with long-term therapy
Griseofulvin	Ataxia, seizures
Hexachlorophene	Neuropathy
Ivermectin	Depression, lethargy, seizures, others
Lidocaine	Seizures
Metoclopramide	Hyperexcitability, lowered seizure threshold
Metronidazole	Ataxia, nystagmus, seizures
Milbemycin	Depression, lethargy, seizures, other
NSAIDs	Nonseptic meningitis (naproxen), exacer- bation of seizures caused by fluorinated quinolones

Sulfonamides	Aseptic meningitis
Vincristine	Neuropathy
Nitrofurantoin	Peripheral neuropathies

CNS, central nervous system; NSAIDs, Nonsteroidal antiinflammatory drugs.

to diazepam therapy. NSAIDs are associated with CNS side effects, particularly if combined with fluoroquinolones with unsubstituted piperazinyl rings (ciprofloxacin) at position 7.⁵⁵

The CNS toxicity of the avermectins, including ivermectin, selamectin, moxidectin, and milbemycin, results from enhancement of gamma-aminobutyric acid-receptor interactions.⁵⁶⁻⁵⁸ The role of P-gp deficiency in avermectin CNS toxicity in Collies, Australian Shepherds,⁵⁹ and related breeds has been well established (see Chapters 2 and 3).⁶⁰ Doses as small as 100 g/kg can cause toxicity in these breeds. Toxicity will, however, also occur in any animal that is sufficiently overdosed. Clinical signs, which may not occur for 2 or 3

days, include emesis, diarrhea, salivation, fever, disorientation, ataxia, trembling, seizures, depression, coma, and blindness. Although picrotoxin or physostigmine (0.06 mg/kg, slow intravenous administration) have been recommended as an antidote, success is not well documented. Treatment with neostigmine (125 µg twice at 6-hour intervals and then daily for 2 days) along with fluid therapy was associated with success in an adult cat receiving 15 mg (16 times the recommended dose) of ivermectin but was unsuccessful in two kittens, each receiving 7.5 or 15 mg of the drug.⁶¹ Picrotoxin is associated with toxicities (seizures), and its use is not recommended unless the patient is comatose. One report cites a dose of 1 mg/min (as a 0.1% dilution in 5% dextrose) given as an intravenous drip until clinical response was evident (8 minutes). Seizures in the patient responded to anticonvulsant therapy.⁶² Supportive therapy is also indicated. Collies and related breeds with the MDR1 deletion mutation may also be at risk of reaction to other CNS-active drugs that serve as a substrate for P-gp (see Chapters 2 and 3). For example, the MDR1 deletion mutation responsible for the toxicity also has been associated with loperamide toxicity in a Collie receiving 0.14 mg/kg twice daily.63

Amitraz has a number of effects. It stimulates alpha-2 receptors in the CNS and alpha-1 and -2 receptors in the periphery, inhibits monoamine oxidases responsible for synaptic removal of monoamines such as dopamine and norepinephrine, and inhibits the synthesis of prostaglandin E2, although the clinical impact of this latter effect is not clear. Sequelae of $\beta 2$ adrenergic stimulation includes cardiovascular effects such as bradycardia and vasodilation, leading to hypotension, although peripheral alpha stimulation may cause hypertension. CNS effects of sedation, disorientation, and ataxia may progress to coma. Decreased insulin release results in hyperglycemia. Gastrointestinal effects include gastrointestinal stasis, and therefore atropine or other anticholinergics are contraindicated. Clinical signs of amitraz toxicity may reflect the vehicle, which contains xylene and propylene oxide. Signs of acute xylene toxicosis include CNS depression, ataxia, impaired motor coordination, nystagmus, stupor, coma, and episodes of neuroirritability. Treatment is largely supportive and includes alpha antagonists such as yohimbine (0.1 to 0.2 mg/kg, administered subcutaneously), which are used to reverse alpha side effects. For life-threatening hypotension, positive inotropes should be used cautiously. Control of seizures with diazepam has been contraindicated in the veterinary literature but is supported for treatment of amitrazinduced seizures in children.64

Metronidazole can cause CNS derangements in dogs receiving 60 mg/kg or less; duration is dose and duration dependent. Signs may not occur for 7 to 12 days after therapy is begun (see Chapter 7). Clinical signs including ataxia and nystagmus and seizures may take up to 2 weeks to resolve; therapy is supportive.

The potential for phosphate enemas to induce life-threatening CNS derangements has been well documented, particularly in cats. Toxicity is associated with hyperphosphatemia, hypocalcemia, hypernatremia, hyperglycemia, hyperosmolality, and metabolic acidosis. Onset of clinical signs (ataxia, tetany, convulsions, weak pulse, and hypothermia) is rapid and may rapidly progress to death. Treatment is supportive, including (cautious) calcium therapy. A similar phenomenon has been reported after administration of a phosphate-containing urinary acidifier in cats.⁶⁵

Benzoic acid (alcohol or benzoate) is a preservative commonly added to oral and parenteral drugs at concentrations of 5% or higher. Benzyl alcohol can cause CNS toxicity (characterized by hyperesthesia and depression), particularly in cats. The drug is rapidly metabolized to benzoic acid and subsequently to hippuric acid and benzyl glucuronide. Glucuronide deficiency in cats results in accumulation of benzoic acid. Pharmacists may not be aware that the glucuronide deficiency of cats predisposes them to toxicity with products containing benzoic acid.⁶⁶ Although the original dose necessary to induce toxicity in the cat was as high as 2 g/kg, clinical cases and experimental studies indicate that even a lower dose can be lethal. Diets containing benzoic acid at 0.2% to 2% (0.2 to 2 gm/dL) have caused clinical toxicities. The death of up to 30 cats in England⁶⁶ led to experimental studies that determined the maximum tolerable single dose of benzoic acid to be 450 mg/kg; accumulation with multiple doses limits the highest daily dose to 200 mg/kg.67 For example, a product containing 5% benzoic acid contains 5 g/dL or 50 mg/mL (50 mg/g for dry weight products), limiting a single dose to 9 mL/kg, or a daily dose to 4 mL (4 g/kg). Drugs also can be prepared as benzoate salts, although toxicity is less likely because less benzoate is administered on a mg/kg basis. For example, 40% of metronidazole benzoate is benzoate. A dose of 20 mg/kg delivers 12 mg/kg of metronidazole and 8 mg/kg of benzoate. A daily dose of approximately 500 mg/kg of metronidazole benzoate would be necessary to induce benzoate toxicity in the cat, a dose that would be difficult to achieve even with exceeding the recommended dose of 16 mg/kg metronidazole benzoate twice daily.

Tricyclic and other antidepressants can cause a variety of CNS disorders by virtue of their stimulatory effect on several CNS neurotransmitters and potentially inhibitory effects at other sites. Because these transmitters often modulate the normal physiology of multiple body systems, the clinical manifestations of events to these drugs can be diverse and subtle and affect other body systems. Manifestations related to the CNS include seizures, change in behavior, and depression. Many of the side effects caused in people probably cannot be detected in animals (e.g., blurred vision, dizziness, dry mouth). These drugs have not been well studied in animals, but clinical reports suggest up to 25% of animals may show an adverse reaction to these drugs. Clinical signs include increased or decreased appetite, hyperactivity, polydipsia, diarrhea, anxiety, and fear. The disposition of the drugs in humans includes lipid solubility, hepatic metabolism, and high protein binding, all of which are conducive to drug interactions. Toxicity is enhanced when drugs are used in combination. Because the effects of these drugs take several weeks to be realized, doses may be inappropriately increased, further increasing the risk of toxicity.

Peripheral neuropathies have been associated with a number of drugs. In humans peripheral neuropathy associated with nitrofurantoin occurred at doses ranging from 1.5 to 4.5 mg/kg, with a time of onset ranging from 3 weeks to 12 months. Peripheral neuropathy was severe and irreversible in some patients. The aminoglycosides cause peripheral neuromuscular blockade by interfering with calcium-mediated acetylcholine release. This effect is potentiated in the presence of other neuromuscular blockers and anesthetics.

Special Senses

Ocular Toxicity

Ocular ADRs can reflect local or systemic administration.⁶⁸ Very occasionally, systemic side effects may result from topical administration of ocular drugs.⁶⁸ Identification of adverse events affecting the eye (Table 4-3) generally depend on postmarketing surveillance systems or case reports; in some cases (e.g., fluoroquinolones in cats), follow-up toxicity studies may document the causal relationship between drug and adversity.⁶⁹ Adverse events to drugs manifested in the eye will most likely reflect systemic administration, with the retina being the most common site of reaction. Among the more commonly reported adverse events affecting the eye is acute retinal degeneration associated with exposure of the retina to a light source in patients receiving phototoxic drugs.70 A number of drugs used to treat cardiac disease have been associated with a variety of ocular lesions, including changes (increased or decreased) in intraocular pressure.71

Among the most notable ADEs manifested as ocular toxicity in animals is retinal degeneration in cats after administration of fluorinated quinolones. Although fluoroquinolones do not appear to cause a similar reaction in humans, reversible (corneal epithelial damage) and irreversible macular changes occur with administration of antirheumatic quinolones, chloroquine, and hydrochloroquine.72 Clinical signs of retinal degeneration associated with fluoroquinolone damage in cats include partial, temporary, or total blindness, with damage generally recognized to be irreversible. Although the incidence is rare, toxicity does appear to be predictable and is associated with a higher incidence in special populations, including geriatric cats and feline patients with renal disease. The mechanism of toxicity appears to reflect a deficiency of an efflux transport protein in the feline retina.* Fluorinated quinolones are structurally similar to compounds known to cause ocular toxicosis associated with accumulation in lysosomes of retinal pigment cells; additionally, fluoroquinolones have a predilection for pigmented cells of the eye. The fluoroquinolones also have been associated with phototoxicity. The combination of fluoroquinolone with ultraviolet radiation produces both a time- and concentration-dependent ocular toxicity, with a methyl group at position 8 of the quinolone ring reducing the risk.73 Reducing exposure to sunlight (dosing at night or keeping cats indoors) might be prudent for cats receiving fluoroquinolones, particularly if in a high-risk group.^{25,69} Drugs associated with fluoroquinolone retinal degeneration are discussed in more depth in Chapter 7.

^{*}Personal communication, K. Mealey, Washington State University.

*Most drugs administered topically in the ear may be associated with ototoxicity in the presence of a perforated ear drum.

Ototoxicity

Ototoxic drugs can damage both the auditory and the vestibular apparatus (Table 4-4).^{74,75} Auditory toxicity is often unrecognized, particularly in the older patient, unless complete deafness occurs. Vestibular ototoxicity might be detected as nystagmus or head tilt. Other clinical signs (e.g., tinnitus) are likely to occur in humans, but these side effects largely go unrecognized in animals. Ototoxic drugs generally are associated with loss of hair cells in the organ of Corti, although the biochemical mechanism is seldom known. Ototoxicity can be either reversible or irreversible and is more likely in the presence of a perforated ear drum if drugs are applied topically.

Aminoglycosides are well known for their ototoxic potential. Aminoglycoside-induced ototoxicity generally is irreversible. In contrast to renal tissues, aminoglycosides are not actively accumulated in perilymph, and drug concentrations generally are less in perilymph than in serum. However, because the half-life of the drug is much longer in the perilymph than in serum, surpassing that in serum by days to weeks, exposure of cells to the drug is longer. Proposed biochemical mechanisms of ototoxicity caused by aminoglycosides include impaired glucose metabolism or inhibition of polyphosphoinositide turnover. Although allowing serum

drug concentrations to become undetectable does not necessarily prevent ototoxicity, low trough concentrations as should occur with once daily therapy are none-the-less the best means of preventing ototoxicity. Ototoxicity is enhanced by the presence of loop-acting diuretics such as furosemide. The potential for ototoxicity varies among the aminoglycosides. Dihydrostreptomycin was designed as an alternative to streptomycin, which was vestibulotoxic,76 but dihydrostrptomycin also proved to be significantly cochleotoxic and was subsequently withdrawn. Streptomycin and gentamicin are more likely to cause vestibular toxicity, whereas neomycin, kanamycin, tobramycin, and amikacin sulfate are more likely to cause auditory damage. Among these, amikacin is least cochleotoxic; neomycin is so cochleotoxic (and nephrotoxic) that it cannot be used systemically. Netilmicin, the newest of the aminoglycosides, may cause the least ototoxicity. Auditory damage induced by aminoglycosides is initially characterized by the damage to outer cochlear hair cells, with progressive damage targeting inner hair cells. Initial loss impacts highfrequency hearing.^{76,77} Topical application of 0.1 mL of 3% gentamicin solution to the tympanic bulla was toxic to sensory receptors of the cochlea and the vestibular apparatus in cats.78 Fluorinated quinolones also may cause ototoxicity when given topically.

Other drugs that cause irreversible ototoxicity include the antineoplastics vincristine and vinblastine. The antineoplastic cisplatin also causes irreversible ototoxicity morphologically similar to that caused by aminoglycosides after accumulation of multiple doses, with the effect being both dose and duration independent.⁷⁷ Toxicity occurs in the hair cells of the organ of Corti and causes predominantly auditory damage. Cisplatin-induced ototoxicity can be unilateral (and hence not always recognized) or bilateral. Occasionally, ototoxic effects are transient. Chloramphenicol also has been associated with ototoxicity in the cat when applied topically with Gelfoam soaked in a concentration of 400 mg/mL.⁷⁹ Vestibular toxicity caused by chloramphenicol has been documented in humans.

Vehicles and cleansing agents also may be associated with ototoxicity. Propylene glycol is a common vehicle of topical preparations. Its use is associated with granulation and ossification of the auditory bulla and morphologic changes in the organ of Corti. Some disinfectants (e.g., 0.5% chlorhexidine in 70% alcohol) or carrier agents (e.g., propylene glycol) can cause ototoxicity. These drugs cause both vestibular and auditory side effects. Whereas chlorhexidine can cause almost complete destruction of the vestibular and auditory apparatus (in animal models), 70% alcohol does not appear to cause any ototoxicity. Quaternary ammonium disinfectants (e.g., 0.1% benzethonium or benzalkonium chloride) are among the most ototoxic compounds studied. Iodophors also cause ototoxicity, but damage will not be as profound as with quaternary ammonium compounds. Although the mechanism is not known and the extent of ototoxicity is not clear, ceruminolytic agents should not be applied topically in the presence of a perforated ear drum if the label indicates.

Reversible ototoxic ADEs are unusual. Loop-acting diuretics are among the few ototoxic drugs that cause damage that is largely reversible; however, hearing defects may be permanent. Toxicity is limited to the auditory system and reflects morphologic changes in the stria vascularis of the cochlea. The mechanism of ototoxicity is not clear but may reflect acute electrolyte disturbances in the cochlear endolymph, similar to that producing diuresis.⁷⁷ Furosemide is the least ototoxic of the loop diuretics; presumably, its combination with aminoglycosides (or other ototoxic drugs) would increase the risk of ototoxicity. Several antiseptics produce irreversible ototoxicity, presumably as a result of cell membrane damage similar to that induced in bacteria.

Aspirin, and potentially other NSAIDs, can cause transient hearing loss in humans. Clinical signs generally resolve in 48 to 72 hours. Several possible sites of damage have been recognized, including a vascular basis (i.e., loss of vasoactive prostaglandins) or impaired neurotransmission. Other drugs known to cause ototoxicity include local anesthetics (0.5% lidocaine can cause cochlear damage), tricyclic antidepressants, and, very rarely, beta-blockers. Although not ototoxic by itself, dimethyl sulfoxide should be used cautiously because of its ability to carry other drugs into the inner ear when used as a vehicle.

Integument

The skin is the organ that most commonly manifests ADEs in humans.⁸⁰ Although the reactions are generally mild, they can become life threatening. The type of lesion varies and includes almost any type of lesion described for the skin. Lesions include wheal and flare reactions, erythema, blisters, lichenoid lesions, purpura, changes in pigmentation, necrosis, pustular lesions, and changes in hair growth. The most common reactions are erythematous macular or papular rashes that resolve in several days even if untreated. These manifestations may also, however, be a precursor to a severe manifestation and thus should be observed closely. As with many organs, because the skin contains drug-metabolizing enzymes, reactions can be due to either the parent compound or its metabolites (or both).

KEY POINT 4-2 The skin may be the organ most commonly associated with adverse reactions.

Drug-induced skin events may be a manifestation of an allergic response or an autoimmune disease mediated by the skin. Both type A and type B events occur in the skin. Of the type B events, all types of allergic events (i.e., types I through IV) can involve the skin. Type IV allergic events are best exemplified by contact dermatitis. "Late" events include allergic vasculitis, purpura pigmentosa, and erythema multiforme. A distinct form of allergic (phototoxic) events has been reported in humans and animals, involving the interaction of a drug (or its metabolite) with ultraviolet radiation; the lesion often manifests in light-exposed skin (discussed later). Fixed drug eruptions are not well understood. In humans they are characterized by erythema, often with a central blister, and may occur because regulation of adhesion molecules in the epithelium is disrupted. Drugs are capable of causing autoimmune reactions in the skin, including lupus erythematosus, pemphigus, and pemphigoid skin lesions. Life-threatening drug-induced events that occur in the skin of people include the Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), hypersensitivity syndrome, serum sickness, vasculitis, and angioedema.

Lesions of SJS and TEN may be difficult to differentiate; SJS may be a milder form of TEN. Both resemble scalded skin and reflect a cell-mediated cytotoxic reaction against keratinocytes (Figure 4-8). The diseases are characterized by blistering and extensive detachment of the epidermis. The lesions are irregular in shape and are distinguished from erythema multiforme, another drug reaction of the skin, by the irregular shapes and absence of a well-defined border and edematous ring. Both TEN and SJS tend to affect the trunk, whereas erythema multiforme has an affinity for extremities. Mucous membranes are frequently involved, and patients are generally febrile, particularly with TEN. The presence of neutropenia is interpreted as a poor prognosis in human patients suffering from TEN. Treatment of TEN includes a management protocol similar to that for extensive burns; infection with Staphylococcus aureus (which by itself can cause a "scalded skin" lesion) is likely to complicate therapy. Drug events are the primary causes of SJS and TEN; erythema multiforme is caused by selected microorganisms, as well as by drugs. Drugs associated with TEN and SJS in humans include sulfonamides, anticonvulsants, allopurinol, oxicams, and (less frequently) other NSAIDs.

The term *hypersensitivity syndrome* has been used in the past to refer to any skin ADR. As such, however, it encompasses a wide variety of skin lesions, each treated differently. More recently, the term has been used in human medicine for a syndrome characterized by mucocutaneous eruptions, fever, lymphadenopathy, hepatitis, and eosinophilia. Arthritis or nephritis may also develop. As with SJS and TEN, sulfonamides and anticonvulsants are the most common causes of drug hypersensitivity.

Vasculitis occurs as a result of necrosis and inflammation in blood vessel walls, most commonly in the lower extremities, after antibody interaction with blood vessel walls. Drugs are the primary cause of vasculitis in humans. Penicillins, sulfonamides, thiazide diuretics, phenytoin, and propylthiouracil are the most common interaction-related drugs. Serum

Figure 4-8 Toxic epidermal necrolysis in a Doberman Pinscher treated with chloramphenicol. Although the lesion is several weeks old, damage was evident within several days of intramuscular treatment.

sickness–like lesions in the skin also can appear as vasculitis. Lesions result from immune complex deposition in small vessels followed by complement activation and white blood cell infiltration. Lesions appear first as erythema and then progress to more severe eruption. Patients are usually febrile. Drugs that cause serum sickness manifested as dermatologic lesions in humans include selected cephalosporins, minocycline, penicillins, and propranolol.

Dermatologic manifestations of type I hypersensitivities occur at mucocutaneous junctions (including the mucous membranes of the eyes, mouth, nose, lips, or tongue) or present as pruritus, flushing, erythema, and urticaria. Of these, angioedema is the most life threatening because of the risk of upper airway obstruction. Treatment includes epinephrine (for acute respiratory distress), antihistamines, and glucocorticoids.

Skin eruptions have been attributed to a number of drugs in small animals (Table 4-5). Type I skin lesions accompany many cancer chemotherapeutic agents and gold-containing antiarthritic agents. Prednisone and phenytoin can cause alopecia. Most skin reactions reflect type B adverse drug events, however, and as such are largely unpredictable. Alopecia has been reported after oral administration of hetacillin (cat), prednisone (dog), parenteral gold therapy (dog), and phenytoin (dog and cat). Eczematous dermatitis has resulted from oral administration of sulfa drugs (dogs and cats), griseofulvin, diethylcarbamazine, and fluorocytosine. Topical neomycin-triamcinolone preparations and coal tar shampoos can produce generalized eczematous reactions. Generalized exfoliation has resulted from oral administration of quinidine, topical administration of lime sulfur dips, and the use of flea collars. Fixed drug eruptions have resulted from the oral administration of ampicillin and the intravenous administration of sodium thiacetarsamide. Pemphigus vulgaris-like reactions have followed thiabendazole oral therapy, and similar lesions have been reported with gold therapy. Erythematous dermatitis has been reported after the parenteral administration of a phenothiazine derivative. Pruritus has been reported after oral diethylcarbamazine, gold, and bromide (anticonvulsant) therapy. Purpura and lesions typical of TEN have occurred after oral administration of chloramphenicol (see Figure 4-8). Intravenous vitamin K and oral tetracyclines have caused urticaria and angioedema in the dog. Drug eruptions have also been associated with the systemic administration of levamisole. Human recombinant products such as erythropoietin have caused skin or mucocutaneous lesions typical of allergic drug events in dogs.

Hormonal therapy is often associated with predictable skin lesions, including bilaterally symmetric alopecia and hyperpigmentation (discussed later in reference to the endocrine system). The effects of glucocorticoids on the skin have been well documented and are often manifested as part of the cushingoid presentation of animals receiving therapy. Cyclosporine has been associated with changes in hair coat.⁸¹

Benzoic acid used as a preservative in topical preparations may cause cutaneous erythema, possibly caused by induction of inflammatory prostaglandins.⁸² Ciprofloxacin was associated in a human patient with the development of erythema multiforme, which histologically was consistent with dermatitis herpetiformis.²⁹ Lesions developed on day 6 of therapy and responded to glucocorticoid therapy.

Photosensitization represents a novel mechanism of toxicity to selected drugs whose treatment occurs during exposure to electromagnetic radiation. Photosensitization occurs if a drug (or biological substrate) is characterized by an abnormally high reactivity to ultraviolet (UV) radiation (artificial or natural). Photosensitization requires the presence of *photosensitizers*, which induce changes in the drug after the appropriate radiation is absorbed (Box 4-5). Structural requirements of the photosensitizer to induce phototoxicity reflect its ability to absorb radiation wavelengths characterized by effective skin penetration (above 310 nm). As such, the photochemical decomposition to stable photoproducts, free radicals, and/or singlet oxygen is facilitated. The probable

Table 4-5Examples of Drugs Associated
with Adverse Dermatologic
Manifestations

Ivial mestations				
Drug	Manifestation			
Ampicillin	Fixed drug eruption			
Anticancer drugs	Alopecia			
Bromide	Pruritus			
Coal tar shampoos	Generalized eczema			
Chloramphenicol	Purpura, TEN			
Diethylcarbamazine	Eczematous dermatitis, pruritus			
Erythropoietin, human recombinant	Skin or mucocutaneous lesions			
Flea collars	Generalized exfoliation			
5-Fluorocytosine	Eczematous dermatitis			
Glucocorticoids	Alopecia, hyperpigmentation			
Gold-containing drugs	Alopecia (dog), pruritus, pemphigus vulgaris-like reaction			
Griseofulvin	Eczematous dermatitis			
Hetacillin	Alopecia (cat)			
Levamisole	Drug eruptions			
Lime sulfur dips	Generalized exfoliation			
Neomycin (topical)	Generalized eczema			
Phenothiazine derivatives	Erythematous dermatitis			
Phenytoin	Alopecia			
Prednisone	Alopecia (dog)			
Quinidine	Generalized exfoliation			
Recombinant products, nontarget species	General skin or mucocutaneous lesions			
Sulfonamides	Eczematous dermatitis			
Tetracyclines (oral)	Urticaria, angioedema			
Thiabendazole	Pemphigus vulgaris-like reaction			
Thiacetarsamide	Fixed drug eruption			
Vitamin K (intravenous)	Urticaria, angioedema			
Cyclosporine	Altered hair coat			
Many	Other cutaneous manifestations of allergies			

TEN, Toxic epidermal necrolysis

Examples of Drugs Associated with Known or Potential* Cases of Photosensitization

Acetazolamide	Isotretinoin
Alprazolam	Ketoprofen
*Amantadine	Levofloxacin
Amiloride	*Meclofenamic
Amitriptyline	acid
*Azathioprine	Methotrexate
*Azithromycin	Minocycline
*Benzocaine	Nabumetone
Captopril	Nalidixic acid
Carprofen	Naproxen
Chlortetracycline	Nifedipine
Chlorothiazide	Nortriptyline
Ciprofloxacin	Ofloxacin
Clofazimine	*Omeprazole
Clofibrate	Orbifloxacin
Clomipramine	*Osalazine
*Cyproheptadine	Oxytetracycline
Dacarbazine	Paroxetine
*Danazol	Pentobarbital
Dantrolene	*Phenobarbital
Dapsone	Phenothiazine
Diclofenac	Phenylbutazone
Diltiazem	Phenytoin
Doxepin	Piroxicam
Doxycycline	*Procaine
Enalapril	Prochlorperazine
Etretinate	Promazine
Felbamate	Promethazine
Flecainide	*Pyridoxine
Fluoroquinolone	*Pyrimethamine
antimicrobials	Quinidine
Fluorouracil	Silver sulfadiazine
Fluoxetine	Sulfamethoxazole
Furosemide	Sulfasalazine
Glipizide	Tetracycline
Glyburide	Tretinoin
Griseofulvin	Thiazine
Haloperidol	Tolbutamide
Hydralazine	Triamterene
Hydrochlorothiazide	Triflupromazine
Imipramine	Trimethoprim
Interferon beta	Valproic acid
Isoniazid	Vinblastine

role of fluoroquinolone antimicrobials as photosensitizers was discussed previously. Photosensitizers can be found in the cellular content of foods (e.g., flavins and porphyrins), plants or their juices, industrial chemicals (dyes, coal tar, derivatives of chlorinated hydrocarbons), and drugs. Exogenous photosensitizers may enter the body through a variety of routes, including ingestion, inhalation, injection, or direct contact with the skin or mucosa.⁸³ Biological targets subject to photosensitization include cell membranes, cytoplasmic organelles, and the nucleus. Photosensitization may be used therapeutically if it can be directed to targeted tissues or if UV radiation can be applied to selected sites (e.g., cancer therapy). Clinical signs vary with the photosensitizer and the amount of radiation absorbed. Signs range from mild cutaneous reactions (e.g., erythema, pruritus, urticaria and rash) to severe reactions including (in humans) genetic mutations and melanoma. Clinical signs generally occur immediately after exposure to the UV radiation. Variation may also reflect the skin type, as well as physiologic factors such as age and gender (human medicine). Photosensitivity is generally dose dependent but may not happen with the initial drug administration but rather with subsequent administration. The reaction is then referred to as a *photoallergy*, reflecting binding of the photosensitizer to a skin protein. Occasionally, the response may be delayed and may occur even in the absence of the photosensitizing substrate.

Endocrine System

The impact of xylitol on insulin secretion was discussed with its hepatotoxicity. Mechanisms of drug interference with the thyroid and adrenal axes have been documented in human patients (Table 4-6). Each axis presents several targets for drug interference. Mechanisms that decrease hormone concentrations include suppression of hormone release at each level (i.e., hypothalamus, pituitary, or target organ), often because hormone synthesis is decreased, or altered by peripheral metabolism of the hormone (e.g., thyroid hormones).⁸⁴ The latter effect is often the result of induction of hepatic drug-metabolizing enzymes. Potent inducers of hepatic drug-metabolizing enzymes include phenobarbital, phenytoin, and rifampin. Whether patients show clinical manifestations of hormone deficiency after induction of metabolizing enzymes remains to be documented. Less commonly, hormone concentrations are physiologically increased by drugs. Again, changes in hepatic metabolism are a common cause. Potent inhibitors of hepatic drug metabolism include cimetidine, chloramphenicol, and ketoconazole.

Drugs can also increase hormone concentrations by competing with and displacing the hormone from carrying proteins. The protein from which hormones are most likely to be displaced is albumin, a nonspecific carrier of many weakly acidic drugs (e.g., NSAIDs). Competition for albumin-binding sites may be less important for those hormones carried by specific carrier proteins, although competition for such binding sites has been documented. In some cases a drug may influence blood hormone concentrations simultaneously at several physiologic sites, complicating interpretation (e.g., the effects of phenytoin on thyroid hormone concentrations). Because animals differ physiologically, extrapolation between species regarding the effect of a drug must be done cautiously. Caution is also advised when extrapolating results of studies in normal animals to the animal suffering from a disease of the endocrine system. For example, propranolol decreases thyroid hormone concentrations in hyperthyroid humans but not in euthyroid dogs.85

In some instances the drug effect on a hormone is well known and is used either diagnostically (e.g., dexamethasone-induced decrease in cortisone or xylazine-induced growth hormone secretion)⁸⁶ or therapeutically (propranolol

Drug	Comment	Drug	Comment	
Cortisol		Thyroid-releasing hormone (TRH)		
Increased		Decreased		
Anticonvulsants			Duploy and a dupinistration may arready home	
Corticotropin Diagnostic intent		Aminosalicylic acid	Prolonged administration may cause hype thyroidism	
Cortisone	For at least 24 hours	Anabolic steroids	Decreased binding to globulins	
Estrogen	Increases binding globulin concentrations	Androgens	Decreased binding to globulins up to	
Fluocinolone	After topical administration	Androgens	1 month per administration	
Hydrocortisone	For at least 24 hours	Anticonvulsants	1	
Insulin	Marked effect with insulin-induced hypo-	Asparaginase		
	glycemia	Aspirin	Displaces T ₄ from binding sites to	
Lithium		1	prealbumin	
Metoclopramide	After intravenous dosing	Barbiturates	Competition for binding to prealbumin	
Opiates	Within 1 hour of intravenous dosing with selected drugs	Bromocriptine	In hypothyroidism (response to TRH unchanged)	
OPPPD (mitotane) [†]	Therapeutic intent	Carbamazepine	Induction of hepatic enzymes; increased	
Prostaglandin F ₂	Slight effect		extrathyroidal metabolism	
Vasopressin	Mild increase	Chlorpromazine	Increased metabolism by liver	
Decreased		Cholestyramine	Decreased intestinal absorption	
Barbiturates	Preoperative use	Glucocorticoids	Up to 1 week after therapy	
Beclomethasone	After inhalant administration	Diazepam	Competition for transport proteins	
Clonidine	In growth hormone-deficient children	Furosemide	Displacement from binding sites and	
Danazol	Displacement from binding and increased free drug	Growth hormone	enhanced clearance Inhibition of thyroid-stimulating hormone	
Deoxycorticosterone	After topical administration		(TSH) response to TRH (?)	
Dexamethasone [†]	Diagnostic intent	Heparin	Modified binding to transport	
Ephedrine	Accelerated clearance caused by increased	-	proteins (?)	
	hepatic blood flow and enzyme activity		Decreased synthesis (therapeutic)	
Etomidate	Direct suppression of adrenal function	Iodides [†]		
Fluocinolone	After topical administration	Lithium	Reduced thyroidal iodine updake, iodin-	
Thyroxine			ation of tyrosine, release of T_4 , hepatic metabolism of T_4 to T_3	
Increased		Methimazole †	Therapeutic intent	
Dessicated thyroid		Mitotane	Competes with T ₄ for binding globulin	
Estrogens	Increased binding capacity of globulin for	Penicillin	Competes for binding globulin	
	up to 1 month	Phenobarbital	Induction of hepatic enzymes	
Fluorouracil Glucocorticoids	Increased binding capacity Inhibition of conversion	Phenylbutazone	Impaired synthesis, competition for bind-	
Halothane	Increased release from liver	-	ing to albumin	
Insulin	Increased release from liver	Phenytoin	Displacement from binding proteins;	
	Suppression of endogenous hormone;	D (1 1 1	induction of hepatic enzymes	
Levothyroxine	exogenous measured	Potassium iodide	Tabibita and basis (is direction of terms in a)	
Lithium	Report of one patient suffering from pre-	Propylthiouracil	Inhibits synthesis (iodination of tyrosine), therapeutic intent	
Dh anvet a i	sumed drug-induced thyrotoxicosis	Ranitidine	Slight reduction	
Phenytoin Proprenelal	Plackage of indethymotics details diversity	Salicylate	Competition for transport proteins	
Propranolol	Blockage of iodothyronine deiodination in hyperthyroid and euthyroid patients	Somatostatin	Inhibition of TSH release (?)	
Prostaglandins	Direct effect	Stanozolol		
Tamoxifen		Sulfonamides [†]		
		Terbutaline	Mild decrease	
Thyroid		Triiodothyronine		
Thyrotropin				

Table **4-6** Drug-Induced Physiologic Changes in the Adrenocortical and Thryoid Axes*

*Table reflects serum or plasma values only and is based on information reported by Young (1990).¹¹ $^{\rm †}Reported$ in the veterinary literature.

Drug	Comment	Drug	Comment

TRH, Thyroid-releasing hormone.

or propylthiouracil-induced inhibition of thyroxine [T₄]). More commonly, the effect is undesirable. Several examples of undesired, drug-induced physiologic changes in endocrine function have been documented in small animal patients. The example most documented in small animals are the effects of drugs, and particularly glucocorticoids, on the hypothalamic-pituitary-adrenal axis. Interference with this axis can become clinically detrimental. Suppression of the adrenal axis by glucocorticoids is most marked after administration of depot (repositol) forms (e.g., those containing acetate esters).87 Interference has also, however, been documented after administration of a single dose of prednisolone or triamcinolone; multiple doses of methylprednisolone;⁸⁷ topical administration of triamcinolone;88 and ophthalmic administration of prednisone.⁸⁹ The impact of other steroids, including dexamethasone and betamethasone, are discussed in Chapter 17.

Glucocorticoids are not the only drugs that interfere with the hypothalamic–pituitary-adrenal axis. The imidazole antifungal drug ketoconazole inhibits the cytochrome P450 enzymes responsible for the synthesis of both sex and adrenal steroids.⁹⁰ Suppression of testosterone and cortisol has been documented in dogs after oral administration of 10 mg/kg ketoconazole once daily.⁹¹ Hormone concentrations are lowered by day 1 and remain low at day 5. Progesterone concentrations increase as testosterone concentrations decrease. The magnitude of testosterone inhibition by ketoconazole apparently resolves, with testosterone concentrations being less predictable 1 month after therapy was started. The inhibitory effect of ketoconazole on testosterone and adrenal steroids has been used therapeutically in the treatment of prostatic cancer and benign prostatic hypertrophy and hyperadrenocorticism, respectively. The newer imidazole antifungal drugs do not appear to inhibit steroid synthesis as effectively as ketoconazole.

Drug interference with evaluation of the thyroid axis is also important because of the prevalence of thyroid dysfunction in small animals. Several drugs, targeting various sites, interfere with thyroid function testing (see Table 4-6).92 Thyroid-stimulating hormone (TSH) response to thyroid-releasing hormone (TRH) is altered by a number of drugs that modulate neurotransmitter (e.g., serotonin, dopamine) concentrations in the brain. Glucocorticoid suppression of TSH response to TRH has been well documented. Higher doses appear to suppress hypophyseal inhibition of TSH, whereas low doses interfere with the hypothalamic response.⁹² Note, however, that interference of the thyroid axis by glucocorticoids does not preclude simultaneous testing of the thyroid and adrenal axes in healthy dogs.93,94 Antithyroid drugs such as propylthiouracil and methimazole are used therapeutically to block thyroid hormone synthesis; their mechanism occurs, at least in part, at the level of transcription.95

The effects of iodide- and iodine-containing products (including radiographic contrast agents) on thyroid hormone concentrations are well recognized and used therapeutically. Through hypothalamic regulation, iodines cause a rapid increase in TSH response to TRH as T_4 and triiodothyronine (T_3) concentrations decrease. Sulfonamides can have a profound effect on thyroid function.⁹⁶ Among the potential mechanisms, direct interference with the conversion of inorganic iodide to diiodotyrosine and thyroxine was demonstrated as early as 1943.⁹⁷ Decreased concentrations of peripheral

hormones are associated with follicular cell hypertrophy and hyperplasia and with decreased colloid formation. Changes are profound in as early as 21 days yet resolve within 3 weeks after therapy is discontinued. These effects occur at high doses that might be used for difficult-to-treat, yet presumably susceptible, higher bacterial or protozoal infections (>60 mg/ kg per day but may also occur at lower doses). The effects of sulfonamide NSAIDs and the anticonvulsant zonisamide on thyroid gland function are discussed in Chapters 29 and 27, respectively.

The effects of non-sulfonamide anticonvulsant drugs, especially phenobarbital and phenytoin, on thyroid hormone disposition are less appreciated. Several sites of interference have been identified for anticonvulsant drugs (see Chapter 27).

Hematologic

As with any drug-induced disorder, the lack of universally standardized definitions of what constitutes an adverse reaction complicates recognition of hematologic disorders induced by drugs. The criteria for drug-induced hematologic disorders have been described for humans and are based on cell count, assessment of time to onset after drug exposure and time to resolution of signs after the drug has been discontinued, and the course of the reaction.⁹⁸ Drug-induced hematologic dyscrasias may reflect a bone marrow response or an effect on peripheral tissues, including blood components (Table 4-7). Bone marrow suppression can result in pancytopenia or affect only a single cell line (i.e., anemia, leukopenia, or thrombocytopenia).⁹⁹ Both direct bone marrow suppression and toxicity to mature circulating cells may occur.

Bone marrow and peripheral cells are susceptible to both drugs and their metabolites; reactions may have an immunologic or nonimmunologic basis. Although drug allergies are a well-recognized cause of damage to stem cells of the bone marrow, many drugs are directly toxic. Discerning an immunologic basis can be difficult, however, if the antibodies involved have not been identified. Drugs most commonly associated with nonimmune-mediated bone marrow suppression include most cancer chemotherapeutic agents because of their predictable effects on DNA and cell division. Other drugs associated with nonimmune-mediated bone marrow dyscrasias include phenylbutazone, estrogen derivatives, and chloramphenicol.

Phenobarbital has caused leukopenia and other hematologic disorders when used to treat epilepsy; white cell counts normalize once the drug is discontinued. Whether or not this is an immune-mediated reaction is not clear, but its lack of dose dependency suggests a Type B reaction (See Chapter 27).

Drugs that affect blood components and the manifestations of anemia include all NSAIDs but particularly aspirin (reflecting inhibition of platelet activity), anticoagulants such as warfarin derivatives, and heparin (these generally reflect a relative overdose). Red blood cell malfunction may occur as a result of methemoglobinemia in cats (Figures 4-9 and 4-10). Although acetaminophen clearly causes hepatotoxicity, the feline red blood cell is more sensitive to the presence of

Table 4-7Examples of Drugs Associated with Hematologic Disturbances				
Drug	Manifestation			
Acetaminophen	Methemoglobinemia (especially in cats)			
Anticancer drugs	Bone marrow suppression*			
Azo dye (urinary antiseptics)	Methemoglobinemia (cats)			
Benzocaine (and related drugs)	Methemoglobinemia (cats)			
Chloramphenicol	Bone marrow suppression*			
Cimetidine	Thrombocytopenia			
Coumarin derivatives	Coagulation dysfunction			
Erythropoietin (human recombinant)	Anemia			
Estrogens	Bone marrow suppression*			
Griseofulvin	Bone marrow suppression*			
Heparin	Thrombocytopenia, platelet dysfunction, coagulation dysfunction			
Methimazole	Methemoglobinemia			
Methylene blue	Methemoglobinemia (cats)			
NSAIDs	Platelet dysfunction			
Phenobarbital	Neutropenia			
Phenylbutazone	Bone marrow suppression*			
Propylthiouracil	Methemoglobinemia			
Ranitidine	Anemia			

NSAIDS, Nonsteroidal antiinflammatory drugs.

*Bone marrow suppression might be manifested as anemia, leukopenia, thrombocytopenia, or any combination thereof.

radical metabolites compared with the feline liver. Several reasons have been suggested for an apparent increased sensitivity of feline red blood cells to methemoglobin formation: feline hemoglobin may be more sensitive to oxidation; feline erythrocytes may contain lower concentrations of intracellular glutathione; the proportion of subtypes of hemoglobin may differ; and, finally, feline hemoglobin may contain more sulfhydryl groups, which are reactive, than that of other species. Drugs associated with methemoglobinemia in cats include urinary antiseptics containing methylene blue or azodyes, acetaminophen and related compounds, benzocaine, DL-methionine, propylthiouracil, and methimazole.

Ivermectin was associated with a prolonged prothrombin time and hematomas in humans after a single oral dose, presumably because of a drug-induced vitamin K deficiency.¹⁰⁰

Human recombinant erythropoietin and granulopoietin have been used to treat anemias associated with chronic renal disease and leukopenia induced by disease (e.g., parvovirus) or drugs (e.g., anticancer drugs) in dogs and cats. Unfortunately, these proteins are foreign, and antibodies may develop after 10 to 14 days, destroying not only the exogenous drug but also endogenous factors.

Drug-induced hematologic disorders have been described in the human critical care patient.¹⁰¹ Among the challenges

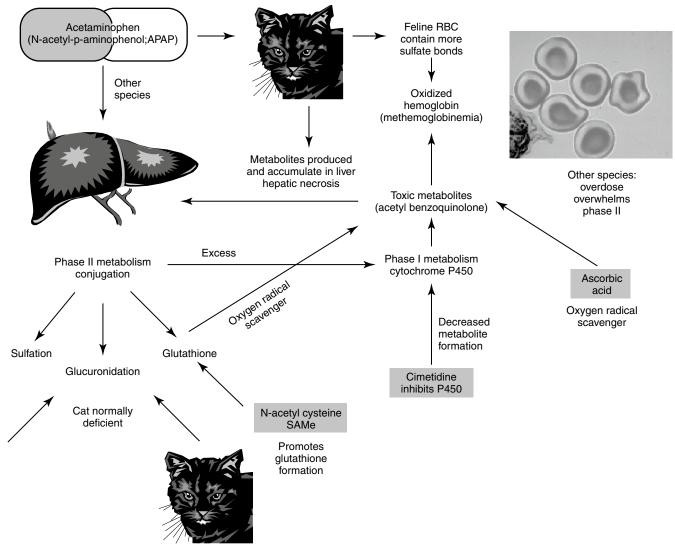

Figure 4-9 Acetaminophen toxicity reflects a cytotoxic type A adverse reaction. Because cats are deficient in glucuronidation, phase II metabolism is easily overwhelmed, and drug is shunted more aggressively back into phase I metabolism. The same process occurs in dogs after an overdose. The products of phase I metabolism are reactive and cause destruction of tissues (liver and red blood cells). Glutathione, an important phase II oxygen-radical scavenger, prevents damage but is easily depleted in cats. Supplementation in the form of *N*-acetylcysteine can decrease damage. Cimetidine is useful because it decreases phase I metabolism and thus the formation of phase I metabolites.

Figure 4-10 Facial edema in a cat with acetaminophen toxicosis. The mucous membranes of this cat were cyanotic.

in the ICU setting is identifying the drug as the cause, and, in the patient receiving polypharmacy, which drug. It is not clear whether ICU patients are at any greater risk to develop these dyscrasias, but certainly they are at greater risk to react adversely should they occur. Bone marrow under production is manifested as pancytopenia if the pluripotential cell is targeted or monocytopenia if a single hematopoietic cell is targeted. Neutropenia can be manifested within hours (7 to 10), thrombocytopenia in days, and anemia generally in weeks unless exacerbated by hemolysis. Bone marrow aplasia has been associated with chloramphenicol, felbamate, sulfonamides, and NSAIDs. If the effect is direct, clinical signs may resolve once the drug is discontinued, unless the effect is irreversible (e.g., selected chloramphenical reactions in humans). If indirect, immunosuppressive doses of immunomodulators

may be indicated. Myelodysplasia as a prelude to acute myelogenous leukemia is associated with high doses or long durations of alkylating or topoisomerase-inhibiting anticancer drugs. Macrocytosis has been associated with drugs that negatively affect metabolic compounds needed for DNA synthesis. Examples include cobalamine, whose absorption is inhibited by neomycin, proton pump blockers, and bifuanide hypoglycemic agents, or folate, whose metabolism is inhibited by methotrexate, phenytoin, and trimethoprim. Drugs that alter the nucleotide pool may cause megablastosis (e.g., hydroxyurea, methotrexate, azathioprine, purine nucleoside analogs). Enzyme deficiencies (thiopurine methytransferase) and druginduced erythropoietin deficiencies (e.g., cisplatin) also have been reported. Cytopenias resulting from direct effects on cells have been reported. Examples include penicillin-induced thrombocytopenia. Heparin-induced thrombocytopenia reflects binding to PF4 immunoglobulin and subsequent activation of platelets; the risk is lower with low-molecular-weight heparins. Thrombotic microangiopathies (thrombotic thrombocytopenia purpura) has been associated with the antiplatelet agents clopidogrel or ticlopidine and anticancer drugs (mitomycin-C).¹⁰¹

Respiratory System

Although compounds toxic to the lungs occasionally arrive by hematogenous routes, most pulmonary toxicities result from direct exposure of the respiratory tract through the nasopharyngeal or oropharyngeal airways and subsequently the tracheobronchial tract and alveoli.¹⁵ Gaseous and particulate toxicants are most common. The airways may also serve as a means of systemic exposure if the toxicant is effectively and rapidly absorbed by the respiratory mucosa. Particulate matter that impacts the airways (generally 5 to 10 μ m in size for the tracheobronchial tree and less than 5 μ m in size for alveoli) can become trapped in the airways.

The mucociliary apparatus may remove entrapped particulate matter before a toxic response occurs. Some chemicals, however, cause direct injury to upper airways (e.g., chlorine, ammonia, water-soluble gases, and chromium). Compounds depositing in the alveoli can be removed only by blood flow (if the compound is absorbed), biotransformation by Clara cells or type II alveolar cells (which contain cytochrome P450 enzymes), or macrophages.

Pulmonary edema, manifested as an acute respiratory distress syndrome, is caused by severe exposure of the alveoli (in humans) to acute toxicants such as phosgene, chlorine, xylene, and nitrogen oxides. Because the lung is the shock organ in cats, type I allergic reactions may manifest as primarily acute respiratory difficulties. Biotransformation in the lung, as in other tissues, may be a source of a toxic compound as an innocuous chemical is converted into a toxic one (e.g., paraquat, a herbicide metabolized by type II alveolar cells). Macrophage clearance may reflect phagocytosis; macrophage death is accompanied by the release of inflammatory mediators that can damage surrounding cells and contribute to the toxic effects of a drug. Compounds that cause pulmonary injury in humans as a consequence of the inflammatory response include asbestos, beryllium, coal dust, silica, and tungsten.¹⁵

AVOIDING ADVERSE DRUG EVENTS

Recommendations for avoiding specific toxicities have been given or are described in specific chapters for some of the described drugs. Appendix 5 offers antidotes for many drugs. The incidence of ADEs in general, and ADRs in particular, may be reduced by several proactive actions (Box 4-6), with client education playing an important role. Type B reactions are difficult to avoid because they are unpredictable. An awareness of potential toxicities will make them less likely. Frequent patient monitoring during therapy is the best means of reducing type B adverse reactions.

REPORTING ADVERSE DRUG EVENTS

Reporting ADEs is complicated by the difficulty in identifying them. In human medicine, methods have been defined whereby the causal relationship between a suspected reaction and a suspected drug can be assessed. None is universally accepted, but each includes some or all of the following criteria: the time between the administration of the drug and the onset of the reaction or the cessation of the drug and resolution of clinical signs; the course of the reaction, which may vary if the drug is continued or interrupted; the role of the drug and underlying disease being treated as a cause of the reaction; response to readministration of the drug; results of

Box 4-6

Actions to Take to Reduce the Risk of Adverse Drug Events

- 1. Obtain a definitive diagnosis before treatment, including previous treatment with drugs known to be associated with type B adverse drug events.
- 2. Use proper drugs according to recommended protocols.
- 3. Use alternative (less toxic) drugs when available.
- 4. Thoroughly evaluate the patient before and during treatment (e.g., physical examination and clinical pathology), with an emphasis on target organs of toxicity. This includes implementation of relevant testing that might identify a genetic predisposition to adversity.
- 5. Modify dosing regimens when appropriate.
- 6. Evaluate the responses to therapy and discontinue therapy if therapeutic effects are not evident.
- 7. Frequently monitor the patient for remission of clinical signs and discontinue therapy as early as possible.
- 8. Minimize multiple drug therapy and use of drugs known to cause drug interactions. This includes avoiding, when possible, drugs metabolized by the liver or other organs.
- 9. Alternate administration times for patients receiving multiple drug therapy, thus reducing the potential for drug interactions.
- 10. Educate the client regarding potential toxicity of a drug and the clinical signs associated with its use.
- 11. Report adverse events.

laboratory tests; and the history of previous administration of the drug.⁹⁸

Reporting of ADEs to the Center for Veterinary Medicine (CVM) of the FDA has markedly increased from 4000 in 1997 to nearly 25,000 a year in the past several years. The increase probably reflects, in part, the increased visibility of the CVM reporting program that accompanied improvements in the collection, analysis, and reporting of the adverse events.^{25,102} Several avenues are available for reporting an ADE. The animal pharmaceutical company can be directly informed by calling the Medical Affairs officer; by law, these ADEs must be reported to the CVM. The sequelae of reporting an animal adverse event to a human drug is not clear, but mandatory reporting is probably unlikely. In such situations the second route should be pursued: the CVM. The CVM provides directions for reporting ADEs. The form (FORM FDA 1932a, "Veterinary Adverse Experience, Lack of Effectiveness or Product Defect Report") can be downloaded or printed from http://www.fda.gov/cvm/adereporting.htm or by writing to the following address: ADE Reporting System, Center for Veterinary Medicine, U.S. Food & Drug Administration, 7500 Standish Place, Rockville, MD 20855-2773. Reports also can be reported by telephone (1-888-FDA-VETS). On receipt of an ADE by the CVM, a six-part scoring system is used to evaluate each reaction. The system takes into account previous experience with the drug, alternative causes, timing of the event in the context of dosing, overdosing, and response to drug removal or rechallenge if available.²⁵ Recently, the CVM's approach to assessing a potential ADE insofar as it's likelihood to lead to label changes or market withdrawals has come under fire; methods of analysis may undergo reassessment, which will, it is to be hoped, further refine the assessment process and improve accuracy. Results of the ADE reporting program and analysis by the CVM can be reviewed for each drug at the previously cited website. A third alternative to ADE reporting may be the Animal Poison Control Center (APCC) affiliated with the Animal Society for Prevention of Cruelty to Animals (ASPCA) (www.aspcsaapcc.org). The latter organization should be contacted by telephone (888-426-4435) if immediate support is desired for identification and treatment of a potential ADE that may prove life threatening to the animal. Support is likely to entail a \$50 consultation fee. Adverse events to animal biologics (vaccines, bacterins, and diagnostic kits) are not handled by the FDA but instead by the U.S. Department of Agriculture (800-752-6255), whereas adverse events to pesticides (topically applied external parasiticides) should be reported to the U.S. Environmental Protection Agency (800-858-PEST). Links to these agencies are available at the FDA website.

ADVERSE EVENTS TO HERBS AND BOTANICALS

Herbal or botanical products, more so than "dietary supplements" of animal origin, may be unsafe for several reasons. Adverse events are more likely when products are used in excess. Five broad classes of active chemicals exist in

plants: volatile oils (e.g., catnip, garlic, citrus), fixed oils, resins, alkaloids, and glycosides. Of these, fixed oils, often used as emollients, demulcents, and bases for other agents, are among the least toxic. Resins can be strong gastrointestinal irritants. Alkaloids are among the most pharmacologically active plant chemicals and include a wide range of potentially harmful products. The risk of adverse effects to herbs is increased by the presence of many active ingredients in the same plant (see the discussion of drug interactions in Chapter 2). Indeed, herbalists often used unpurified plant extracts because of the possibility that different chemicals might interact synergistically. The amount of active ingredients may vary dramatically with the portion of the plant (i.e., leaf, flower, stem, root, seed) administered, thus influencing safety. Whereas one portion of the plant might be safe, another portion might not be. Herbalists often administer the whole plant in the belief that, in contrast to the purified extract, toxicity is reduced by a buffering effect of the whole herb. During growth of the plant, environmental contaminants may become unintended residues during the manufacturing process. Microorganisms, including bacteria, fungi, and molds, can either directly contaminate the product or produce contaminating toxins. Bacterial contamination is more likely with root products as opposed to flower or leaf products. Heavy metals such as lead, cadmium, or mercury increasingly are contaminating plants exposed to environmental pollutants. Further, unless the herbal products are grown organically, insecticides and pesticides may contaminate them. Factors during production and storage, such as storage length and conditions, can alter herbal potency and quality. Finally, herbal products might be supplemented with active ingredients (often referred to by the herbal or botanical name or simply not labeled) such as ephedrine, caffeine, or fenfluramine (the latter ingredient being one of the two ingredients in the notorious Fen-phen dietary supplements).

KEY POINT 4-3 The risk of an adverse drug effect with dietary supplements is increased by unsupervised client use; the lack of mandated premarket approval or premarket assessment of quality, safety, and efficacy; the inherent properties of herbal products; and the lack of an effective postmarket surveillance program.

The lack of quality control in labeling of herbals, botanicals, or other novel ingredients (e.g., "nutraceuticals") may contribute to the advent of adverse effects with these products.¹⁰³ Many herbal products are not labeled with the concentration per dosing unit of the ingredient of interest. Those that do may contain more or less than the labeled dose, presenting a risk of overdosing or underdosing. Manufacturers may improperly identify plants. Even if properly identified, the consumer may have difficulty in identifying a product as potentially dangerous because an herbal name often is used in place of the more easily recognized chemical name (e.g., guarana for caffeine or ma huang for ephedrine). Further, an herbal agent may be referred to by many different names. The FDA has become more proactive in directing manufacturers to list generic drug names instead of or in addition to herbal names. Proposed sources of quality assurance data for animal dietary supplements include the manufacturer of the product; the Association of American Feed Control Officials; the National Animal Supplement Council; laboratories such as Consumer Lab (www.consumerlab.com); the United States Pharmacopeia (USP) dietary supplement verification program (http://www.usp.org/USPVerified/dietarySupplements); the American Herbal Pharmacopeia (http://www.herbal-ahp.org), which offers the Botanical Safety Handbook and Herbs of Commerce; and Consumer Laboratories, a for-profit organization that provides quality assessment for a fee. However, much of its work is also independent, supported by income generated through its website. For approximately \$30 per year, this site provides results of quality testing for a variety of products. Although most of the products are marketed for humans, several veterinary products recently have been evaluated for quality.

A number of other herbs have been associated with adverse effects (Table 4-8). This list is far from inclusive, in part because an effective adverse event reporting system is lacking

Table 4-8	or Bot	amples of Therapeutic Herbs Botanicals Associated with dversities*		
Ginkgo biloba		Bleeding, altered platelet function		
St. John's wort		Gastrointestinal disturbances, allergic reactions, fatigue, dizziness, confu- sion, dry mouth, photosensitivity		
		Serotonin syndrome (when combined with other similarly acting drugs)		
Ephedra (ma hı	iang)	Hypertension, insomnia, arrhythmia, nervousness, tremor, headache, seizure, cerebrovascular event, myocardial infarction, kidney stones		
Kava		Sedation, oral and lingual dyskinesia, torticollis, oculogyric crisis, exacer- bation of Parkinson's disease, painful twisting movements of the trunk, rash		
Aconitine		Cardiotoxic		
Garlic		Altered platelet function		
Ginger		Altered platelet function, tachycardia and/or hypertension		
Ginseng		Altered platelet function		
Feverfew		Altered platelet function		
Echinacea		Hepatotoxicity		
Valerian		Hepatotoxicity		
Goldenseal root	t	Electrolyte disturbance		
Licorice		Electrolyte disturbance		
S-adenosylmeth	nionine	Serotonin syndrome (when admin- istered in combination with other similarly acting drugs)		
*Many borbo or boto	nicolo oro oco	ediated with advaraities. The use of various borbal name		

*Many herbs or botanicals are associated with adversities. The use of various herbal names for each product may preclude detection of adversity. The lack of an effective adverse event reporting system hinders detection and reporting of adversities involving herbs.

in either human or veterinary medicine. Although infrequently reported, adverse events have occurred in veterinary patients receiving novel ingredients. The ASPCA APCC published a report of adverse reactions in 47 dogs that ingested a popular weight loss dietary supplement containing guarana (caffeine) and ma huang (ephedrine); 17% of the dogs died after the appearance of clinical signs associated with central and cardioactive compounds.

Although mechanisms for reporting adverse events in human or veterinary medicine toward herbal or botanical products currently are limited, effective mechanisms are evolving. Among the FDA's postmarket responsibilities toward (human) dietary supplements is the monitoring of product safety. Note, however, that the FDA may remove a potentially dangerous supplement only when and if the product presents an "imminent hazard to public health or safety." The burden of proof is on the FDA, not (as with drugs) on the manufacturer. The FDA recently implemented the Adverse Events Reporting System (AERS) to be used as a monitoring tool for dietary supplements as well as other medicinal products. Adverse events also can be reported for human products through the FDA's MedWatch program. Some recent FDA actions taken to address the safety of dietary supplements can be reviewed at www.consumerlab.com, at the FDA's Medwatch program, or the FDA's Center for Drug Evaluation and Research (CDER). Unfortunately, the current FDA sites for reporting adverse events to dietary supplements do not pertain to veterinary products. Reporting to the APCC may continue to be the most effective means of reporting adverse reactions of animals to medicinal agents, particularly those for which a designated watchdog does not exist (e.g., unapproved products), in part because of the APCC's ability to analyze and quickly report important trends.

ADVERSE EVENTS TO COMPOUNDED PREPARATIONS

Quality compounding is critically important to the safe and effective administration of drugs to animals, particularly the very small and very large. The role of compounding in small animal medicine was recently reviewed.¹⁰⁴ Compounding of animal drugs is specifically legalized by the Animal Medicinal Drug Use Clarification Act (AMDUCA; 21 C.F.R Section 530) (See Appendix 5). However, compounding must be implemented in accordance with the relevant provisions of extralabel drug use. According to the FDA, legal sources of drugs to be compounded are limited to FDA-approved finished forms of either animal or human drugs; the FDA makes no distinction as to which (animal versus human) is the preferred source for companion animal compounding. Because no other source is legalized, all other sources are considered by the FDA to be illegal, including bulk substances (e.g., pure powder) or non-FDA-approved finished drug products obtained outside of the United States. However, formulation of selected compounded prepartions is likely to be easier, yielding a better product, if prepared from pure active ingredient (i.e., bulk). The risk of supporting compounding from bulk includes the temptation to manufacture, rather than compound. Compounding, particularly for products that mimic a commercially available drug, serves as a major disincentive for manufacturers of animal drugs to pursue the approval process. Further, whereas approved animal or human drugs have undergone rigorous, scientific testing to ensure drug safety and efficacy for the patient, compounded products have not. Although pharmacists are directed to compound from written protocols and maintain written records of compounding activities, pharmacists are not currently required to ensure accuracy in product preparation, including product stability. Although a reputable pharmacy may randomly check accuracy of selected drugs, this act currently is voluntary and will be limited to selected drugs and aliquots. Although guidelines exist for establishing expiration dates of compounded products, dates are not necessarily based on scientific data. The United States Pharmacopeia has published a Pharmacist's Pharmacopeia. Further, the Pharmaceutical Compounding Accreditation Board (PCAB) has recently implemented a robust accreditation program. Adherence to its guidelines will minimize the risk of adverse reactions associated with compounded products (see www. pcab.org).

KEY POINT 4-4 The risk of an adverse drug effect with compounded products is increased by the existence of regulatory oversight and can be minimized by prescribing only through pharmacies accredited by PCAB.

The risks associated with failed delivery (too much or too little) of a compounded product are added to risks associated with the approved finished dosing form of a drug. Adverse events associated with compounded products should be reported to either the (veterinary) pharmaceutical manufacturer or the FDA; if reported to a veterinary manufacturer, the manufacturer is required by law to forward the report to the FDA, although whether this is true for a modified finished dosing form is not clear. Adverse events associated with compounded products may occur at the pharmaceutical phase (during preparation) or, largely because of failed absorption, at the pharmacokinetic phase. The more sophisticated the preparation, the more likely it is that adverse events will occur because of diminished or excessive drug delivery.

Ingredient Errors

Compounding from bulk substances is easier than from approved finished dosing forms because excipients or other materials do not interfere with product preparations. Further, excipients in the finished dosing form will not interfere with dissolution of the drug in the vehicle. However, the use of an approved finished dosing form of a drug for compounding offers a major advantage to use of a bulk substance in that the approved drug has passed stringent tests of analysis regarding drug purity and potency and the absence of contaminants. As such, products formed from bulk substances are associated with greater risks compared with products compounded from approved drugs. In contrast, for bulk substances the burden of purity and accuracy lies with the pharmacist, and there is no mechanism to ensure that this burden has been met. All products, active ingredient or excipients (fillers, preservatives, etc.), domestic or foreign, should either meet USP or equivalent standards or be purchased after FDA inspection. Drugs that are still under U.S. patents are often obtained in this manner. Bulk substances will be accompanied by a credible certificate of analysis. The need for validation of ingredient sources (including all active and inactive substances) is paramount as inexpensive bulk substances increasingly are being acquired from uninspected foreign (particularly Asian) sources.

The active drug in a compounded product might also be substituted for an alternative drug; the substituted drug may not have the same pharmacokinetic or pharmacodynamic characteristics (discussed in more detail in the next section). Veterinarians should indicate on prescriptions that unapproved substitutions are not acceptable for compounded products.

Mathematical Errors

Mathematical errors are probably the most common and potentially the most lethal reason for pharmaceutical compounding errors. Compounding is vulnerable to mathematical mistakes because of its very nature (prescription driven, small volumes) and because much of the equipment and technology that facilitate accuracy and precision of finished dosing forms are not (or should not be) used during compounding. In addition to the source of the ingredient being potentially problematic, pharmacists may substitute drugs without acquiring clinician permission. Mathematical errors may also reflect substitution of the active ingredient. For example, the active drug content may differ, as is demonstrated by metronidazole. The recipe for metronidazole benzoate should contain 1.6 mg for each 1 mg of metronidazole hydrochloride (or the dose must be similarly increased). Bromide offers another example: 1 g of the sodium bromide contains more bromide (774 mg) than the potassium salt (692 mg).

Preparation and Storage Errors

Chemical reactions (oxidation, reduction, hydrolysis) are facilitated by changes in humidity, light, pH, presence of oxidizing trace metals, and increasing environmental temperature. Excipients may enhance instability as a result of changes in pH or the presence of disintegrating agents. Degradation products (drugs or excipients) can cause adverse events. Excipients that are critical to the finished dosing form increase the risk of instability in product compounded from an approved source. Whereas approved products undergo intensive scrutiny with regard to stability and potency, compounded products do not; recipes for compounded preparations rarely are associated with studies that ensure stability or delineate conditions for storage.

Simple syrups (which tend to be acidic), preservatives, combination drugs, or other ingredients can alter drug pH and thus ionization (diffusibility) or stability. The more drugs mixed together in a single preparation, the greater the risk of chemical drug interactions. For example, weak acids and weak bases are likely to chemically inactivate one another. Interactions may occur among the drugs or excipients. As an example, only 54% of a fluorinated quinolone (orbifloxacin) was found to be present when prepared in Lixotinic as a vehicle compared with simpler syrups.

Particle Size

Compounding from approved drugs (legal) is more difficult than from bulk drugs (illegal) because excipients are more likely to result in undissolved macroscopic or microscopic precipitates that indicate undissolved and thus nondiffusible ineffective drug. Sedimentation of undissolved particles may result in caking at the bottom of the drug receptacle; difficulty in shaking or rapid sedimentation (common) after shaking can result in erratic and unpredictable doses. Crushing of any oral tablet may result in unequal particle sizes in the preparation, which in turn will yield different surface areas and different rates of absorption. Fine crushing of the product such that it is no longer a suspension increases the concentration of soluble excipient; chemicals, including those added to the finished dosing form to facilitate degradation, can cause drug instability. Crushing an oral tablet for preparation in a syrup may also lead to unequal distribution of dissolved drug in the finished preparation, and mixing the drug such that it is equally distributed throughout the preparation may not be possible. Repackaging oral tablets or capsules into smaller dosing units may also affect drug efficacy. Diluents such as starch and dextrose might impede oral absorption. Preparation of an oral formulation from an injectable solution to enhance accuracy of dosing is more likely to be inappropriate if the drug salt is different between the preparations. If the injectable product is presented in powder form, the drug is likely to be unstable in liquids and may be destroyed when added to liquid (oral solutions). The addition of flavoring agents to oral products may increase drug instability because of changes in pH or the increased risk of microbial growth (e.g., as with syrups).

Because selected commercial oral preparations have been formulated to alter (slow or facilitate) drug delivery, reformulation of such products is discouraged. Compounding altered release products from bulk substances requires sophisticated techniques not generally available through pharmacists. Enteric-coated or spansule products should not be crushed. Although spansule products might be reformulated without crushing, the amount of drug in each spansule is not necessarily predictable, and random distribution of drug content is likely to yield erratic dosing. Cyclosporine is a complex molecule characterized by poor oral bioavailability; oral absorption requires bile acids or special formulation as a microemulsion product. As such, it is an example of a drug for which compounding should be approached cautiously and be supported by therapeutic drug monitoring. In the author's drug-monitoring laboratory, cyclosporine blood concentrations were not detectable (two different samples, 2 weeks apart) in one cat receiving a product compounded from an approved microemulsion human product. In keeping with recommendations that the unadulterated animal-approved version be used at the same dose, concentrations expected at the administered dose were detected within 1 week of the change in drug product.

Injectable Products

Administration of injectable products is inherently associated with a higher level of risk compared with administration of topical or oral products because of more rapid drug delivery, risks associated with administration of suspensions rather than solutions, potential impact of impurities (including endotoxin), and need for sterility. Actions taken to ensure sterility and removal of impurities may cause drug degradation. Endotoxin (which is essentially ubiquitous in the environment) is difficult to remove. Without testing, its absence is impossible to document, yet its presence can be lethal. The USP has generated guidelines, and state laws generally delineate regulations specifically for the compounding of injectable products. Veterinarians should be reluctant to prescribe compounded injections, and when doing so, they must be confident that the compounding pharmacist follows these criteria.

Topical Products

Although administration of topical products generally is associated with fewer risks compared with administration of systemic products (the exception is ophthalmic products, which also should be sterile), compounding the proper product can be challenging. The USP has promulgated guidelines for the compounding of topical ingredients, including guidelines designed to ensure drug dissolution and drug movement from the vehicle into the skin. For example, solid ingredients should be reduced to the smallest reasonable particle size, and the active ingredient should then be added to other substances necessary to dissolve the drug so that a uniform liquid or solid dispersion is achieved. Uniformity of dispersion should be demonstrated by spreading a thin film of the finished formulation on a flat transparent surface. Visual examination of a compounded product should be implemented to identify obvious problems with dissolution and so on. Care must be taken to ensure that ingredients are not caustic, irritating, or allergenic. Vehicle selection can be quite difficult: undissolved drug cannot pass into the skin; drug that has too great an affinity for the vehicle will remain in the vehicle. Transdermal gels are examples of products in which particular care must be exercised.

Few published reports exist that delineate adverse events resulting from inappropriate compounding. Despite indications of frequent problems with compounded products, the FDA receives few reports regarding adverse events related to compounded products. This reflects, in part, the lack of mandated reporting of adverse events. However, it also reflects the difficulty in recognizing therapeutic failure resulting from failed delivery. The latter is likely to be detected only if the information is sought and the drug or response to the drug can be easily monitored. Numerous studies have focused on accuracy in labeling of compounded products, particularly in equine medicine. Products found to be mislabeled include omeprazole, ivermectin (both pirated drugs), ketoprofen (one product contained only 50% of the labeled content, whereas 12 of 13 contained close to 100%), amikacin (the percentage of labeled content ranged from 59% to 140%; none was within 10%), and boldenone (all within 15% of labeled content, but two of five contained up to 5% of impurities).

DRUG EFFECTS ON CLINICAL LABORATORY TESTS

A drug-induced disease is often first suspected on the basis of an abnormality in a diagnostic test that cannot be easily attributed to a disease process. Many drugs cause changes in diagnostic tests but are not associated with disease. Confirming the cause-and-effect relationship between drug and abnormalities can be very difficult unless the drug can be discontinued and then readministered.

Drugs interfere with diagnostic tests either directly, at the level of the analytical procedure (in vitro), or by induction of a physiologic change in the patient (in vivo). Of the two levels of interference, it is likely that analytical interferences will occur regardless of the species from which the sample was collected. Thus interferences affecting analytical procedures are better documented in veterinary medicine because they generally can be extrapolated from human analytical testing. Mechanisms of in vitro interference vary. Drugs that interfere with endocrine testing are described as adverse drug events of the endocrine system.

If analytical (in vitro) interference by a drug is suspected, the laboratory should be contacted and questioned. This is particularly important if the patient is receiving drugs structurally similar to the drug being tested. Cross-reactivity between the drug and the test can falsely increase test values. For example, therapeutic corticosteroids cross-react with endogenous corticosteroid hormones, although the percentage of cross-reactivity varies with the assay and the drug. Some drugs cause cytotoxicity (e.g., aminoglycoside-induced nephrotoxicity); some stimulate changes without toxicity (e.g., glucocorticoidinduced alkaline phosphatase); and others interfere with hormones. Drugs can interfere with diagnostic tests in many other ways. The American Association of Clinical Pathologists publishes a handbook that summarizes changes in clinical pathology that might be drug induced. Access to this text or its information may be possible by contacting the appropriate diagnostic laboratory.

Few studies focus on the impact of drugs on clinical laboratory tests. Examples include the impact of bromide (when used as an anticonvulsant) on chloride concentrations when flame ionization is used: the two cannot be distinguished when this method is used, and bromide, being present in much higher concentrations, will artifactually increase chloride. The impact of selected antimicrobials on urine glucose also has been documented in the dog. At 22 mg/kg, cephalexin caused falsepositive glucose in 50% of dogs at 6 hours and 33% of dogs at 24 hours when using selected commercially available glucose strips (Chemstrips, Boeringer Ingelheim). A tablet test (Clinitest, Miles Inc.) indicated false-positive results in 100% of dogs (n=6) at 6 and 24 hours after administration of cephalexin at 22 mg/kg; 50% of dogs receiving enrofloxacin at 5 mg/kg and 100% receiving 10 mg/kg also yielded false-positive results.¹⁰⁵ Enrofloxacin also caused false negatives at concentrations as low as 20 µg/mL in urine spiked with dextrose at 0.5% and above.

Therapeutic Drug Monitoring

Dawn Merton Boothe

Chapter Outline

DRUGS AND INDICATIONS IMPLEMENTATION Number and Timing of Samples: One Versus Two, Peak Versus Trough Other Considerations

INTERPRETATION

Information Needed for Therapeutic Drug Monitoring Dose Modification with Kinetic Calculations Dose Modification Without Kinetics (Proportional Adjustment) SUMMARY

Therapeutic drug monitoring (TDM) is a tool for guiding the design of an effective and safe regimen for drug therapy in the individual patient. Monitoring can be used to confirm a plasma drug concentration (PDC) that is above or below the therapeutic range, thus minimizing the time that elapses before corrective measures can be implemented for the patient.¹⁻³ Knowledge of the principles of drug disposition (see Chapter 1) and the factors that determine these principles in the individual patient (see Chapter 2) facilitate an understanding of the use of and need for TDM.

Fixed dosing regimens are designed to generate PDCs within a therapeutic range-that is, achieve the desired effect without producing toxicity. Dosing regimens are based on the patient's clinical response to the drug. Therapeutic success is most likely to occur if doses are based on scientific studies performed in the target species intended to receive the drug for the intended reason. Marked interindividual variability has, however, been confirmed for many drugs^{4,5} owing to physiologic (e.g., species, breed, age,⁶ gender), pathologic (e.g., renal, hepatic, cardiac diseases)7-10 or pharmacologic (i.e., drug interaction)^{5,7,11,12} effects. Prudent clinicians modify dosing regimens when possible to compensate for the impact of some of these factors on drug disposition. However, the combined effects of these factors are often unpredictable. A trial-and-error approach to dose modification may be successful but is most appropriate when response to the drug can be easily measured. Examples include "to effect" drugs such as gas inhalants and ultrashort thiobarbiturate anesthetics, rapidly acting anticonvulsants such as diazepam, and lidocaine for the treatment of ventricular arrhythmias. The trial-and-error approach also might be reasonable for illnesses that are not serious or do not require immediate resolution and for drugs characterized by large therapeutic windows, that are generally safe at high doses, However, trial-and-error modification can be inefficient and potentially dangerous when the drug response cannot be easily measured, the drug is characterized by a narrow margin of safety, or the patient's life is threatened.

DRUGS AND INDICATIONS

TDM is not indicated for all drugs; rather, it is indicated when patient health is at risk (Box 5-1). Not all drugs can be monitored by TDM; certain criteria must be met (Box 5-2).¹³ Patient response to the drug must correlate with PDC. Drugs whose metabolites are active (e.g., diazepam) or for which one of two enantiomers compose a large proportion of the desired pharmacologic response generally cannot be monitored effectively by measuring the parent drug.14 Rather, all active metabolites, the parent drug, or both or the pharmacologically active enantiomer should be measured. The drug must be measurable at concentrations within the targeted therapeutic range in a relatively small sample size, and analytic methods must be available to detect the drug rapidly, precisely and accurately in the target species.¹⁵ Methods must be specific for the drug of interest and able to differentiate it from other compounds. Prior to choosing a laboratory for monitoring purposes, the laboratory also should be queried regarding quality-control procedures to ensure that they are followed and assays used in animals have been validated for that species. Ideally, the laboratory will participate in some type of external validation program. Attention should be given to how the sample collected from the patient is handled. The cost of the analytic method must be reasonable. Drugs that meet these criteria and for which TDM has proved useful in veterinary medicine include, but are not limited to, selected anticonvulsants (phenobarbital, bromide, selected benzodiazepines zonisamide and levetiracetum), antimicrobials (e.g., aminoglycosides-gentamicin, and amikacin); cardioactive drugs (digoxin, procainamide, lidocaine, and quinidine); theophylline, and cyclosporine (Table 5-1).

Monitoring may be most effective if either or both minimum (C_{min}) and maximum (C_{max}) ranges have been established for the drug in the species and for the disease being treated.⁴ However, the importance of the therapeutic range should not be overestimated. Although not "normals," therapeutic ranges of drugs also are population statistics, based on

Box 5-1

Drugs for Which TDM Is Most Useful

- 1. Serious toxicity (e.g., phenobarbital, cardiac drugs)
- A poorly defined or difficult to detect clinical end point (e.g., anticonvulsants, behavior modifying drugs, immunomodulators)
- 3. A steep dose–response curve for which a small increase in dose can result in a marked increase in desired or undesired response (e.g., theophylline, phenobarbital for cats)
- 4. A narrow therapeutic range (e.g., most cardiac drugs)
- 5. Nonlinear pharmacokinetics that may lead to rapid accumulation of drugs to toxic concentrations (e.g., phenytoin or, in cats, phenobarbital)
- 6. Combination drug use that may lead to undesirable adverse effects caused by drug interactions (e.g., enrofloxacin-induced theophylline toxicity or chloramphenicol-induced or cloraz-epate-induced phenobarbital toxicity)
- 7. Drugs for which therapeutic failure may lead to patient harm (e.g., anticonvulsants, cardiac drugs, antimicrobials)
- 8. A target therapeutic range (C_{max} and /or C_{min}) has been validated in the target species with the target drug

the PDC at which most patients (e.g., 95%) with the targeted disease might be expected to respond. However, although the therapeutic range offers a reasonable target for most animals, exactly *where* in the range the individual patient will respond is not known. It is this patient-specific concentration that is identified through monitoring—that is, monitoring establishes the therapeutic range for the individual patient. As such, it is indicated to establish the baseline response in a patient that has adequately responded to therapy. Note that some animals will respond at concentrations below or above an established therapeutic range. However, dosing regimens need not necessarily be increased or decreased, respectively, for those patients unless the patient is put at risk for subtherapeutic failure or toxicity, respectively.

Therapeutic ranges do offer a target for drug therapy and are ideally based on well-controlled clinical trials in the target species. However, most recommended therapeutic ranges in animals have been extrapolated from those determined in humans. Although these ranges have proven useful, nonethe-less, studies confirming the applicability of these ranges to animals are warranted. Determination of these ranges can be facilitated if adequate patient information accompanies a patient sample submitted for monitoring (see Box 5-1). Procainamide is an example of a drug for which recommended therapeutic ranges might differ between dogs and humans because of pharmacokinetic differences. Dogs do not produce the acetylated active metabolite as efficiently as humans; therefore procainamide concentrations should be higher in dogs than in humans. Primidone (rarely used currently) is an example in cats: its efficacy in dogs depends on conversion to phenobarbital, which does not happen to a significant degree in cats. Bromide offers another example of pharmacodynamic differences: whereas concentrations above 1.5 mg/mL might be considered toxic in people, they

Box 5-2

When to Implement Monitoring

- (1)"Start-up": (a) Maintenance dose. Monitoring at baseline in a responding animal to establish the therapeutic range for the patient. (b) Loading dose maintenance dose combination (including a "mini" loading dose): a sample should be collected after a loading dose has distributed (the day after loading bromide or within 2 hr after loading with phenobarbital) and at one half-life into the maintenance dose. If the two samples do not match, the maintenance dose should be proportionately adjusted. A steady state sample should be collected once steady state has been reached.
- (2)"Check up": Rechecks: to proactively ensure that effective concentrations are maintained and safe concentrations are not exceeded. The frequency varies with the seriousness of therapeutic failure or the risk of toxicity. Intervals of 6 to 12 months are generally recommended for the well-controlled patient and 3 to 6 months for the poorly controlled patient. For immuno-modulators, 3- to 6-month intervals for life-threatening disease.
- (3)"What's up": (a) Establish a cause for therapeutic failure or to confirm toxicity. For patients that have not responded well to a new drug or a new dose, despite doses at the mid-to-high end of the recommended dosing range; or in previously wellcontrolled patients that fail therapy or develop signs of adversity. (b) Respond to changes in patient factors: progression or improvement of cardiac, renal, or hepatic disease; changes in clearance and, to a lesser degree, volume of distribution may change elimination half-life and thus peak or trough concentrations.(c) Detect drug-drug or drug-diet interactions. Changes in diet or addition of drug that may interact: baseline concentrations should be reestablished before and after a change if there is a risk that the change in diet or drug therapies may alter the disposition of the drug of interest. For example, bromide should be measured before and at steady state after the administration of a new diet; phenobarbital should be monitored before and after beginning chloramphenicol or an imidazole antifungal, cyclosporine should be monitored before and after ketaconazole (or any imidazole) or azithromycin therapy is implemented, etc.

are in the low- to mid-therapeutic range in epileptic dogs. The therapeutic range for a drug also varies with the therapeutic intent (e.g., cyclosporine and perianal fistulas versus immunosuppression).

As with clinical pathology reference ranges, the range for a specific laboratory also may vary with the methodology, and specifically whether or not metabolites are detected by the methods. As such, the laboratory should be specifically queried regarding its therapeutic range for a particular assay. Assays that are based on antibodies (e.g., enzyme-linked immunosorbent assay [ELISA], radioimmunoassay [RIA], polarized immunofluorescence [PIFA]) may detect both the parent compound and those metabolites most chemically similar to it. Monoclonal antibody–based immunoassays are less likely to detect metabolites than polyclonal antibodybased assays but nonetheless, may not be able to discriminate among very subtle changes in drug chemistry induced by metabolism. Therapeutic ranges for antibody-based assays

Drug	Therapeutic Range*	Half-Life	Time to Steady State	Peak	Trough	Comments
Amikacin	2-25 μg/mL	1-2 hr	NR	0.75-1 hr	2 HL (3-6 hr)	Collect in or transfer to plastic; concentrations are likely to be nondetectable at true trough. Collect trough at 4 to 6 hr after peak for kinetics.
Amitryptyline	250-750 nmol/L (human)					
Aspirin	50-100 μg/mL	8 hr (D) 38 hr (C)	NR 8 days	2-4 hr	BND	
Benzodiazepines	100-200 ng/mL	<8 hr	NR		BND	
Bromide (sodium or potassium)	1-3.5 mg/mL	14-21 days	2-3 days		BND	Bromide will interfere with many assays that measure chloride, causing false increases.
Carbamezepine	16-51 μmol/L					Human data; includes epoxide metabolite, which contributes to efficacy. Relevance to animals questionable.
Carvedilol	Trough above 100 ng/mL	0.3 to 4.3 (D)	NR	2 hr	BND	Concentrations may be nondetectable at trough in some patients. A peak and trough might be initially collected to determine half-life and collection times for subsequent sampling.
Clomipramine	800-1600 mmol/L					Human data; relevance to animals questionable.
Cyclosporine (CsA)	Immunosuppression: 2 hr peak: 800-1400 ng/mL Immunosuppression: 12 hr trough: 400-600 ng/mL Inflammatory allergic disease: 12 hr Trough: 250 ng/mL Perianal fistula: 12 hr trough: 100-600 ng/mL	3-8 hr	NR	2 hr	BND (12 hr)	For atopy (and all other diseases), monitoring might be implemented once patient has responded to deter- mine the range for that patient. Monitoring of peak and trough is particularly important in the presence of drugs that decrease or increase CsA metabolism of absorption.
Digoxin	0.8-2 ng/mL	36 hr (see comments)	7 days	Toxicity : 2 (glass only)	Efficacy: BND	Glass only. Do not use red rubber stopper. Marked variability in kinetics induced by disease and drug therapy indicates the need for both peak and trough concentrations such that a half-life can be calculated for this toxic drug.
Fluoxetine	350-3000 nmol/L					Human data; relevance to animals questionable.
Gabapentin	14 to 50 μmol/L					Human data; relevance to animals questionable. This is not an established range in humans but a range in which response appears to be reasonable.
Gentamicin	0.5-1.5 µg/mL 5-8 µg/mL	0.9-1.3 hr	NR	0.75-1 hr (plastic only)	2 half-lives (3-6 hr)	Collect in or transfer to plastic; concentrations are likely to be nondetectable at true trough. Collect trough at 4 to 6 hr after peak for kinetics.

Levetiracetam	5.5-20 ng/mL	2-3.6 hr (regu- lar release product)	- NR	2 hr	BND	Peak and trough recommended initially to determine patient half-life; if single samples thereafter, trough concentration should target therapeutic range. Peak concentration may need to be four-fold to eight-fold higher than trough.
Methotrexate	Less than 1 µmol/L					
Phenobarbital	14-45 μg/mL	32-75 hr	14-16 days	4-5 hr	BND	Peak and trough recommended only in difficult-to- control patients so that short half-life might be detected. Trough recommended as single sample.
Phenytoin	40 to 80 μmol/L					Inactive cross-reacting metabolite may accumulate with renal disease and cause false increase.
Primidone	Based on phenobarbital	32-75 hr	14-16 days	4-5 hr	BND	See information on phenobarbital.
Procainamide	25-50 μg/mL	2.9 hr	NR	2-4 hr	BND	
Sirolimus	5-15 ng/mL					Human data; relevance to animals questionable. This is not an established range in humans but a range in which response appears to be reasonable.
Theophylline	10-20 µg/mL	5.7 hr		2 hr	BND	
		7.9 hr	NR	2 hr	BND	
Thyroxine (T ₄)	1-3.5 μg/dL (12.9-45 nmol/L) (D) 1-4 μg/dL (12.9-51.5 nmol/L) (C)	12-15 hr (D)	NR	4-6 hr	BND	
Free Thyroxine (fT_4)	1-3.5 ng/dL (12.9-45 pmol/L) (D) 1-4 ng/dL (12.9-51.5 pmol/L) (C)	5-6 hr (D)	NR	4-6 hr	BND	
Thyronine (T ₃)	0.5-1.8 ng/mL (D) 0.4-1.6 ng/mL (C)	5-6 hr	NR			
Zonisamide	10-40 µg/mL	16-65 hr	3-10 days	2 hr (D)	BND	Peak and trough recommended initially to determine patient half-life; if single samples thereafter, trough concentration should target therapeutic range.

BND, just before next dose; NR, not relevant; HL, Half-life (elimination or disappearance); D, *dog*; C, cat *See also Chapter 27, Anticonvulsants. Serum separator tubes, in general, should not be used for therapeutic drug monitoring samples. Some human therapeutic ranges have not been applied to animals.

generally are higher than those that detect only the parent compound. Which assay is preferred depends on the activity of the metabolites: if the metabolite is active, immunoassays may more accurately predict response compared with assays based on parent compound only. Cyclosporine, benzodiazepines, procainamide, behavior modifying drugs, and beta blockers are examples of drugs that might have active metabolites.

KEY POINT 5-1 A therapeutic range, is not a "normal," but like a "normal" is a population statistic. Monitoring should be used to determine the patient's therapeutic range, which may be below or above the population therapeutic range.

The cost of monitoring will vary among drugs, depending in part on the methods used. An advantage of high-performance liquid chromatography (HPLC) assays is their specificity for the target compound, and discrimination between parent compound and metabolites. However, assays based on HPLC tend to be more expensive because the methods are tedious, generally requiring very lengthy assay time, greater instrument and personnel dedication, and more sophisticated technology compared to that required for automated assays. Automated assays tend to more predictable, with quality assurance easier to achieve.

IMPLEMENTATION

Number and Timing of Samples: One Versus Two, Peak Versus Trough

Samples for monitoring generally are collected at peak (C_{max} , highest PDC during a dosing interval), trough (C_{min} , lowest, generally just before the next dose), or midway during the dosing interval. The type of sample and the number of samples collected depend on the goal of monitoring and the amount of drug that is eliminated during a dosing interval—that is, the elimination half-life of the drug.

For drugs with a long half-life compared to the dosing interval, because drug concentrations will not fluctuate significantly during the interval, variability in drug concentrations may reflect instrument variability, rather than drug disposition. For such drugs (e.g., bromide and, in most patients, phenobarbital or zonisamide), the timing of sample collection probably is not important and a single sample collected at any time is sufficient. However, a trough sample just before the next dose is almost always the lowest concentration that will occur with each dose, and as such is generally recommended if a minimum concentration must be maintained (e.g., anticonvulsants). In general, response to therapy and TDM should not be performed unless maintenance dosing has been sufficiently long for PDC to reach "steady state" (3 to 5 drug half-lives). An exception includes situations in which a loading dose has been administered (see below). If a loading dose is not given, the drug will accumulate (see Chapter 1) as steady state is reached (Figure 5-1). The time to steady state varies among drugs and for some drugs is quite variable among animals (see Table 5-1).

For drugs with very-long half-lives, the clinician may want to proactively assess the likelihood that the dose will result in targeted drug concentrations at steady state. Concentrations achieved after one half-life of dosing can be doubled to predict steady state concentrations. If predicted deviates substantially from target, the dose can be modified at that time, with a confirmatory check at steady state.

In contrast to drugs with a long half-life compared to the dosing interval, if the drug elimination half-life is sufficiently smaller than the interval such that peak and trough concentrations fluctuate by 25% or more, both timing and number of samples should be based on the intent of monitoring. For example, if toxicity is a concern, a single concentration might be sufficient and a peak concentration (generally 2 hr post oral dosing) is preferred. In contrast, if efficacy throughout a dosing interval is the priority, a single sample might be sufficient, but a trough sample might be preferred. The least helpful sample is one collected mid-interval. However, caution is indicated with either a single peak or a trough because in both situations the information provided with a single sample does not reflect the state of drug concentrations for the duration of the dosing interval. For drugs with short half-lives, while each dose is likely to reach or exceed peak concentrations that approximate the maximum recommended range, each trough concentration that occurs just before the next dose is likely to reach or drop below the minimum therapeutic range. If trough concentrations for such a drug are determined to be nontherapeutic and a decision is made to increase the dose, while trough concentration may exceed the target minimum as intended, peak concentrations may also become toxic. If peak concentrations are toxic and a decision is made to lower the dose, although peak concentrations may drop below the toxic range as intended, trough concentrations may then become subtherapeutic. An added advantage to collection of both peak and trough concentrations is that the elimination half-life of the drug can then be determined, providing a basis for determining the most appropriate dosing interval.

One reason that either a peak or trough might be selected is the recommended therapeutic range is based on either a peak or a trough sample. However, such recommendations generally assume the recommended dosing interval also is being followed. This is exemplified by cyclosporine, for which the recommendations for efficacy for immune suppression (extrapolated from humans) are based on the assumption of a 12-hour dosing interval and a sample collected at either a 2-hour peak or a 12-hour trough.

For some drugs, the elimination half-life changes across time in the patient. The decision to collect both a peak and trough for such drugs may depend on the elimination half-life, which in turn, can be documented as short only by collecting both a peak and a trough sample. This is exemplified by phenobarbital, for which the elimination half-life may initially be longer than the dosing interval (i.e., more than 48 hours) but after induction (i.e., several months into therapy) may be much shorter (i.e., less than 12 hours) in the same patient (Case Study 5-1). Digoxin provides a good example of the risk associated with collecting only a single sample when assessing

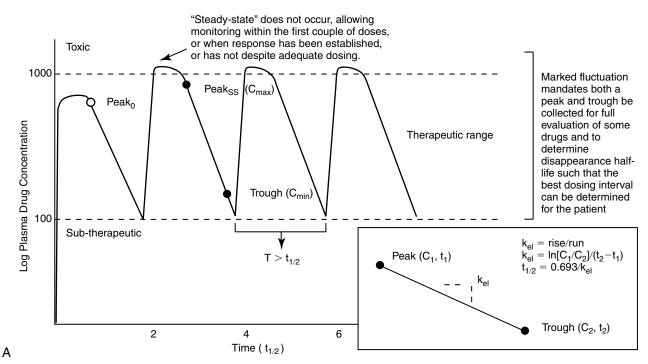

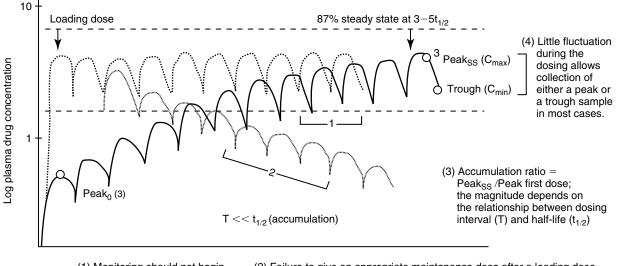

Figure 5-1 The timing of sample collection and the duration of therapy that should elapse before monitoring is implemented varies with the relationship between dosing interval and half-life of the drug. (A) Drug concentrations across time for a drug dosed at an interval that approximates its elimination half-life. For such drugs, concentrations fluctuate by 50% during a dosing interval, and drug concentrations at steady state will accumulate twofold compared to the first dose. Response to therapy and thus therapeutic monitoring are likely to occur within the first three to five doses. Both peak and trough samples should be collected to characterize the degree of fluctuation in drug concentrations during the dosing interval, thereby ensuring both that toxic concentrations do not occur as the drug peaks and that subtherapeutic concentrations do not occur just before the next dose. Peak and trough samples allow calculation of the elimination half-life *(inset)* and thus a more accurate determination of a proper dosing interval.

efficacy. Digoxin is characterized by a half-life that ranges from less than 12 hours, thus allowing concentrations to become subtherapeutic during a 12-hr dosing interval, to more than 36 hours (particularly in patients with renal disease), which is likely to lead to drug accumulation (Case Study 5-2). The half-life can change again if the patient responds to therapy for cardiac failure. If toxicity is suspected, a single sample collected at the time that clinical signs of toxicity appear can confirm toxicity. Neither toxicity nor efficacy can be confirmed throughout the dosing interval, however, unless two samples (peak and trough) are collected (Case Study 5-3).

If a kinetic profile of a patient is the reason for TDM, at least two samples must be collected to establish a PDC-versus-time relationship (Case Study 5-5). For such drugs, the samples preferably are collected at the peak and trough times. Regardless of the route of drug administration, with two data points, elimination (disappearance) half-life can be calculated. However, a more comprehensive kinetic profile can be built from the same two data points for a patient receiving an intravenous dose: volume of distribution (Vd) and clearance can then be estimated in addition to drug elimination half-life.

Loading doses warrant a special note. Loading is implemented with the goal of achieving steady state concentrations immediately. The advantage is to avoid the delay that otherwise will occur as steady state is gradually reached. The

disadvantage is that the body will not have time to accommodate to side effects. As such, loading should be limited to situations in which failed response might be life-threatening. Although the design of the loading dose may be successful in achieving target steady state concentrations (see calculations below), the patient is not yet at steady state and will not be until the same dosing regimen has been implemented for 3 to 5 half-lives. Thus, as the patient transitions from the loading to the maintenance dose, the time to steady state begins again. If the maintenance dose fails to maintain what the loading dose achieved, then drug concentrations will gradually decline or increase until steady state is achieved (Figure 5-1, B). Because the majority of the change will occur in the first half-life of maintenance dosing, clinical signs of failure or toxicity may be more likely to occur during this initial half-life. Proactive monitoring after the loading dose has been absorbed and again at the first half-life will allow the clinician to assess the effectiveness of the maintenance dose. However, both samples must be collected for the assessment. Collecting a sample one half-life after the loading dose without a postload sample is minimally informative. For example, when using a loading dose for bromide, TDM should be performed three times. The first time to monitor is after oral absorption of the last of the loading doses to establish what the loading dose accomplished (i.e., day 6). The second time is at one drug half-life later

 (1) Monitoring should not begin until patient is at steady state; however proactive monitoring might occur at the first half-life as long as a final check occurs at steady state. Drug concentrations should be 50% of steady state at one half-life.

В

(2) Failure to give an appropriate maintenance dose after a loading dose may result in a gradual decline or increase in drug concentrations compared to the post load sample as steady state is reached with the maintenance dose. Monitoring post load and at one half-life may pro-actively detect an inappropriate maintenance dose.

Figure 5-1, Cont'd (B) For drugs whose elimination half-life is much longer than the dosing interval, the drug will accumulate across time, with maximum accumulation occurring only at three to five drug elimination half-lives. Steady state will be achieved only at this time. The time to steady state starts over each time the dosing regimen is changed, including transitioning from a load-ing dose to a maintenance dose (coarse dotted lines). The maintenance dose is designed to maintain what the loading dose achieved (fine dotted line). However, if over or under dosed, drug concentrations will gradually change (decline demonstrated with fine dotted lines), until a new steady state is reached. Therapeutic failure may occur. C_1 , C_2 = concentration of samples 1 and 2, respectively; k_{el} = elimination rate constant; peak₀ = peak following first dose; peak_{ss} = peak at steady state; T = interval; $t_{1/2}$ = drug elimination half-life; t_1 , t_2 = time samples 1 and 2 were collected, respectively.

(e.g., at 21 days for bromide) to ensure that the maintenance dose is able to maintain concentrations achieved by loading. Collection of this second sample at the one drug half-life point is recommended because most of the change in drug concentrations that will occur if the maintenance dose is not correct will occur during the first half-life. If the second sample (collected at one drug half-life) does not approximate the first (collected immediately after the loading doses), the maintenance dose can be modified at this time rather than wait for steady state, with the risk of therapeutic failure or toxicity. The third time to monitor bromide when using a loading dose is at steady state (e.g., 3 months) to establish a new baseline.

KEY POINT 5-2 The maintenance dose that follows the loading dose must maintain what has been achieved with the loading dose. Monitoring of drugs dosed as a load should occur shortly after the loading dose is given and then one half-life into the maintenance dose. If the two concentrations do not match, the maintenance dose should be modified.

The timing of sample collection also must take into account the pharmacodynamic response of some drugs. For example, many antimicrobials (e.g., aminoglycosides) are characterized by a half-life that is less than 2 hours (e.g., amikacin in dogs)

but are given at much longer dosing intervals (e.g., 24 hours). The peak sample is important for determination of efficacy of this concentration-dependent drug. Because 12 half-lives will have elapsed before the next dose, less than 2% of the original dose will remain in the body at true trough concentrations, and concentrations are not likely to be detectable at true trough (i.e., 24 hrs after dosing). Although the absence of detectable drug may be sufficient information if safety is the reason for monitoring an aminoglycoside, kinetics (e.g., half-life) cannot be determined. Therefore collection of both a 2-hour peak and and a sample two to four elimination half-lives later will allow calculation of a half-life and extrapolation of concentrations at trough (Case Study 5-5). Cyclosporine is another example: if administered every 24 to 48 hours, because its half-life in normal dogs approximates 4 to 5 hours, little drug will be detected at 24 to 48 hours.

Specific timing of peak PDC collection is more difficult to determine accurately than that of trough concentrations. Peak PDC should be determined after drug absorption and distribution are complete (see Chapter 1). Route of drug administration can influence the time at which peak PDCs occur, which varies among drugs. For orally administered drugs, absorption is slower (1 to 2 hours), and distribution is often complete by the time peak PDCs have been achieved. The absorption rate can, however, vary widely due to factors such

CASE STUDY 5-1 THERAPEUTIC FAILURE DUE TO PHENOBARBITAL INDUCTION OF DRUG METABOLIZING ENZYMES

Signalment

3.5-year-old male Labrador Retriever

Chief Complaint

Seizures

Pertinent History

A diagnosis of epilepsy was made 6 months before presentation. Patient was suffering from severe cluster seizures. There was an initial response to phenobarbital, but seizures occurred again 6 months into therapy.

Drug of Interest Phenobarbital

Concern Efficacy

Other Drugs None

Dosing Regimen

4.1 mg/kg every 12 hours, administered orally

Duration of Current Regimen

Six months. Phenobarbital concentrations at 3 months (baseline) were 35 μ g/mL (peak) and 31 μ g/mL (trough). Elimination half-life at that time was 40 hours.

Patient Response

Seizure control initially improved, and there was no evidence of grogginess. The patient suffered a series of cluster seizures this weekend. The referring veterinarian was interested in adding an alternative anticonvulsant (e.g., bromide).

Drug Concentration

18 μg/mL; time: 5 hours 15 μg/mL; time: 12 hours

as product preparation, the effect of food, and patient variability. Obviously, a drug prepared as an elixir will be absorbed more rapidly than the same drug prepared as a capsule or tablet. Because food can slow the absorption of many drugs, fasting is generally indicated (if safe) before TDM. Generally, peak PDCs occur 1 to 2 hours after oral administration. Some drugs are simply absorbed more slowly than others (e.g., phenobarbital), and the time of peak PDC sample collection is longer (e.g., 2 to 5 hours for phenobarbital). For drugs administered intravenously, distribution, but not absorption is a concern. For delayed-release drugs, a sample at any time may be acceptable. For some intramuscular and subcutaneous administrations, absorption occurs rapidly (i.e., 30 to 60 minutes), but, again, drug distribution may take longer. Thus peak PDCs **Drug Elimination Half-Life** 27 hours

Predicted Peak NA

Predicted Trough NA

Recommendation

Increase phenobarbital dose to 7.5 mg/kg every 12 hours (4.5 mg/kg \times 30 µg/mL per 18 µg/mL), targeting a peak concentration of 30 µg/mL. Retest at new steady state (which will take only 3 to 5.5 days in this patient).

Comments

Phenobarbital concentrations decreased in this patient by nearly 50% without a decrease in dose. The elimination half-life decreased by 50%. The decrease most likely reflects induction of drug-metabolizing enzymes by phenobarbital, resulting in increased clearance and decreased drug concentrations. Induction occurs in most animals and should be anticipated by using a sufficiently high starting dose (2 mg/ kg) for phenobarbital and measuring drug concentrations at steady state (approximately 2 weeks after therapy is begun) and then again at 3 months.

Follow-Up

The dose was increased to 6.5 mg/kg. Drug concentrations 1 month later were 33 mg/mL (peak) and 29 mg/mL (trough). The patient has been seizure-free for 6 months. The high phenobarbital dose and the short half-life indicate that induction, and thus metabolism, may be marked in this patient. It is possible that increased production of metabolites places this patient at risk for phenobarbital-associated hepatic disease. Accordingly, the addition of a second anticonvulsant that will allow a decrease in phenobarbital dose might be appropriate.

generally are measured 1 to 2 hours after parenteral drug administration (see Table 5-1).

Other Considerations

Sample requirements vary not only in the blood component (e.g., serum, plasma, whole blood, urine, etc) but also in the volume and sampling handling. Constituents in plasma differ substantially among species, and these constituents can interfere with the methodology of some assays. Removal of these constituents varies with the methodology, with the sample size generally being larger for assays that require more clean-up (e.g., HPLC vs. antibody-based assays). Laboratories chosen for monitoring should be queried before sample submission to ensure that the proper submission procedures are followed.

CASE STUDY 5-2 DIGOXIN-INDUCED TOXICITY; LONG ELIMINATION HALF-LIFE

Signalment

6-year-old male Dachshund cross

Chief Complaint Congestive heart failure; renal failure

Pertinent History

The patient has been receiving digoxin therapy for 6 months. Within the last 3 months, renal disease has become decompensated. The day before presentation, the patient vomited and became ataxic and disoriented. Patient blood urea nitrogen is 82 mg/dL, and creatinine is 1.57 mg/dL.

Drug of Interest Digoxin

Concern Safety

Other Drugs Enalapril, furosemide, thyroxine

Dosing Regimen 0.005 mg/kg every 12 hours, administered orally

Duration of Current Regimen 90 days

Drug Concentration 2.40 ng/mL; time: 2 hours 2.47 ng/mL; time: 12 hours

Drug Elimination Half-Life >52 hours

Predicted Peak NA

Predicted Trough NA

Recommendation

Concentrations are at the upper end of the therapeutic range and are not necessarily consistent with toxicity, but a decrease in dose by about 20%, targeting 2.0 ng/mL, would be prudent. Clinical signs of uremia cannot be distinguished from clinical signs of digoxin toxicity. Prolonging the interval to at least 24 hours also would be appropriate. Collecting a peak and 24-hour trough concentration would be indicated to determine the proper dosing interval.

Comments

The prolonged half-life for digoxin in this patient presumably reflects decompensated renal disease. Note that both a peak and a trough sample were helpful in establishing the prolonged drug elimination half-life. Without both samples, the duration of the half-life and the magnitude of decreased clearance could not have been appreciated (see Case Study 5-4). Should the patient respond to therapy for its renal disease and digoxin elimination improve, monitoring is again indicated to establish a new dosing regimen because drug half-life is likely to decrease.

Follow-Up NA

CASE STUDY 5-3 DIGOXIN THERAPY; RESPONSE AND SHORT HALF-LIFE

Signalment

8-year-old female Hound cross

Chief Complaint Congestive heart failure resulting from mitral insufficiency

Pertinent History

The patient has been receiving digoxin therapy for 8 days. Patient has responded to therapy and is showing no evidence of toxicity.

Drug of Interest Digoxin

Concern Baseline check

Other Drugs

Enalapril, furosemide, a nonsteroidal antiinflammatory, and chlorpheniramine

Dosing Regimen 0.008 mg/kg every 12 hours, administered orally

Duration of Current Regimen 8 days

Drug Concentration 2.88 ng/mL; time: 1.25 hours 1.42 ng/mL; time: 9 hours

Drug Elimination Half-Life 8 hours

CASE STUDY 5-3 DIGOXIN THERAPY; RESPONSE AND SHORT HALF-LIFE-cont'd

Volume of distribution NA

Predicted Peak NA

Predicted Trough NA

Recommendation

Concentrations are above the upper end of the therapeutic range, but with no evidence of toxicity, the dose should not necessarily be changed. With a 12-hour half-life, the dosing interval should not be prolonged (and could be reduced to an 8-hour dosing interval with the same total daily dose). Leave dosing regimen as is, or decrease dose by 10%.

Comments

Compare the drug half-life in this patient with the reported normal (24 hours) and with that in Case Study 5-2. Had a single sample been collected halfway through the dosing interval, concentrations would have been in the lower end of the therapeutic range, and the dose may have been inappropriately increased. The half-life in this patient indicates that the dosing interval should not be longer than 12 hours. Should a 24-hour dosing interval be used, trough drug concentrations would approximate 0.35 ng/mL.

Follow-Up

NA

CASE STUDY 5-4 THEOPHYLLINE-ENROFLOXACIN DRUG INTERACTION

Signalment

6-year-old male neutered Collie

Chief Complaint

Hyperactivity. Allergic rhinitis has been present for 2 months. There is radiographic evidence of lung lobe consolidation, and clinical signs are compatible with pneumonia that developed 1 week before presentation.

Pertinent History

Theophylline therapy begun 3 days before presentation. The patient began exhibiting signs of hyperactivity and restlessness 24 hours before presentation.

Drug of Interest

Theophylline

Concern Toxicity

Other Drugs

Enrofloxacin 2.5 mg/kg every 12 hours orally (begun at the same time as theophylline); prednisolone 1 mg/kg every 48 hours

Dosing Regimen

21 mg/kg every 12 hours (slow-release product), administered orally

Duration of Current Regimen 3 days

Patient Response Restlessness, pacing, irritability

Drug Concentration 47 μg/mL; time:12 hours 31 μg/mL; time: 24 hours **Drug Elimination Half-Life** 19 hours

Volume of distribution NA

Predicted Peak Approximately 65 μg/mL

Predicted Trough NA

Recommendation

Decrease the dose by half, or decrease the dose by 25% and prolong the dosing interval by 12 to 24 hours. Retest at the new steady state (in 3 days) and at discontinuation of enrofloxacin.

Follow-Up

After monitoring, the dosing interval was prolonged to 24 hours, and the dose was decreased by 50% from 20 to 10 mg/ kg. A recheck revealed a peak and trough concentration of 12.3 μ g/mL and 10.3 μ g/mL at 2 and 22 hours, respectively. Near subtherapeutic concentrations indicated that either the dose might be increased or the interval decreased to 12 hours.

Comments

The fluorinated quinolones can increase concentrations of theophylline when the two drugs are given simultaneously. The mechanism is presumed to be due to impaired drug metabolism by enrofloxacin with subsequent decreased theophylline clearance. This drug interaction is well established for ciprofloxacin in humans and also has been documented for enrofloxacin. The drug elimination half-life of theophylline in this patient while receiving enrofloxacin was 19 hours, which is twice that expected in dogs.

CASE STUDY 5-5 AMINOGLYCOSIDE AND INTENSIVE FLUID THERAPY

Signalment

2-year-old male intact Staffordshire Bull Terrier

Chief Complaint

Peritonitis and bacteremia secondary to prostatic abscess

Pertinent History

Surgical correction of prostatic abscess; drug samples collected 24 hours postoperatively

Drug of Interest Gentamicin

Concern Efficacy and safety

Other Drugs

Antiemetics (metoclopramide); intensive fluid therapy (balanced crystalloid)

Dosing Regimen 4 mg/kg every 24 hours, administered intravenously

Duration of Current Regimen 24 hours

Patient Response Febrile, nonresponsive

Drug Concentration 5.34 μg/mL; time: 2 hours 0.73 μg/mL; time: 9 hours

Drug Elimination Half-Life 2.4 hours

Volume of distribution: 0.45 L/kg

Some drugs may require refrigeration or freezing. Sample size may vary for each drug or even for the same drug depending on the method the laboratory uses. Drugs can interact with the containers in which they are collected or mailed. In general, serum separator tubes should not be used to collect or mail samples containing drug. Drugs can bind to the silicone gel, which decreases concentrations measured in blood. Aminoglycosides can bind to glass; samples should be collected and submitted in plastic tubes. The effects of hemolysis and hyperlipidemia on drug assays vary. In general, it is wise to avoid either in sample collection. Although sample handling is often the same for each drug, the laboratory to which the sample will be submitted should be contacted before the sample is sent for TDM analysis. Details regarding timing of sample, collection, Predicted Peak

10 µg/mL

Predicted Trough Nondetectable

Recommendation

A peak concentration of 10 μ g/mL is sufficient for anticipated efficacy toward a microbe susceptible to gentamicin at 1 μ g.mL or less. Double the dose to target 20 μ g/mL (assuming a minimal inhibitory concentration of 1 to 2 μ g/mL), and maintain current 24-hour dosing interval.

Follow-Up

The patient's condition remained critical for 2 more postoperative days but then began to improve progressively. The patient was discharged 10 days postoperatively.

Comments

Actual peak gentamicin concentration was lower than expected (expected: 10 µg/mL), presumably because of intensive fluid therapy. The reported volume of distribution for gentamicin in dogs is 0.25 L/kg, but it was 0.45 L/kg in this patient. Gentamicin is distributed to extracellular fluid, which was probably increased in this patient by fluid therapy. A nearly doubled distribution volume resulted in a near halving of peak concentrations. The drug elimination half-life in this patient is 2.4 hours, which is normal. Doubling of the dose will add only one drug half-life to the time that target trough concentrations (<1 µg/mL) will be reached, which currently occurs by 9 hours in this patient. Even if the drug elimination half-life were to double (to 5 hours), sufficient time will elapse during a 24-hour dosing interval to allow drug concentrations to reach the targeted 1 µg/mL. Note that the trough sample was not collected in this patient just before the next dose (i.e., at 24 hours). The drug would not have been detectable at that time; hence trough concentrations were collected after two predicted drug half-lives had elapsed.

storage apparatus (i.e., tubes and anticoagulants), mailing instructions (including conditions), and cost should be known before collection.

INTERPRETATION

Information Needed for Therapeutic Drug Monitoring

For best results, a sample submitted for monitoring should be accompanied by all relevant information that the clinical pharmacologist needs to evaluate the relationship among dose, concentration, and response in the context of physiologic, pharmacologic, and pathologic factors that might alter this relationship (Box 5-3).

Box 5-3

Maximizing the Interpretation of Therapeutic Drug Monitoring

First and foremost, involve a clinical pharmacologist in the interpretation of problematic cases.

The minimum information necessary for interpretation of therapeutic drug monitoring (TDM) by a clinical pharmacologist includes the following:

- The total daily dose of drug, presented as mg/kg for each dose. Total units (capsules, tablets, or mL) are useless if not provided in the context of mg/kg.
- 2. Time interval of drug administration. This is particularly important for drugs with short half-lives (e.g., aminoglycosides). If half-life is to be determined, the timing of sample collection in relation to dose must be given for both the peak and trough sample.
- 3. The time that the sample was collected in relationship to the dose. For example, a concentration that puts levetiracetam in the high therapeutic range means much more if that concentration was measured at 12 hours versus 2 hours.
- 4. The reason for TDM should be given (e.g., has the patient failed therapy, or is the patient exhibiting signs of toxicity?).
- 5. The disease being treated with the drug (i.e., the therapeutic range for cyclosporine varies with the syndrome being treated).
- 6. Patient status at the time of sample collection and/or submission.

- 7. Pathologic factors that might affect drug disposition. This includes the extent of disease (that is, how abnormal is the serum creatinine in a patient with renal disease, or how low is the albumin in the patient with liver disease?).
- 8. Concurrently administered drugs may alter drug disposition patterns and thus contribute to individual differences in drug disposition. Frequency, dose, amount, and the actual times of all drugs given to the patient must be known in order to recognize or predict potential drug interactions. For example, cyclosporine administered with azithromycin may result in concentrations that are disproportionate to the dose.
- 9. For selected concurrently administered drugs that can be monitored, current concentrations should be provided. For example, recommendations for a seizing patient receiving bromide at a dose that has achieved concentrations in the midtherapeutic range may differ if the phenobarbital the patient is currently receiving is in the subtherapeutic range.
- 10. Physiologic characteristics such as patient species, breed, and age are often important to the interpretation of the plasma drug concentration because known or predictable differences may induce drug disposition and because there may be known differences in pharmacodynamic responses. For example, cats, Greyhounds, and working (Collie-related and other) breeds are all at risk to develop toxicity with selected drugs.

Concentrations must be evaluated in the context of the clinical patient, the mechanism of drug action and the therapeutic intent of monitoring or drug administration. The history of the patient also may be important information. For example, a subtherapeutic range in a controlled seizure patient may not require manipulation if the seizure history of the patient is not severe, but higher concentrations might be prudent if historically, the patient suffers cluster seizures. The absence of seizures in a dog with subtherapeutic concentrations also is not justification for discontinuing the drug. At the other end of the range, some animals may respond only if concentrations are higher than the recommended maximum concentration. Drug concentrations need not necessarily be reduced if there is no concern regarding toxicity or unacceptable side effects, even if the maximum therapeutic range has been surpassed (e.g., bromide).

Dose Modification with Kinetic Calculations

Most dose modifications do not require kinetic calculations (discussed in more detail later). Target calculations include elimination half-life on which the proper dosing interval and time to steady state can be based, and, for a drug given intravenously, Vd or clearance. The minimum number of data points needed to develop a pharmacokinetic profile in a patient is two. Generally, for TDM these two samples consist of the peak and trough (see Figure 5-1, A) collected during a single dosing interval at steady state. Alternatively, for the sake of convenience, a trough sample can be collected just before a dose and the peak sample collected 2 to 5 hours (when appropriate for the drug) after dosing. This protocol assumes that the drug is handled the same way by the body during each dosing

regimen and that the dose is the same. Although this may be true, conditions such as diurnal variation can alter drug disposition between dosing intervals. Oftentimes, the dose is not the same for both morning and evening.

Regardless of when the samples are collected (assuming that they are collected after absorption and distribution are complete), when the points are plotted on semilogarithmic paper, the slope between the two points reflects k_{el} (or, if non-IV administration, $k_{disappearance}$) (see Figure 5-1, A), which is used to determine drug half-life in the patient (see Chapter 1). Halflife can be either calculated or estimated from the PDC-versustime curve drawn on semilogarithmic paper. The two points are connected, and the resultant line is extrapolated to both the x and y axes. For estimation, the time that must elapse between any two concentrations on the line where one concentration is twice the second is the half-life (see Figure 5-1, A). The halflife also can be calculated from k_{el} (the slope, or rise $[C_1-C_2]$ over the run $[\tilde{t}_2-t_1]$). Because concentration is logarithmic, the equation becomes half-life = $\ln [C_1 - C_2] / [t_2 - t_1]$. Thus, although it is not necessary to actually plot the line to determine elimination half-life, the time that each dose was given and each sample was drawn must be known for its calculation (see Figures 5-1 and 5-2). Half-life determines the maximum time that can elapse between doses in the patient before PDCs fall below the recommended minimum effective concentration during the dosing interval (T_{max}) (see Figures 5-1, A and 5-2).

The Vd of drugs administered intravenously can be calculated from the peak PDC and dose (see Figure 5-2 and Case Study 5-5). If the drug is 100% bioavailable after oral, subcutaneous, or intramuscular administration, Vd can also be estimated

Elimination rate constant:	$k_{cl} = \ln (C_1/C_2)/(t_2-t_1)$			
Drug elimination half-life:	$t_{1/2} = 0.693/k_{el}$			
Maximum time that can lapse between doses:	$T_{max} = In \; (C_{max}/C_{min})/k_{el}$			
Amount of drug to be administered during a dosing interval:	$D_{M,max} = (V_{d'}F) \times (C_{max} - C_{min})$			
Dose per unit time:	$D_{M,max}/T_{max}$			
Dose each interval:	D _{M,max} × Interval T_max			
	l _{max}			
Loading dose where Css = concentration at steady state	$D_L = (V_d\!/F) \times C_{ss,max}$ e:			
Accumulation ratio: (relationship between C first dose and C at steady state):	$1/(1-[1/2]^Z)$ or $1/1-e^{T/t}_{1/2}$			
New (proportional) dose increase: <u>Curren</u>	New dose = $t dose \times new target concetration$ current concentration			
C _{max} = maxi	imum PDC (peak)			
C _{min} = minin	num PDC (trough)			
C _{ss,max} = maximum (target) PDC at steady-state (ss; ed, mg/ml)				
Vd = apparent volume of distribution (L/kg)				
F = bioavailability (100% if IV)				
$Z = T/t_{1/2}$ (Interval/half-life)			

Figure 5-2 The data necessary for calculating dosing regimens can be obtained from therapeutic drug monitoring and, if necessary, from values reported in the literature, as modified (e.g., Vd) for the patient. C₁, C₂ = concentration of samples 1 and 2, respectively; C_{max} = maximum PDC (peak); C_{min} = minimum PDC (trough); C_{ss, max} = maximum (target) PDC at steady state (mg/ mL); F = bioavailability (100% if intravenous); In = interval; K_{el} = elimination rate constant; PDC = plasma drug concentration; t₁, t₂ = time samples 1 and 2 were collected, respectively; Vd = volume of distribution (L/kg); Z = T/t_{1/2} (interval [T]/half-life [t_{1/2}]). For patient calculation of Vd and CI, the drug must be given IV.

from these data, assuming the drug also would be 100% bioavailable in the patient. For orally administered drugs for which the bioavailability is not known, a population bioavailability and Vd measured in normal animals must be used if new dosing regimens are to be calculated rather than proportionately adjusted. Like bioavailability, however, individual patient Vd may not be accurately estimated by population Vd. Changes in patient Vd compared with those in normal animals can be somewhat accommodated if information regarding patient factors that influence Vd, such as obesity, edema, ascites, dehydration, and serum protein concentrations, are known (see Chapters 1 and 2). The Vd is used to calculate the amount of drug that must be administered to achieve C_{max} , the target (generally maximum) effective drug concentration (loading dose $[D_L]$), and the amount of drug necessary to replace drug eliminated during the dosing interval (maintenance dose, D_M) (see Figure 5-2). Once D_M and T_{max} have been established, dosing regimens can be appropriately altered to ensure that PDCs fall within a recommended therapeutic range (see Figure 5-2). For drugs with short half-lives, both a peak and a trough drug sample should be collected post dose modification to ensure that a minimum effective concentration (C_{min}) is achieved and concentrations above the maximum (C_{max}) are avoided during the designed dosing interval.

Dose Modification Without Kinetics (Proportional Adjustment)

Not all modifications in dosing regimens require pharmacokinetic calculations. If a patient has drug concentrations outside the therapeutic range, the dose should be modified to change the drug concentrations into the therapeutic range by a proportional adjustment. Generally, a dose can be proportionately modified using one of the following equations:

New dose = Old dose × Targeted PDC/ Observed patient PDC or for drugs that accumulate New interval = Old interval × Observed PDC/ Targeted PDC

In general, targeting a 25% to 50% change is reasonable, if time allows a gradual adjustment. Because TDM identifies the therapeutic range specific for the patient, some patients will respond at the low end of the population range, some will not respond until the maximum is reached, and a smaller percentage of the population will respond at concentrations outside the recommended range.

If a patient has not responded, even for patients within the therapeutic range, drug concentrations can be gradually increased (in a stair-step fashion) until either the patient responds or the maximum end of the range is reached and the risk of adverse effects becomes too great. The direction can be reversed if drug concentrations are too high to establish a minimum effective dose. The decision as to whether to change the dose or the interval depends on the drug itself, its therapeutic index, and the need to maintain PDCs within the therapeutic range throughout a dosing interval. However, for drugs with a short half life, shortening the interval may be less expensive than increasing the dose.

Even TDM is used to ensure that the PDC stays within a targeted concentration (that is, the patient's therapeutic range) during a dosing interval, a patient may react adversely (including the failure to respond therapeutically). Disease, age, and other factors may play a role in the minimum or maximum effective concentration appropriate for each patient (see Case Studies 5-2, 5-3, and 5-5). Therefore it is imperative that PDCs be interpreted in conjunction with the desired therapeutic end point (i.e., complete eradication of seizures versus a decrease in the severity and frequency) as well as the clinical status of the patient. This is particularly important for tests for which there is great overlap between normal and abnormal ranges (e.g., digoxin, thyroid hormones).

Phenobarbital

Generally, a single trough sample should be sufficient for TDM. However, if induction of drug-metabolizing enzymes has occurred, the elimination half-life may be sufficiently short to allow excessive fluctuation in PDC during the dosing interval. This short half-life can be detected only if both peak and trough samples are measured. In a phenobarbital-naïve dog, or when phenobarbital doses are changed, baseline samples should be determined at steady state, 9 to 14 days after beginning therapy. A recheck trough sample 1 to 3 months later would be prudent to detect induction. Many of our patients respond to phenobarbital at concentrations below the minimum therapeutic range of 15 μ g/mL, which suggests that a lower therapeutic range may be indicated in dogs.

Bromide

Because the elimination half-life of bromide is so long, manipulating the dose before steady state is reached may be necessary for some patients. Collection of a sample at one half-life after the start of therapy (i.e., 2-4 weeks) can be performed to proactively assess the dose; doubling the 3 weeks concentration should approximate the steady state concentration. Baseline should be established at 2.5 to 3 months. If the patient is loaded, a sample should be collected the day after loading is complete, and then at one half-life. The former sample is indicated to determine what the loading dose achieved and the latter to ensure that the maintenance dose is maintaining what the loading dose has achieved; the two samples should be within 15% of each other. If not, the maintenance dose can be adjusted proportionately. Note that a 3-week sample in a patient that received a loading dose is minimally useful without the postload monitoring sample for comparison: concentrations may increase or decrease, depending on the accuracy of the maintenance dose. In all patients, regardless of the method of dosing, a final sample should be collected at steady state to establish baseline. Finally, bromide should also be checked before and after any change in diet or medication that impacts chloride excretion has occurred.

Zonisamide

The half-life of zonisamide is generally longer than 24 hours; therefore, concentrations should not fluctuate sufficiently during a 12-hour dosing interval to routinely justify a peak and trough sample. Because toxicity is not likely to be as great a concern as therapeutic failure, a trough sample is recommended for routine monitoring. In problematic patients a peak and a trough may be justified to rule out a short half-life as a contributing cause of difficult control. Currently, zonisamide is among the drugs for which the maximum therapeutic range, which has been established in humans, can be exceeded with minimal adverse effects in dogs.

Levetiracetam

The half-life of levetiracetam (standard release) can be as short as 1 to 2 hours. However, the half-life also can be longer than 8 to 10 hours; longer half-lives should be anticipated if the slow release preparation is used. Because the duration of the half-life is not known, peak and trough samples are recommended at the beginning of therapy to determine the half-life in patients. Control is much more likely to be accomplished with an 8-hour dosing interval in a patient with a longer half-life. Once the half-life is established, a trough sample is recommended if only single samples are to be collected. A midsample concentration has little to offer, particularly given that drug concentrations may drop 50% or more from mid-interval concentrations. Thus it is prudent to identify the lowest concentration possible during the interval. The recommended therapeutic range should be targeted by trough, rather than peak, concentration. Note that in a drug with a very short half-life (e.g., 2 hours), peak concentrations in a patient may be as much as 8 times as high as trough concentrations. Levetiracetam is sufficiently safe that a high peak concentration is likely to be tolerated. Because drug concentrations do not accumulate with drugs administered at an interval substantially longer than the half-life, steady state does not occur. Therefore levetiracetam (or another drug with a short half-life) might be monitored in the first 3 to 5 days of therapy. Waiting one seizure interval to ensure that seizures are adequately controlled is reasonable. The approach for monitoring levetiracetam can be followed with other anticonvulsants associated with a short half-life compared to the dosing interval (e.g., gabapentin), unless the drug is potentially toxic. In such situations, monitoring peak and trough concentrations routinely may be prudent.

Digoxin

Although a mid-interval sample traditionally has been recommended for digoxin, unless the half-life is known to be long, a mid-interval sample provides incomplete information regarding either toxicity or efficacy. For patients in which the halflife is less than 24 hours, both a peak (2-3 hour) and trough (before next dose) sample should be collected for this drug, particularly if a 24-hour dosing interval is used. The elimination half-life is often short, particularly in animals responding to afterload reduction, and the narrow therapeutic window (which differs approximately twofold) mandates the need to know the behavior of this drug throughout the dosing interval. For example, if the half-life is 12 hr, it is likely that concentrations will be either above or below the therapeutic range (1-2 ng/mL). A single peak sample can be collected if only toxicity is the concern; a single trough sample is indicated if the question to be answered by monitoring is whether concentrations are above the minimum therapeutic range throughout the dosing interval.

Theophylline

Single trough samples may be sufficient for slow-release products such as theophylline in cats if efficacy is the concern; a peak sample would be indicated if toxicity is the concern. Both peak and trough samples should be collected in dogs receiving

CASE STUDY 5-6 PHENOBARBITAL-CHLORAMPHENICOL DRUG INTERACTION

Signalment

3.5-year-old male German Shepherd Dog

Chief Complaint

Acute onset of depression, anorexia, and lethargy. Concern: Bromism.

Pertinent History

A diagnosis of epilepsy was made 1 year before presentation. The patient was suffering from severe cluster seizures. The response to phenobarbital was initially acceptable, but seizures worsened and potassium bromide was added 6 months into therapy (see monitoring below). The dose was re-adjusted 3 months later (3 months before presentation). Although the patient has stopped seizuring, the patient was treated for a cough 1 week before presentation. Lower respiratory infection was diagnosed and antimicrobial therapy begun. Phenobarbital but not bromide was measured at that time (32 μ g/mL). Three days later, the patient presented for the chief complaint. Physical examination reveals the patient to be moribund, but vital signs are otherwise normal. Clinical laboratory tests are normal. The referring veterinarian is concerned that the bromide dose is responsible for clinical signs.

Drug of Interest Bromide (25 mg/kg bid for 3 months)

Concern Toxicity

Other Drugs

Phenobarbital 4 mg/kg every 12 hours, administered orally (at current dose for 2 weeks; last phenobarbital collected was at steady state with the current dosing regimen); chloramphenicol 25 mg/kg every 8 hours for 3 days

Dosing Regimen

A 450 mg/kg loading dose measured 6 months before presentation was 0.9 mg/mL. The maintenance dose was 10 mg/ kg every 12 hours. Although concentrations were not measured, this maintenance dose would predictably result in steady state concentrations of 0.75 mg/mL. Two months after the loading dose, a dose increase to 25 mg/kg every 12 hours was implemented. Concentrations were not subsequently measured at steady state.

Duration of Current Regimen

Bromide, 6 months; phenobarbital 1 year; chloramphenicol, 50 mg/kg tid, 4 days

Patient Response

Seizure control was improved. Patient was not groggy until recent episode.

Drug Concentration 2.10 μg/mL; time: 12 hours

Drug Elimination Half-Life NA

Volume of distribution: NA

Predicted Peak NA

Predicted Trough NA

Recommendation

Although bromide concentrations are in midtherapeutic range, they are not sufficiently increased to cause the profound nature of the clinical signs. The concentrations are comparable to the dose. Phenobarbital concentrations were measured: peak concentration was 50 μ g/mL; trough concentration was 46 μ g/mL. Phenobarbital elimination half-life was 58 hours. This increase occurred in a week time period.

Comments

This patient was presented for presumed bromide toxicity. The bromide concentrations were not, however, consistent with the profound depression the patient was exhibiting. Phenobarbital concentrations were checked to identify a possible contribution to lethargy in a sample of blood collected just before the onset of chloramphenicol therapy. Phenobarbital concentrations had increased in this patient by 40% to 50%, despite no dose change; it is likely that concentrations would continue to increase as a new steady state was reached. The increase was presumed to be due to chloramphenicol therapy. Chloramphenicol is a potent inhibitor of drug-metabolizing enzymes, resulting in decreased phenobarbital clearance. Drug elimination half-life had not been previously determined for phenobarbital in this patient, so a change in half-life could not be documented.

Follow-Up

Chloramphenicol therapy was discontinued. Phenobarbital therapy was discontinued for one drug elimination half-life and then restarted at the same dose. Within 48 hours, the patient was normal.

slow-release preparations. For regular preparations, both samples should be collected.

Cyclosporine

Monitoring cyclosporine is complex and is addressed in depth in Chapter 31. The elimination half-life of cyclosporine in normal dogs or cats is 4 to 8 hours, and, as such, both a peak and trough might be indicated. Recommendations may also depend on therapeutic intent (i.e., immunosuppression, treatment of chronic allergic diseases such as atopy, perianal fistulas or asthma, etc). Recommendations as drawn from humans are based on either a peak or trough concentration, although a peak concentration correlates more closely to area under the curve during a dosing interval when targeting graft-versushost rejection. Certainly, peak target concentrations are easier to achieve than trough target concentrations in patients with a short half-life. Monitoring also is complicated by the presence of drugs which might prolong the elimination half-life due to inhibition of drug metabolizing enzymes or enhance absorption through competition with P-glycoprotein; ketaconazole and azithromycin are examples of drugs that appear to do both. For such patients, both peak (2 hours) and trough (before next dose) samples are indicated to calculate half-life. This is particularly important to determine the time to steady state, a state which will occur only in those situations where the half-life of cyclosporine is markedly prolonged. For such situations the time to steady state may be very long, and final monitoring should not take place until steady state is reached. The time to steady state can be determined only by collection of a peak and a trough sample.

Antimicrobials

Because both the aminoglycosides and fluorinated quinolones are concentration-dependent drugs, peak concentrations are of critical interest. However, determination of true peak concentration requires that two samples be collected: a peak and a second sample approximately two half-lives later. The peak sample should be collected after drug distribution has occurred, or approximately 45 to 60 minutes after dosing. A true trough sample (i.e., just before the next dose) should not be collected because it is likely that concentrations will be undetectable for both fluorinated quinolones and aminoglyclosides (given once daily with half-lives less than 3 hours). An exception might exist for determining aminoglycosides' toxicity: documentation of trough concentrations below the minimum requires a sample just before the next dose.

SUMMARY

TDM can aid clinicians in the titration of drug doses to the individual patient, thus helping prevent adverse reactions that are a direct consequence of patient variability in drug disposition. In addition, TDM ensures that optimal drug concentrations are established promptly and that therapeutic drug concentrations are maintained, which spares patients a protracted period of ineffective drug therapy.

JUDICIOUS ANTIMICROBIAL USE

"Even experienced practitioners may not realize that giving a patient antibiotics affects not just that patient, but also their environment, and all the other people that come into contact with that environment." Dancer's¹ statement, intended as a warning to practitioners of human medicine, emphasizes the importance of judicious antimicrobial therapy. It is understood that the goal of antimicrobial therapy is successful treatment of infection. However, the less judicious the approach taken to achieve that goal, the more likely a path to future failure is paved. The goal of antimicrobial therapy must be further modified to include avoidance of resistance, a goal that is not necessarily accomplished with successful resolution of infection. Although it might be tempting to consider that human and veterinary medicine are differentially affected by antimicrobial resistance, in reality both are inexorably linked, and what affects one will affect the other. As early as 1998, the National Foundation for Infectious Diseases estimated the cost of antibiotic-resistant bacteria to be as high as \$4.5 billion annually and that they are responsible for more than 19,000 (human) deaths per year.² The impact is evident globally, nationally, in the community setting, in the hospital environment, and within the hospital, particularly with regard to at-risk patients (e.g., critical care).³ Any antimicrobial used to treat a patient ultimately must be excreted into the environment; the impact of this is just now being addressed scientifically.

Empirical antimicrobial selection may become an approach of the past. As medical communities struggle to assess impact,

^{*}The author would like to acknowledge the input regarding culture and susceptibility testing and interpretation and infection control provided by Terri Hathcock, MS, Diagnostic Veterinary Microbiologist, Auburn University.

causes, and means of avoidance, inappropriate antimicrobial use clearly is a consistent contributing factor to antimicrobial resistance. Inappropriate use includes both excessive and unnecessary use, as well as inappropriate dosing regimens. In the United States alone, approximately 350 million pounds of antibiotics are consumed annually in human medicine.² The numbers in veterinary medicine are less clear, but 20 million pounds were consumed by food animals during the same period.^{2,4} Approximately 40% of human consumption of antimicrobials is considered unnecessary.² That we do not have a similar statistic regarding therapeutic antimicrobial use in veterinary patients reflects, perhaps, a somewhat cavalier attitude regarding antimicrobial stewardship both on the part of the manufacturers and the users. The veterinary profession has been intensely scrutinized by the medical community regarding its use of antimicrobial products in animals. This sometimes scientific and frequently emotional focus began with use in food animals but is shifting to companion animals.⁵ Guardabassie⁶ has described the role of the family pet as a reservoir of potentially resistant zoonotic organisms. Resistant strains of Staphyloccocus intermedius, Campylobacter, Salmonella, and Escherichia coli were cited as possible zoonotic concerns. At least 1% of annual salmonellosis cases in humans are assumed to be associated with companion animals.⁶ Approximately 6% of Campylobacter jejuni infections in humans (children) are transmitted from pets.^{6,7} Methicillin-resistant Staphyloccoccus aureus (MRSA) has been isolated in family members and pets in the same household⁸⁻¹⁰; methicillin-resistant Staphylococcus *intermedius*^{*} (MRSIG) has been reported in human patients¹¹; and, perhaps disconcertingly, MRSA of animal origin (not previously identified in humans) has been identified in animals, albeit food animals (pigs).¹² In dogs E. coli strains are phylogenetically similar to pathogenic strains causing infection in humans; more than 15% of canine fecal deposits in the environment contain E. coli strains related to virulent human strains.⁶ The concern regarding E. coli relates, in part, to its ability to develop resistance in the presence of antibiotic concentrations considered therapeutic.^{13,14} Extraintestinal pathogenic E. coli (ExPEC, the "other" bad E. coli) appears to easily colonize the gastrointestinal tract, potentially displacing commensals and eventually emerging as infectious organisms in other body tissues, particularly in the urinary tract.¹⁵ Further, E. coli is able to share mechanisms of resistance with other enteric pathogenic coliforms such as Salmonella.13 Evidence exists for the transfer of resistance between E. coli and Salmonella and subsequent transfer of these organisms between animals (pet and farm animals) and humans¹⁶

KEY POINT 6-1 Antimicrobial use by veterinarians affects the global medical community; the veterinary hospital, the patient; and, as is increasingly being recognized, the pet owner.

The pernicious advent of resistance over decades of antimicrobial use reveals that, despite their safety to the patient, antimicrobials are not innocuous drugs.¹⁷ As in human medicine, antibiotic stewardship (i.e., judicious antimicrobial use) should become the focus for reducing resistance in veterinary medicine.¹⁸ Prudent veterinarians and veterinary practices will implement decision-making processes (antimicrobial use paradigms) that minimize the temptation to use antimicrobials as alternative therapies. Designing a dosing regimen on the basis of cost and convenience, rather than on pharmacodynamics and pharmacokinetics, must become a paradigm of the past. Antimicrobial stewardship begins by recognizing the problems and issues and successfully implementing procedures that reasonably minimize the impact of antimicrobial use in the patient while not forfeiting the likelihood of therapeutic success. It is with this appproach this chapter emphasizes the rational basis for decision making in the selection of the proper antimicrobials.

DEFINITIONS AND GOALS

The terms antibiotic, antibacterial, and antimicrobial are often used interchangeably, despite their different meanings. Antibiotics are natural chemicals (e.g., penicillin) produced by organisms intended to suppress other organisms (generally, but not exclusively, bacteria), whereas antimicrobial refers to any compound, whether natural, synthetic, or a combination thereof, that suppresses microbial growth. Antibacterials target bacteria, antifungals target fungi, and so forth. The term microbes usually refers to bacterial organisms but also includes fungal and other (nonviral) organisms. Bacteria can be further categorized on the basis of their Gram-staining characteristics and their morphology (Box 6-1). This classification is helpful when matching bug to drug. In addition to staining characteristics, bacteria can be defined as aerobic-that is, those that generate energy (ATP) by aerobic respiration of oxygen. Some aerobes have minimal capacity to generate energy in the absence of oxygen and can be referred to as obligate aerobes. Although Pseudomonas aeruginosa might be classified as an obligate aerobe, it has the capacity to function, as with many other aerobes, as a facultative anaerobe. Facultative anaerobes prefer an oxygen-rich environment but are quite capable of switching to fermentation in the absence of oxygen. An example environment in which P. aeruginosa is able to survive in reduced oxygen environments (in humans) is cystic fibrosis. Other examples of facultative anaerobes include the families Enterobacteriaceae (e.g., E. coli, Klebsiella pneumoniae, Proteus mirabilis), Vibrionaceae (e.g., Vibrio, Aeromonas), and Pasteurellaceae (Pasteurella, Haemophilus). In contrast, obligate anaerobes cannot tolerate the presence of oxygen more than a few seconds. Examples include members of the family Bacteroides. Clostridia sp. is an example of an anaerobic organism whose oxygen toleration ranges from moderately tolerant (e.g., Clostridia tetani) to highly tolerant (e.g. Clostridia perfringens). Microaerophilic bacteria lie somewhere between aerobic and obligate anaerobes, in that they require low concentrations of oxygen to survive. Examples include

^{*}Staphylococcis intermedius is likely to be renamed Staphylococcus pseudintermedius. Until official, the term Staphylococcus intermedius group (SIG) will be used to refer to this organism.

Helicobacter and *Borrelia* spp.¹⁹ When collecting a culture sample for such organisms, extreme care must be taken to prevent its exposure to oxygen. **Aerotolerant** organisms are not affected by either the presence or the absence of oxygen.

KEY POINT 6-2 Antibiotics are natural antimicrobials secreted by one microorganism to inhibit another. A microbe that secretes antibiotics also carries the genes for resistance to that antibiotic.

The term **organism** refers to either the genus or the genus and species of a microrganism. Examples include *E. coli, Staphylococcus pseudintermiedius group* (SIG), *Enterococcus faecalis,* and *Bacteroides fragilis*. For each of these organisms, multiple **strains** exist. An **isolate** refers to one **colony-forming unit** (CFU) of the resident population of that organism. This might be from any site, such as a lake, a feedlot, a surgical table, or the sample collection site of a patient. The cultured isolate is only one among what are likely to be thousands or hundreds of thousands of CFUs that make up the resident population, or **inoculum**, of the organism in the patient. Whether the inoculum in the patient represents a true infection rather than normal flora is based, in part, on the size of the inoculum—that is, how many CFUs of that organism are present in the animal.

KEY POINT 6-3 An infection is defined by the size of the inoculum, which varies with the tissue and method of culture collection.

The goal of antimicrobial therapy is to achieve sufficient concentrations of an appropriate drug at the site of infection such that the infecting organism is killed, while simultaneously avoiding side effects of the drug in the patient. In today's age of emerging resistance, the goal must be modified to include the avoidance of antimicrobial resistance. Therapeutic decisions concerning antimicrobial therapy for the infected patient are among the most challenging (Figure 6-1). Unlike most other drug therapies, antimicrobial therapy must take into account microbe, drug, and patient factors (i.e., the chemotherapeutic triangle), many of which confound successful therapy to the point of causing failure (Figure 6-2). Antimicrobial therapy is most likely to be successful when the target (and thus spectrum of antimicrobial activity) is known such that pharmacodynamics (PD) of the infecting organism can be integrated with the pharmacokinetics (PK) of the drug in the patient.

IDENTIFYING THE NEED FOR ANTIMICROBIAL THERAPY

The first decision to be made regarding antimicrobial therapy is determining the need to treat (see Figure 6-1). The decision includes confirming, to the extent possible, the existence of infection; identification of the cause of the infection bacteria (or fungal, etc), the need for treatment of the infection; and, if treatment is deemed necessary, whether antimicrobials should be part of the therapy. This first decision is probably given the least consideration yet may be the most important if resistance is to be avoided. It also may be the most difficult to make. The presence of infections frequently cannot be confirmed for a variety of reasons, such as the lack of (infection-) specific clinical signs, location in an inaccessible site, and costs associated with accurate diagnosis. Infection is supported, but not necessarily confirmed, by clinical signs or laboratory tests indicating fever, inflammation, and organ dysfunction or structural changes detected by imaging techniques such as radiology, ultrasound, and magnetic resonance imaging. Culture may support, but does not necessarily confirm, infection. Newer detection methods based on molecular diagnostic techniques (e.g., polymerase chain reaction) may ultimately prove to be important tools in the rapid bedside diagnosis of infectious diseases, including multidrug-resistant bacteria.²⁰ However, simply documenting the presence of these microbes may not be a sufficient indication of cause and effect. These methods may not discriminate infection (reproducing, pathogenic organisms) and colonization (the presence, growth, and multiplication of the organism without observable clinical

symptoms or immune reaction), or pathogens from normal microflora. An exception can be made if cytology reveals organisms phagocytized by white blood cells, but the absence of phagocytosis does not eliminate infection.

KEY POINT 6-4 The first and most critical decision to be made regarding antimicrobial therapy is determining the need to treat. This includes confirming, as much as possible, the existence of infection; deciding if it must be treated; and, if so, whether antimicrobials should be part of the therapy.

Identifying the presence of infection is important in avoiding indiscriminate antimicrobial use. Increased risk of toxicity, cost, and inconvenience are obvious reasons that antimicrobial drugs should not be used indiscriminately. Less obvious reasons are an increased risk of superinfection and the potential emergence of resistant microbes. These latter reasons reflect, in part, the impact of antimicrobial therapy on normal flora.

Internal structures and organs (e.g., bone, heart, kidneys, the lower respiratory tract) are normally sterile. Sterility may be maintained, in part, by secretions, which constantly clean or clear the site. In addition to bulk flow, secretions may

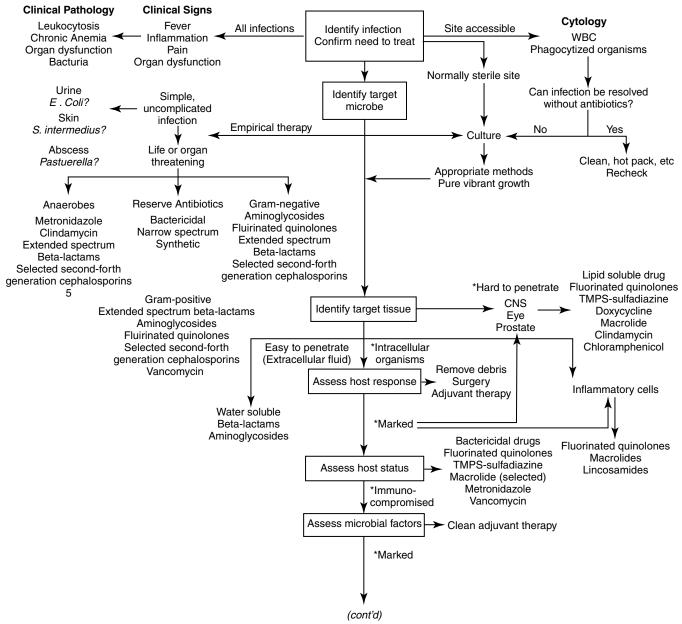

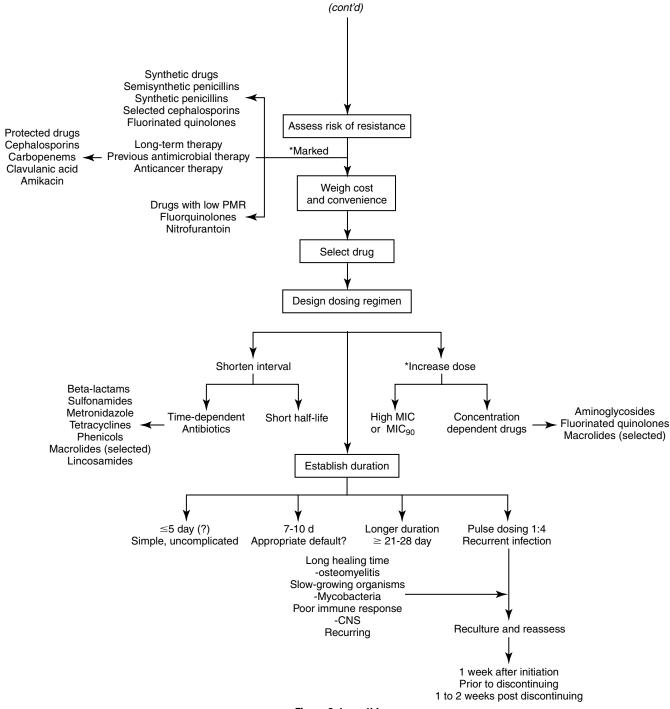

Figure 6-1 Therapeutic decision making for judicious antimicrobial therapy requires multiple steps. Antimicrobials should not be used indiscriminately; whenever possible, the most narrow-spectrum drug that targets the infecting organism should be used. Achieving adequate drug concentrations at the site of infection is critical to successful therapy. Dosing regimens should be modified for the patient; modifications should include changes in the dose and/or interval as is relevant. The asterisk at the ^{*}Design Dosing Regimen step refer to those indications previously encountered that should also lead to either a shortened interval or an increased dose, depending on whether the drug is concentration versus time dependent.

contribute to sterility by the presence of endogenous antimicrobial compounds (e.g., tears, saliva, respiratory tract secretions, gastrointestinal acidity). However, in contrast, external (skin and conjunctiva of the eye) and internal (linings of the respiratory, digestive, and urogenital systems) surfaces are characterized by normal microflora. Normal flora may be further defined according to their contribution to host health or well-being. Most normal flora are **commensals** that appear to neither harm nor help the host. Some commensals, however, are also **opportunistic** in that they may become pathogenic, particularly if host health is impaired. A **pathogen** is a microbe that is associated with and capable of causing host damage.²¹ Pathogens often reflect the normal flora of infected sites, with *E. coli, P. aeruginosa, K. pneumoniae*, and *S. aureus* being common examples of opportunistic normal flora that can become pathogenic (Table 6-1). **Mutualistic** organisms help maintain microbial balance through host–microbe interactions. They provide beneficial effects such as producing acids that lower pH and blocking colonization by more dangerous microbes. Antibiotics secreted by mutualistic organisms help maintain the composition of aerobic and anaerobic commensal bacteria, resulting in a population that is most appropriate for host

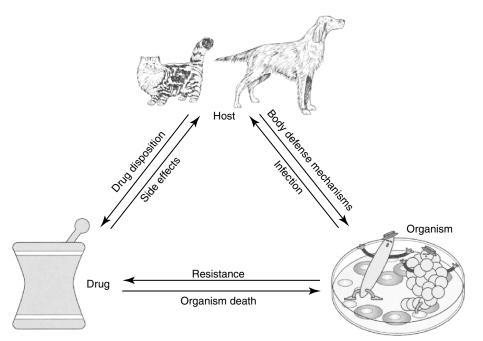

Figure 6-2 In contrast to other drug therapies, antimicrobial therapy involves not only the host and drug but also the microbe. Interactions among the three profoundly complicate successful antimicrobial therapy.

health and preventing colonization by pathogenic organisms. Opportunistic organisms may not originate from normal microflora but rather may be acquired from the environment (e.g., Aspergillosis, fungal organisms). Nosocomial organisms cause infections as a result of medical treatment, usually in a hospital or clinic setting. As such, a nosocomial infection is defined as one that arises 48 hours after hospital admission. Disruption of the environment, such as might occur with the use of antimicrobials that alter the anaerobic population, will also disrupt the balance of normal microflora, increasing the risk of infection (see the section on antimicrobial resistance). Not only will death of normal flora leave a void that can be filled in with more hardy and potentially pathogenic microbes, but the constant exposure of the microbes to antibiotics leads to ongoing development of mechanisms such that the microbes resist environmental drugs. Therefore the organisms are primed for resistance. Narrowing the spectrum of the chosen antimicrobial will help limit, although probably not prevent, the development of resistance.

KEY POINT 6-5 Discriminating among commensal versus pathogenic organisms is difficult and often cannot be determined simply by culture.

IDENTIFYING THE TARGET ORGANISM

Empirical Antimicrobial Therapy

After it has been determined that infection does exist and warrants medical management with antimicrobial drugs, identification of the target is the second critical decision to be made. Antimicrobial selection is probably most often made empirically—that is, on the basis of assumptions regarding the infecting organism and its susceptibility to drugs. These assumptions are based on historic data that identify organisms most commonly associated with infections of various body systems (see Table 6-1).²² However, older data may not have discriminated between commensals and pathogens — indeed even today such discrimination often is not possible — which complicates the accuracy of prediction. More problematic, as resistance has emerged, the risk of incorrectly identifying the susceptibility pattern of an infecting microbe has increased. Thus the clinician should carefully balance the risk of therapeutic failure, including recurrence of infection with a resistant microbe, with the cost associated with more accurate diagnostic procedures.

The utility of Gram staining in the selection of an antimicrobial should not be overlooked as a means to narrow the spectrum of the chosen antimicrobial. Gram stain characteristics differ on account of differences in the layers penetrated by the Gram (purple) stain. The cell wall is many layers thicker in gram-positive organisms than in gram-negative ones thus rendering them more susceptible to some drugs that target the cell wall; further, the gram-positive isolates do not have an external lipopolysaccharide (LPS) covering that is present in gramnegative organisms (Figure 6-3). Whereas the LPS layer is the source of endotoxin responsible for the morbidity and mortality associated with many gram-negative infections, just as this external covering precludes stain movement into the cell wall, it also serves as a barrier to drug movement into the organism (see Figure 6-3).²³ Movement, particularly of water-soluble drugs, is generally restricted to outer membrane proteins that span the breadth of the covering (porins); however, changes in porin size and efflux pumps are mechanisms by which gramnegative organisms overcome drug movement through porins.

*Numbers in parentheses refer to probable percentages of infections in this tissue that are caused by the organism, as cited by Aucoin (1993). Unless noted otherwise, the percentages refer to both dogs and cats (D = dog; C = cat). Note that the probable percentage is likely to vary geographically and may be biased toward patients referred to a specialty service. †Numbers in parentheses refer to probable percentages of infection in this tissue that are caused by the organism, as cited by Greene (1990). *Number in parenthesis reflects the range of percent cited by both Aucoin (1993) and Greene (1990). §¶ For each tissue, the symbol is defined in the *Comment* column. **Organisms that are cultured from clinically healthy animals may be difficult to distinguish from those that cause infection.

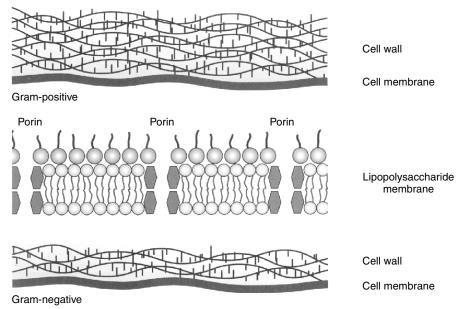

Figure 6-3 The gram-positive cell wall is thicker than the gram-negative cell wall, but the gram-negative cell wall is protected by an outer membrane including a layer of lipopolysaccharides. Endotoxin, derived from the lipopolysaccharides, contributes to the mortality and morbidity of gram-negative infections. The membrane also presents a challenge to drug movement. Although lipid-soluble drugs can diffuse through the membrane, movement of water-soluble drugs must occur through channels in outer membrane proteins called *porins*, which form aqueous channels that filter unwanted molecules. These porins are also associated with efflux pump proteins (the latter are also present in gram-positive organisms). Reduction in porin size or increased efflux pump activity are important mechanisms by which gram-negative organisms develop multidrug resistance.

In addition to Gram staining, determining the source of infection may help identify the microbe because some organisms are more likely than others to infect certain body systems. For example, genitourinary tracts are often infected with gram-negative aerobes, whereas abdominal infections generally are caused by gram-negative aerobes initially, followed by anaerobes after several days (see Table 6-1).^{24,25} Skin is most commonly infected with Staphylococcus pseudintermedius (to be referred to as S. intermedius group, or SIG), abscesses with anaerobes and Pasteurella spp., and the urinary tract with E. coli. Indeed, E. coli is one of the more common pathogens, infecting many tissues. One study of 674 E. coli isolates collected from dogs found the vast majority (n=424) associated with urinary tract infections (UTIs) (n=424); however, 61 were also collected from skin, respiratory tract (52), ear (43), female (42) and male (25) reproductive tracts, and other organ systems (23). However, although E. coli may indeed be the most common isolate associated with UTIs, it does not necessarily represent the majority of UTIs. In a study by the author, only 50% of UTIs were caused by E. coli, with the remaining 50% caused by Staphylococcus spp., Enterococcus spp., Proteus, and others. For critical patients, organisms generally represent the normal flora of the alimentary canal or a nosocomial organism.²⁶ Granulocytopenic or otherwise immunoincompetent patients also are more likely to be infected by aerobic gramnegative organisms.

Even if the organism is correctly identified, the greater risk of failure associated with empirical treatment lies in the inability to correctly predict susceptibility patterns. This is not a new concern: As early as 1996, a study of critical-care patients revealed that empirical selection of antimicrobials was incorrect, on the basis of cultures collected before antimicrobials were started, in nearly 45% of patients.²⁷ Further, isolates of four organisms collected between 1998 and 2000 (P. aeuriginosa, P. mirabilis, E. coli, Staphylococcus spp.) widely considered to be susceptible to enrofloxacin (which had been approved for approximately 10 years) were characterized by a higher than expected incidence of resistance (28% for E. coli).²⁸ More recently, a high level of resistance was ascribed to drugs used empirically to treat otitis interna²⁹ and pyothorax.³⁰ Finally, our laboratory has demonstrated that more than 40% to 60% of E. coli associated with UTIs in dogs are characterized by resistance to first- and second-choice drugs (amoxicillin/clavulanic acid, cephalexin, potentiated sulfonamides, and enrofloxacin).³¹ These differences may be regional but the absence of a robust surveillance program for dogs and cats limits empirical antimicrobial selection. These studies suggest culture and susceptibility (C&S) testing will become increasingly important.

Culture and Susceptibility Testing

C&S data can be a powerful guide for judicious antimicrobial use. However, C&S testing is only one of several tools that should support antimicrobial therapy. Among the advantages of culture is facilitation of input from a veterinary diagnostic microbiologist. As such, it has multiple roles in antimicrobial therapy: identifying the potential pathogen, providing a list of potentially effective drugs, offering guidance regarding the most effective drug, and serving as a basis for design of a dosing regimen of that drug through integration of pharmacokinetics (PK) and pharmacodynamics (PD).³²

KEY POINT 6-6 The more at risk a patient is for resistance to be present or emerge, the more important culture and susceptibility testing becomes in the support of drug selection and design of the dosing regimen.

To date, not all infections require C&S testing to be effectively treated. Indeed, basing treatment on C&S does not guarantee therapeutic success. However, C&S can be particularly prudent for at-risk patients. It is particularly important for patients that have been treated with antimicrobials in the past several months. Testing is important to critical patients; although empirical therapy will begin before its receipt, culture of blood, urine, respiratory secretions (collected by bronchoscopy) and other pertinent body fluids (i.e., pleural, peritoneal, or cerebrospinal fluid [CSF]) should be carefully sampled before antimicrobial therapy is begun. Testing is also critical if infection by nosocomial organisms is of concern because their complex resistance patterns often require more expensive and potentially toxic drugs.³³

Among the disadvantages of C&S testing is the time that often elapses between sample collection and receipt of results. Ideally, antimicrobial therapy will be withheld until the information is received and the accuracy of empirical choices is confirmed. The more a patient is at risk for developing resistance, the more important it may be to withhold therapy until results are received. However, treatment generally cannot be withheld. Still, if the data indicate that an incorrect choice may have been made regarding empirical antimicrobial selection, the data may no longer accurately reflect either the current infecting population or the susceptibility pattern. The clinician has several options, given that scenario (see Figure 6-1). If the patient has responded to therapy, the most prudent approach may be to stay the course, or perhaps add a second (nonantagonistic) drug to which the isolate is susceptible. If the patient has not responded sufficiently to therapy, therapy might be changed in light of the new data. However, the more prudent approach might be to reculture and wait until the new data arrive before changing course.

As with any tool, C&S data can be detrimental if misused. Contributing to improper use are the many pitfalls of testing, which begin with sampling, continue through the testing procedures and interpretation of results, and end with the design of the dosing regimen.

Culture data are only as good as the sampling methods of collection; the importance of proper culture techniques cannot be overemphasized (Box 6-2). For skin wounds the surface always contains commensals; normal flora, regardless of the site of collection, will cause background noise that must be filtered out. Swabs are often not ideal for sampling for a variety of reasons,³⁴ the most compelling of which is that only 3 out of 100 CFUs will actually make it to the culture stage. For anaerobes in particular, air between the fibers inhibits growth.

Despite the greater level of difficulty in sample acquisition, tissue is the preferred sample. This might be an aspirate of fluids or macerated tissues (the laboratory may prefer to perform the macerating). Cleansing before sample collection is indicated, particularly for contaminated sites. For the same reason, cystocentesis is the most acceptable sample for interpretation of bacteriuria; catheterized sample often contain microbes colonizing the catheter and associated biofilm. The properly collected obligate anaerobic sample is particularly difficult to achieve and the absence of anaerobes may simply reflect improper techniques. An anerobic infection should be suspected if clinical signs are supportive (e.g., foul smell, adjacent to mucosal membranes or gas). Note that facultative anaerobes may be cultured and tested as susceptible under aerobic conditions but fail to respond to therapy as expected if the infection in the patient occurs under anaerobic conditions.

Even a properly collected culture may not confirm infection or identify the infecting pathogenic microbe. Cytology coupled with Gram staining should be considered when possible, with phagocytosis of the organism indicative of pathogenicity. Pathogenicity reflects virulence, which is often misconstrued as resistance. The chances of proper identification of the cultured isolate pathogen are greatest if vibrant growth is obtained in an otherwise sterile environment. However, for tissues characterized by a normal flora, culture may not be able to discriminate colonization and infection by normal opportunistic organisms that have become pathogenic. Most normal flora comprises commensals that are opportunistic, i.e., able to cause disease without the support of virulence factors. A population shift from colonization to infection by such organisms is more likely to occur in at-risk patients, such as the critical-care patient, or at sites for which local immunity is compromised. Infection generally reflects normal flora, such as E. coli, P. aeruginosa, K. pneumoniae, and S. pseudintermedius., although opportunistic organisms also may be acquired from the environment.

The culture may give some indication as to the quality of the sample based on evidence of contamination. If C&S data indicate contamination, the site should be resampled (tissue collection rather than swab) after proper cleansing. For example, selected organisms, such as Bacillus sp. and Corynebacterium spp. are common contaminants, and their presence in wounds may be indicative of contamination and thus, potentially, a poorly representative sample. The location of culture may also be important in identifying the organism as a contaminant. For example, whereas beta-hemolytic Streptococcus sp. (e.g, S. canis) collected from a wound may be important, it is a likely contaminant if cultured from the ear. Streptococcus sp. pathogenicity (i.e., the likelihood of infection) can be associated with its ability to hemolyze hemoglobin, with alpha designation (hemoglobin is simply reduced) being the least and beta (red blood cells disrupted) potentially the most hemolytic and pathogenic designation. Gamma hemolysis is actually the absence of hemolysis and is demonstrated by Enterococcus spp. (previously a subset of Streptococcus spp.). However, alpha-hemolytic also can be pathogenic under the right circumstances, such as in the patient that has undergone

Box 6-2

Techniques in Culture Sampling

Commonalities Regardless of Site*

- *Site preparation:* Don sterile gloves. Clean wound. Do not culture purulent or necrotic debris. Thoroughly cleanse wound by removing excessive debris, flushing with saline, and blotting with sterile gauze. Change to sterile gloves before collection.
- *Tissue aspiration:* Clean intact skin with antiseptic (e.g., 70% alcohol and 10% povidone-iodine). Allow to air dry (do not fan). Expel air from an appropriate-size syringe to which is attached a 22-Ga needle. Insert needle into intact skin at the deepest portion of the lesion. Aspirate approximately 0.5 mL fluid. Needle can be moved back and forth at different angles in skin. Remove needle with hemostat. Discard needle and recap syringe with blood-gas cap, or, particularly if anaerobes are suspected, transfer fluid to transport vial.
- *Swab techniques:* Swab techniques are acceptable only for eye, ear, and uterus cultures. Note that only 3 of 100 colony-forming units collected in a swab are likely to be successfully cultured. Use a swab in appropriate carrier medium. The swab should be moistened with sterile, preservative-free solution if wound is not moist. Sample should be collected without touching the edge of the wound or skin. Rotate swab over 1-cm area of open wound for 4 seconds. Place swab aseptically in transport sleeve, making sure tip comes into contact with liquid transport medium (break ampule if present). One swab should be collected for each sample type (i.e., aerobic, anaerobic, and a third if cytology is of interest).

Skin or Wound Biopsy

Swab is strongly discouraged; aspirate is acceptable, but macerated tissue is preferred: Clean intact skin with antiseptic and allow to air dry (do not fan). Collect biopsy aseptically. Place in transport tube containing liquid medium. Clinical microbiology laboratory will macerate.

Bone

Place in transport system. Moisten with sterile physiologic saline as necessary.

Drain Tube Site

Treat as a contaminated wound. Care must be taken not to culture the biofilm associated with the foreign body. The drain tube should be removed, the site surgically cleaned and flushed, and the area cultured. Ideally, tissue will be collected at the presumed site of infection.

Respiratory Tract

- Bronchoscopy specimens include bronchoalveolar lavage, bronchial washing, bronchial brushing, and transbronchial biopsy specimens. The bronchoscope should be passed transorally in nonintubated patients or through the endotracheal tube in intubated patients. Bronchial wash or bronchoalveolar lavage specimens should be obtained before brushing or biopsy to minimize blood in the recovered fluid.
 - For lavage, sterile nonbacteriostatic 0.85% NaCl should be injected from a syringe through a biopsy channel of the bron-choscope. Recovered fluid should be placed in the transport vial.

- Bronchial brush specimens should be collected through a telescoping double catheter plugged with polyethylene glycol at the distal end (to prevent contamination of the bronchial brush) through the biopsy channel of the bronchoscope. The sample should be transported in a sterile container with a small amount of sterile nonbacteriostatic 0.85% NaCl.
- Lung aspirations should be placed in transport vial for laboratory submission.
- Pharyngeal samples are not acceptable.
- Nasal samples are of limited value. Culture requests should be limited to pathogen-specific samples, e.g., *Bordetella bronchiseptica*.

Urine

Samples should be collected by cystocentesis only. Catheterized samples generally are not preferred; if there is no alternative, collect from a fresh catheter, or (less ideal) discard the initial 5 to 10 mL of urine before collecting sample. Catheter tips or urine from a collection bag are not acceptable. Sample can be submitted in a red-top serum collection tube. Samples should be kept cold by submitting on ice and ensuring that samples are received by the laboratory within 24 hours of submission. Consider a urine paddle collection system supplied by some commerical diagnostic laboratories.

Blood Culture

Liquid medium is indicated. Volume is critical to maximize recovery. Bacteremia may consist of less than one colony-forming unit per mL of whole blood. Prepare the collection site using aseptic methods, and for blood cultures, note that at least three collections at three time points are indicated. Collection during a fever spike is recommended. For blood, the volume should be 1 part blood to 10 parts broth.

Cerebrospinal Fluid or Joint Fluids

Use blood culture bottle, and add entire sample asceptically to broth.

Other Body Fluids

See discussion of tissue aspiration.

Ocular

- In general, instill 1 or 2 drops of topical anesthetic. Organisms are more readily detected in scrapings than from a swab.
 - For conjunctival scrapings, scrape the lower tarsal conjunctiva with a sterilized spatula and place material directly into medium. Alternatively, use a calcium alginate swab or a cottontipped applicator to swab the inferior tarsal conjunctiva (inside surface of eyelid) and the fornix of the eye.
 - Consider collecting a conjunctival sample first, which might help you assess the possibility of contamination. Using short, firm strokes in one direction, scrape multiple areas of ulceration and suppuration with a sterilized spatula. The eyelid should remain open, and care should be taken to avoid eyelashes. Multiple scrapings are recommended because the depth and extent of viable organisms may vary. Inoculate each scraping directly to appropriate medium.

Box 6-2

Techniques in Culture Sampling-cont'd

• Intraocular fluid should be collected using needle aspiration. Aspirate should be used to directly inoculate appropriate medium, with immediate transport to the laboratory in an anaerobic transport system.

Gastrointestinal Tract

Fecal specimens are submitted primarily for the detection of *Campylobacter, Shigella*, and *Salmonella* spp.; *Clostridium difficile*; and, in certain cases, to detect Yersinia, Vibrio, and *Aeromonas* spp. and enterohemorrhagic *Escherichia coli*. Care should be taken to ensure that the sample is not contaminated with urine. Fecal white blood cells should be ordered on liquid stools to indicate degree of inflammation. Stool specimens should be mixed with transport medium to maintain viability of pathogens that may be present. Sample should be collected digitally wearing a sterile glove or using a sterile fecal loop.

*The laboratory to which the sample will be submitted should be consulted before collection to ensure that its recommendations are followed. These general guidelines are offered in the absence of specific guidance.

invasive procedures such as intubation (e.g., *S. pneumonia* in humans). *Enterococcus* also has expressed beta hemolysis. The laboratory may choose not to implement susceptibility testing for those isolates considered nonpathogenic, with the interpretation of pathogenicity by the microbiologist depending on the host circumstances, including sampling site. Such decision making can only be improved with effective communication between clinician and microbiologist.

The number of organisms may be helpful in identifying the cause and effect of microbial presence and infection. Isolation of multiple organisms from a site that is easily contaminated by normal flora may represent floral colonization rather than a polymicrobial infection.²⁴ In contrast, pure growth generally indicates infection and the potential need for therapy. For example, Pasteurella as one of several organisms collected from a nasal swab may not be relevant, but if cultured as a pure isolate, it is probably indicative of infection. A related indicator of infection is the intensity of growth. For countable tissues, the number of CFUs per mL of tissue should be considered when assessing whether the inoculum represents an infection (see previous discussion of inoculum size). Vibrant growth of a single organism generally is indicative of infection by a pathogen, even in an environment that is easily contaminated. If multiple organisms are cultured and the culture was improperly collected, cleansing of the site (if possible) and reculture may facilitate correct identification of the pathogen. If the culture was a properly collected sample, those isolates characterized by lighter growth might be deemphasized in favor of organisms with significant growth. Controlling the heavier growth may facilitate the patient's capacity to eradicate the less dense population. For example, E. coli, SIG, or alpha-hemolytic Streptococcus are rapid growers, and if present together, the organisms with the greater growth might be targeted. However, P. aeruginosa is an example of a slow grower that is easily overwhelmed by other organisms. The impact on different growth rates exemplifies the importance of post-collection sample handing (e.g., the need to refrigerate). The presence of slow-growing organisms in a properly collected sample generally indicates the need for treatment. Specialized procedures may be necessary to identify growth in tissues normally sterile (e.g., blood culture, cerebrospinal fluid, or well-collected

bronchial alveolar lavage). Thus as few as two colonies of *Pseudomonas* sp. cultured from a properly collected bronchial alveolar lavage might be considered significant, whereas the need for antimicrobial therapy might be reconsidered if growth is less than 10⁵ CFUs from a site that is easily contaminated (e.g., wounds, clean-catch or catheterized urine). Patient health also should be considered: whereas, up to 10³ CFU/mL of urine collected by cystocentesis may not be significant in normal dogs, it may be indicative of infection in a patient that is not concentrating urine (e.g., because of renal disease, diuretic or fluid therapy).

Although the susceptibility patterns of an isolate may offer clues as to pathogenicity of the cultured isolate, care must also be taken with this approach. Contaminants are often characterized by patterns of susceptibility rather than resistance. However, such an isolate may yet be a pathogen, particularly in a patient with no previous history of antimicrobial exposure. Complex patterns of resistance may suggest the isolate is an infecting pathogen rather than a colonizing commensal. This is exemplified by nosocomial organisms associated with medical treatments (arising within 48 hours of hospital admission). However, Stenotrophomona and Serratia are common contaminants of antiseptics or disinfectants that are characterized by complex patterns of resistance. Multidrug resistance (discussed later) must also be considered in the context of the inherent susceptibility of the organism, being relevant only if expressed toward drugs to which the organism should be susceptible. For example, P. aeruginosa may be tested toward drugs to which it is inherently resistant, yielding results that appear to suggest the isolates as multidrug resistant. However, multidrug resistance should not be considered unless expressed toward ticarcillin, carbapenems, or aminoglycosides.

The clinical microbiologist can be a powerful ally in determining the significance of isolates yielded from a sample culture. The microbiologist that is trained in veterinary medicine will be of most benefit in providing guidance regarding the relevance of the isolated microbe. However, the contributions of the clinical microbiologist will be markedly curtailed if an insufficient history of the patient from which the sample was collected is provided.

Interpreting Culture and Susceptibility Test Results

The in vitro data generated by C&S testing eventually must be applied to in vivo patient conditions. Testing methods themselves may influence results such that the data are misinterpreted. The complex nature of C&S procedures mandates standardization and a well-documented quality control program. The Committee on Laboratory Standards Institute (CLSI; previously the National Committee for Clinical Laboratory Standards [NCCLS])³⁵⁻³⁹ validates method protocols, guidelines, and interpretive standards for C&S and molecular testing; one of its subcommittees promulgate veterinaryspecific standards.^{37,38} These standards and guidelines, which are applicable throughout the nation, and are often used internationally, reflect careful and exhaustive review of PD (microbial response to drug) and PK (host handling of drug) data. Because microbial populations are dynamic, standards and guidelines addressing their culture and susceptibility are likewise dynamic. Intermittent re-examination results in new guidelines and adjusted criteria, as is appropriate for changing microbial trends. CLSI publishes its findings so that clinical microbiological laboratories can access and implement the standards. An important caveat to C&S testing is that manufacturers supplying materials to the laboratory may not implement recommended changes in their materials in a timely fashion. Further, some veterinary diagnostic micribiological laboratories do not necessarily adhere to these standards but rather generate their own guidelines. Yet only CLSI standards undergo national peer review assessment and discussion among unbiased experts representing government, industry, academia, and clinical practice.

CLSI has generated guidelines for a variety of C&S testing methods. The PD information varies with the susceptibility procedures, with disk diffusion (Figure 6-4) and broth dilution (Figure 6-5) offering excellent examples of contrasts in advantages.⁴⁰ It is the latter that provides the minimum inhibitory concentrations (MICs) necessary for comparison among drugs and design of dosing regimens. The data generated from culture and susceptibility testing represents the PD portion of PK–PD integration in that it indicates what is needed to target the microbe.

KEY POINT 6-7 The veterinary clinical microbiologist is a powerful ally in the interpretation of culture and susceptibility testing data.

Disk Diffusion Versus Broth Dilution Techniques

Both methods of susceptibility testing require rapid growth of organisms and therefore may not be available for all organisms. Broth dilution data are particularly dependent on rapid growth, and for some organisms disk diffusion may be the only available means of obtaining data. The disk diffusion method (e.g., Kirby–Bauer) involves disks that contain a known amount of the drug of interest. The agar is streaked with a standardized inoculum of the isolated organism, and the disks are placed in standardized positions on the inoculated gel. Drug diffuses from the disk into the agar at a known rate (see

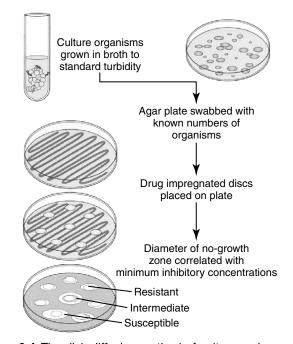

Figure 6-4 The disk diffusion method of culture and susceptibility testing. Drug diffusion from the disk results in concentrations that are higher close to the disk and gradually decrease as the diameter of the zone surrounding the disk increases. Resistant organisms can grow close to the disk despite high drug concentrations in the agar, whereas susceptible organisms will be inhibited at a standard distance from the disk. Concentrations in the agar correlate with the minimum inhibitory concentration (MIC) of the drug.

Figure 6-4),⁴⁰ such that, at a standard time, the concentration in the agar correlates with the minimum inhibitory concentration (MIC) of the drug as would be determined by the broth dilution procedures (the most common method serving as a gold-standard to other methods). At the prescribed time (i.e., as specified by CLSI³⁵⁻³⁷), a zone of no microbial growth (in mm) is measured around the disk. Because the concentration of the drug decreases with the distance (zone) diameter from the disk, the larger the zone, the lower the concentration of drug necessary to inhibit the growth of the organism and the more likely effective drug concentrations will be achieved at the site of the infection. A susceptible ("S") designation is given if the zone is sufficiently large. Growth up to the designated zone indicates that the concentration of drug necessary to inhibit the organism is too high to achieve in the patient, leading to a resistant ("R") designation. Intermediate ("I") designation is provided for some drugs. Zone sizes necessary for an organism to be considered susceptible as opposed to resistant to a specific drug are variable and are very sensitive to disruptions in protocols, which underscores the importance of following standards. An advantage to the disk diffusion method is that multiple drugs might be simultaneously tested on one plate. This is in contrast to the more tedious and costly, yet more informative, broth dilution methods. Because disk

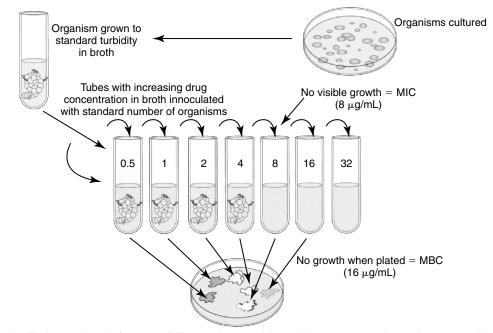

Figure 6-5 The broth dilution method of susceptibility testing provides a drug concentration to be targeted in the patient. Tubes containing serially increasing concentrations of drug are inoculated with a standard amount of the bacterial organism. At the proper time, tubes are observed for evidence of growth. The first tube (i.e., the one with the lowest concentration) that shows no evidence of growth contains the minimum inhibitory concentration (MIC) of the drug. The MIC can be used to evaluate relative drug efficacy and development of resistance and to calculate dosing regimens. This method is also one means by which the minimum bactericidal concentration (MBC) of a drug is determined. If the tubes exhibiting no growth are then used to inoculate solid agar, those tubes that yield no bacterial growth contained sufficient drug to kill, rather than simply inhibit, bacteria. The test tube that contains the lowest concentration of drug that yields no growth contains the MBC. If the MBC approximates the MIC, then the drug can be considered bactericidal.

diffusion results are reported as S, I, or R, it is described as semiquantitative.

In contrast to the disk diffusion method, the broth dilution method provides quantitative data regarding the amount of drug necessary to inhibit microbial growth (see Figure 6-5).⁴¹ For each drug of interest, tubes of liquid media are spiked with concentrations of the drug of interest, with the highest concentration generally being that just below the CLSI threshold of susceptibility (resistant MIC breakpoint). Subsequent test tubes containing serially diluted (by half) concentrations of the drug. As such, MICs are generally reported out as logarithmic fractions or multiples of 1 µg/mL (i.e., from lowest to highest 0.0312, 0.0615, 0.125, 0.25, 0.5, 1, 2, 4, 8, 16, 32, 64, 128, 256, 512; see Figure 6-5). Each drug to be tested must involve multiple test tubes or wells. The low and high range of concentrations tested for each drug will vary depending on concentrations achieved in tissues (including blood) when administered at recommended dosing regimens to the target species. For example, the ranges tested for ticarcillin would be expected to be much higher than the concentrations tested for enrofloxacin because the maximum concentration achieved in serum after administration of a recommended dose will be much higher for ticarcillin than for enrofloxacin (see Chapter 9). Occasionally, the MIC for some drugs deviates from the aforementioned tested concentrations; generally, these are drugs marketed as combinations (e.g., trimethoprim/sulfonamide combination). PD data generated for package inserts

or scientific reports also may incorporate dilutions other than those delineated by CLSI. It is important to remember that CLSI guidelines are intended only to support clinical microbiological laboratories that provide direct support for patient care.

The tubes that contain broth (standardized type and amount) of the appropriate dilutions of the drug of interest must be inoculated with a standard number of the isolated bacterial organism during the logarithmic phase of growth. Microbial growth continues under standardized conditions for the standardized period (as set by CLSI³⁵⁻³⁷). At the end of the incubation period, each tube is observed for evidence of growth. Evidence of growth is determined visually or using computer systems that allow miniaturized automation (see Figure 6-5 and Figure 6-6) The tube with the lowest concentration of drug that exhibits no detectable growth contains the MIC (in $\mu g/mL$), or the minimum amount of antimicrobial necessary to (in vitro) inhibit the growth of the organism cultured from the patient.^{23,41} Because of the complexities of the procedures, laboratories that provide clinical C&S testing may find MIC results on the same isolate that vary, even if CLSI guidelines and interpretive standards are followed. Generally, variations within 1 broth dilution are not considered significant. Laboratories ensure that quality standards of testing are met by performing drug MIC determination for control isolates (i.e., obtained from American Testing Cell Culture: e.g, E. coli ATCC 25922, Staphylococcus intermedius ATCC 45222).⁴¹

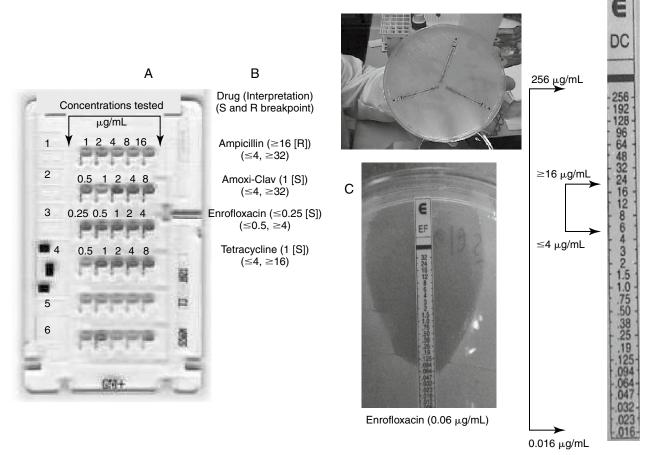

Figure 6-6 A, A commercially available antibiogram card and an E-test (C-D) with interpretation. The commercially available antibiogram card is a miniaturized broth dilution procedure that generates minimum inhibitory concentration (MIC) using a microwell design. Generally, one card is made for gram-negative isolates and another for gram-positive isolates. The size of the card limits testing of the number of drugs and the range of concentrations, with concentrations approximating the susceptible and resistant breakpoints (indicated under each drug). Some cards test only the susceptible and resistant breakpoints. Growth is indicated by a color change (all wells had growth in row 1, indicating resistance to ampicillin, but no wells had growth in row 3, indicating susceptibility to enrofloxacin). The ranges tested (above the wells) and interpretations (to the right of each drug) are provided for four of the drugs tested on the card. None of the isolates tested intermediate. A limitation of the cards is ability to indicate how susceptible an isolate is. This limitation is largely overcome with the E-test system (C; strip is enrofloxacin). Each strip releases the drug into the medium at logarithmic rates. Growth in susceptible isolates follows a tear-shaped pattern, with the point of the tear indicating the MIC. Advantages of the E-test include a very broad range of test concentrations (over16,00-fold) indicated by outer bracket (see Table 6-3), exceeding both the susceptible and resistant breakpoints (indicated by inner bracket) by several magnitudes, thus allowing assessment of how susceptible or resistant the isolate might be to the drug of interest. The MIC of this isolate is 0.06 µg/mL; for comparison, the lowest concentration that would be tested on the antibiogram. The E-test suggests that this isolate is moderately susceptible to doxycycline. The differences in the MIC between the microwell dilution and the E-test may reflect subtle differences in methodology but also the lipophilic nature of doxycline (better penetrability), thus highlighting a caveat of susceptibility testing: model drugs do not always represent the drug of interest well. Another advantage of the E-test is the smaller increments of change, and thus greater precision provided compared with tube dilution procedures. A more precise dosing regimen can thus be designed. For example, with standard tube dilution, concentrations increased from 8 to 16, whereas with E-testing, concentrations increased from 8 to 12 to 16 µg/mL. Finally, the individual nature of the test strips allows a "pick and choose" approach to individualizing drug therapy. This also, however, is a disadvantage in that costs are higher when multiple drugs are tested.

Research publications that address bacterial PD likewise should demonstrate adherence to CLSI guidelines, including quality-control procedures.

Broth dilution reports provide both the MIC (a concentration, reported in $\mu g/mL$) and (assuming CLSI procedures

are followed), the CLSI interpretation of S, I, or R for that MIC. The basis of the interpretation (S, I, or R) for broth dilution procedures is addressed later in this chapter. The MIC for selected drugs may be accompanied by a " \leq " or " \geq ". Using Figure 6-7 as an example, *Pseudomonas* have an MIC for

D

		Staphylo	ococci	s sp Pse	udomon	as sp.

Figure 6-7 An example of a C&S report for broth dilution. The breakpoints have been added in parantheses this report; for ampicillin and penicillin, a second breakpoint in [brackets] is for the gram-negative organisms (see text and Table 6.2). The relative in vitro efficacy of antibiotics to which an organism is susceptible can be evaluated by comparing the minimum inhibitory concentration (MIC) of the organism. For Staphylococcus, the resistant MIC breakpoint to MIC ratio is 64/4, whereas that for gentamicin is 16/4 or two tube dilutions from the breakpoint. Although the isolate is considered susceptible to both drugs, amikacin presumably would be more effective (although neither generally should be used alone to treat Staphylococcus). Differences greater than one tube dilution should be considered significant. For the beta-lactams, effective treatment of Staphylococcus with cephalothin (the model drug for cephalexin) may be more easily achieved (ratio of 8/2) compared to amoxicillin clavulanic acid (ratio of 0.25/0.25). However, as time-dependent drugs, elimination half-life of both drugs would need to be considered. All values (concentrations) are in up per mL. S = susceptible; R = resistant; I = intermediate.

amikacin of $\leq 4 \mu g/mL$. The \leq indicates the absence of growth in the lowest concentration of amikacin tested by this laboratory (8 µg/mL); this lowest concentration may be different among laboratories that use different systems. However, often the lowest dilution tested is at or just below the lower threshold of susceptibility (the susceptible MIC breakpoint; see later definition) set by CLSI. Testing at concentrations at or very close to the susceptible breakpoint of a drug is a major disadvantage of current susceptibility testing methods: either isolate may be very susceptible to amikacin such that their actual MIC may be several tube dilutions below the lowest concentration tested (see below). As such, the closest approximation to the actual MIC for either isolate will be the concentration below the lowest dilution tested by the laboratory (i.e., $\leq 4 \mu g/$ mL or $<8 \,\mu\text{g/ml}$ both indicate the same result). The isolate will be accompanied by an "S" designation, indicating susceptibility because the MIC is at or below the susceptible breakpoint determined by CLSI (Table 6-2). At the other end of the testing range, an MIC accompanied by \geq indicates that growth was present in the highest concentration tested by the laboratory.

Generally, for most automated procedures, the highest concentration tested is 1 tube dilution below the upper threshold of susceptibility (the resistant MIC breakpoint) set by CLSI for each drug (Table 6-2). For example, for cephalothin (the model drug for cephalexin in this example), the upper threshold of susceptibility (the resistant MIC breakpoint) set by CLSI is 8 µg/mL. Thus for Pseudomonas, growth was present in the well containing 4 µg/mL, indicating that the actual MIC is equal to or higher than 8 μ g/mL (\geq 16 μ g/mL or >8 μ g/ mL both indicate the same result). However, again the testing range limitations of the current procedures emerges in that level of resistance of the isolate cannot be assessed. The isolate may be characterized by low-level resistance, although this is unlikely for P. aeruginosa and first-generation cephalosporins (indeed, testing of P. aerugniosa toward cephalothin is not appropriate). However, unless the range tested extends beyond the resistant breakpoint, all that is known is that the isolate is resistant, and the MIC will be accompanied by an R designation.

KEY POINT 6-8 Culture and susceptibility testing ideally is performed following the guidelines of the Clinical Laboratory Standards Institute (CLSI).

Among the pitfalls of C&S testing are the stepwise dilutions and the range of concentrations tested for each drug. The twofold dilutions at which MIC are tested affect the design of dosing regimens at the higher MIC. Precision in the design of dose would be facilitated if MICs could be determined between the tube dilutions. For example, the dose to target 64 µg/mL would be substantially cheaper and potentially safer than that necessary to target 128 µg/mL. The limited range of concentrations tested for each drug negatively affects the ability to identify the drug to which the isolate is most susceptible (see Figure 6-6).⁴¹ Ideally, concentrations tested by broth dilution procedures should span the range of drug concentrations that characterize the range of MICs established in a sample population of isolates of the organisms, with the highest concentration being at least one dilution above the highest drug concentration acheived in target biological fluids.⁴¹ However, automated systems test in a very narrow range. As previously noted, because the lowest concentrations are at or just below the lower limit of susceptibility, isolates that are very susceptible to the drug of interest cannot be indentified (see Table 6-2). Therefore standard antibiograms are more indicative of resistance rather than susceptibility.

A third testing system approved by the Food and Drug Administration (FDA) offers advantages to the standard commercial broth dilution card. The "E test" (Epsilon test) combines the simplicity of disk diffusion with the informative nature of broth dilution, but goes beyond standard broth dilution procedures. (see Figure 6-6). In general, MICs generated by the E-test correlate well with MICs generated from broth dilution procedures.⁴² A disadvantage of the E-test is that the length of the test strip limits the number of drugs that can be tested on a large plate (three strips for a large plate, one for a small plate), which contributes to the cost of the testing.

Drug	Breakpoint μg/mL Susceptible ¹	Breakpoint MIC (µg/mL) Resistant ¹	Drug	Breakpoint μg/mL Susceptible¹	Breakpoint (μg/mL) Resistant ¹

 Table 6-2
 Interpretive Standards for Disk Diffusion Equivalent Minimum Inhibitory Concentration

 Breakpoints for Selected Antimicrobials

MIC, Minimum inhibitory concentration.

*Old breakpoints replaced by Clinical Laboratory Standards Institute (CLSI) for amoxicillin–clavulanic acid for all organisms were, for *Staphylococcus* \leq 4/2 = S, and \geq 8/4 = R and for non-staphylococci, \leq 8/2,=S and \geq 32/16 = R. The provision of a separate breakpoint of \leq 8 µg/mL for UTI is new.

¹Clinical Laboratory Standards replaced by CLSI for cephalexin were $\leq 8 = S$, and $\geq 32 = R$. The new breakpoints were becoming official at the time of publication.

Institute Interpretive standards that are based on animal pathogens are designated by an asterisk.

²When testing *Staphyloccocus* organisms

³When testing gram-negative enteric organisms

⁴Ampicillin is used to test amoxicillin

⁵When testing *Pseudomonas* organisms

⁶Oxacillin is used to treat methicillin, cloxacillin

⁷Cephalothin is used to test all first-generation cephalosporins. Does not represent cefazolin, which should be tested separately if a gram-negative organism.

⁸Clindamycin is used to test lincomycin, which is less susceptible to *Staphylococcus*.

⁹When testing *Streptococcus (S. pneumoniae* for levofloxacin)

¹⁰When testing pathogens associated with food animal respiratory disease

¹¹Trimethoprim–sulfamethoxazole is used to test trimethoprim–sulfadiazine and ormetoprim–sulfadimethoxine

¹²For urinary tract infections

¹³For soft tissue infections

¹⁴Used to test chlortetracycline, oxytetracycline, minocycline, doxycycline

¹⁵When testing Enterococcus organisms

¹⁶A human criteria deemed relevant to dogs and cats. Note reduced oral bioavailability (mean of 40%) in dogs and negligible (0%-20%) in cats.

Drug Class	Antimicrobial Drug	CLSI Breakpoints (S, R)	MIC range (µg/mL) of E-test
Penicillins	Ampicillin	≤8,≥32	0.5-256
	Amoxicillin-clavulanic acid	≤8/4,≥32/16	0.25-512
Cephalosporins	Cefpodoxime	≤2,≥8	0.12-128
Fluoroquinolones	Enrofloxacin	≤0.5,≥4	0.06-128
Tetracyclines	Doxycycline	≤4,≥16	0.25-512
Aminoglycosides	Gentamicin	≤4,≥8	0.12-256
Potentiated sulfa	Trimethoprim-sulfamethoxazole	≤2,≥8	0.06-128

Table 6-3 Examples of Minimum Inhibitory Concentration Banges Covered by the E-test

CLSI, Clinical Laboratory Standards Institute; *MIC*, minimum inhibitory concentration; *R*, resistant; *S*, susceptible.

However, because the drugs can be chosen for each patient, the method lends itself well to expanded susceptibility testing in the presence of a multidrug-resistant isolate. Although E tests are tedious and expensive, the wider range of concentrations tested (up to 1600-fold differences; Table 6-3) includes MICs well below the lower and higher thresholds of susceptibility, thus allowing identification of very susceptible isolates. Further, isolates with low-level resistance might be identified, potentially justifying the use of the drug, albeit at a higher dose or in combination with another drug.

KEY POINT 6-9 The E-test, but not current broth dilution procedures, allows identification of very susceptible isolates and isolates with low-level resistance.

Because of the inherent risks of inaccuracy associated with any C&S testing procedure, results yielded from procedures that are not based on CLSI standards should be interpreted with caution. Aspects subject to variability include pH; cation content and osmolality of the media; inoculum size; media volume; temperature and duration of incubation; humidity; and, for broth dilution, the method of observing growth.⁴¹ Accordingly, in practice, culture methods should be considered less than ideal unless CLSI protocols are followed. Further, preliminary data, quick "snap" tests, or other methods intended to generate rapid results must be interpreted cautiously; the role of the organisms in causing infection and the susceptibility of the organisms (unless identified as a multidrug-resistant microbe) may require full C&S testing. Whereas the FDA is responsible for approval of diagnostic tests for human medicine, such a pathway is not required for veterinary diagnostic tests.

Population Pharmacodynamic Statistics

Agar Gel Versus Broth Dilution Pharmacodynamics

A nonquantitative but helpful summary of PD data is an antibiogram that indicates the proportion of isolates that are susceptible (or resistant) to the drug of interest (Figure 6-8). Although it does not provide information regarding the level of susceptibility, it can provide direction regarding empirical drug selection by indicating the likelihood that an organism is susceptible to the drug of choice. The antibiogram might be generated for each practice on the basis of cumulative data summarized on an annual basis.

Population statistics generated from MICs can provide even more useful information. They are particularly helpful if MIC data is not available for an isolate infecting a patient. Population MIC statistics can be generated from a sample population of the same organism; ideally, at least 100 isolates will be collected from different patients. Pertinent PD (MIC) statistics that describe the population distribution include the range (lowest and highest MICs recorded for any isolate representing the organism), mode (the most frequently reported MIC), median (the middle MIC, the 50^{th} percentile or MIC₅₀), and the MIC₉₀ (or the 90th percentile MIC; the MIC at which 90% of the organisms are inhibited (see Figures 6-9 to 6-11). The two-fold dilution nature of MIC determination mandates that the geometric mean (converted to account for the noncontinous nature of MIC) be reported rather than arithmetic mean. If an MIC is not available for an organism infecting a patient, the MIC_{90} (or even more ideally, the MIC_{100}) of a drug for an organism is the preferred surrogate indicator of "what is needed" by the author. For example, if S. pseudintermedius is a known or suspected cause of pyoderma in a patient and the drug to be chosen empirically is cephalexin, the MIC₉₀ of S. intermedius for cephelexin⁴³ can be used as an indicator of "what is needed"-that is, the PD target for therapy in the patient. PD information can be found on many package inserts scientific literature^{43,44} or textbooks (veterinary for animal drugs, human if not), and other resources (see Table 6-4 and Chapter 7). However, the dynamic nature of microbes in response to the presence of antimicrobials may render some population data obsolete even within several years of collection. In addition to the species, a number of host factors are likely to affect the sample population statistics and its applicability to the patient. Among the more important factors is previous exposure to antimicrobials, which is likely to be associated with higher MICs compared with MICs of isolates collected from antimicrobial-naïve animals (i.e., not pathogens). Ideally, separate statistics might be promulgated for isolates collected from animals not previously exposed to antimicrobials.

KEY POINT 6-10 Recent population pharmacodynamic data such as the MIC_{90} can serve as a reasonable surrogate for patient data.

Klebsiella	No. of Isolates	Amikacin	Amoxicillin/CA	Ampicillin	Cefazolin	Cefoxitin	Ceftiofur	Cephalothin ^b	Chloramphenicol	Clindamycin	Enrofloxacin	Erythromycin	Gentamicin	Marbofloxacin	Orbifloxacin	Oxacillin	Penicillin	Tetracycline	Ticarcillin	Ticarcillin/CA	Trimethoprim/Sulfa

Figure 6-8 A cumulative antibiogram generated for the target species can be helpful in identifying drugs to which acquired resistance has emerged. The data will be specific to the facility (i.e., hospital). The number in each cell refers to the number of tested isolates designated as susceptible to the drug. When present, the number in parentheses in each cell refers to the number of isolates tested for that drug; otherwise, the number of isolates tested is indicated in the second left-hand column. Note that the data indicate that one species in a genera may not be well represented by another species in the same genera, particularly for *Enterococcus* and *Staphylococcus* genera.

Comparing PD data of a drug reveals differential susceptibility among organisms toward each drug. For example, using the antimicrobial package insert, comparison of MIC_{90} among different organisms reveals that *P. aeruginosa* tends to be susceptible (if at all) only at high concentrations compared with the more susceptible *Pasteurella multocida* (see Figure 6-11). The MIC_{90} of *P. aeruginosa* more often than not approaches or surpasses the upper threshold of susceptibility for most drugs. Thus achieving effective antimicrobial concentrations is more likely to be difficult in the patient infected with *P. aeruginosa* compared with one infected with *Pasteurella*. A review of the antimicrobial package insert reveals other differential susceptibilities.

The distribution of the MICs of organisms for drugs can help identify emerging resistance. For example, the distribution of *E. coli* for several drugs (see Figure 6-10) is bimodal, representing two different populations. The majority of isolates in the first population are characterized by an MIC well below the susceptible threshold of susceptibility (i.e., susceptible MIC breakpoint). This data demonstrates that even isolates considered susceptible are characterized by MIC that are close to the susceptible breakpoint. Further, a substantial portion of the population is higher than the upper threshold of susceptibility—that is, the MIC₉₀ exceeds the resistant MIC breakpoint. It is very possible that the second population, characterized by higher MICs, probably represents isolates previously exposed to antimicrobials; as such, culture would be prudent for those animals previously exposed to antimicrobials. Finally, detecting increasing MICs determined from sequential cultures of the same organisms in a patient with recurrent infections might indicate emerging resistance, likewise, comparison of the MIC₉₀ of a sample population of an organism across time can reveal emerging resistance.

The Minimum Inhibitory Concentration: Determining Susceptibility Versus Resistance

Susceptibility data based on broth dilution procedures that are reported for a patient will include the MIC, as well as a susceptible, intermediate, or resistant (SIR) interpretation.

KEY POINT 6-11 Simplistically, the MIC is the pharmacodynamic target of antimicrobial therapy, indicating the minimum concentration to be achieved at the site of infection. However, it is only a starting point.

The clinical microbiology laboratory provides the interpretation on the basis of CLSI interpretive criteria. The criteria for broth dilution procedures are presented as thresholds or breakpoint MICs (MIC_{BP}) whose values will also be in terms of the concentrations tested for each drug (i.e., multiples or

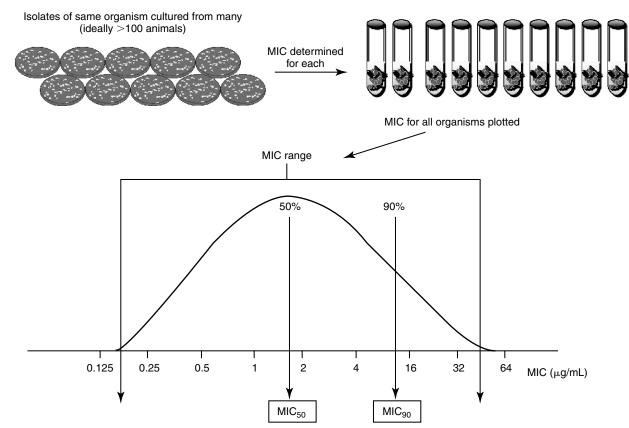

Figure 6-9 Population pharmacodynamic data. Each sample collected from a different animal (same species) yields an isolate of the organism of interest. Ideally, at least 100 representative isolates will be tested. The minimum inhibitory concentration (MIC) of each isolate is determined, and all are plotted in a distribution curve. The range represents the lowest and highest MIC determined for the isolate; the mode would be the most frequent MIC reported and the median represents the middle MIC or the 50^{th} percentile (which, for normally distributed data, also represents the MIC) The MIC₉₀ is the 90th percentile MIC. A representative package insert demonstrating the presentation of population pharmacodynamic data can be found in Figure 6-11.

fractions of 1 μ g/mL) (see Table 6-2). Two breakpoints are provided for each drug. An isolate inhibited at a concentration at or below the lower threshold or susceptible MIC breakpoint will be designated "S," whereas an isolate that is able to grow after in vitro exposure to a drug concentration that equals the upper threshold or the resistant MIC breakpoint will be designated "R." The susceptible breakpoint is at least one broth dilution below the resistant breakpoint for all drugs; for some drugs the susceptible breakpoint is 2 or more broth dilutions below the resistant breakpoint, allowing for an intermediate, or "I," designation (see Figure 6-6). For example, for enrofloxacin, the susceptible and resistant MIC_{BP} are ≤ 0.5 and $\geq 4 \ \mu g/mL$, respectively. Thus an isolate whose growth (under in vitro conditions specified by CLSI) is inhibited with as little as $0.5 \,\mu\text{g/mL}$ or less will be designated as "S." On the other hand, if growth is present in the well that contains 2 μ g/mL, then 4 μ g/mL (the next broth dilution) or more will be necessary to inhibit the growth of the isolate, and the isolate will be designated as "R," or resistant to enrofloxacin. An additional broth dilution occurs between 0.5 and $2 \mu g/mL$. Isolates that are inhibited by enrofloxacin at $1 \mu g/mL$ will be designated as intermediate, or "I." An isolate with an "I" designation has developed some level of resistance, and such isolates should be treated with that drug only cautiously, at higher doses, or in combination with a complementary antimicrobial drug. The more prudent approach would be to consider "I" isolates as "R" for that drug. Use might also be considered in circumstances in which the drug accumulates in active (i.e., unbound) form at the site of infection such that concentrations exceed that achieved in plasma. Examples might include urine (produced by the normally functioning kidney) or accumulation in phagocytic white blood cells (selected drugs). Note, however, that such concentrations may yet be insufficient.

KEY POINT 6-12 Interpretive criteria for susceptibility testing by CLSI is dynamic, changing across time as microbes acquire resistance. However, once generated, the data is applicable for all laboratories in the United States.

CLSI determines the thresholds of susceptibilities—that is, the lower (susceptible) and upper (resistant) breakpoint MIC_{BP} for each drug after exhaustive evaluation of both PK data in the target species and PD data for the drug of interest toward the microbes of interest. For animal drugs approved

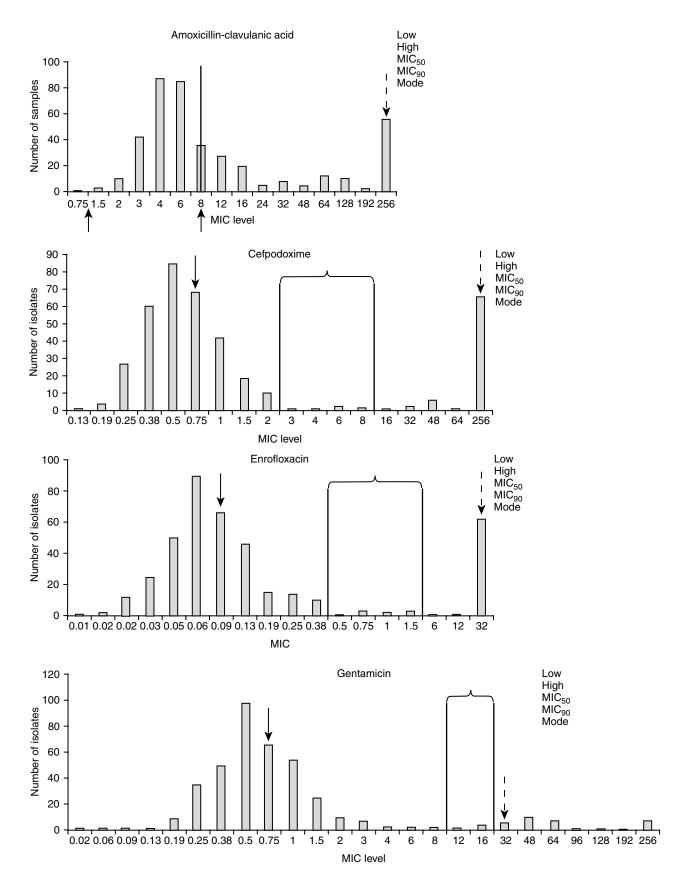

Figure 6-10 Population distributions of canine and feline *Escherichia coli* pathogens' minimum inhibitory concentration (MIC) based on E-testing for two time-dependent drugs (amoxicillin–clavulanic acid, and cefpodoxime, *upper plots*) and two concentrationdependent drugs (enrofloxacin, and gentamicin, *lower plots*). The susceptible *(left)* and resistant *(right)* breakpoints, as identifed by Committee on Laboratory Standards Institute, are indicated in brackets and lines except for amoxicillin. CLSI's new breakpoints are indicated by arrows ($\leq 8 \mu g/mL$ for the susceptible breakpoint for isolates collected from the urinary the resistant breakpoint for other isolates; indicated by arrows below x axis). The distribution is bimodal for all drugs except gentamicin, as is indicated by a second distribution of isolates with an MIC well above the resistant breakpoint. This second population of isolates will cause the MIC₉₀ *(dashed arrow)* to exceed the breakpoint. The range is represented by the lowest and highest MIC recorded (either may be limited by the range tested), the median is the 50th percentile (or MIC₅₀) *(solid arrow)* the MIC₉₀ is the 90th percentile, and the mode is the most common MIC reported for that isolate and drug. Because an E-test was used, the MIC tested are not limited to two-fold dilutions. Because these isolates are pathogens that have been cultured from dogs or cats with spontaneous disease, they may represent isolates already exposed to antimicrobials which may explain the bimodal distribution (i.e., these isolates may have undergone stepwise mutations). The population distribution of drug-naïve only isolates is likely to be somewhat lower.

Parameter For oral use in dogs and cats only	Dog Mean ± SD* (2.5mg/lb) n=6	Dose Dog Mean ± SD* (5.5mg/lb) n=6	Cat Mean ± SD* (5.5mg/lb) n=7

Volume of distribution (area)/F ^c	4.7 L/kg				
Table: Plasma pharmacokinetics following administration of FQB tablets (5 mg/kg body weight) to dogs (n=20).					

Figure 6-11 Package insert information two fluoroquinolones, FQA (top) and FQB (bottom). Comparison of MIC₉₀ among isolates for FQA suggests that *Pasteurella* sp. should be more easily treated compared with *Escherichia coli* for both drugs. Integration of pharmacokinetic data (C_{max} for these concentration-dependent drugs) and pharmacodynamic data (MIC₉₀) can be used to identify which drug is best used to treat each microbe and which dose might be used to treat the microbe. For example, for FQA at the low dose of 2.5 mg/kg, when treating *E. coli* (and no patient-specific MIC is available), the C_{max} is 2 µg/mL and the MIC₉₀ is 0.06 µg/mL, resulting in a C_{max} /MIC₉₀ ratio of 25. For *Proteus*, the ratio is 2/0.125, or 16. For concentration-dependent drugs, the target ratio is ≥10, suggesting the low dose may be effective for both, but the large dose might be considered for *Proteus* if the patient is considered at risk. The number of isolates of *P. aeruginosa* is not sufficient to represent the population. If the process is repeated for FQB with a C_{max} of 1.8 µg/mL at the low dose, the MIC₉₀ for *E. coli is* 0.11 µg/mL, resulting in a ratio of 16. For *Proteus*, the MIC₉₀ is 0.8 µg/mL, resulting in a ratio of only 1. Although the dose might be sufficient for *E. coli*, the target ratio could not be reached even at the higher dose for *Proteus*. Note that the number of organisms on which the data are based for each organism often does not reach the ideal target of 100. The smaller the sample size, the more caution is indicated when extrapolating this data to the general population. (From Pfizer, Package Insert and Fort Dodge, Package Insert)

in the last several decades (only since then have MIC become standard testing procedures), it is likely that some of the data were collected by the drug manufacturer during the approval process. However, both PK and PD data may be drawn from peer-reviewed literature or other sources, particularly for drugs not approved for use in the target species, or for drugs whose susceptibility thresholds are being re-evaluated by CLSI.

Three criteria must be met for CLSI to establish an MIC_{BP} for each drug. The primary and initial consideration is the population distributions, with a focus on both the statistics as well as the type (i.e., modal or bimodal; see Figure 6-10). Obvious patterns of low versus high MICs can be used to identify susceptible "cutoffs" or breakpoints. Statistics will be compared among different strains of the same species being tested. Note that some organisms may be much more susceptible to the drug of interest—that is, they have MIC_{50} and MIC_{90} that are much lower compared with other organisms (e.g., *pasteurella* and *pseudomonas*). However, CLSI generally provides only one set of criteria for all susceptible isolates.

The second consideration upon which criteria are based is, the clinical pharmacology of the drug, ideally in the target species. Among the more important PK parameters evaluated by CLSI are the peak and trough plasma drug concentrations (C_{max} and C_{min}), area under the curve (AUC) for a 24-hour dosing period, and the drug elimination half-life (see later discussion of PD indices) (Figure 6-12).41,45-51 Volume of distribution; protein binding; and, when available, tissue (including urine) concentrations are also considered. Presumably, the MIC of an isolate considered susceptible should be below the peak plasma or tissue drug concentrations or C_{max} of a given drug when administered at a recommended dose. Indeed, selected resistant breakpoints correlate with C_{max}, as is demonstrated for amikacin when administered to dogs at 22 mg/ kg. The C_{max} of 65 µg/mL (see Chapter 7) is similar to the resistant breakpoint for amikacin. However, for some breakpoints, the correlation does not exist, as is exemplified by amoxicillin/clavulanic. The C_{max} of the labeled dose of 13.5 mg/kg, administered orally, will generate a C_{max} of approximately 4 to 6 μ g/mL of amoxicillin in dogs, yet the resistant breakpoint for nonstaphylococcal organisms has been \geq 32 µg/mL, well beyond the concentrations that can be achieved in plasma at any reasonable dose. (In response to this disparity, CLSI has recently re-examined and readjusted the breakpoint for amoxicillin-clavulanic acid as is discussed below; see Table 6-2). Another limitation of setting breakpoints based on peak plasma drug concentrations is their lack of precision: breakpoints are limited to concentrations used for susceptibility testing and thus will be reported using twofold dilutions. As such, a resistant breakpoint concentration may be considerably higher or lower than the actual concentration achieved at the recommended dose. As such, the actual MIC reported for an infecting isolate should be compared to C_{max} reported in a sample population of the target species is an ideal default when selecting drugs (and the dosing regimen; see later discussion). The original veterinary fluoroquinolones were

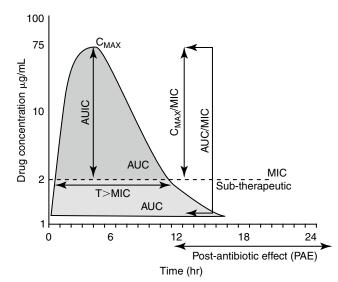

Figure 6-12 Pharmacodynamic indices (PDI) resulting from integration of pharmacokinetic (PK) data (from sample population of target or closely related surrogate species), represented here by C_{max} (µg/mL; target of 10 to 12) or area under the curve (AUC) (µg*hr/mL; target of 100-125), and microbial or pharmacodynamic (PD) data, represented here by minimum inhibitory concentration (MIC). Note that the PDI are based on (Mouton 2005⁴⁷ and Amsterdam 2005⁴¹). Note that activity should be based on free (unbound) drug. The pertinent PK parameters for this hypothetical drug and infecting microbe would be as follows: C_{max} of 75 μ g/mL, half-life of approximately 2 hours and AUC of 159 µg*hr/mL. The PD parameter, or MIC of the infecting organism, is 2 µg/mL. The PDI for this drug and microbe combination would be as follows: Cmax/ MIC = 37.5 (surpasses target for a concentration-dependent drug); AUC/MIC = 80 (insufficient for a gram-negative organism if a fluorinated guinolone but potentially sufficient for a gram-positive organism); and T > MIC = 8 hours, which would allow a 12, 16, or 24- (32 hr is not a reasonable interval) hour dosing interval for a time-dependent drug if the target T > MIC were 75%, 50%, or 25%, respectively. The AUIC (area under the inhibitory curve) is the integrated area of the curve above the MIC. Although somewhat similar to AUC/MIC, its use among investigators has caused confusion, leading experts in the field to focus on AUC/MIC as the area-based PDI of choice.

approved with "flexible labels" (multiple doses); for those drugs, the susceptible and resistant breakpoints reflect the C_{max} resulting from the lowest and highest labeled doses of the drug.

The third criteria that must be met as CLSI determines thresholds of susceptibility is one of clinical relevance. The MIC_{BP} must be clinically relevant—that is, the microorganisms defined as susceptible should respond clinically to the drug, and in vitro data must correlate adequately with in vivo findings.^{46,51} The MIC_{BP} values established by CLSI for each drug are generally not included in the susceptibility reports. However, having this information would be helpful because the MIC of the infecting organism might then be compared with the MIC_{BP} of the drug, allowing an assessment of "level" of susceptibility of the isolate to the drug of interest (discussed in more detail later). Breakpoints set by CLSI are based on isolates collected from across the country and accordingly are relevant for any clinical microbiology laboratory that uses CLSI protocols. As such, CLSI breakpoints generally can be obtained by any microbiology laboratory that uses CLSI criteria for its testing procedures (the preferred choice). Interpretive standards generally also are delineated on package inserts (including sources such as *Physicians' Desk Reference* for human-marketed drugs or similar veterinary compendiums).

In order to simplify the use of interpretive criteria, when possible, CLSI breakpoints are generally inclusive to organisms whose spectrum is included in the drug, regardless of the site of infection. However, notable exceptions occur for both organisms and tissues. Organism exceptions generally are those either very susceptible to the drug or for organisms that easily develop in vivo resistance. For example, lower or more stringent penicillin breakpoints have been promulgated for Staphylococcus spp. because their beta-lactamases are particularly destructive toward penicillins compared to cephalosporins. Because destructive activity decreases the amount of drug at the site, a second set of lower breakpoints are provided. A higher breakpoint has been established for other susceptible isolates (e.g., gram-negative organisms; see Table 6-2). In contrast to Staphylococcus, P. aeruginosa is particularly susceptible to ticarcillin; accordingly, while another coliform is considered resistant if it is inhibited at 16 µg/mL P. aeruginosa is still considered susceptible even if, in vitro, it grows in the presence of 64 µg/mL (see Table 6-2). Another consideration regarding inclusivity is the generation of tissue specific breakpoints. Interpretive criteria are based on plasma drug concentrations. However, renally excreted drugs achieve much higher concentrations in urine compared to plasma. New interpretive criteria for ampicillin and amoxicillin-clavulanic acid includes a separate breakpoint that is tissue dependent: a higher breakpoint ($\leq 8 \mu g/mL$) has been set for *E. coli*-associated urinary tract infections, compared to much lower breakpoints for other tissues. However, caution is recommended when selecting a drug for treatment of a UTI when the "S" designation for a urinary isolate is based on breakpoints that differ from plasma (see Chapter 8) as it assumes, among other considerations, that infection occurs only in the bladder, that urine is concentrated by the patient, and the duration of exposure fulfills the needs of a time-dependent drug (see later discussion). Just as resistance can be detected in an infecting organism collected from a patient, across time, statistics may also indicate resistance (i.e., the MIC and MIC statistics [mode, median, MIC₅₀, and MIC₉₀]). Because CLSI reviews new data intermittently, their criteria for interpretive standards should result in new MIC_{BP}, and laboratories will implement these changes. The sequelae of increasing MICs in certain populations should result in an increasing number of isolates designated as "R" for drugs to which the organisms traditionally have been considered susceptible. An example is amoxicillin-clavulanic acid, whose susceptible breakpoint was recently decreased by CLSI (see Table 6-2).

Integration of Pharmacokinetics and Pharmacodynamics: How Much Is Needed Versus How Much is Achieved?

The information provided on the C&S report can be used effectively beyond the simple identification of "S" drugs. The MIC is an indicator of what is needed to target the organism and thus provides the PD information for the infecting isolate. Often, an organism will be designated as susceptible to several drugs. One advantage to the broth dilution method compared with the disk diffusion method of C&S is the ability of the

KEY POINT 6-13 The closer the MIC (or MIC_{90}) of an organism is to the C_{max} , the greater the risk of therapeutic failure and the more important the need to modify the dosing regimen for the patient.

former to rank the drugs according to relative efficacy based on MIC. However, the relative efficacy of antimicrobials designated as "S" against a specific pathogen should not be determined by directly comparing MICs among different drugs, even drugs in the same class. The MIC varies among the drugs for a number of reasons beyond susceptibility. These include, but are not limited to, differences in molecular weight (one drug is simply heavier than another), the ability of the drug to penetrate the organism, the number of molecules necessary to "neutralize" the target, and differences in the mechanisms of action. Further, each drug achieves different concentrations in the patient as a result of differences in disposition. Thus antimicrobials differ in potency and MIC.⁴⁷ Rather than direct comparison to an isolate MIC for one drug to an MIC for another drug, one should also consider the concentration of drug that will be achieved in the patient when the drug is administered at the recommended dose (i.e., what is achieved; C_{max}). A less than ideal method of standardizing MIC is to compare how far the MIC of the drug of interest is from the resistant breakpoint (i.e., ratio of resistant MIC breakpoint of the drug to MIC of the organism). This is less ideal, as was previously discussed, because the resistant breakpoint does not always equate with the C_{max}.

The limitations in using MIC breakpoint as an indicator of what will be achieved in the patient reflect the serial concentration used for susceptibility testing. If a drug achieves a C_{max} of 24 µg/mL at the recommended dose, this concentration falls between 16 and 32 µg/mL serial dilutions. A susceptible breakpoint of 16 µg/mL might underestimate while a resistant breakpoint of 32 µg/mL would over overestimate what will be achieved at the recommended dose. Thus, a more relevant choice among the susceptible drugs might be based on comparing what is needed to what is achieved—in plasma (e.g., the C_{max}) when the drug is administered at the recommended dose. The ratio of C_{max} to MIC, however, requires that PK information be available for the drug of interest, ideally in the species of interest. This information often is available on package inserts for animal-approved drugs but must be collected from the literature for other drugs (see Chapter 7). The United States Pharmacopiea antimicrobial monographs published

by the Journal of Veterinary Pharmacology and Therapeutics (2007) offers a compilation of PK information for a variety of antimicrobials and animal species. The integration of PD and PK is the first step in selecting a drug. However, this step is preliminary in that it does not take into account other factors that affect tissue concentrations, including host and microbial factors.

The relationship between the MIC of the infecting organism (what is needed) and the C_{max} also should be used as a basis for designing a dosing regimen.⁴⁸⁻⁵⁰ The closer the MIC (or MIC₉₀) to the C_{max} (or the MIC_{BP}), the higher the dose and for time-dependent drugs, the shorter the interval that is indicated. For a more specific design of a dose, the MIC can serve as the targeted drug concentration (see Enhancing Antimicrobial Efficacy). If MIC data is not available from the isolate collected in the patient, population PD [MIC₉₀] data might be used as a surrogate PD indicator of how much is needed; (see Figure 6-11).

Caveats to Culture and Susceptibility Interpretation

Despite the usefulness of C&S testing, the information nonetheless reflects in vitro testing that must be applied to in vivo situations.^{40,41} Results can be misleading or misinterpreted, despite ideal sampling and C&S techniques. Some of the pitfalls reflect the limitations presented by practicalities in testing (e.g., economics, technology), whereas others reflect limitations of applying in vitro data to an in vivo system. Examples include the following:

1. The limitations presented in the number of drugs and range of concentrations tested were previously addressed. The hazards of interpreting an "S" designation without knowing *how* close the MIC is to the susceptible breakpoint may facilitate emerging resistance for those isolates whose MICs are approaching the breakpoint of the drug or the C_{max} of the drug given at the recommended dose. For example, an isolate whose MIC for enrofloxacin is 0.5 µg/mL is likely to already have undergone the first step toward resistance, compared to an isolate whose MIC is 0.06 µg/mL.

KEY POINT 6-14 Culture and susceptibility testing is an in vitro procedure and as such, cannot accurately mimic the conditions to which the data is applied—that is, the infected patient.

- 2. CLSI does not provide interpretive standards for all drugs; as such, these drugs do not appear on C&S testing, and MIC_{BP} are not available. This may be a decision on the part of the manufacturer of the drug not to pursue CLSI validation, the lack of adequate data for CLSI to determine criteria, or failure of the data to correlate with patient response. For such drugs population PD and PK data as reported in the literature, for example, may be the only reasonable approach to assess antimicrobial efficacy (see later discussion).
- 3. For some drug classes, CLSI has established criteria for a model drug that serves to reflect patterns of susceptibility

for other members in the same class. In some instances cross-susceptibility and resistance justify this approach (e.g., fluorinated quinolones might represent all veterinary fluorinated quinolones, ampicillin accurately predicts amoxicillin, and sulfamethoxazole/trimethoprim appears to predict other potentiated sulfonamides). However, exceptions to the relevance of model drugs to other members in the class occur. For example, ampicillin-sulbactam serves as a model for amoxicillin-clavulanic acid, but several diagnostic microbiologists find the latter to overestimate the efficacy of the latter. Generally, CLSI has indicated the exceptions in its interpretive guidelines (many are summarized in Table 6-2), and the veterinary diagnostic laboratory should indicate these exceptions in the C&S report. For example, cephalothin (which is no longer available) represents first-generation cephalosporins, yet cefazolin generally is less effective against S. aureus and more effective against E. coli. The spectrum of third- and fourth-generation cephalosporins is markedly disparate, and thus the class cannot be well represented by a model drug. Among the newer aminoglycosides, gentamicin is generally more effective than tobramycin against Serratia spp. and more effective than amikacin against Staphylococcus, whereas tobramycin and amikacin are more effective than gentamicin against P. aeruginosa.

4. Limitations in extrapolations of susceptibility data are not restricted to spectrum but also may reflect a mismatch between in vitro and in vivo response. For example, despite in vitro evidence of susceptibility, aminoglycosides should not be used to treat Enterococcus spp. or as sole agent to treat Staphylococcus spp. Potentiated sulfonamides are not considered by CLSI to be clinically effective toward enterococci, despite in vitro susceptibility. However, recent reports in the literature challenge this assessment, supporting the importance of continued surveillance of the data by CLSI. Generally, laboratories will not test drugs against organisms for which clinical efficacy has not been demonstrated. (see Figure 6-8). This is most obviously exemplified by gram-negative versus gram-positive susceptibility panels, with the drugs tested against the isolate being grouped according to anticipated efficacy for the type of organism (e.g., gram-negative isolates will not be tested against clindamycin or erythromycin; gram-positive isolates generally are not be tested against ticarcillin, which was developed for gram-negative infections; anaerobes will not be tested against aminoglycosides; methicillin-resistant Staphylococcus should not be tested against any beta-lactam, and Pseuodmonas generally is not tested against a variety of drugs to which it is consistently resistant). A more recently recognized limitation of susceptibility testing is detection of acquired resistance that is rapidly induced by the presence of the drug. This might be best exemplified by gram-negative organisms that produce extendedspectrum beta-lactamases (ESBLs). These enzymes destroy selected third- and fourth-generation cephalosporins but are induced at the site of infection by the presence of the drug.⁵² Therefore ESBLs generally are not expressed by the isolate culture in vitro. Their detection may require additional testing of the isolate in the presence of cefpodoxime and ceftazidime alone or in combination with clavulanic acid, which is not susceptible to ESBL. A fourfold or greater reduction in cephalosporin MIC when it is combined with clavulanic acid versus when present as the sole drug has been interpreted as indicative of the presence of ESBL. At the time of publication, the criteria and need for special testing of ESBL was under scrutiny. Newer ESBLs are constantly emerging as resistance evolves. For example, an ESBL produced by *K. pneumoniae*, which targets carbapenems, was recently identified, thus highlighting the need for rapid incorporation of appropriate testing procedures into microbiology testing labs.⁵³

- 5. For any C&S method, generally only the parent drug is included in the interpretive standards, yet an active metabolite may contribute markedly to activity. For some drugs (e.g., ceftiofur), interpretive criteria include the metabolite, but for others, activity of the metabolite is not addressed. For example, most animals metabolize enrofloxacin to its de-ethylated metabolite, ciprofloxacin. Because the drugs act in an additive fashion, up to 40% to 50% of the C_{max} or area under the plasma bioactivity curve for enrofloxacin may be represented by ciprofloxacin, as has been demonstrated in dogs (see Chapter 7).54 Consequently, efficacy of enrofloxacin may be underestimated by C&S methods, particularly because ciprofloxacin tends to be more potent than enrofloxacin toward gram-negative coliforms. PK of antimicrobial drugs characterized by activity of both parent and metabolite must be based on either bioassays, or analytic techniques that include the activity contributed by metabolites
- 6. As organisms are exposed to microbes, MICs increase across time. CLSI reevaluates and adjusts interpretive criteria to address these changes when possible. However, new criteria depend on the generation of new data. Current antimicrobial resistance surveillance systems focus on human medicine and thus largely address food animals (e.g., National Antimicrobial Resistance Monitoring System). Thus the lack of new data needed by CLSI to promulgate new guidelines may prevent timely reassessment. Clearly, a coordinated surveillance system for monitoring antimicrobial resistance of companion animal pathogens is needed. Additionally, the relevance of population PD data provided on labels and through scientific literature will decline with the passage of time, and caution might be taken when basing the use of a drug on population data that are more than a decade old.
- 7. Ideally, as MICs change, drug dosing regimens also should change. However, modification of dosing regimens cited on labels of approved drugs requires reapproval by the FDA, and manufacturers are not likely to pursue modification because of the cost associated with reapproval. Data necessary for dose modification may not be available for CLSI review. Thus modification of dosing regimens is likely to depend not only on generation of PD data but also on PK data by independent sponsors. Without CLSI

direction, manufacturers of commercial antibiogram materials are unlikely to adjust the range of concentrations. Laboratories and manufacturers of C&S materials also have been slow to incorporate the new standards into their interpretations.

- Ideally, both PK and PD data on which CLSI bases MIC_{BP} 8. should be collected from and promulgated for the target species to be treated. However, much of this data simply does not exist for the target species. For drugs approved for use in animals, assuming the manufacturer supplied the data, CLSI interpretive standards often do exist and are published separately³⁸ from those established for human medicine.³⁹ However, some of these standards published in veterinary interpretive criteria are actually human standards that CLSI has deemed relevant to animals (see Table 6-2). For other human drugs, human interpretive standards are used but have not been evaluated for relevancy in animals. Although the standards may be equivalent among species for some drugs, for others, PK data and possibly PD data may be substantially different among species. Data should be interpreted cautiously for such drugs. Drugs that are water soluble (Vd \leq 0.3 L/kg) may be most applicable among species (see Chapter 1), whereas added caution is indicated for lipid-soluble drugs (Vd \ge 0.6 L/kg). Amikacin offers an example of a water-soluble drug for which interpretive standards might be similar between animals and humans. Ciprofloxacin offers an example of the need for caution. Although oral bioavailability of ciprofloxacin is 80% to 100% in humans, oral bioavailability averages 40% to 60% in dogs (information courtesy of Bayer Animal Health) and is 0% to 20% in cats (see Chapter 7). Accordingly, C_{max} will be about 40% to 60% lower at equivalent doses in dogs. Drugs with variable (particularly low) oral bioavailability, a large Vd (≥ 0.6 L/kg), and clearance by the liver are less likely to behave similarly among species than are drugs characterized by close to 100% oral bioavailability, a Vd indicative of extracellular distribution and renal clearance. As such, greater caution should be taken when extrapolating human interpretive criteria to animals for lipid-soluble versus water-soluble drugs.
- 9. The greatest caveat to the use of C&S data as a basis for drug selection and design of the dosing regimen is the disparity between the controlled environment of the in vitro test system and the dynamic in vivo environment of the host. Once the list of susceptible drugs has been narrowed down, host, drug, and microbial factors must be considered when making the final selection, as well as the design of the dose.

DRUG FACTORS THAT AFFECT ANTIMICROBIAL EFFICACY

The conditions of C&S testing cannot mimic conditions of in vivo drug behavior. Most notably, drug concentrations in the host are not static, as occurs in the in vitro system, but are dynamic, with duration of exposure dependent on elimination half-life. The importance of the PK of the drug will be addressed with discussion of concentration- and timedependent drugs. In addition to the static exposure to drugs, in vitro systems currently do not take into account binding of drug to circulating proteins (e.g., doxycycline, cefovecin). Because only unbound drug is free to enter the microbe, and protein is not present in culture media, MICs generated from C&S should be compared with unbound, not total C_{max} . Finally, the in vitro system cannot take into account a variety of host (e.g., immunoglobulins, cytokines, secretory proteins, etc) or microbial (e.g., biofilm or other virulence factors) activities oriented toward defense.

Bactericidal Versus Bacteriostatic Antimicrobials

The MIC is a drug concentration that inhibits but does not necessarily kill the target microbe. The MIC is a reasonable clinical outcome target because the success of antimicrobial therapy usually depends on host defenses that sequester and ultimately kill the microbial population after its inhibition by the drug. Antibacterials are frequently classified according to their ability to kill (bactericidal) rather than inhibit (bacteriostatic) microbial growth. Whereas bacteriostatic activity is indicated by the MIC, bactericidal activity of a drug is indicated by its minimum bactericidal concentration (MBC). However, this classification is based on in vitro methods. The MBC can be determined in several ways. For example, those tests tubes in which no visible sign of growth was observed following the broth dilution procedures can be reinoculated on nutrient-rich agar plates (see Figure 6-5). Those test tubes that yield no growth contained concentrations that killed, rather than inhibited, the microbe. Thus the test tube with the lowest concentration that yielded no growth contained the MBC of the drug. All antimicrobial drugs are characterized by an MBC; however, those drugs whose MBC approximates the MIC (e.g., within one broth dilution) might also be considered bactericidal. The MBC is most appropriately determined based on killing curves, which measure the number of surviving bacteria after exposure to fixed concentrations of drug; the concentrations are based on those achieved in serum at defined time intervals.⁴¹ For organisms noted as "S" to bacteridical drugs, achieving sufficient drug at the site to kill, rather than simply inhibit, the infecting pathogen is possible. For bacteriostatic drugs achieving the concentration necessary to kill the organisms without causing harm to the patient is much more difficult.^{23,41} Exceptions might occur for drugs that are accumulated (in an unbound state) at the site of infection (e.g., urine or phagocytic white blood cells); in selected instances bactericidal concentrations of a bacteriostatic drug can be achieved.

KEY POINT 6-15 Bactericidal and bacteriostatic activities are defined according to vitro conditions, which may not necessarily translate to the patient.

Categorization of static versus cidal activity of a drug can be associated with its mechanism of action (Table 6-5). In general, drugs that target cell walls (beta-lactams, glycopeptides),

*Accumulation in white blood cells may allow achievement of bactericidal concentrations.

cell membranes (polymixin B, colistin), or DNA (fluorinated quinolones) tend to act bactericidal in vitro. Ribosomal inhibitors that target more than one subunit (i.e., 30s and 50s; or 70s) also tend to be bactericidal. In contrast, drugs that target a single ribosomal subunit (tetracyclines, macrolides, lincosamides) or metabolic pathway (sulfonamides) tend to act bacteriostatic. Combinations of two bacteristatic antimicrobials that act in an additive or synergistic fashion may also result in bactericidal effects (e.g., a sulfonamide combined with a potentiating dipyrimidine). However, the distinction between bactericidal and bacteriostatic effects of a drug depends on the concentration; a bactericidal drug can be rendered nonbactericidal if concentrations sufficient to kill the organism are not reached at the site of infection the site of infection, or under conditions that slow the growth of the target organism (e.g., hypoxic environment or if used in combination with drugs that antagonize bactericidal actions). In such instances, the bactericidal drug will act in a bacteriostatic fashion. On the other hand, drugs classified as bacteriostatic may act bactericidal if high enough concentrations can be achieved, as might occur if the drug is accumulated in an unbound form (e.g., WBC or other tissues).

Because host defenses must be effective to kill those organisms whose growth is merely inhibited, achieving bactericidal concentrations of an antimicrobial drug are paramount to therapeutic success in immunocompromised hosts (e.g., viral infections, granulopoietic patients, use of immunohibiting drugs) or immunocompromised sites (septicemia, meningitis, valvular endocarditis, and osteomyelitis).^{23,26}

Integration of Pharmacokinetics and Pharmacodyamics: Pharmacodynamic Indices

Although the MIC of a (presumed) infecting organism offers a target concentration for antimicrobial therapy, simply achieving the MIC of the organism in plasma may not be sufficient to ensure efficacy. Among the relationships that affect efficacy is the PK/PD relationship-that is, the dynamic relationship between the drug concentration to which the organism is exposed throughout the dosing interval (PK) and the response of the infecting organism to the drug, as estimated, for example, by the MIC (PD).⁵⁵⁻⁵⁷ This relationship is affected by many host and microbial factors. Definitions of terms used to describe the integration of PK and PD (PD indices or PDI) are varied, depending on the author. For the purposes of this text, definitions will be drawn from Mouton.47 It is important to note that many of the terms are based on parameters determined through in vitro testing. Therefore host and microbial factors still need to be considered. Further, most PDI are based on a 24-hr-dosing interval, thus modifications in dosing regimens should be based on a 24-hr period (Figure 6-12). The relevance of PDI to drugs with half-lives longer than 24 hr (e.g., azithromycin, cefovecin) is not clear.

Postantibiotic Exposure

Antimicrobials may continue to exert an effect even though the drug is no longer present at concentrations that exceed the MIC. The term *postantibiotic exposure* has been promoted to refer to the combined definitions that have emerged experimentally. Among the terms is the *postantibiotic effect (PAE)*, which has both an in vitro and an in vivo definition.⁴⁷ The PAE is exhibited by drugs, and is defined in vitro as the period of suppression of bacterial growth after a short exposure of the organism to the antimicrobial.⁴⁷ The PAE for a drug, is determined in vitro by exposing a standard inoculum to it, removing the drug and determining the time that elapses (in hours) before the culture CFUs increase by tenfold. In vivo, the PAE is the time it takes for the number of CFUs to increase tenfold in treated animals after concentrations drop below the MIC at the tissue site.⁴⁷ Clinically, the PAE indicates the ability of a drug to inhibit bacterial growth after the drug is no longer present or is below the MIC of the infecting microbe.49,58-60 As such, it also takes into account an effect a drug might have at subinhibitory concentrations. The impact of the PAE on antimicrobial efficacy can be profound, particularly for concentration-dependent drugs. It is the PAE that allows some drugs to be administered at long intervals despite short half-lives. 41,50, 52,59,61,62 The PAE may be absent for some organisms or some patients (e.g., some immunocompromised patients).49 The duration of PAEs varies with each drug and each organism and the relationship between PDC and MIC (Table 6-6).63 In general, concentration-dependent drugs appear to exhibit longer PAEs, with the duration of the PAE being proportional to the magnitude of the peak PDC (i.e., longer with higher PDC).64 However, for each drug, and within drug classes, the PAE is markedly variable, depending on the organism.⁶⁵ Whereas beta-lactams exhibit a substantial PAE toward selected streptococci (i.e., thus making treatment less time dependent for streptococci), their PAE toward gram-negative organisms is minimal.⁶⁶ Applying information regarding the PAE to clinical patients is complicated by variable results (reflecting marked variability in methods) among investigators. The PAE is enhanced by combination antimicrobial therapy.⁶⁷⁻⁶⁹ The duration of the PAE should be included in estimates of doses or dosing intervals. Some antimicrobials also have been associated with a postantibiotic sub-MIC effect (PASE) that may further prolong the dosing interval^{70,71}; further, a postantibiotic leukocyte enhancement effect (PALE) has been described for some antimicrobials. These are incorporated in in vivo estimates of PAE. However, clinical relevance of measurements of PAE, PASE, and PALE based on in vitro observations is not clear.^{66,72} These studies do point out the reasons that some antimicrobials are effective at long intervals and indicate the need for a better understanding of the relationship of PDC, MIC, and PAE in the clinical patient.

KEY POINT 6-16 The postantibiotic effect is particularly important to the efficacy of concentration-dependent drugs.

Time- Versus Concentration-Dependent Drugs

The relationship among efficacy, MIC, and the magnitude and time course of PDC can be categorized, in vitro, as either *concentration-dependent* (sometimes referred to as *dose-dependent*) or *time-dependent* (sometimes referred to as *concentration-independent*) (see Figure 6-13; and Table 6-4).⁴¹ A third classification has emerged with characteristics from each of these classes. (e.g., as shown by fluoroquinolones). Although studies that categorize drugs are largely in vitro, the categorizations generally are supported by in vivo studies that include animal models and human clinical trials.⁵⁷ Concentration-dependent drugs, best represented by the fluoroquinolones and aminoglycosides, are characterized by efficacy that is best predicted by the magnitude of PDC (C_{max}) compared to

the MIC of the infecting organism (see Figures 6-11 to 6-13)73-79 For such drugs the magnitude of C_{max}/MIC (or C_{max}/MIC_{90}) generally should be 10 to 12; for more difficult infections (e.g., P. aeruginosa, or infections caused by multiple organisms), the higher index should be targeted.⁵⁷ The time that PDC is above the MIC-that is, the duration of exposure, (T > MIC or $T > MIC_{90}$)—is not as important as is the C_{max}/MIC ; in fact, efficacy may be enhanced (e.g., for the aminoglycosides) by a drug-free period (i.e., a long interval between doses; see Figure 6-13).^{61,73,74,80-82} This may reflect, in part, the phenomenon of adaptive resistance.⁸³ Adaptive resistance refers to a reversible refractoriness to the bactericidal effects of an antibacterial agent. This phenomenon has been documented particularly for gram-negative organisms and the aminoglycosides, but it appears to occur with the quinolones as well. The resistance appears to reflect a protective phenotypic alteration in the bacteria, such as reversible downregulation of aminoglycoside active transport. Adaptive resistance occurs rapidly (within 1 to 2 hours) of antimicrobial therapy; duration reflects the elimination half-life of the drug. In humans adaptive resistance to aminoglycosides may last for up to 16 hours after a single dose of aminoglycoside, with partial return of bacterial susceptibility at 24 hours and complete recovery at approximately 40 hours.83

For concentration-dependent drugs, a dose that is too low is particularly detrimental. In a mouse model of *E. coli* peritonitis, the antibacterial efficacy of ciprofloxacin, but not

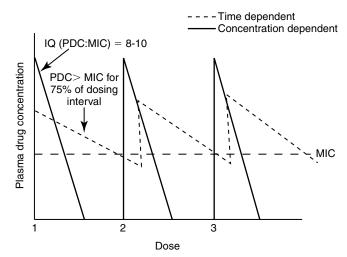

Figure 6-13 The relationship between plasma (tissue) drug concentration, and the minimum inhibitory concentration (MIC) of the organism may determine drug efficacy. The efficacy of concentration-dependent drugs (e.g., aminogly-cosides; fluorinated quinolones; and, in some cases, azithromycin or other azalides) depends on a high C_{max} to MIC ratio. Doses might be increased to ensure sufficiently high plasma drug concentrations to achieve the target ratio. In contrast, for time-dependent drugs, such as beta-lactams, sulfonamides, and nonaminoglycoside ribosomal inhibitors, efficacy is maximized by ensuring that plasma drug concentration remains above the MIC for most (50% to 75%) of the dosing interval.

[‡]Wang 200165

imipenem (or meropenem), was improved by doubling the dose. For some concentration-dependent drugs, efficacy may be both dose- and time-dependent, with the best predictor of efficacy being AUC/MIC. For example, efficacy of fluorinated quinolones can be predicted by both a C_{max}/MIC (target 10 to 12) or AUC/MIC (target 100 to 125) (see Figure 6-13).^{41,84-86} The AUC/MIC may be particularly predictive for fluoroquinolones when treating gram-positive isolates; adding a second full dose may be prudent for some infections. Otherwise, concentration-dependent drugs generally can be administered at longer intervals (e.g., once a day).

In contrast to concentration-dependent drugs, efficacy of time-dependent drugs (e.g., beta-lactams) is best predicted by the time that PDC remains above the MIC. For such drugs PDC should be 2 to 4 times the MIC of the infecting microbe and should be maintained above the MIC (T > MIC) throughout a significant portion of the dosing interval (see Figures 6-12 and 6-13). However, the recommended duration of T > MIC varies from a low of 25% for carbapenems to 50% to 70% for extended-spectrum penicillins to potentially 100% for penicillin and aminopenicillins (an exception being treatment of streptococci).56,57,61,74,87,88 With time-dependent drugs, increasing the dose may be necessary to ensure that PDCs are above (ideally severalfold) the MIC.⁵⁷ Maintaining T > MICmay be problematic for drugs with a short half-life unless the isolate is extremely susceptible (e.g., most beta-hemolytic streptococci for penicillins). Given that drug concentrations decrease by 50% every drug half-life, a C_{max}/MIC of 2 will result in a PDC that will reach the MIC in 1 half-life. The duration of the dosing interval then depends on the desired target duration (i.e., 25% to 100%) of T > MIC. If T > MIC is 100%, then the dosing interval would be 1 half-live. If T > MIC is 50%, the dosing interval would be 2 half-lives, and if T > MICis 25%, the dosing interval could be as long as 4 half-lives. For each additional half-life to be added to the duration that T > MIC, concentrations, and thus dose, must be doubled again (i.e., quadrupuled if T > MIC = 2 half-lives, increased eightfold if T > MIC=3 half-lives, and so on). Table 6-4 demonstrates the impact of C_{max}:MIC and half-life on time-dependent drugs. Although efficacy of time-dependent drugs requires T > MIC for a sufficient time, efficacy might be enhanced by increasing the dose for drugs with a sufficiently long half-life, shortening the interval for drugs with a short half-life, or both. Constantrate infusion,⁸⁹ or slow-release products,⁹⁰ might be ideal for time-dependent drugs with short half-lives. Drugs characterized by longer elimination half-lives might be preferred (e.g., cefovecin^{43,44}). Efficacy also should be enhanced for timedependent drugs that persist to accumulate in the unbound state in selected tissues (i.e., macrolides, clindamycin,⁹¹ or drugs that accumulate in phagocytes.) The downside to using antimicrobial drugs with a very long half-life is that the time to steady-state concentrations and thus peak effects might be prolonged. Moreover, a "hit hard, get out quick" approach to therapy is difficult to implement with such antimicrobials.

The relationship between PDC, MIC, and time- versus concentration-dependency might be explained, in part, by the mechanism of antimicrobial action. Efficacy of the aminoglycosides or fluorinated quinolones depends on drug binding to the target (ribosome and topoisomerase or DNA gyrase, respectively); once sufficient binding occurs, protein synthesis or DNA activity, respectively, is prevented and does not re-initiate. However, beta-lactams substitute as a substrate for cell wall synthesis, and, as long as the organism is growing, it is synthesizing cell wall. Thus, the drug needs to be present as long as the organism is growing. The glycopeptides (e.g., vancomycin), which also target the cell wall, are also time-dependent drugs.

KEY POINT 6-17 Efficacy of concentration-dependent drugs can be enhanced by increasing the dose such that peak concentrations are 10 to 12 times the MIC of the infecting microbe (C_{max} /MIC \ge 12).

Increasingly, CLSI is using PDI as the basis for determination of breakpoint MIC. However, not surprisingly, the optimal relationship between PDC and MIC that determines efficacy of a drug is not so simple and varies with organisms and drugs. The optimal relationship between PDC and MIC and the parameter that best predicts antimicrobial efficacy (e.g., peak PDC; the ratio of area under the drug concentration versus time curve to the organism's MIC; duration of PDC above MIC) have not been established definitively for all antimicrobials.^{52,61,84,85} However, for drugs characterized by inhibition (bacteriostatic drugs), T > MIC may best predict efficacy. For some fluoroquinolones, and particularly for gram-positive organisms, efficacy is best predicted by the ratio of AUC (which is influenced by both dose and interval) to MIC rather than simply the C_{max}/MIC. The optimal AUC/ MIC also varies with the organism, ranging from as low as 30 to 40 for S. pneumoniae and levofloxacin to greater than 350 for P. aeruginosa and ciprofloxacin. The area under the inhibitory curve (AUIC) reflects the integrated AUC above the MIC during the dosing interval. This parameter is similar to but varies from AUC/MIC in that it is the AUC that is above the MIC (in contrast, AUC/MIC involves the complete area). The AUIC should exceed 125 for fluorinated quinolones to achieve bacterial killing; an AUIC that exceeds 250 results in rapid killing.⁵⁷ Thus for treatment of some infections with concentrationdependent drugs, the dosing regimen might be designed to maximize both the C_{max}/MIC and the AUC/MIC. Some drugs (e.g., macrolides) are characterized by time-dependency for some organisms but concentration-dependency for others.

Table 6-4 offers examples of PDIs that are achieved using current recommended dosing regimens for selected drugs and selected PD data from selected pathogens that cause infection in dogs. The PD data are based on MIC_{90} obtained from package inserts of drugs approved in dogs or literature that provided PD data specific for canine pathogens that was more recent than package insert data. For some drugs PD was not available for canine pathogens, so PD from human pathogens was used. Doses were chosen from Table 7-1 and generally reflected the highest dose for which PK was available. When possible, nonintravenous routes were chosen because C_{max} from intravenous data may not represent C_{max} following distribution. Table 6-6 is intended to demonstrate how PDI might be used to assess a dosing regimen. It is not unusual to find that the target C_{max}/MIC (>10) often is not reached for concentration-dependent drugs) or T > MIC (50% for most) for time-dependent drugs. One could argue that the MIC₉₀ is an unreasonable PD target; indeed, for some isolates it may be. The preferred PD statistic would be the MIC from the isolate infecting the patient; it can be substituted in this table for the MIC₉₀. Likewise, the 95th lower confidence interval is preferred to the mean C_{max} or half-life for the PK component of PDI. For concentration-dependent drugs, doses can be increased (whenever safety permits) to achieve the target C_{max}/MIC; for time-dependent drugs, both the dose (increase) and interval (shorten) might be modified. Alternatively, or perhaps in addition to, combination therapy might be considered. Note that the PDIs are based on plasma drug concentrations (PDCs). For some drugs, PDC underestimates concentrations in extracellular fluid. However, for others, PDC frequently overestimates by 25% to 50% or more extracellular fluid drug concentrations. Doses may need to be increased by 25% to 50% to adjust for this difference. As important as PK/PD integration is to the design of the dosing regimen, its application to the clinical patient will be facilitated by an understanding of the microbial and host factors that influence response to the drug.

KEY POINT 6-18 Efficacy of a time-dependent drug can be enhanced by ensuring that concentrations at the site of infection are above the MIC (T > MIC) for most of the dosing interval.

MICROBIAL FACTORS THAT AFFECT ANTIMICROBIAL EFFICACY

Among the most obvious ways that microbes can affect antimicrobial efficacy is the advent of resistance. However, microbes can negatively affect antimicrobials through mechanisms that do not influence MIC. These effects are not as obvious to detect as resistance but nonetheless can profoundly affect therapeutic success.

Inoculum Size

The larger the bacterial inoculum at the target site, the greater the concentration (number of molecules) of antimicrobial necessary to kill the organism. Further, more CFUs are more likely to produce greater amounts of enzymes or other materials that can destroy the drug. The "inoculum effect" of ESBL resistance describes the increasing MIC of the organisms toward cephalosporins at a larger (10⁷) compared with smaller (10⁵) inoculum.⁹² In addition, the larger the inoculum, the greater the risk that spontaneous mutation will contribute to resistance or virulence. Note that resistance and virulence do not necessarily co-exist. In general, emerging resistance appears to be associated with *decreased* rather than increased virulence, although increasingly studies are identifying exceptions. For example, community-acquired infections may be associated with increased virulence, but less resistance. For example, although hospital-acquired infections tend to be caused by nonvirulent organisms, community-acquired infections reflect virulent organisms that can infect even the overtly healthy patient. Concern regarding MRSA reflects, in part, its apparent acquisition of virulence factors that have facilitated its transition from a hospital to community-acquired infection.

Virulence Factors

The degree of pathogenicity of bacteria (virulence) will affect antimicrobial efficacy indirectly by facilitating infection. The ability of microbes to cause disease reflects the size of the inocululm, the effectiveness of host defense mechanisms, and the intrinsic pathogenicity of the microbes resulting from the presence of virulence factors. Like biochemical mechanisms of resistance, virulence factors generally involve proteins encoded by DNA of chromosomal or shared (e.g., plasmids, transduction) origin. Contributing to the negative impact of virulence factors is host response to their effects. Virulence factors facilitate adhesion to host cell surfaces, colonization (e.g., urease of *Helicobacter pylori*, which protects it from gastric acidity), invasion (facilitated by disruption of host cell membranes or stimulation of endocytosis), immunosuppression (e.g., antibody-binding proteins), or bacterial toxins that cause local, distant, or both (e.g., endotoxin) host damage. Pathogen attachment to host cells is a crucial early step in mucosal infections and is facilitated in epithelial tissues by bacterial adherence. Adherence is a specific two-phase process involving bacterial virulence factors called adhesins and complementary receptors of the host epithelial cells.93,94 Adhesins are generally found on the surface of microbes, (e.g., bacterial fimbriae) and along with other virulence factors facilitating infection, may be targets for alternative (to antimicrobial) therapy. Species differences exist among the types of receptors in the host epithelial cells. The predominant receptor type in humans is glycolipid in nature, and its presence varies with blood cell types, implying individual variation in susceptibility to bacterial adherence in several body systems. Bacterial adherence is discussed with regard to specific body systems in Chapter 8.

Another virulence factors that facilitate infection are *invasins*. Invasins are enzymes that damage physical barriers presented by tissue matrices or cell membranes, facilitating rapid bacterial spread. Examples include clostridial hyaluronidase, which is able to destroy connective tissue, and lecithinases and phospholipases of clostridial and gram-positive organisms. Bacteria have developed siderophores, which are specialized virulence factors that mediate the release or scavenging of iron critical for microbial virulence. Bacteria also have developed specialized transport systems that secrete toxic materials into the extracellular matrix. It is not clear whether the efflux proteins that transport toxins are related to those that transport drugs (see the discussion of resistance). Bacteria also facilitate invasion through materials (e.g., proteins, "slime") that prevent phagocytosis or, if the microbe is phagocytized, preclude intracellular killing. Examples include lytic enzymes of gram-positive cocci or exotoxin A produced by *P. aeruginosa*. Toxins include both endotoxins (discussed in depth later) and exotoxins. Bacterial exotoxins are among the most potent toxins known, acting on either the cell surface (e.g., *E. coli* hemolysins, "superantigens" of *S. aureus* or *Streptococcus pyogenes*); membrane; or, once the membrane is penetrated, intracellular targets (e.g., A/B toxins).

KEY POINT 6-19 *Virulence* refers to the ability of the microbe to cause infection. However, a virulent organism often is not resistant.

Biofilm

Among the most effective and probably least appreciated protective microbial factors is biofilm. Bacteria exist in either a planktonic (free floating) or sessile (attached) state; while it is the former state that characterizes C&S testing, but it is the latter state that enables persistence of the resident population, as well as the formation of biofilm.95-97 Biofilm is defined as a biopolymer, matrix-enclosed bacterial population in which bacteria adhere either to one another or to a surface.95 The outer layer of the biofilm may lose water such that it is hardened, thus providing better protection from the environment, including exposure to antimicrobials. The inner sactum of the biofilm is largely aqueous, composed of glycocalyx or slime (e.g., Staphylococcus spp.). In addition to passive diffusion, aqueous pores permeate the structure, allowing movement of nutrients and metabolic debris. Biofilm populations containing normal microflora in the skin or mucous membranes (e.g., urinary bladder) are lost with shedding of the skin (or bladder) surface or by the excretion of mucus; new cells and mucus are rapidly colonized by biofilm-forming bacteria. Microbes released from the surface may colonize new surfaces and subsequently produce new biofilms and new (e.g., persistent or recurring) infections. Bacterial communication during biofilm formation is sophisticated, involving quorum-sensing systems that ultimately may be targets of microbial therapy.96 Biofilm may facilitate and protect growth of normal or pathogenic flora on foreign surfaces and can facilitate subsequent translocation of microbes to otherwise sterile tissues. Persistent, chronic bacterial infections may reflect biofilm-producing bacteria; persistent inflammation associated with immune complexes contributes to clinical signs. Dental plaque is a prototypic example of the impact that biofilm might have on preventing antimicrobial penetration. Cystic fibrosis associated with Pseudomonas is a disease in which biofilm contributes to mortality. Pathogens associated with biofilm in veterinary medicine include, but are by no means limited to, Acinetobacter, Actinobacillus, Klebsiella, P. aeruginosa, and Staphylococcus (aureus and pseudintermedius).95 Glycocalyx may contribute to protective mechanisms of other organisms as well (e.g., sulfur granules and Nocardia; Figure 6-14). Not all pathogens associated with biofilm cause infection (e.g., urinary catheters). However, because they ultimately may be

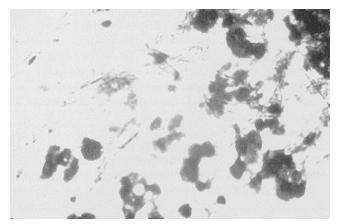

Figure 6-14 An example of combined host and microbial factors that negatively impacts therapy, *Nocardia* causes a marked inflammatory response by the host. Additionally, the organism causes secretion of calcium that combines with its biofilm, resulting in the formation of "sulfur" granules that protect the organisms from drug penetrations.

the source of infection, clinical resolution may not be possible until the biofilm is destroyed. Yet, its nature is difficult to predict based on the planktonic growth of individuals in cultures compared to the consortium that occurs in vivo.⁹⁷ Catheters (urinary or intravascular), orthopedic fixation devices, and materials used in wound management are examples of surfaces on which biofilm might develop.

KEY POINT 6-20 Biofilm can form on many foreign or natural surfaces and may profoundly decrease the likelihood of successful antimicrobial therapy.

Antimicrobial Resistance

The role of resistance in therapeutic failure of antimicrobials is well established.^{23,98} The use of antimicrobials increasingly is associated with emergence of resistance. For each class of antimicrobial drugs approved for use in human medicine, resistance generally has emerged within 1 to 2 decades of use. Clinically relevant resistance toward sulfonamides, the first class of antimicrobials approved in the United States (1930s) was documented by the 1940s. Penicillins, tetracyclines, streptomycin (aminoglycoside), and erythromycin (macrolides) were all approved within a 10-year span, with resistance documented within 5 years for methicillin versus approximately 10 years for streptomycin. Resistance to nalidixic acid, the progenitor of fluoroquinolones (approved in 1950), took 3 decades to emerge, perhaps convincing manufacturers that resistance to fluoroquinolones would emerge very slowly. However, resistance to norfloxacin, the first fluoroquinolone approved in the United States, took less than 3 years to emerge, despite the fact that the lack of plasmid-mediated resistance was among the attributes of this class. Resistance to extendedspectrum cephalosporins emerged within 4 years of approval and to amoxicillin-clavulanic acid, within 5 years. Resistance to vancomycin, specifically developed to treat MRSA, emerged in its second decade of use.

KEY POINT 6-21 Antimicrobial resistance increasingly will prevent the successful empirical selection of antimicrobial drugs.

Inherent Versus Acquired Resistance

Antimicrobial resistance might be inherent to the microorganisms or acquired, either through chromosomal mutations or transfer of genetic information.⁹⁹ Generally, spectrums of antimicrobials (listed on package inserts and elsewhere) reflect inherent resistance patterns rather than acquired resistance patterns. Examples include limited efficacy of aminoglycosides toward anaerobic organisms because the drugs must be actively transported into the cell (oxygen dependent) or the resistance of gram-positive organisms, which lack an outer cell membrane, to polymyxin B, which targets the same. Acquired resistance, on the other hand, generally renders a previously susceptible organism resistant. As such, it is not necessarily predictable and can occur during the course of therapy (leading to changes in a C&S pattern). More problematically, it is often shared among microbes.

Shared resistance among bacteria reflects the ability of bacteria to incorporate extrachromosomal DNA carrying the information for resistance from other organisms. Extrachromosomal DNA (including plasmids and bacteriophages) encode for resistance to multiple drugs and can be transmitted vertically (to progeny) or horizontally, across species and genera. Transposons are individual or clusters of resistance genes bound by integrons, which move resistance genes back and forth between chromosomes to plasmids. Consequently, bacterial resistance is extremely mobile and can spread rapidly.¹⁰¹ Among the mechanisms by which genetic resistance information is shared is (sexual) conjugation. Conjugation occurs particularly in gram-negative organisms and may be accompanied by genetic material that confers bacterial pathogenicity as well as altered metabolic functions. However, Enterococcus spp. and selected other gram-positive bacteria also transfer resistance to glycopeptides through conjugative transposons.¹⁰¹ Transduction, which requires a specific receptor, involves transfer of information by a bacterial virus (bacteriophage) and is implemented especially by Staphylococcus spp. Resistance, including methicillin resistance, can be transferred between coagulase-negative and -positive Staphylococcus.1 Transformation involves transfer of naked DNA from one lysed bacterium to another; this mechanism of transfer tends to be limited (in humans) to pneumococcal meningitis.

Although present for eons, acquired antimicrobial resistance increasingly is becoming problematic. The impact of antimicrobial resistance can be extensive. In some human intensive care units, selected isolates are characterized by a resistance prevalence of 86%. The impact of resistance on the patient includes increased morbidity, mortality, and increased hospital costs.¹⁰⁷ Patterns of resistance have emerged in veterinary medicine, although differences appear to occur in the ability of organisms to develop resistance to an antimicrobial, varying with species and strain. Many organisms remain predictably susceptible to selected drugs (e.g., *Brucella, Chlamydia*), whereas others are becoming problematic (e.g., P. multocida). Several organisms traditionally have developed resistance that can rapidly impair efficacy of new antimicrobials (e.g., E. coli, K. pneumoniae, Salmonella, S. aureus, S. pneumoniae). In general, these organisms have developed multidrug resistance (MDR). MDR is now considered the normal response to antimicrobials for gram-positive cocci pneumococci, enterococci, and staphylococci.¹⁰² Among these, Staphylococcus spp. is considered most problematic: it is intrinsically virulent, is able to adapt to many different environmental conditions, increasingly is associated with resistance to other classes of antimicrobials, and tends to be associated with life-threatening infections.^{102,103} In a veterinary teaching hospital the percentage of patients with S. intermedius susceptible to cephalexin and amoxicillin-clavulanic acid decreased from a high of 96% in 2005 to < 60% in 2007, a trend that appears to be emerging in other veterinary hospitals.110

KEY POINT 6-22 Acquired resistance can occur during the course of antimicrobial therapy.

E. coli is among the organisms that have developed multi-drug resistance.^{104,105} Fluoroquinolone-resistant *E. coli* emerged as early as 1998, little over a decade after the approval of enrofloxacin for dogs or cats.²⁸ Multidrug-resistant *E. coli* has emerged as a cause of nosocomial infections in dogs¹⁰⁸ and UTIs in canine critical care patients.^{104,109} The presentation is similar to the that in human critical care patients, with risk factors such as sex (males), hospital stay, and previous antimicrobial therapy being similar for both.

Factors Contributing to the Emergence of Resistance

Development of antimicrobial resistance is facilitated by several factors¹¹¹; among the most important is exposure to antimicrobials. In the individual patient, single-dose ciprofloxacin prophylaxis increased the prevalence of ciprofloxacin-resistant fecal E. coli from 3% to 12% in humans.112 Ciprofloxacin treatment for prostatitis resulted in posttreatment fecal colonization with quinolone-resistant E. coli that was genetically distinct from the infection-causing strains after treatment in 50% of the patients.¹¹³ Our laboratory has demonstrated that standard doses of either amoxicillin or enrofloxacin given orally will cause close to 100% of fecal E. coli to become resistant to the treatment drug within 3 to 9 days of therapy; for enrofloxacin the isolates generally are multidrug resistant. As with MRSA or MRSI (S. intermedius), the advent of resistance by E. coli and other gram-negative organisms has been associated with increased cephalosporin use.1

The gastrointestinal flora offers a natural environment that exemplifies the impact of antimicrobials on selection pressure. The normal flora of the gastrointestinal tract is extremely diverse, with anaerobes predominating. Among the aerobes, *E. coli* are the major gram-negative and *Enterococcus* the major gram-positive organisms.¹⁰¹ Environmental microbes maintain an ecologic niche through suppression of the competition by either consumption of nutrients or secretion of antibiotics. Therefore commensal organisms are constantly being exposed to antibiotics, and are "primed" to develop resistance.¹⁰¹ However, the microbes producing the antibiotic, as well as surrounding normal flora, are resistant to the antibiotic. Thus genes for resistance develop along with genes directing antibiotic production.

Rapid microbial turnover in the gastrointestinal tract supports the development of resistance by ensuring active DNA replication and thus mutation potential (see previous discussion). Chromosomal (DNA) mutations (10⁻¹⁴ to 10⁻¹⁰ per cell division) are DNA mistakes that have been missed by bacterial repair mechanisms. These mistakes occur spontaneously and randomly, regardless of whether the antibiotic is present. If the mutation that confers resistance to an antimicrobial occurs in the presence of the antimicrobial when it is administered to the patient, the surviving mutant, reflecting its single-step mutation, confers a low level of resistance (see the discussion of mutant prevention concentration). The MIC of the organism is likely to increase. Further microbial turnover and continued therapy can lead to multistep mutations and rapid emergence of high-level resistance characterized by increasingly higher MIC. Stepwise mutations can lead to specific resistance such as that demonstrated toward fluorinated quinolones (stepwise mutation in the DNA gyrase gene). Nonspecific mechanisms of resistance, including that shared among organisms, are more likely to result in MDR. Microflora of the gastrointestinal tract can serve as a reservoir of resistance genes; a single drug, via integrons, plasmids, and transposons, facilitates the rapid transfer of MDR among organisms. The gastrointestinal environment exemplifies a pattern whereby resistance can emerge as a result of a combination of selection pressure and mutation. Clinically, similar mechanisms of emerging resistance are likely to occur at sites of infection.

Mutant Prevention Concentration

Drlica and coworkers¹¹⁴ have hypothesized the mutant selection window, (see Figure 6-15) comprised of a lower threshold represented by the culture MIC of the infecting organism and an upper threshold or boundary, the MPC. Should a dose be designed such that drug concentrations fall within this window (i.e., between the MIC and MPC) at the site of infection, the mutant isolate is likely to emerge as a resistant colony. The practical application of the hypothesis explains the observed behavior of mycobacterium organisms toward fluoroquinolones (FQs). Increasing concentrations of the FQs inhibits the nonresistant (wild-type) organisms and colony numbers rapidly decrease. But this period of decline is followed by a plateau period of minimal or no growth. During this plateau phase, remaining resistant isolates recover and start to multiply again. The resistance of this emerging, second population presumably reflect a single-step (chromosomal or plasmid-mediated) mutation that resulted in an increase in the MIC to low-level resistance (e.g., MIC is close to the breakpoint). However, when these first-step mutants are exposed to even higher drug concentrations, a second rapid decline in numbers occurs, this time reflecting inhibition of the mutated, resistant organisms. Again, once sufficient bacteria recover, a second plateau occurs as the first-step mutants mutate. This stepwise or multistep mutation confers high level resistance (MIC exceeds the breakpoint several fold) that can be overcome only by very high concentrations of the FQ. The mutant selection window, which is to be avoided with initial therapy, describes drug concentrations on either side of the initial plateau for the single-step mutants. The lower boundary is defined by those drug concentrations sufficiently high to remove the majority of the wild-type competitors (MIC), whereas the higher boundary (the MPC) is defined by the concentrations necessary to inhibit the least susceptible (most resistant) isolates (the single-step mutants).¹¹⁵ Above this concentration, a second mutation step (which is very rare) would be required for a population of resistant organisms to develop; the risk of this happening is reduced by preventing microbial turnover (i.e., killing all isolates).

KEY POINT 6-23 The mutant prevention concentration (MPC) is the highest MIC of any of the colony-forming units causing infection in the patient. Failure to achieve this concentration may allow resistant microbes to emerge, particularly in the at-risk patient.

On the basis of this observation, Drlica and coworkers contend that MIC-based strategies used to design dosing regimens readily select for resistant mutants.¹¹⁵ Their contention is based on the observation that only one resistant mutation is needed for bacteria to grow in the presence of an antimicrobial and that infections generally contain an adequate number of CFUs for several first-step resistant mutants to be present prior to treatment. They coined the term MPC as an in vitro measure of preferred antimicrobial concentration target. If the MPC (rather than the MIC) is achieved at the site of infection, the risk of resistance is minimized because isolates that exceed the MPC concentration must have undergone a second concurrent resistance mutation step prior to therapy. As such, the MPC, not the MIC, would be the concentration targeted at the site of infection in the patient. Indeed, simply achieving the reported MIC of the infecting microbe at the site of infection is probably the approach that is most likely to yield clinically resistant organisms. Accordingly, consideration should be given to assuring that "dead bugs don't mutate." If the least susceptible of the isolates is inhibited with the dosing regimen, then the recovering population should not be resistant.

Drlica¹¹⁵ has demonstrated that MPCs do not correlate to MICs. In vitro, the MPC would be defined in vitro as the (lowest) drug concentration (in the media) that yields no recovered organisms when over 10¹⁰ CFUs (mimicking bacterial load in the patient) are plated. Currently, determining the MPC is costly, requiring multiple testing steps and large numbers of cells; for example, standard culture procedures are based on 10⁶ CFUs, whereas determination of the MPC requires at least 10⁸⁻¹⁰ CFUs. However, an MPC-based strategy to dosing clinically makes sense and should be an effective means of blocking the growth of first-step resistant mutants. Such a strategy

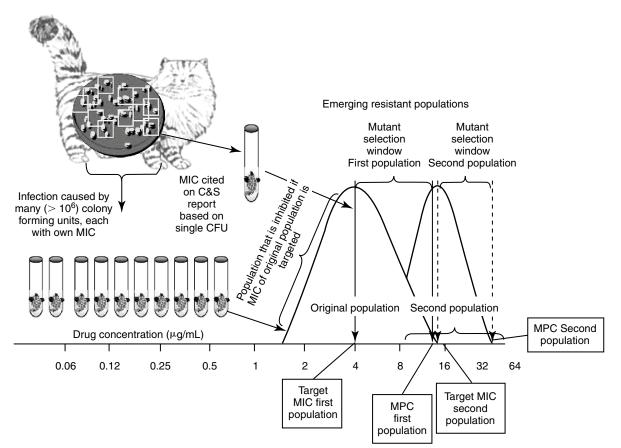

Figure 6-15 Stepwise mutation can emerge as a result of selection pressure induced by antimicrobial therapy that targets the minimum inhibitory concentration (MIC) of the infecting microbe. The mutant prevention concentration (MPC) is the concentration of drug that is necessary to inhibit first-step mutants, or the MIC of the least susceptible isolate in a resident population of pathogens. As the resident population or inoculum of wild (nonresistant) pathogen isolates reaches 10^{8-10} colony-forming units (CFUs), some isolates will spontaneously mutate such that resistance emerges to the drug of interest. However, when cultured, the MIC reported for the population is likely to represent the mode (the most commonly reported MIC), which in a normally distributed population, is also the MIC₅₀ for the population. In contrast, the MIC of the first-step mutant will be the high end of the dosing regimen is designed to target the the mutant selection window, that is, the MIC of the wild population rather than the MPC (the MIC of the first-step mutant)—treatment with the drug will inhibit all isolates at or below the MIC. The void in isolates will allow the remaining, more resistant first-step mutants to recover, particularly in patients not sufficiently healthy to suppress recovering microbes. As this new population expands, a second distribution curve emerges. If recultured, the MIC of the second first-step mutant population will be higher than the wild population. If the population reaches a sufficient size (e.g., 10^8 CFUs), a second, spontaneous mutation is likely to occur, resulting in a new, higher MPC. Targeting the MPC is particularly important when using drugs for which resistance emerges in response to mutations.

would force wild-type cells to acquire two resistance mutations for growth, an event that is rare. Experimental in vitro data¹¹⁴ have confirmed that MPC levels of an FQ do indeed inhibit strains that harbor first-step *gyrA* mutations (the mechanism of microbial resistance to FQ).¹¹⁶ Application of the MPC is most appropriate for drugs and organisms that develop resistance by chromosomally mediated point mutations (e.g., the fluorquinolones).¹¹⁷ However, the spirit of targeting the MPC might be assumed even for other drugs, in order to minimize the impact of selection pressure on emergent resistant populations. The mutant selection window can be narrowed if more than two bacterial sites are targeted, such as might occur with combination antimicrobial therapy, or with drugs that simultaneously target more than one site (e.g., the FQs).¹¹⁴

Biochemical Mechanisms of Resistance

Bacteria often respond to the presence of the antimicrobial by altering their physiology such that resistance occurs, often to multiple drugs. Microbes develop antimicrobial resistance by two primary mechanisms: modification of the target site or altered intracellular drug concentration. Methods by which intracellular drug concentration can be decreased include changes in porin sizes for gram-negative organisms (e.g., most drugs; see Figure 6-3). Porins are transmembrane proteins (e.g., OmpF) that form an aqueous channel that allows passive movement of large hydrophilic molecules. Porins are one of the few means by which drugs can gain access to intracellular targets. A change in porin size (i.e., by the addition of side chains that filter out drugs) or number increases antimicrobial

resistance, as is demonstrated by the loss of the OprD protein that imparts resistance to imepenem by Pseudomonas spp. Closely associated with the porin proteins are efflux proteins that pump drug out of the organism; the pumps often are associated with porin proteins (e.g., FQs and tetracyclines). Most of these pumps are fueled by energy associated with proton exchange, the most notable in gram negative organisms being of the RND (resistance nodulation division) family. The best characterized in this family is the Acr-AB/TolC system, which is a complex bacterial stress response system that allows bacteria to pump out toxic molecules.¹⁰¹ These and other pump systems are often characterized by a wide range of substrate specificities and, along with porins, are a common mechanism whereby an isolate can express multidrug resistance. In contrast, a number of microbes generate enzymes that destroy antimicrobials (e.g., aminoglycoside acetylases, beta-lactamases that destroy penicillins or cephalosporins, transferases that destroy chloramphenicol); in such instances resistance conferred by these mechanisms is generally limited to a single drug or drug class. Enzymatic inactivation is more likely for natural drugs to which microbes have previously been exposed (and thus presented with a greater opportunity to develop enzymes). In contrast, enzymes are less likely to destroy synthetic drugs.¹¹⁸ However, plasmid-mediated enzymatic destruction of FQs has recently been described, once again highlighting the resourcefulness of bacteria.¹¹⁹ Changes in target structure are another major mechanism of resistance. Example targets that have been modified include, but are not limited to, cell wall proteins (e.g., penicillin-binding proteins [PBs], particularly for MRSA [PB2] or Enterococcus [PB5]), or binding sites (i.e., on ribosomes, as for aminoglycosides, or DNA gyrase for FQs).^{120,121} Organisms often are characterized by more than one mechanism of resistance. Multiple mechanisms are well documented for some organisms against selected beta-lactams and have been described against FQs (e.g., altered DNA gyrase and increased efflux pumps) and others. Resistance can be induced, as is exemplified by betalactamase formation in Staphylococcus spp. which greatly increases in the presence of a beta-lactam antibiotic, or for fluoroquinolone, for which efflux pump activity is markedly upregulated. Discussion of specific mechanisms of resistance will be addressed with the appropriate drugs (see Chapter 7).

Avoiding Antimicrobial Resistance

Among the approaches to reducing resistance are pharmacologic manipulations and changes in antimicrobial use practices. Pharmaceutical manufacturers have been able to manipulate antimicrobial drugs in a variety of ways such that resistance is minimized, and these options can be selected in an attempt to minimize resistance. For example, bacterial resistance has been decreased by synthesizing smaller molecules that can penetrate smaller porins (e.g., the extendedspectrum penicillins ticarcillin and piperacillin); synthesizing larger molecules that force the microbe to develop more than one point mutation (e.g., later-generation FQs), "protecting" the antimicrobial from enzymatic destruction (e.g., with clavulanic acid, which diverts the beta-lactamase from the

Box 6-3

Reducing Transmission of Resistant Microbes (Decontamination)

Treating infected patients in order of least-at-risk to most-at-risk Dedicated diagnostic or handling equipment Proper bandaging of infected sites Dedicated bandage areas Protection during animal handling (disposable gloves, masks, gowns, eyewear) Decreased contact with body fluids Dedicated disposal for contaminated materials Proper hand washing between patients Easy access to hand sanitizers (alchohol based) Strict asepsis during surgery Dedicated cleaning materials Clean in order of cleanest to dirtiest Proper disinfection of the following: Exposed or at-risk rooms · Tables, doors, counter surfaces, floors, and so on • Equipment (stethoscopes, keyboards, pens, and so on)

• Isolate carriers (not always necessary)

penicillin); modifying the compound so that it is more difficult to destroy (e.g., amikacin, which is a larger and more difficult to reach molecule than gentamicin and carbapenems, later generation cephalosporins); and developing lipid-soluble compounds that are more able to achieve effective concentrations at the site of infection (e.g., doxycycline compared with other tetracyclines). Increasingly, drug design-based tactics will be implemented to minimize emergent resistance. Increasingly the role of the practitioner is equally important. A three "D"s approach might reduce the risk of emergent resistance: De-escalate antimicrobial use, design a treatment regimen that minimizes resistance (dead bugs don't mutate), and **decontaminate** the environment through proper hygiene. These approaches are exemplified by strategies implemented by intensive care units to reduce antimicrobial resistance that often involve a multitiered approach (Box 6-3). Actions include the following:

KEY POINT 6-24 The goal of antimicrobial therapy is twofold: resolving clinical signs associated with infection and avoiding emergent resistance. The two goals are not mutually inclusive.

 De-escalate. De-escalation begins with not using an antimicrobial when an alternate therapy (including no therapy) is more or perhaps equally effective. Enacting primary prevention by decreasing length of hospital stay, decreasing use of invasive devices, and implementing newer approaches (e.g., selective digestive decontamination and vaccine development).¹⁰⁷ De-escalation also includes setting limits on the duration of antimicrobial therapy (see later discussion) and rotating the use of antimicrobial drugs on a regular schedule.^{107,125} De-escalation might also refer to changing from a higher to a lower tier category of drugs (following a "hit hard, get out quick") in a critical patient.

- 2. **Design:** Improving appropriate antimicrobial use through proper dosing regimens includes selection of the most appropriate drug for the bug while narrowing the spectrum. This approach also should be applied to empirical antimicrobial therapy. Design of the dosing regimen should take into account the appropriate PDI for concentration or time-dependent drugs, and when possible, targeting the MPC. More controversial approaches to design include techniques implemented in hospitals include adhering to prescribed formularies or requiring prior approval for using certain antibiotics.
- 3. **Decontaminate:** Approaches intended to reduce bacterial exposure are among the most important to avoiding resistance. These include improving infection control through selective decontamination procedures, prevention of horizontal transmission through proper hand-washing technique, and use of gloves and gown, or prevention by reducing exposure to bandages or other contaminated materials by identifying proper work areas and disposal sites. Other approaches include, provision of soap alternatives, easy access to disinfectants (which should complement, not replace, hand washing) and improvement of the workload and facilities for health care workers.

Improved information systems technology also plays a role. Each proposed or implemented strategy has theoretical benefits and limitations, but good data on their efficacy in controlling antimicrobial resistance are limited.^{107,125} However, it is clear that decreased antimicrobial use is associated with a decrease in the advent of resistance.

Risk factors for emerging resistance in the hospital or community setting include but are not limited to increased antimicrobial use, host factors such as severity of illness and length of stay, and lack of adherence to infection control practices.¹⁰⁷ Consequently, among the de-escalation efforts implemented in human hospital and community environments is restricted antimicrobial use. In humans the increasing presence of drugresistant bacterial infections among hospitalized patients is linked to the greater numbers of patients receiving inappropriate antimicrobial treatment.¹²³ A recent on-line report found that in human medicine, antimicrobials were often prescribed despite infection being an infrequent cause of the illness (i.e., pharyngitis). Further, the chosen antimicrobial often was inappropriate for those bacteria potentially causing infection in the treated body system.¹²⁴ Accordingly, reducing inappropriate antimicrobial use has become a priority in human medicine.

Among the more rational paradigms for antibacterial deescalation, is an approach to empirical antimicrobial use in the hospital setting for patients with serious bacterial infections.¹²³ Such antimicrobial de-escalation attempts to balance the need to provide appropriate initial antibacterial treatment while limiting the emergence of antimicrobial resistance. The goal of de-escalation in this setting is to prescribe an initial antimicrobial regimen that will cover the most likely bacterial pathogens associated with infection while minimizing the risk of emerging antimicrobial resistance.¹²³ The three-pronged approach includes narrowing the antimicrobial regimen through culture, assessing isolate susceptibility for dose determination, and choosing the shortest course of therapy clinically acceptable. Judicious antimicrobial use combined with restricted use of ceftazidime led to a decreased antimicrobial resistance to beta-lactams, in general, in a human teaching hospital environment.¹²⁶ Note that this strategy does not exclude the use of "big gun" antimicrobials. The approach of withholding use of high-impact drugs (e.g., meropenem or vancomycin) in patients whose need for effective therapy is critical to avoid emerging resistance that might limit drug use in later patients may not be rational or in the best interest of the patient. A more appropriate approach is to use the drug correctly. However, routine use of less powerful drugs is appropriate but only if these alternatives are just as effective. Regardless of the choice, once the decision is made to use an antimicrobial, attention must be paid to dosing regimens that minimize the advent of resistance by ensuring that infecting microbes are eradicated.

Another strategy to decrease the impact of antimicrobial use on resistance is a decreased duration of therapy (see the discussion of enhancing antimicrobial efficacy). One study in human critical care patients found that reducing the duration of antimicrobial therapy from 14 days to 10 days decreased the emergence of resistance.¹²⁷ Increasingly, clinical trials will focus on demonstrating efficacy of shorter (i.e., < 5 to 7 days) treatment regimens.

Rapid detection of the correct microbe and the presence of resistance would facilitate the proper design of a therapeutic regimen. Genetic changes (e.g., mutations) that result in resistance lend themselves to molecular detection. However, molecular tests are often limited to those mutations characterized by few polymorphisms (e.g., MRSA, potentially MRSIG, and Enterococcus sp.). Generally, these tests require culture conditions that are often designed to facilitate expression of the resistant gene and are based on amplification techniques. Yet, as with culture, although they are able to determine phenotypic expression, they do not necessarily document the isolate as the cause of infection. Further, they generally do not detect low levels of resistance that increase the MIC but do not render the microbe as "resistant" by susceptibility testing.¹²² Topical therapy should be considered when possible. Therapeutic drug monitoring may be helpful for some drugs (e.g., aminoglycosides). With at-risk patients in whom emergent mutants may not be sufficiently suppressed. Drugs inherently more resistant to bacterial inactivation should be selected (e.g., amikacin rather than gentamicin). Combination antimicrobial therapy (e.g., beta-lactamase-protected antimicrobial combinations; combination of beta-lactams with aminoglycosides) also reduces the incidence of resistance; for example, the use of an FQ reduced the advent of resistance to cephalosporins in one study.³³ Care should be taken in selecting a drug simply because of cost. Cost should be a factor only after other considerations have been taken into account. The cost of an excellent antimicrobial can be easily surpassed by the selection and use of several less expensive, but also less effective, antimicrobials.

HOST FACTORS THAT AFFECT ANTIMICROBIAL EFFICACY

Careful consideration must be given to host factors that can reduce concentrations of active drug at the site of infection.^{23,75,128} The impact of host factors on antimicrobial efficacy is often underestimated; such effects can be profound.

Among such host factors is distribution of the drug to the site of the infection (drug distribution is discussed under drug factors). Thus far, discussions on antimicrobial efficacy have been focused on achieving the MIC of the infecting isolate in the patient plasma. However, infections generally are not in plasma, and patients are not generally normal. The relationship between the MIC of the infecting organisms and drug concentrations achieved at the site of infection (both magnitude and duration) is so complex that predicting efficacy is difficult. Ultimately, mathematical models that integrate the major determinants of efficacy (bactericidal activity, relationship between PDC and MIC, duration of postantibiotic effect, and susceptibility versus resistance) may prove most predictive.¹²⁹ The determinants of this relationship and the influence of drug, microbial, and host factors on efficacy warrant further discussion.

The MIC_{BP} of a drug is based on plasma C_{max}, yet infections generally occur in tissues rather than plasma. More specifically, the site of infection generally is interstitial fluid. However, detection of drug in tissues is difficult, leading to PDC as the surrogate marker of tissue concentrations. In instances in which PDCs overestimate extracellular fluid, care must be taken to adjust doses. For such drugs C&S testing may overestimate efficacy of the drug (see the section on drug distribution). On the other hand, for some tissues, drug concentrations at the site may far exceed PDC (see below). Inflammation may profoundly alter drug efficacy (Table 6-7).23,128 Acute inflammation may initially increase drug delivery and drug concentration to the site of infection because of increased blood flow, increased capillary permeability, and increased protein release at the site (the latter effect increases the concentration of total, but not necessarily active, drug). However, chronic inflammation may do the opposite. Purulent exudate presents an acidic, hyperosmolar, and hypoxic environment that impairs the efficacy of many antimicrobials (Figure 6-16). Hemoglobin and degradative products of inflammation can bind antimicrobials.130 Selected drugs, including aminoglycosides (and probably highly protein-bound drugs) are bound to and thus inactivated by proteinaceous debris that accumulates with inflammation. Some antimicrobials can inhibit neutrophil function. Accumulation of cellular debris associated with the inflammatory process can present a barrier to passive antimicrobial distribution. The deposition of fibrous tissue at the infected site further impairs drug penetrance and distribution (Figure 6-17).

KEY POINT 6-25 Although the host inflammatory response initially may facilitate therapeutic success, it can ultimately profoundly decrease the likelihood of success.

	roenvironment on Antimicrobial cacy
Environmental	
Factor	Effect
Acidic pH	Penicillins inactivated at pH < 6.0
	Aminoglycosides and enrofloxacin more effective in alkaline pH
Hypertonicity/ hyperosmolarity	Impaired efficacy of beta-lactam antibiotics
Pus	Acidic pH
	Hypertonic
	Hyperosmolar
	Protein binding of selected drugs
	Binding to sediment (aminoglycosides)
Low O ₂ tension	Aminoglycosides inactive
	Growth of organisms slowed → decreased efficacy of bactericidal drugs
	Impaired phagocytic activity of leukocytes
Large inoculum	Greater concentration of antimicrobial inactivating enzymes
	Greater concentration of drug molecules required
Leukocytes	Impaired chemotaxis, phagocytosis, metabolism

Negative Effects of the

Table **6-7**

Local pH becomes more acidic as degradative products such as lysosomes, nucleic acids, and other intracellular constituents from white blood cells accumulate. The efficacy of many antimicrobials can subsequently be impaired. In humans a pH level ranging from 5.5 to 6.8 can adversely affect both host defenses and antimicrobial activity. White blood cell oxidative bursts and phagocytosis are diminished in the presence of a low pH level. Some antimicrobials are inactive at a low pH level. Erythromycin loses all of its activity when pH is below 7. Similar effects have been reported for beta-lactam antibiotics. Although beta-lactam antibiotics are weak acids and therefore less ionized in an acidic environment, they are generally less effective at a pH 6. The activities of cefoxitin, piperacillin, and imipenem (or meropenem) are significantly less at pH 6 than at pH 6.5 with piperacillin being least affected. The activity of clindamycin is similarly decreased. In addition, the accumulation of some drugs in white blood cells that might otherwise facilitate efficacy is impaired in an acidic environment. Changes in pH also lead to changes in the concentration of un-ionized and thus active drug. Weak bases such as aminoglycosides and FQs are predominantly ionized in an acidic environment and are less effective than in a less acidic environment, in part because of impaired diffusibility.

Low tissue oxygen tension, which can accompany pus, reduces white blood cell phagocytic and killing activity; slows the growth of organisms, making them less susceptible to many drugs; and specifically prevents the efficacy

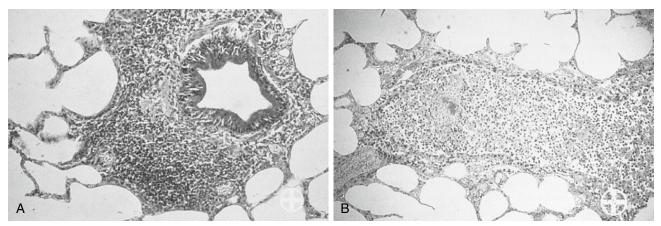

Figure 6-16 The inflammatory response to bacteria is intended to support the host in overcoming an infection. However, the response can become a confounding factor. For example, the inflammation of pneumonia of bronchitis dilutes the drug, presents a barrier to passive diffusion, and may bind and thus inactivate the drug. Local pH and thus drug ionization may impair drug action, and generation of a decreased oxygen tension further decreases drug efficacy. (Photo courtesy Bayer Animal Health.)

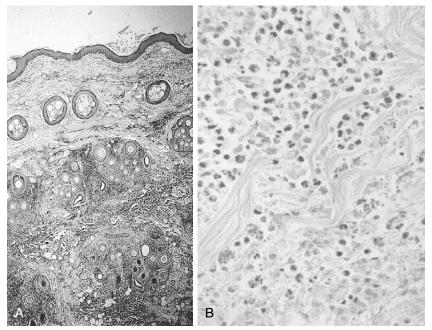

Figure 6-17 Deposition of fibrous tissue in deep pyoderma presents a barrier to drug penetration. (Photo courtesy Bayer Animal Health.)

of aminoglyosides, which depend on active transport into bacterial organisms. The aerobic component (i.e., facultative anaerobes) of a mixed infection may also be resistant to aminoglycoside therapy because the oxidative transport systems of such organisms (e.g., *E. coli*) may shut down in an anaerobic environment. Drugs that target cell walls, and beta-lactams in particular, are less effective in a hyperosmolar environment, which might occur as inflammatory debris accumulates and osmotic destruction of organisms is reduced.

Host response to infection and its impact on antimicrobial therapy may vary with the organ system infected. For example, in respiratory tract infections, mucus produced by the host can directly interfere with antimicrobial therapy. Aminoglycoside efficacy may be decreased by chelation with magnesium and calcium in the mucus. Antimicrobials may bind to glycoproteins, and mucus may present a barrier to passive diffusion. In addition, some antimicrobials may alter the function of the mucociliary apparatus, either by increasing mucous viscosity or by decreasing ciliary activity (e.g., tetracyclines).

Changes in the health of the host can lead to changes in drug disposition that can result in lower than anticipated PDCs (see Chapter 2).⁵⁰ The volume to which a drug is distributed can be affected by the fluid compartments, which vary with age, species, and hydration status. Distribution to target organs can be affected profoundly by cardiovascular

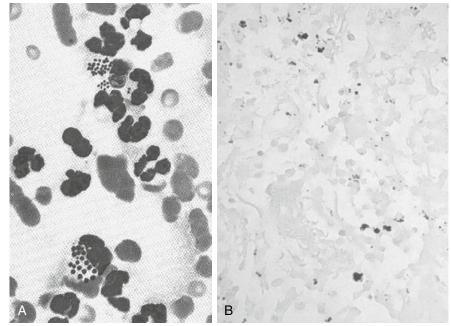

Figure 6-18 The intracellular location of organisms presents a barrier to drug penetration. Some organisms are obligate intracellular organisms, whereas others, such as *Staphyloccocus* spp., demonstrated cytologically **(A)** and by special stain of infected skin **(B)**, may survive phagocytosis, serving to reinfect tissue once the phagocytic white blood cell has died.

responses, particularly in the shock patient. Elimination of the drug must be considered when selecting antimicrobials for the critical patient. Changes in glomerular filtration cause parallel changes in renal excretion of drugs. Serum creatinine concentrations should be used to modify doses or intervals of potentially toxic drugs that are excreted renally (see Chapter 2).¹³¹ Likewise, severe changes in hepatic function may indicate selection of an antimicrobial drug not dependent on hepatic function for activation or excretion.

Host Factors That Facilitate Drug Efficacy

Host factors may also facilitate antimicrobial efficacy. Among the most important host factors are local and systemic defenses ranging from compounds that directly target microbes to healthy tissues that provide mechanical barriers and a competent immune system. The role of host defenses are beyond the scope of this chapter but cannot be underemphasized.

Other host factors that facilitate therapy include the accumulation of the drug in active form at the site of infection, which may facilitate antimicrobial efficacy and decrease the risk of resistance. Obvious examples include drugs that undergo renal or biliary excretion. For such drugs urine or bile concentrations (respectively) may exceed PDC thirtyfold to several hundredfold (see the discussion of treatment of urinary tract infections, Chapter 8). Another site of drug concentration is the phagocytic leukocyte (WBC), both in peripheral circulation and at the site of inflammation. Active concentrations of some antimicrobials (e.g., macrolides, lincosamides, and FQs) may increase concentrations 20 to 100 or more times the PDC.^{28,132-137} Phagocytic accumulation may facilitate treatment of intracellular infections (e.g., Brucella spp., cell wall-deficient organisms, intracellular parasites, and facultative intracellular organisms such as Staphylococcus spp.). Thus drugs that achieve only bacteriostatic concentrations in plasma may become bactericidal inside the cell, particularly against organisms that locate and survive inside cells (Figure 6-18). Additionally, accumulated drug released by dying phagocytes at the site of infection may increase concentrations to which the infecting microbe is exposed. Accumulation of drug inside WBC has been assumed as an explanation of the disconnect of azithromycin efficacy in pulmonary infections despite low PDCs.91 Note, however, that drug accumulation does not necessarily enhance drug efficacy. Often, the accumulated drug is sequestered into subcellular organelles, where it cannot reach the organism. In addition, the drug may become otherwise inactivated once inside the cell. The different mechanisms of action of these drugs may not occur in an anaerobic environment, and concentrations by the WBCs might be impaired in an anaerobic environment. The FQs are an example of a class of drugs whose uptake by WBCs is facilitated in an acidic environment; these drugs are distributed throughout the cytosol, where they remain active. The drug will leave the WBCs and enter a drug-free environment and thus may facilitate drug concentrations at the site of infection. Phagocytic WBCs with accumulated enrofloxacin delivered drug to inflamed tissue cages in dogs, demonstrating that accumulation may increase therapeutic response.¹³⁷ Drugs that do not accumulate in WBCs include the beta-lactams, aminoglycosides, and metronidazole. Drugs that are moderately accumulated in WBCs include chloramphenicol (onefold to fivefold) and selected sulfonamides (threefold to fivefold).138

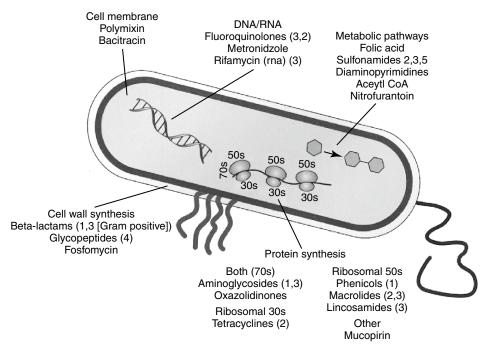

Figure 6-19 Targets of antimicrobial actions for the different classes of antimicrobial drugs. The number in parentheses refers to the major mechanism(s) of acquired resistance (other mechanisms also exist; see Chapter 7): 1 = enzymatic destruction (e.g., beta-lactamases for beta-lactams, acetylases for phenicols); 2 = increased efflux pump activity (may be associated with altered porin influx in gram-negative isolates); 3 = altered targeted site (e.g., mutations in DNA gyrase for fluoroquinolones or penicillin-binding proteins for gram-positive isolates); 4 = interfering protein and 5 = increased production of targeted metabolite. Decreased porin size is a common mechanism of resistance associated with increased efflux pump activity for many gram-negative isolates.

Another potential facilitating host factor is infection at a site that is topically accessible. In such situations several 1000fold concentrations of the MIC may be reached with topical administration. The rationale for collecting C&S data for such infections might be controversial, but identification of the organism and some indication of susceptibility is prudent, particularly if initial therapy fails.

DRUG FACTORS THAT AFFECT ANTIMICROBIAL EFFICACY

Mechanisms of Drug Action

Knowledge of the mechanism of action (see Figure 6-19) of a particular antimicrobial is important for several reasons:

- 1. The mechanism of action of a drug determines whether the antimicrobial can act in a bactericidal or bacteriostatic manner (assuming proper concentrations are achieved at the tissue site; see previous discussion). Drugs that are capable of bactericidal effects at therapeutic doses are listed in Table 6-7.
- 2. The mechanism of action may determine whether or not the drug is concentration-dependent or time-dependent, which will impact the design of the dosing regimen.
- 3. The therapeutic efficacy of some antimicrobials can be impaired by host factors that alter the mechanism of action of the drug. Knowledge of the mechanism of action will facilitate anticipation of therapeutic failure.
- 4. The mechanism of antimicrobial action often reflects the mechanism of resistance. Identifying mechanisms by

which resistance might be avoided or minimized requires an appreciation of these mechanisms of action.

- Understanding or anticipating selected host toxicities associated with antimcirobials can be improved by understanding their mechanism of action.
- 6. Understanding antimicrobial mechanisms of action provides a basis for the selection of antimicrobials to be used in combination. Such drugs should be selected on the basis of mechanisms of action that complement rather than antagonize one another (see Combination Antimicrobial Therapy section).

The cell wall is an important target for several antimicrobials, protecting the hypertonic intracellular environment of the organism from the hypotonic extracellular environment.²³ A variety of proteins located in the cell wall (penicillin-bound proteins) are important in the formation of the cell wall during division of growth of the organisms. These proteins are the target of several antimicrobial agents. Destruction of the peptidoglycan layer, which provides support to the cell wall, increases the permeability of the cell wall to the hypotonic environment, resulting in osmotic lysis of the cell. Intracellular structures are also major targets for various antimicrobial agents. Binding of ribosomes, the site of protein synthesis in the cell, can either inhibit protein formation or result in the formation of faulty proteins that eventually prove detrimental to the organism. The nuclear material of microbes is another target: Interference with cellular DNA inhibits cellular division, as well as initial cellular functions. Generally, impaired DNA synthesis results in cell death. Other intracellular targets

include selected metabolic pathways such as folic acid synthesis, which, when interfered with, prevents formation of materials vital to the microorganism.

Drug Disposition

Absorption

Care must be taken when selecting the antimicrobial that the disposition of the drug meets the needs of the patient (see earlier discussion of host factors). The availability of drug preparations determines drug selection in many instances because not all drugs are available for administration by all routes. To maximize plasma and thus tissue drug concentrations, intravenous administration is the preferred route for critically ill patients or difficult-to-penetrate tissues, with intramuscular and subcutaneous administration being second and third choices, respectively. Oral administration of antimicrobials, however, is preferred for long-term use, for nonhospitalized patients, and when drug therapy is targeting the gastrointestinal tract.

Note that although a drug may be 100% bioavailable after oral administration (i.e., the drug is completely absorbed), the rate of absorption may be sufficiently slow that the peak effect is minimized (although the duration of drug in circulation may be prolonged). Efficacy may be impaired, particularly for organisms with a high MIC or for concentration-dependent drugs. Slow-release preparations, either orally or parenterally administered, should be used cautiously because prolonged absorption (controlled rate of release) may be so slow that therapeutic concentrations are not achieved. The risk of resistance may be increased in such situations. Although slow-release products might improve compliance for timedependent drugs, their use may also preclude shorter duration therapy. Topical administration is the sole route for drugs that are too toxic to the host to administer systemically. Care must be taken, however, with drugs applied to skin whose surface has been damaged. Sufficient drug absorption may occur to render the patient at risk of developing toxicity. Drugs applied to the ear canal may be ototoxic, particularly in the presence of a perforated tympanic membrane.

Distribution

Once in circulation, the antimicrobial must distribute well to target tissues (i.e., the site of infection). The principles determining drug distribution to and from tissues are discussed in Chapter 1, and movement of each antimicrobial is discussed in Chapter 7. Whereas sinusoidal capillaries, found primarily in the adrenal cortex, pituitary gland, liver, and spleen, present essentially no barrier to drug movement. Fenestrated capillaries such as those located in kidneys and endocrine glands contain pores (50 to 80 nm in size) that facilitate movement between plasma and interstitium. Because the ratio of capillary surface area to interstitial fluid volume is so large, unbound drug movement from plasma into the interstitium occurs very rapidly in these tissues.^{139,140} Continuous capillaries, such as those found in the brain, CSF, testes, and prostate, present a barrier of endothelial cells with tight junctions.¹³⁹ Muscle, lungs, and adipose tissue also contain continuous

capillaries.¹³⁹⁻¹⁴¹ Therapeutic antimicrobial failure in a number of body systems in humans has been associated with failed drug penetration, including soft tissue infections, osteomyelitis, prostatitis, otitis, endocarditis, ocular infections, peridontitis, and sinusitis.¹⁴¹

KEY POINT 6-26 Interstitial fluid concentrations often parallel plasma concentrations for tissue with fenestrated capillaries. The same is not likely to be true for other tissues or in the presence of host or microbial factors that impair effective drug movement.

Models for detection of drugs in tissues focus, appropriately so, on interstitial (extracellular) concentrations.^{141,142} Methods that measure concentrations in tissue homogenates (including both intracellular and extracellular fluid) do not accurately represent interstitial concentrations. Extracellular fluids can be collected by a variety of methods, although a major limitation is the volume of fluid that can be collected. Detection of drug in fluids is often based on methods that require at least 1 mL or more of fluid. Of these models, those that are based on ultrafiltration techniques appear to be most accurate representations of extracellular fluid in the normal animal.¹⁴³ Tissue cages that contain an inflammagen are reasonable methods to study the impact of inflammation on drug distribution.¹³⁷ Determination of drug in tissues protected by specialized barriers is difficult, generally requiring anesthesia.144 If concentrations are compared with plasma, data must be based on the entire time versus concentration curve (i.e., AUC, C_{max}) rather than single-point comparisons because drug does not distribute immediately into tissues. Care must also be taken to address the impact of protein binding, as can be demonstrated for cefovecin, a drug that is 90% to 99% bound to serum protein. Total serum concentrations are markedly higher than that in extraceullar fluid because the latter contains less protein.46

Doses for drugs generally should be higher when treating infections in tissues with continuous capillaries, particularly for water-soluble drugs. Comparison of MIC data with tissue drug concentrations may be useful when designing dosing regimens for such tissues.

Examples of different distribution patterns might be predicted somewhat based on Vd (Box 6-4; see also the section on antimicrobial drugs in Chapter 7). Although the Vd of a drug does not indicate to which tissues drug is distributed, it can be used to approximate likelihood of tissue penetration in that a lipid-soluble drug is more likely than a water-soluble drug to move beyond extracellular fluid. Urine and the central nervous system (CNS) offer two divergent examples of tissue penetration. Urine is easy to target by drugs that are renally eliminated. Other components of the urinary tract, such as the kidney and particularly the prostate, can, however, be more difficult to penetrate. Antimicrobial therapy of the CNS is very difficult, although success may be facilitated by inflammation, which enhances drug penetration. However, once

Box 6-4

Tissue Distribution Pattern of Selected Drugs

Drugs Distributed to Extracellular Fluid (V_d≤0.34 L/kg) Beta-lactams Aminoglycosides

Drugs Distributed to Total Body Water (Vd 20.6 L/kg)

Chloramphenicol Clindamycin Doxycycline/minocycline Erythromycin Fluorinated quinolones Sulfonamides/trimethoprim

Drugs Concentrated in Urine

Beta-lactams Aminoglycosides Fluorinated quinolones Sulfonamides/potentiated sulfonamides Vancomycin

Drugs Concentrated in Bile

Clindamycin Doxycycline/minocycline Macrolides (erythromycin) Rifampin

Drug Penetration of the Blood-Brain Barrier

Drugs that readily enter the cerebrospinal fluid (CSF) Chloramphenicol Doxycycline/minocycline (unbound) Fluorinated quinolones (for some organisms) Metronidazole Rifampin Sulfonamides/trimethoprim Drugs that enter the CSF in the presence of inflammation Penicillins Selected cephalosporins (e.g., cefotaxime, ceftriaxone, ceftazidime) Fluorinated quinolones Vancomycin Drugs that do not enter the CSF Aminoglycosides Carbenicillin Cephalothin Cefazolin Cefotetan Clindamycin Erythromycin Tetracycline

Drugs that Accumulate in White Blood Cells Clindamycin Erythromycin (macrolides) Fluorinated quinolones Rifampin

inflammation resolves, drug distribution may again decrease. The blood-brain or CSF barrier represents a particularly challenging site because it not only prevents movement of antimicrobials into the CNS but also actively transports out or destroys some antimicrobials (i.e., penicillins and selected cephalosporins) (see Box 6-4). Care must be taken even with tissues normally characterized by excellent blood flow. For example, distribution of beta-lactams, aminoglycosides, and selected sulfonamides into bronchial secretions is generally <30% of that in plasma (see Chapter 8).^{130,145,146}

Lipid-soluble antimicrobials should be used for infections that are more difficult to treat, including those associated with tissue reaction or those caused by intracellular organisms, and when the site of infection presents a distribution barrier. Tissue distribution of aminoglycosides and most beta-lactam antimicrobials is limited to extracellular fluid; in contrast, many other antimicrobials (e.g., FQs, macrolides, and trimethoprim/sulfonamide combinations) are distributed well to all body tissues, including the prostate gland and eye. Enrofloxacin approximates or surpasses unity with plasma in many tissues.¹⁴⁴ Imipenem (or meropenem), trimethoprim/sulfonamide, and FQs can achieve bactericidal concentrations for some infections in the CNS (particularly organisms with a low MIC); chloramphenicol will achieve bacteriostatic concentrations.¹⁴⁷ Accumulation of antimicrobials in WBCs facilitates treatment of intracellular infections.132-137

Protein binding of a drug to plasma proteins may affect antimicrobial efficacy both in the patient and in vitro as data supporting drug selection and dose design are generated. Only unbound drug is pharmacologically active (see impact on cefovecin).⁴⁵ In vivo, bound drug is retained in the vasculature; once in the interstitial fluids or inside the cell, the drug may again be bound and inactivated. In vivo C&S testing and determination of MIC occur in the absence of protein. Further, PK on which MIC_{BP} is based (C_{max} being a major consideration) frequently is based on total drug, rather than the fraction of unbound. For a drug insignificantly protein bound, this disconnect is generally not significant. However, as the fraction of bound drug increases, C&S testing may markedly overestimate efficacy by the proportion of drug that is bound (i.e., a drug that is 50% proteinbound will actually yield an "active" C_{max} that is 50% of the total). Clearance and Vd may be underestimated. Attempts should be made to base therapeutic decisions on unbound drug.130,148

Drug movement into bacteria must also be considered. The roles of drug pK_a and the environmental pH of a target tissue on drug efficacy have already been addressed. Ionization may impair drug movement through the LPS for drugs that passively move through this layer.

Drug Elimination

The route through which the drug is eliminated is an important consideration for two reasons. First, if the site of infection is also a route of elimination for that drug, higher drug concentrations can be expected at the site. Second, if the drug is toxic to an organ of elimination, use of the drug should be avoided if the organ is already diseased. Also, if the drug is toxic to any tissue, the drug should be used cautiously in the presence of disease of the organ of elimination or dosing regimens should be appropriately modified.

Nonantimicrobial Effects of Antimicrobials

A number of antimicrobials influence various aspects of the immune system. The phagocytosis of drugs (e.g., macrolides, lincosamides, and FQs) was previously discussed.^{23,132-134,138} In addition to accumulation in WBCs, antimicrobials can influence WBC function. However, the effect can be variable. The negative effect of antimicrobials on phagocytic function has been well established, although the clinical relevance of this effect is less clear.¹⁴⁹ Functions that are targeted include chemotaxis (increased, decreased, or unchanged by clindamycin, erythromycin, chloramphenicol, and lincomycin and decreased or unchanged by gentamicin), phagocytosis (increased by erythromycin and chloramphenicol and decreased by tobramycin and polymyxin B), oxidative burst (increased by clindamycin, cefotaxime, and quinolones and decreased by cefotaxime, trimethoprim/sulfonamides, chloramphenicol, and erythromycin), bacterial killing (increased by cefotaxime and decreased by sulfonamides and aminoglycosides), and cytokine production or activity (interleukin 1 [IL-1] increased by cefotaxime and cefaclor and IL-10 by erythromycin; IL-1 and tumor necrosis factor decreased by cefoxitin, erythromycin, and ciprofloxacin).¹³⁸ Apoptosis of neutrophils may be accelerated.¹⁵⁰

The clinical relevance of these potentially beneficial effects on phagocyte function is not clear, but relevance is supported by some studies. For example, long-term use of azithromycin appears to improve lung function in children with cystic fibrosis and is increasingly being included in its therapeutic regimen; the disease appears to progress more rapidly if azithromycin is not added to therapy. This effect of macrolides appears to target inflammation, because the effect occurs at concentrations below the MIC of the infecting organisms. Potential mechanisms include a reduction in IL-1 β , IL-8, and neutrophils in bronchoalveolar lavage fluid.^{151,152} In addition to the antiinflammatory effects, macrolides appear to decrease *Pseudomonas* virulence by reducing the number of pili, thus altering adherence to tracheal epithelium, altering membrane proteins, and decreasing alginate formation.^{153,154}

KEY POINT 6-27 Selected antimicrobials facilitate therapeutic success through immunomodulation or their ability to decrease virulence of the infecting microbe.

Antimicrobial Effects of Nonantimicrobial Drugs

Antimicrobial effects have been described for a number of nonantimicrobial drugs at plasma concentrations achieved when the drug is used for noninfective indications. For example, a number of phenothiazines, including those with antihistaminergic effects, are antibacterial. Because these effects occur both in vitro and in vivo, the effects cannot be attributed simply to immunomodulation. Chlorpromazine is antimycotic at concentrations much higher than can be achieved safely in plasma, but its accumulation over a hundredfold in macrophages containing phagocytized pathogens facilitates effective therapy at recommended doses.¹⁵⁵ The less psychotically active thioridazine enhances the antimycotic activities of rifampin and streptomycin; between 2 and 3 months of use has been promoted as adjuvant therapy. Trifluoperazine and prochlorperazine inhibit S. aureus at concentrations of 10 to 50 µg/mL and selected other microbes (Shigella, Vibrio) at the same or higher concentrations and have demonstrated inhibitory effects in an animal model.^{156,157} Selected cardioactive drugs, including oxyfedrine and dobutamine, exhibit antimicrobial effects, again toward selected microbes.¹⁵⁸ Amlodipine has broad antibacterial efficacy at concentrations as low as 5 to 10 µg/mL, with S. aureus being the most susceptible and gramnegative organisms (E. coli, Klebsiella, and Pseudomonas) requiring higher concentrations.¹⁵⁹ Other drugs with demonstrated antimicrobial effects include the antispasmodic drug dicyclomine¹⁶⁰ and selected nonsteroidal antiinflammatories.¹⁶¹ Among the dietary supplements with recognized antibacterial effects are the flavones. Flavone dietary supplements exhibited antibacterial activity to a variety of microbes in a mouse infection model.^{162,163} Chitosans have demonstrated efficacy toward a number of bacterial organisms, particularly gram-negative isolates at concentrations as low as 0.05 µg/ mL.¹⁶⁴ Several antifungal drugs have antibacterial properties, which are addressed in Chapter 9.

Adverse Drug Events and Antimicrobials

Actions that minimize host toxicity enhance therapeutic success. However, host cells are eukaryotic, whereas the bacteria are prokaryotic. As such, targets of antibacterial therapy are sufficiently different from mammalian cells that, as a class, antibacterials (but not antifungals) tend to be safe. For example, beta-lactam antibiotics are among the safest antimicrobials because they target cell walls, a structure not present in mammalian cells. Often, even if cellular structures are present in both microbe and host, differences in the structure will result in different antimicrobial binding properties. For example, sulfonamides and FQs tend to be safe because the antimicrobials have a much greater affinity for the bacterial target enzymes than the mammalian enzymes. As with other drugs, the incidence of predictable (type A) drug reactions to most antimicrobial therapy correlates with maximum or peak PDC. However, aminoglycoside-induced nephrotoxicity and ototoxicity are an exception; toxicity tends to be related to duration of exposure and is more likely if minimum or trough PDCs are above a maximum level.^{76,165,166} Occasionally, toxicity of antimicrobials does reflect their mechanism of action, if the microbial target occurs in mammalian cells and is structurally similar (see Chapter 7). For example, colistin and polymyxin target both microbial and host cell membranes. Administration of either drug is associated with a high incidence of nephrotoxicity (probably because drug is concentrated in renal tubular cells), and subsequently their use generally is limited to the topical route of administration. Drugs that inhibit protein synthesis by binding to ribosomes (e.g., tetracyclines, chloramphenicol) may cause (limited) antianabolic effects in the host at sufficiently high doses. For most antimicrobial drugs, host toxicity may occur through mechanisms unrelated to its mechanism of action, but as a result of targeting structures in host cells. Aminoglycosides cause nephrotoxicity and ototoxicity, not because of their ribosomal inhibition (their antibacterial mechanism of action) but because they actively accumulate in renal tubular (or otic hair) cells (as they do in bacterial organisms) and in lysosomes causing lysosomal disruption. Topical application is more likely to cause ototoxicity with aminoglycoside and other drugs (see Chapters 4 and 7). FQs cause retinal degeneration in cats, through mechanisms yet to be defined. Tilmicosin causes (potentially lethal) betaadrenergic stimulation; the caustic nature of doxycycline can cause esophageal erosion in cats. Allergies are a less common adverse reaction caused by antimicrobials. Some drugs cause anaphylactoid reactions as a result of direct mast cell degranulation. True allergic reactions should be differentiated from anaphylactoid reactions (more common with intravenous administration of FQs). The latter may occur with the first dose and may be dose dependent. Anaphylactoid reactions can be minimized by administration of a small first dose before therapy. In contrast, drug-induced allergies generally require previous administration or a duration of therapy sufficient to allow antibody formation to the drug, which acts as a hapten (generally 10 to 14 days). Few drug allergies have been documented in animals. Among the most notorious are reactions to the potentiated sulfonamides.

KEY POINT 6-28 Because antimicrobial targets are prokaryotic and hosts are eukaryotic, adverse events seldom reflect the mechanism of antimicrobial activity.

Among the adverse reactions associated with antimicrobial use are those associated with drug interactions. Those most clinicaly relevant involve drug metabolizing enzymes. Examples of drugs that inhibit the metabolism of other drugs are the macrolides; chloramphenicol; and for selected drugs, the fluoroquinolones. In contrast, rifampin is an inducer. Increasingly, drugs that alter drug metabolizing enzymes are emerging as drugs that compete for or alter drug transport proteins (e.g., P-glycoprotein). Drug interactions involving antimicrobials are discussed with each class (see Chapter 8).

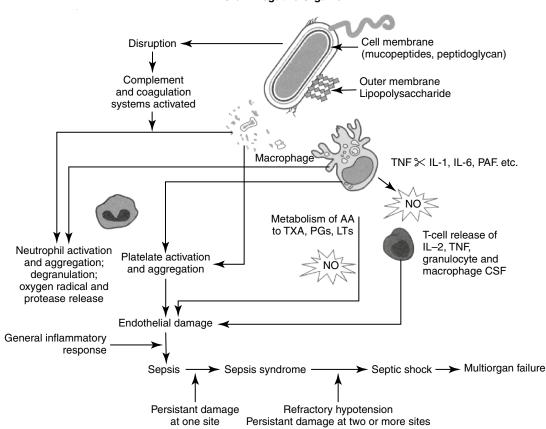

Adverse reactions to antimicrobials may reflect their antimicrobial success. Many orally administered drugs cause disruption of normal gastrointestinal microflora (see previous discussions). For example, the author has detected emergence of Clostridium perfringens in dogs treated with fosfomycin. Streptococcus spp. are generally associated with opportunistic infections. However, infections caused by members of this genus (S. pyogenes in humans and Streptococcus canis in animals) are associated with streptococcal toxic shock syndrome (STSS) and necrotizing fasciitis (NF).¹⁶⁷ These syndromes appear to reflect the presence of lysogenic bacteriophageencoded superantigen genes encoded in the bacterial organisms.¹⁶⁷ The superantigen genes are powerful inducers of T-cell proliferation; the presence of the superantigens then causes release of host cytokines in quantities that may be sufficient to cause lethal effects. In one study a bacteriophageencoded streptococcal superantigen gene was identified in the majority of S. canis isolates. Induction of these genes can lead

to bacterial lysis and subsequent release of proinflammatory and other destructive cytokines. Indeed, use of the FQs has been associated with STSS and NF in dogs (see Chapter 7).¹⁶⁸

Release of endotoxin is another example of seeming therapeutic success potentially leading to therapeutic failure (Figure 6-20). However, the clinical relevance of endotoxin release may be species dependent. Endotoxin release is a side effect of antimicrobials that occurs with therapeutic success, and it may influence antimicrobial selection for the patient infected with a large number of gram-negative organisms.⁸⁴ Endotoxins cause further release of cytokines and other mediators of septic shock (see Chapter 8). Most of these effects are mediated by the inner lipid A component of the LPS molecule that becomes exposed after antimicrobial therapy. In human patients suffering from endotoxic shock, outcome of antimicrobial therapy has been related to plasma endotoxin levels. A number of antimicrobials cause release of endotoxin from gram-negative organisms. Attempts have been made to correlate the amount of endotoxin released to the class of antimicrobial and specifically to its mechanism of action.

Continued bacterial growth or rapid cell lysis and death have been suggested as important criteria for endotoxin release after antimicrobial therapy. In contrast, the rate of bacterial killing and antimicrobial efficacy do not appear to be related to the rate and amount of endotoxin release. The amount of endotoxin release varies among the antimicrobial classes and even within the classes. Release can be related to mechanism of action. Among the drugs traditionally used to treat septicemia, aminoglycosides have been associated with the least and beta-lactams with the greatest endotoxin release (with imipenem or meropenem causing the least amount of endotoxin release among the beta-lactams).¹⁶⁹ The different amounts of endotoxin released by beta-lactams may reflect different affinities of the drugs for different penicillin-binding proteins. In vitro studies indicate that those beta-lactam antibiotics that specifically bind penicillin-binding protein (PBP)-3 are associated with endotoxin release, whereas those that bind PBP-2 cause little to no endotoxin release.¹⁷⁰ The difference may reflect the fact that PBP-3 appears to form a complex with PBP-1, 4, and 7;171 binding of PBP-3 might thus affect a larger component of cell wall synthesis compared to binding of another PBP. The release of endotoxin by quinolones varies depending on the study. However, in a study of mouse E. coli peritonitis, imipenem (or meropenem) and ciprofloxacin caused less endotoxin release than did cefotaxime.⁸⁴ Selected third-generation cephalosporins also appear to be associated with less endotoxin release: In a study of septicemic patients with acute pyelonephritis, the amount of endotoxin released did not differ among cefuroxime, ciprofloxacin, or netilmicin and each was deemed safe in the septicemic patient.172

KEY POINT 6-29 As a class, aminoglycosides are associated with the least and beta-lactams (excluding carbapenems and selected later generation cephalosporins) the most endotoxic release.

Gram-Negative Organism

Figure 6-20 Among the adverse reactions of antimicrobial therapy is release of bacterial toxins. The risk of damage to the host is greater with a large inoculum. In this example, rapid death of gram-negative organisms can result in rapid release of endotoxin. Drugs whose mechanism results in osmotic lysis (e.g., penicillins) are more likely to be associated with sufficient endotoxin release to cause harm to the patient.

The release of endotoxin may also be dose (concentration) dependent. For example, endotoxin release is greater at half the recommended dose of ciprofloxacin (3 mg/kg versus 7 mg/kg ciprofloxacin) according to the previously described model.⁸⁴ Actions that might minimize the sequelae of endotoxin release after antimicrobial therapy have not been established. Presumably, administering a dose more slowly may decrease the rate of endotoxin release. Binding and subsequent inactivation of endotoxin by antimicrobials have been documented, particularly for cationic antimicrobials (e.g., quinolones, aminoglycosides, and polymyxin).^{84,173}

ENHANCING ANTIMICROBIAL EFFICACY

Selecting the Route

Drugs may be selected on the basis of their route of administration. Not all drugs are available for parenteral or oral administration. Parenteral, and particularly intravenous, administration is indicated for life-threatening infections or whenever tissue concentrations must be maximized. Parenteral drugs are also indicated for the vomiting animal. Oral drugs are indicated for long-term use, outpatient therapy, and treatment of gastrointestinal tract illness. Topical therapy may be selected to enhance drug delivery while minimizing toxicity. Topical therapy with lipid-soluble drugs might, however, best be limited to situations in which systemic therapy of the same drug is implemented, thus preventing development of subtherapeutic drug concentrations in tissues other than the site of topical application, as might occur if topical administration alone is implemented.

Designing the Dosing Regimen

Antimicrobial therapy must be implemented in a timely fashion. An effective dose of antimicrobials administered at the first appearance of a clinical infection has a much greater therapeutic effect than therapy initiated a week later; in critical care patients, hours can mean the difference between patient recovery or death. Dosing recommendations printed on the label generally might be followed for recently approved drugs; however, exceptions occur, particularly for older drugs as we learn more about optimizing antimicrobial therapy and identify changing patterns of susceptibility. In general, to maximize efficacy, doses should be increased particularly for serious or chronic infections, tissues that are difficult to penetrate, or infections associated with detrimental changes at the site of infection. Product labels may not reflect new findings regarding antimicrobial efficacy because pharmaceutical companies may choose not to incur the costs associated with gaining approval for a new label that reflects the new dosing regimen. Dose modification beyond that on the label should be based on C&S data, current literature, and clinical signs of the patient. Adverse reactions also should be considered. Although antimicrobials are safe as a class, several are associated with dose- or duration-dependent adversities, and client counseling with informed consent is indicated when off-label dosing presents potential harm to the patient.

The approach taken to determine a dosing regimen for a patient depends on the information that is available—that is, how much is needed (PD) and how much is achieved (PK) (Table 6-4). In each instance it is assumed that patient factors are well known.

A target C_{max} can be calculated from MIC data that have been adjusted for time or concentration dependency. The dose of a drug administered intravenously is calculated as dose = target concentration * V_d For orally administered drugs, the V_d must be corrected for bioavailability (F): dose = target concentration $* V_d/F$ (see Chapter 1). For antimicrobials the target concentration, or "what is needed," is the MIC of the infecting microbe or a reasonable surrogate, such as the MIC₉₀ modified as needed to account for host, drug, or microbial factors For a concentration-dependent drug, the MIC or MIC₉₀ must be multiplied tenfold to achieve the targeted PDI C_{max}/MIC \geq 10. Thus for amikacin, a concentration-dependent drug, the targeted PDI for a patient infected with an *E. coli* with an MIC of 4 µg/mL is 40 µg/mL. If infection is in extracellular tissue and concentrations that are lower than in plasma are anticipated, the target C_{max} plasma may need to be multiplied by 2 or more to achieve the target in tissues. Thus the target becomes 80 µg/mL.

For amikacin the reported V_d in dogs is 0.23 L/kg. Assume an infection is in the lungs, where drug concentrations reach 50% of PDC. The dose of amikacin to target a microbe causing infection in the lungs then would be 4 μ g/mL (mg/L) * 10 * 2* 0.23* L/kg or 18.4 mg/kg. If the drug is given by a route other than intravenous, the dose must be modified further for bioavailability. For example, if amikacin is generally about 70% bioavailable (F=0.7) following subcutaneous administration, the subcutaneous dose for *E. coli* would be $(4 \mu g/mL (mg/L) *$ 10 * 2 * 0.23 * L/kg)/0.7 = 27 mg/kg. As the MIC for this *E. coli* and amikacin was quite low, next consider the same approach for a *P. aeruginosa* with an MIC of 16 µg/mL. If the infection is in the upper respiratory tract (e.g., sinus of a cat), distribution will probably be <30% of that in plasma (multiply dose by 3). The calculated dose would be 16 mg/L * 10 * 3.3*0.23 L/kg or 121 mg/kg. This is well beyond the recommended dose, and although it might be safe given once daily in a normal patient (drug concentrations would reach the target trough of 2 µg/mL by 6 to12 hours after dosing), the risk of adversity may outweigh the benefits of treatment with this dose. Combination therapy is indicated for this patient.

The design of a dosing regimen for a time-dependent antimicrobial is more complicated. For a time-dependent drug, the magnitude of C_{max} depends on how many half-lives are to elapse between doses. The ratio of C_{max} /MIC is important for determining the number of half-lives that can elapse before PDC = MIC. A good start is to multiply the MIC fourfold (C_{max}) MIC = 4) to allow a duration of two half-lives for T > MIC(each doubling of the ratio or dose provides another half-life of T > MIC). The duration of the dosing interval then depends on the desired duration of T > MIC. For T > MIC = 50%, the duration of the dosing interval is twice the number of half-lives that T > MIC; in this case, ($C_{max}/MIC = 4$), the dosing interval will be 4 half-lives. Although this sounds adequate, in reality, it may not be for drugs with a short half-life. For example, if the drug of interest is amoxicillin (half-life = 1 to 1.5 hr), the duration of the interval is 4 to 6 hrs, assuming all drug in plasma makes it to the site of infection. Thus, the ratio of C_{max}/MIC may need to be higher for drugs with a short half-life if a convenient dosing interval is desired. Alternatively, a drug with a longer halflife can be chosen. Using cefpodoxime as an example, based on package insert data, the MIC₉₀ of S. *intermedius* is 0.5 μ g/mL. Peak concentrations at 10 mg/kg approximate 15 µg/mL, yielding a ratio C_{max} /MIC of 30. The time that elapses before C_{max} and MIC reach unity is just under 5 half-lives (30 to 15 to 7.5 to 3.5 to 1.75 to 0.75. With a half-life of 4.5 hours, T > MIC duration approximates 24 hours. Theoretically, if the target is T > MIC = 50%, a dosing interval of 48 hours might be possible. However, the PDI upon which time and concentration dependency are based are limited to a 24 hr period, thus a 24-hr-dosing interval is prudent. This is particularly true if the drug is targeting tough-to-penetrate tissues or inflammatory debris: the concentration might then be reduced to 10 µg/mL, yielding a C_{max}/MIC of 10, or a duration of 2 half-lives, or 9 hours, for T > MIC. In this situation, a 24-hour dosing interval might be more appropriate; a 12-hour dosing interval might be prudent. Further, these calculations are based on a target of T > MIC of 50%. Although this target is often recommended, T > MIC of 75% to 100% might be better to minimize the risk of resistance, particularly in a patient at risk. Therapeutic drug monitoring can be used to establish or confirm a dose or interval for a drug for the individual patient and is ideally the basis of dose modification for critical patients. Unfortunately, few drugs (primarily the aminoglycosides and vancomycin) can be rapidly and accurately measured at a reasonable cost. The risks associated with these drugs, including the potential cost of using them at ineffective doses, however, may justify the cost.

Duration of Therapy

Among the most difficult decisions regarding antimicrobial therapy is the duration of administration. Generally, the duration of therapy should be 2 to 3 days beyond resolution of clinical signs. Indeed, if the dosing regimen is designed according to the saying "dead bugs don't mutate," then clinical signs of resolution should emerge rapidly. This is true, however, only if the clinical signs are discreet and able to respond rapidly. Such is not likely to be true in the absence of fever, or when radiographic resolution of inflammation or healing of inflamed skin are benchmarks. Not surprisingly, clinicians often adhere to the "longer is better" approach. However, emerging data in human medicine suggest a more pro-active approach to therapy duration reduction is prudent. Animal models have demonstrated that therapy beyond 5 days increases the intensity

Drug One	Drug Two	Organisms
Dicloxacillin	Ampicillin, penicillin, cephalothins	Escherichia coli, Klebsiella, Pseudomonas aeruginosa
β-Lactam: cephalothin, ampicillin, piperacillin, cefotaxime, cefamandole	Aminoglycoside: gentamicin, amikacin	Escherichia coli, Pseudomonas, aeruginosa, enterococci, others
Chloramphenicol	Ampicillin	Salmonella typhimurium, Staphylococcus aureus (effect is bacteriostatic in nature)
Penicillin	Gentamicin	Bacteroides melaninogenicus
Imipenem	Vancomycin	Staphylococcus aureus
β-Lactam, vancomycin	Aminoglycoside	Staphylococcus aureus
Trimethoprim/sulfonamide	Imipenem, amikacin	Nocardia asteroides (effect is bacteriostatic)
Imipenem	Trimethoprim/sulfonamide, cefotaxime	Nocardia asteroides (effect is bacteriostatic)
Ethambutol	Rifampin, aminoglycosides, ciprofloxacin (enrofloxacin), clarithromycin	<i>Mycobacterium avium</i> (effect is bacteriostatic)

of drug therapy necessary to prevent emergent resistance.¹⁷⁴ In human medicine a number of clinical studies have investigated the impact that reduced duration of therapy might have on efficacy and resistance. In general, the longer-is-better approach is not appropriate.¹⁷⁵ Five days of therapy has been suggested as the upper limit in selected populations, including intrabdominal infections,^{175,176} community-acquired pneumonia,¹⁷⁷ and other respiratory tract infections,¹⁷⁸ and 3 days for pneumonia characterized by a low likelihood of becoming nosocomial.¹⁷⁹ These studies demonstrate the increasing focus on the role of duration of therapy in the advent of resistance. However, their extrapolation to companion animals is not clear, in part because compliance differences might affect results. Exceptions for which duration of therapy might be longer include infection of sites characterized by poor local immunity (or the immunocompromised patient), tissues in which healing is prolonged, or in the presence of foreign bodies that facilitate antimicrobial growth. Exceptions also may apply to slow growing organisms.

KEY POINT 6-30 For uncomplicated infections the duration of therapy should be 5 to 7 days or less.

Combination Antimicrobial Therapy

Combination therapy can be used to achieve a broad antimicrobial spectrum for empirical therapy, treat a polymicrobial infection involving organisms not susceptible to the same drugs, reduce the likelihood of antimicrobial resistance, and reduce the risk of adverse drug reactions by minimizing doses of potentially toxic antimicrobials.^{23,24,26,137} Rational combination antimicrobial therapy may be the single most effective action taken to enhance antimicrobial efficacy for the chronic or serious infection. Primary reasons to avoid combination therapy include increases in risk of suprainfection, risk of toxicity (if both drugs are potentially toxic), high cost, and inconvenience to the patient.²⁴

Antagonistic combinations

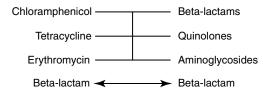

Figure 6-21 Combining antimicrobials can have different sequelae. Antagonistic antimicrobial combinations most commonly result when a drug that inhibits bacterial growth is combined with a drug whose action depends on rapid cell growth. Drugs that act at the same site may be antagonistic, additive, or synergistic (e.g., beta-lactams, depending which penicillin binding protein is targeted).

Synergism and Antagonism

Antimicrobials to be used in combination therapy should be selected rationally and based on target organisms as well as on mechanism of action (Table 6-8). Combinations might result in antagonistic, additive, or synergistic antimicrobial effects (Figure 6-21).¹⁸⁰ Generally, these effects are defined by in in vitro systems; clinical relevance is more difficult to establish. Also, the combined effects of two or more antimicrobials are likely to differ with the organism. Avoidance of antagonism is particularly important for patients with inadequate host defenses.^{23,24,26,180} In general, bacteriostatic drugs that inhibit ribosomes and thus microbial growth (e.g., chloramphenicol, tetracyclines, erythromycin) should not be combined with drugs whose mechanism of action depends on protein synthesis such as growth of the organism (e.g., beta-lactams) or formation of a target protein. The bactericidal activity and continued degradation or destruction of the microbial target of beta-lactams and FQs depend on continued synthesis of bacterial proteins. Antagonistic effects have been well documented between beta-lactam antibiotics and inhibitors of ribosomal activity. The degree of antagonism between FQs and growth inhibitors is controversial; antagonism has been has also been documented.¹⁸⁰ Occasionally, the combination of a bacteriostatic ribosomal inhibitor and a drug whose efficacy depends on rapid growth might enhance efficacy, even though the "-cidal" drug will act only in a "static" fashion. For example, chloramphenicol enhances the efficacy of ampicillin toward *Salmonella typhimurium* and *Staphylcoccus* spp., presumably because it inhibits the production of beta-lactamases by the organisms that might otherwise destroy ampicllin.

KEY POINT 6-31 The appropriate combination of two drugs characterized by resistance may render the microbe susceptible.

Chemical antagonism is also possible between two or more antimicrobials (see Chapter 2).^{181,182} Aminoglycosides and quinolones are chemically inactivated by penicillins at sufficient concentrations. Ticarcillin has been used therapeutically to reduce the risk of toxicity in a patient overdosed with an aminoglycoside.¹⁸³ Chemical antagonism is unlikely in most clinical uses of these drugs. The risk of antagonism is increased, however, with simultaneous intravenous use of high doses of both ticarcillin and aminoglycosides, such as might occur if aminoglycosides are administered once daily. Potential chemical interactions between other antimicrobials should be identified before combination therapy. Certainly, antimicrobials should not be mixed in the same syringe or intravenous line unless a lack of antagonism has been confirmed.¹⁸²

Drugs that have the same mechanism of action may act in an additive or synergistic fashion. For example, chloramphenicol and clindamycin bind the same 50S ribosomal subunit and will antagonize each other. Because tetracyclines bind to the 30S ribosomal subunit, combination with antimicrobials that target the 50S subunit might be considered (e.g., the phenicols, macrolides, and lincosamides) if there is scientific support. One study indicates an in vitro synergistic effect of the combined use of doxycycline and azithromycin against *P. aeruginosa*.^{183a}

Additive effects probably occur when active metabolites are produced from an active parent compound, such as metabolism of enrofloxacin to ciprofloxacin.¹⁸⁴ Antagonistic effects might occur, however, if the drugs compete for a limited number of target sites (e.g., chloramphenicol and erythromycin). In contrast, synergistic actions might occur if the antimicrobial targets are subtly different. For example, a combination of different beta-lactams generally results in additive antimicrobial activity. If the two antimicrobials target different PBPs, however, their combined effect may actually be synergistic ("double beta-lactam therapy").^{185,186} In contrast, combinations of other beta-lactam antibiotics (including combining selected cephalosporins) are antagonistic.¹⁸⁶ The different sequelae of combined beta-lactam therapy might be caused by the PBPs targeted by each drug.

Synergism between antimicrobials can occur if the two antimicrobials kill bacteria through independent mechanisms

or through sequential pathways toward the same target.^{180,187} The combination of trimethoprim and a sulfonamide exemplifies synergism resulting from sequential actions in the same metabolic pathway (see discussion of potentiated sulfonamides) (see Chapter 7). Clavulanic acid "draws" the beta-lactamase activity of the microorganism away, allowing the protective beta-lactam to impair cell wall synthesis. Synergism between beta-lactams and aminoglycosides exemplifies synergism resulting from killing by independent pathways. Synergism is expected because their mechanisms of action complement one another, but efficacy is enhanced further because aminoglycoside movement into the bacteria is enhanced by increased cell wall permeability induced by the beta-lactam (Figure 6-22).180,188 Indeed, aminoglycoside activity against enterococci is adequate only when used synergistically with a cell wall-active antimicrobial, such as beta-lactams and vancomycin. Synergism also has been demonstrated against some strains of Enterobacteriaceae; P. aeruginosa; staphylococci, including MRSA; and other microorganisms. However, these organisms are not always inhibited by the combination of aminoglycoside and cell wall-active compounds. Indeed, antagonism has been described between aminoglycosides and beta-lactams against an MRSA, presumably because of induction of an aminoglycoside-modifying enzyme. Enhanced movement in a bacteria may occur with other drugs (e.g., potentiated sulfonamides, FQs) when combined with beta-lactams (see Figure 6-22). Rifampin is another drug for which combined use enchances antimicrobial efficacy of a number of drugs.

Combination therapy is a powerful tool for enhancing efficacy (Figure 6-23) as well as preventing resistance. Occasionally, the combination of drugs, which by themselves would not be expected to have efficacy against organisms not included in their spectrum, may exhibit efficacy against the organisms. For example, azithromycin and clarithromycin may exhibit synergistic effects with several other drugs against *P. aerugi*nosa. When studied in patients with cystic fibrosis, the most active combinations demonstrating synergy were azithromycin combined with sulfadiazine/trimethoprim or doxycycline. Azithromycin occasionally demonstrated synergism against P. aeruginosa when combined with timentin, piperacillin/ tazobactam, ceftazidime, meropenem, imipenem, ciprofloxacin, travofloxacin, chloramphenicol, and tobramycin.¹⁸⁹ In the treatment of S. aureus, clindamycin inhibits early rapid killing of amikacin but acts synergistically with it at 24 to 48 hours.190

Polymicrobial Infections

Combination antimicrobial therapy may be selected because of the presence of a polymicrobial infection (Figure 6-24).^{23,24,77,191} Aminoglycosides or FQs are often combined with beta-lactams, metronidazole, or clindamycin to target both aerobic gram-positive and gram-negative infections or infections caused by both aerobes and anaerobes. The combined use of selected antimicrobials may result in therapy effective against a given microbe when either drug alone was ineffective.

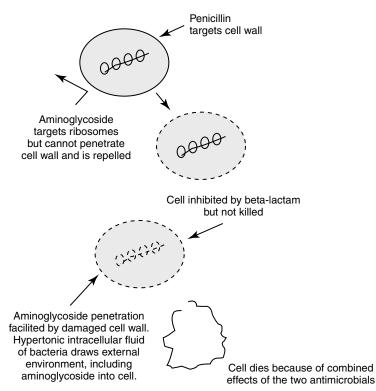

Figure 6-22 The combination of any number of drugs with a beta-lactam may result in synergistic antimicrobial effects. The prototypic example is a beta-lactam combined with an aminoglycoside, a class of water-soluble drugs whose movement through the cell to target ribosomes is limited. Changes in the cell wall permeability associated with the beta-lactam exposes the hypertonic (compared with the host) intracellular cytoplasm to the isotonic host, resulting in the influx of solutes into the organism. Intracellular access is thus facilitated for drugs also in the environment. Together, the two drugs are now more likely to kill the microbe. Such synergism has been documented in vitro between beta-lactams and a number of drugs, particularly those classified as bactericidal.

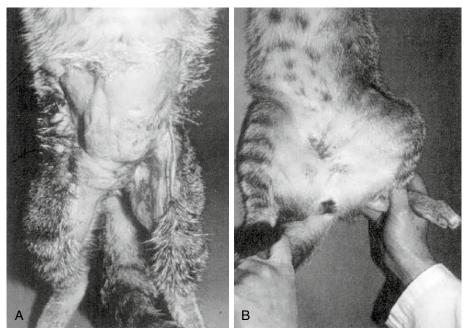

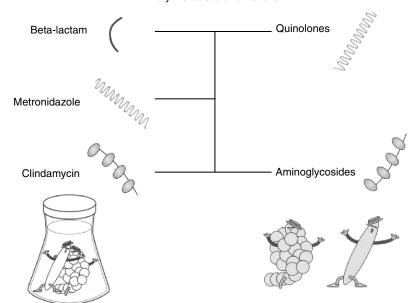

Figure 6-23 Atypical mycobacterium in a cat is associated with marked inflammation, including deposition of fibrous tissue deposition. This cat was successfully treated with a combination of sulfadiazine/trimethoprim and enrofloxacin after 3 months of therapy.

Polymicrobial combinations

Figure 6-24 Polymicrobial infections may require combination therapy. The quinolones and aminoglycosides offer excellent aerobic gram-negative coverage; the beta-lactams (especially penicillins), metronidazole, and clindamycin offer excellent gram-positive and anaerobic coverage.

ANTIMICROBIAL PROPHYLAXIS

The prophylactic use of antimicrobials should be distinguished from treatment. The presence of infection or anticipated infection after bacterial contamination (e.g., an open fracture, contamination of abdominal contents with intestinal fluid) indicates the need for treatment rather than prophylaxis. If antimicrobial prophylaxis is to be implemented in anticipation of an invasive procedure (e.g., surgery), the following should serve as a basis for selection: The antimicrobial should target the most likely pathogenic organism, adequate concentrations of drug should be at the site of invasion before potential contamination, the antimicrobial should either have a long elimination half-life or be redosed during lengthy procedures, the least toxic drug should be selected, and the duration of therapy should be as short as possible.^{23,26}

Prophylactic antimicrobials should not be used indiscriminately in the immunocompromised animal. The granulocytopenic patient is particularly predisposed to the development of suprainfection. Suprainfection occurs in 10% to 20% of human granulocytopenic patients receiving empirical broadspectrum antimicrobials. Prolonging therapy increases the chance that suprainfection will occur.²⁶ Prophylactic suppression of gastrointestinal flora is recommended in human patients who are profoundly granulocytopenic for more than 2 weeks. Traditional use of nonabsorbable antimicrobials effective against aerobic gram-negative organisms (e.g., neomycin) and drugs that target anaerobic organisms (e.g., metronidazole) are being replaced by use of trimethoprim/sulfonamide combinations or FQs.26 Trimethoprim/sulfonamide combinations are more palatable and less expensive, yet they are equally effective in preventing infections when compared with more expensive drugs in human critically ill patients. FQs

allow persistence of anaerobic organisms in the gastrointestinal tract, thus reducing overgrowth of resistant gram-negative organisms and preventing rapid repopulation and overgrowth of aerobic gram-negative organisms as the antimicrobial is discontinued.

Other indications for medical prophylaxis include dentistry and prevention of recurrent, chronic infections (e.g., urinary tract, skin). The use of antimicrobials prophylactically for these conditions is discussed separately in the corresponding chapter.

SURGICAL PROPHYLAXIS

Antimicrobial prophylaxis is defined as the administration of an antimicrobial agent in the absence of infection. The aim of antimicrobial prophylaxis is to reduce the number of viable bacteria present in the surgical wound to a level that normal host defenses can handle, thus preventing infection. Contaminating bacteria can enter the surgical wound from exogenous sources or the patient's endogenous flora. Exogenous sources include surgical equipment, the surgery room, and surgical personnel. Duration of the surgical procedure plays a role in the incidence of wound infections, especially for procedures that last longer than 90 minutes.

Endogenous bacterial sources probably play a greater role in postoperative infections than exogenous sources. Endogenous sources include skin and mucosal surfaces that are transected during surgery. Hematogenous spread of bacteria may result from overt or occult septic foci or dental manipulations.

*Harry W. Boothe

Such sources should be either eliminated before surgery by appropriate therapeutic antimicrobial agents or avoided by not combining dental manipulations with surgery of body cavities (abdominal or thoracic) or orthopedic procedures.

Antimicrobial prophylaxis is not a substitute for good surgical practices, which include aseptic technique and gentle tissue handling. Considerations in the use of antimicrobial prophylaxis are the type of surgery, potential pathogens encountered, host competence, and pharmacologic and antibacterial properties of the antimicrobial agent.

Type of Surgery

Surgical wounds are classified as clean, clean-contaminated, contaminated, or dirty. Clean wounds are made under aseptic conditions, are closed primarily, and are not drained. Prophylactic antimicrobial therapy is not warranted for most clean procedures because bacterial contamination is minor, and the patient's competence helps prevent wound infection. Possible indications for the use of antimicrobials in clean surgical procedures are when the consequences of infection would be catastrophic (e.g., total joint replacement) or when surgical implants are used.

Clean-contaminated wounds include those made in the gastrointestinal, genitourinary, or respiratory tract without significant intraoperative spillage. Also, clean procedures in which a break in sterile procedure occurred are considered clean-contaminated. Clean-contaminated wounds may benefit from prophylactic antimicrobial therapy, and consideration of the following factors seems appropriate when contemplating the use of perioperative antimicrobial therapy: number of resident bacteria encountered, amount of spillage expected, and impact of disease condition on bacterial colonization. Resident bacterial numbers vary depending on the site of the tract incised and the nature of disease. In the normal gastrointestinal tract, resident bacteria are numerous in the oropharyngeal cavity, distal ileum, and colon. Numbers are normally much lower in the distal esophagus, stomach, and most of the small intestine. The normal genitourinary tract above the distal urethra has low bacterial populations. The normal trachea and bronchi also have relatively sparse flora. Although amount of spillage cannot always be predicted preoperatively, prophylactic antimicrobials are probably indicated if the risk of intraoperative spillage seems high. Diseases, in general, tend to modify both bacterial numbers (usually increased numbers) and populations (usually more virulent forms).

Contaminated wounds include those in which there is acute, nonpurulent inflammation or those in which gross contamination from a hollow viscus occurs. Antimicrobial prophylaxis is generally warranted when surgery is performed on contaminated wounds. Also, the presence of extensive tissue damage or accumulation of blood within wounds may warrant prophylactic drug administration, because bacterial colonization is usually promoted.

Dirty or infected wounds benefit from irrigation with antiseptics. Chlorhexidine (0.05%) is an effective wound disinfectant for infected wounds. Use of antimicrobials (systemically, topically, or both) is generally indicated before surgery to treat an infected or dirty wound. Such use is more appropriately termed *therapeutic antimicrobial therapy*.

Potential Pathogens Encountered

The most frequently encountered pathogenic bacterial contaminants of surgical wounds are Staphylococcus spp. and E. coli. The most common skin bacteria are Staphylococcus spp., although many other organisms may be present as transient, topical flora. The oropharynx has a mixed population of gram-positive organisms (especially Staphylococcus spp., Streptococcus spp., and Actinomyces pyogenes), gram-negative organisms (Proteus, Pasteurella, Pseudomonas, and E. coli), and anaerobic organisms. The stomach and small intestine have very few organisms normally present, whereas the distal ileum and large intestine have large numbers of gram-negative (especially E. coli and Klebsiella, Pseudomonas, and Salmonella spp.) and anaerobic organisms. Potential pathogens encountered in the genitourinary tract include both gram-positive and gram-negative organisms (especially Staphylococcus and Streptococcus spp., E. coli, and Proteus and Pseudomonas spp.). Pathogens of the respiratory tract (especially lower respiratory tract) include both gram-positive organisms (Staphylococcus spp., Streptococcus spp., and A. pyogenes) and gram-negative organisms (Pseudomonas spp., E. coli, and Klebsiella, Pasteurella, and Enterobacter spp.).

Host Competence

Host resistance may be compromised systemically or locally. Patients with systemic immunodeficiency often have chronic, recurrent, or partially responsive infections. Prophylactic antimicrobial therapy is probably indicated for such patients regardless of the surgical procedure to be performed. Secondary immunodeficiencies have been associated with a variety of diseases, including hepatic or renal failure, hyperadrenocorticism, diabetes mellitus, and neoplasia. Other factors that may affect systemic host competence include advanced age, severe malnutrition, obesity, immunosuppressive drugs, and splenectomy.

Local factors of importance in the maintenance of host competence include tissue perfusion and tissue trauma. The competence of local defense mechanisms may be affected adversely by obstruction, neoplasia, ulceration, and hemorrhage. For example, the bacterial flora of a stagnant loop of jejunum caused by intestinal obstruction resembles that of the normal distal ileum (i.e., large numbers of resident bacteria). For the purposes of selecting perioperative antimicrobials, the clinician should accurately assess host competence before the surgical procedure.

Pharmacologic and Antibacterial Properties

The primary goal to be achieved by administration of prophylactic antimicrobial agents is to produce adequate concentrations of antimicrobial at the surgical incision site at the time of wound contamination. Also important is the concept that the major risk of contamination is at the time of surgery until a fibrin seal develops between wound edges (approximately 3 to 5 hours postoperatively). Factors of importance in the use of perioperative antimicrobials are absorption (timing and route of administration), distribution, and elimination characteristics. Absorption issues are of least concern with intravenously administered antimicrobials. For most antimicrobials distribution is relatively rapid and complete within 30 to 60 minutes after intravenous administration. The concentration of drug achieved in the tissue correlates with the concentration of free drug in the serum. Highly protein-bound drugs (i.e., little free drug in the serum) achieve lower tissue concentrations than do weakly bound agents (e.g., cefazolin, gentamicin, and ampicillin). Other factors such as lipid solubility, pH, and local environment may also influence tissue penetration of the drug. Elimination of most antimicrobials is principally by way of the kidneys. The rate of elimination determines the dosing interval that is selected. More rapidly eliminated drugs require more frequent administration. Cefazolin, for example, should be administered at 2-hour intervals during the surgical procedure to maintain adequate tissue and serum levels.

The following prophylactic antimicrobial regimen seems appropriate: an intravenous dose of drug given 30 to 60 minutes before incision (i.e., at anesthetic induction) and another dose given at the completion of the procedure. If the surgical procedure lasts longer than 3 hours, an additional intraoperative dose of antimicrobial should be given approximately 2 to 3 hours after the initial dose. There is no rationale for continuing antibiotic administration longer than 24 hours after surgery in the absence of documented infection. If infection is documented, therapeutic antimicrobial therapy is initiated.

The selected drug should be bactericidal for the pathogens that are most likely to contaminate the surgical site. Firstgeneration cephalosporins (e.g., cefazolin) are generally as effective as and less expensive than second- and third-generation cephalosporins. Surgery of the lower gastrointestinal tract may require a more elaborate schedule of prophylactic drug administration, partly because of the presence of anaerobic organisms. A second-generation cephalosporin (e.g., cefoxitin) or an aminoglycoside/anaerobic combination (e.g., amikacin and clindamycin or gentamicin and amoxicillin) should be administered systemically. The use of oral antimicrobials for prophylaxis may not be prudent, in part, because peak concentrations are likely to be less than with intravenous administration, even if bioavailability is close to 100% (and many are not).

Inappropriate perioperative antimicrobial use has been shown to increase the incidence of complications. Examples of inappropriate perioperative antimicrobial use include use of antimicrobials for clean surgical procedures, initiation of prophylactic antimicrobials postoperatively, and continuation of antimicrobial administration for longer than 24 hours. Each of these actions risks the occurrence of one or more of the following complications: reduced efficacy, suprainfection, selection of resistant bacterial pathogens, greater client cost, and a potential for higher incidence of drug-associated complications.

Although surgical prophylaxis has been integrated into the perioperative surgical plans for veterinary patients, surprising little information supports its use. In one controlled study of dogs (n = 329) and cats (n = 544) undergoing clean and clean-contaminated surgical procedures, the postoperative infection rate did not differ in placebo (9.4%) compared with the cephalexin-pretreated group (8.9%).¹⁹² In another study investigating the impact of flushing in dogs undergoing total ear canal ablation, organisms were characterized by a higher incidence of antimicrobial resistance to cefazolin,²⁹ suggesting that cefazolin may not be a rational choice in all presurgical candidates.

Antimicrobial Drugs

Dawn Merton Boothe

Chapter Outline

DRUGS THAT TARGET THE CELL WALL
Beta-Lactam Antimicrobials
Vancomycin
Teicoplanin
Fosfomycin
DRUGS THAT TARGET RIBOSOMES (BACTERICIDAL)
Aminoglycosides
DRUGS THAT TARGET NUCLEIC ACIDS
Fluorinated Quinolones
Rifamycins
Metronidazole
DRUGS THAT TARGET FOLIC ACID
Inhibitors of Folic Acid Synthesis:/Sulfonamide/
Trimethoprim or Ormetoprim Combinations

DRUGS THAT TARGET RIBOSOMES (BACTERIOSTATIC) Tetracyclines Phenicols Lincosamides: Lincomycin and Clindamycin Macrolides and Azalides Tylosin Ketolides MISCELLANEOUS ANTIMICROBIALS Oxazolidinones Topical Antimicrobials

The principles that guide proper antimicrobial selection are discussed in Chapter 6. This chapter focuses on the individual drugs or drug classes and their use to successfully treat bacterial infections. This includes not only resolution of clinical signs but avoidance of resistance. Characteristics discussed for each drug class include structure-activity releationship; the mechanism of antimicrobial action, including whether the drug is time- or concentration- dependent (Table 7-1); the spectrum of antimicrobial activity (Table 7-2), including pharmacodynamics (minimum inhibitory concentrations [MIC] (Tables 7-3 and 7-4) for selected organisms; mechanisms of antimicrobial resistance; clinically relevant aspects of the drug; the disposition of the drug in the patient (as it relates to both safety and efficacy); adverse drug effects; and drug interactions. The breakpoint MICs (the concentration at which an infecting isolate is considered susceptible or resistant to a drug of interest) are delineated in Chapter 6, Table 6-2). Pharmacokinetics were drawn from individual manuscripts, and the Antimicrobial's Monograph issue of the Journal of Veterinary Pharmacology and Therapeutics.² In addition, Albarellos¹ also has provided a review of disposition of selected antimicrobials; these have been included, when appropriate, in Table 7-1. Tissue distribution of antimicrobials is addressed when available; Table 7-5 provides information regarding the relative proportion of tissue versus serum concentrations of drugs, with a focus on body fluids and phagocytic cells. As a reminder (see Chapter 6), drug concentrations measured in tissue homogenates are minimally relevant to concentrations to which microbes are exposed. Data collected by ultrafiltration probes is preferred. However, interstitial fluid is not free of factors that might preclude drug activity (i.e., proteins or ionization; see discussion of cefovecin in cats); as such, dosing errors should be on the side that increase concentrations in tissues. Therapeutic indications are offered when relevant. The dissociation constant of a drug (pKa) and selected information regarding the chemical characteristics of selected drugs or preparation stability are provided for selected drugs in Table 7-6. Doses are indicated in Table 7-7; however, doses ideally should be designed on the basis of intergration of pharmacokinetic (PK) and pharmacodynamic (PD) data (see Chapter 6). Treatment of specific infection is addressed by system in Chapter 8.

Chapter 6 addressed the importance of integrating PK and PD MIC data when designing a dosing regimen. The PK parameters on which integration is most commonly based are the maximum drug concentration (for both time-dependent and concentration-dependent drugs) and elimination halflife. The latter is particularly important for time-dependent drugs but will also increase area under the curve (AUC), which predicts the efficacy of selected concentration-dependent drugs (e.g., fluoroquinolones; see Table 7-1). Among the sources of PK data to be consulted beyond this chapter are the Antimicrobial Monographs published by the United States Pharmacopiea² in conjunction with the Journal of Veterinary Pharmacology and Therapeutics. The PD data on which integration is based ideally is the MIC of the isolate cultured from the site of infection in the patient. If not available, the high range of the MIC or the MIC₉₀ might be a reasonable population statistic surrogate indicator of "what is needed" (see Tables 7-3 and 7-4). When available, PD information for

	Pharmacokinetic Data for Selected Antimicrobials-cont'd
	Pharmacokinatic Liata for Salactad Untimicropials - contra
	-1 Halfhauukineliu Dala IUI Deleuleu Ahliifiiuuuuais $-$ uufii U

Vd, Volume of distribution; C, cat., I, bactericidal D, dog; IV, intravenous; IM, intramuscular; SC, subcutaneous; T, time dependent; PO, by mouth; T, bactericidal; Vd_{ss}, volume of distribution at steady state; S, bacteriostatic; F, bioavailability f_{ub}, fraction unbound PI, Package Insert, constant-rate infusion; ICF, intracellular fluid.

*CD or TD = Concentration or time dependency (see Chapter 6). 1 C_{max} refers to the maximum serum concentration obtained at the dose given by the route in parenthesis. Data refer to both cat and dog unless indicated otherwise (D=dog; C=cat). A new dose can be determined by proportionally changing the dose based on the desired change in C_{max}. For example, a 20 mg/kg IV dose of amikacin resulted in C_{max} of 40 µg/mL. If a patient is given 10 mg/kg IV amikacin, the resulting C_{max} should approximate about 20 µg/mL. The data should be used in conjunction with a minimum inhibitory concentration (see Chapter 6, Table 6-2).

+Source as indicated by drug name.

*USP Veterinary Pharmaceutical Information Monographs—Antibiotics, J Vet Pharmacol Ther 26(Suppl 2), 2003.

[§]Half-life or C_{max} of ciprofloxacin (µg/mL) is that achieved from metabolism of enrofloxacin when enrofloxacin is administered at the indicated dose. The drugs should work in an additive or synergistic fashion.

190% protein binding in dog, 99% in cats; amount reported is peak concentration in transudate.

Static if sole agent, bactericidal if the sulfonamide is combined with a diaminopyrimidine (trimethoprim, ormetoprim)

canine and feline pathogens (e.g., see Table 7-3) is offered for selected drugs; in addition, relevant information from the human-medicine literature is provided (see Table 7-4). Care should be taken when extrapolating information regarding human pathogens to dogs and cats, although a growing amount of evidence suggests that relative susceptibility of isolates is similar for many drugs (indeed, isolates are likely to be shared), and the data are likely to include both patients that have previously received and not been exposed to antimicrobials. For time-dependent drugs, the relevant PD index (PDI) to be targeted is T > MIC, with a target of at least 50% to 75% of the dosing interval necessary to enhance efficacy, and longer to avoid resistance. An exception can be made for the carbapenems, for which T > MIC of 25% of the dosing interval is sufficient. For concentration-dependent drugs, the relevant PDI

is a $C_{max}/MIC \ge 10.^3$ This ratio should be reached at the site of infection. Alternatively, the AUC/MIC should target 125 to 250. Although as low as 30 has been supported for selected gram-positive drugs, this is particularly true for Streptotoccus pneumoniae, which is an organism that is particularly problematic in humans. This low AUC/MIC may not be relevant to other gram-positive organisms, including other streptococci. Because availability of AUC data is limited, this chapter will focus on C_{max}/MIC as the target for concentration-dependent drugs. For PDI for both time- and concentration-dependent drugs, doses should be modified as indicated by drug, host, and microbial factors.

The discussion of antimicrobial drugs is based on their classification by mechanism of action (Figure 7-1; see Table 7-1). The mechanism of action of each drug determines drug

*When testing Enterococcus spp.

efficacy (i.e., bactericidal versus bacteriostatic) and mechanisms of resistance⁴; influences time- versus concentrationdependence and duration of postantibioitic effect; and, for some drugs, affects safety. Mechanisms of action also influence the selection of combination antimicrobial therapy. For drugs that are approved for use in humans but not animals and for which information regarding use in dogs and cats is not available, PK information in humans will be summarized.

DRUGS THAT TARGET THE CELL WALL

Beta-Lactam Antimicrobials

The broad spectrum, low toxicity, and reasonable cost of beta-lactam antibiotics contribute to their frequent use for treatment of infections. In addition, their effects on cell wall synthesis result in their frequent selection for combination antimicrobial therapy. The beta-lactam antibiotics include the

MW, Molecular weight; pKa, dissociation constant PC, octanyl-water partition coefficient. Note that the PC is dependent on ambient pH.

cephalosporins, penicillins (including combination penicillin/ beta-lactamase inhibitors), carbepenems, and monobactams (see Table 7-1).

Structure–Activity Relationship

Beta-lactam antibiotics contain a four-member beta-lactam ring as the active site. A second member ring establishes the drug as either a cephalosporin—one carbon larger—or a penicillin (Figure 7-2).⁵⁻⁹ Chemically, the beta-lactams are classified as weak acids (see Table 7-6). They include natural, and semisynthetic drugs (see Table 7-2). Penicillin is a natural drug derived from the molds of the genus *Penicillium*. Penicillin serves as a base for the semisynthetic aminopenicillins (ampicillin, amoxicillin), the extended-spectrum penicillins (carbenicillin, ticarcillin, piperacillin), the carpabenems (imipenem, meropenem), and the monobactams (aztreonam).

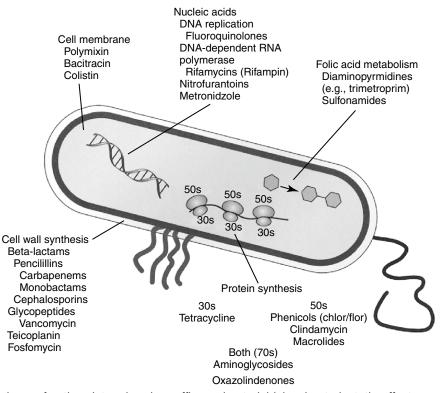

Figure 7-1 Drug mechanisms of action determine drug efficacy, bactericidal or bacteriostatic effects, mechanisms of bacterial resistance, and appropriateness of combination therapy. Occasionally, the mechanism of drug action predicts the mechanism of host toxicity.

Penicillin G is the basis for the definition of the international unit (IU) of penicillin, which is equivalent to 0.6 mg of the international pure crystalline sodium penicillin (1.6 IU/mg). The conversion of USP units varies with the salt, with 1 mg of penicillin G equivelant to the following units: sodium (1500-1750); potassium (1440-1680), and procaine (900-1050).As a group the natural penicillins are unstable and subject to hydrolysis at the beta-lactam ring. Degradation can occur when combined with other solutions. Degradation also occurs for most penicillins exposed to gastric acidity, precluding oral absorption.⁹

The cephalosporins are derived from a chemical produced by the fungus Cephalosporium acremonium. The six-member ring of the cephalosporins renders them more stable; this increased stability also causes them to be less susceptible to resistance. More than 22 cephalosporins are approved for use in the United States, including the cephamycins (e.g., cefoxitin, cefotetan) and oxyimino-cephalosporins (e.g., ceftazidime, cefotoxime, ceftiofur, cefpodoxime, cefovecin) (see Figure 7-2). The cephalosporins have been variably categorized, with the original "generation" designation being the most widely accepted (Table 7-8).^{8,10,11} The designations began as an indicator of chronologic approval but have evolved such that each indicates relative resistance to beta-lactamase destruction; the first generation is most and the later generations least susceptible to destruction.¹⁰ The advent of extended-spectrum beta-lactamases renders the classification less clear in that

these beta-lactams specifically target later-generation drugs. Spectrum and pharmacologic properties of drugs within the generations vary, particularly in the third or later generations. Reclassifying the cephalosporins into groups according to the route of administration, and spectrum has been proposed (see Table 7-8).

Mechanism of Action

The mechanism of action of beta-lactams reflects interference with bacterial cell wall synthesis (Figure 7-3). The bacterial cell wall comprises several layers of a peptidoglycan matrix. The peptidoglycan strands are composed of five repeating disaccharide units of N-acetylglucosamine and N-acetylmuramate; these units are formed by the bacteria in stages. A pentapeptide, which ends with a D-Ala-D-Ala terminus, is attached to each of the repeating units of these disaccharides. The units are joined to form a chain or peptidoglycan strand. The resulting chains are then cross-linked to provide cell wall rigidity. Cross-linking between the D-Ala-D-Ala terminals is catalyzed by transpeptidase enzymes, one of several types of proteins that bind penicillin (referred to as penicillin-binding proteins [PBPs]) located in the cell wall (see Figure 7-3).¹² The bacterial substrate for the transpeptidase enzyme is the pentapeptide of the peptidoglycan and, specifically, the terminal amino acids D-Ala-D-Ala. The beta-lactam ring is the functional (active) group of all drugs in this class. It is structurally similar to the D-Ala-D-Ala terminus of the pentapeptide,

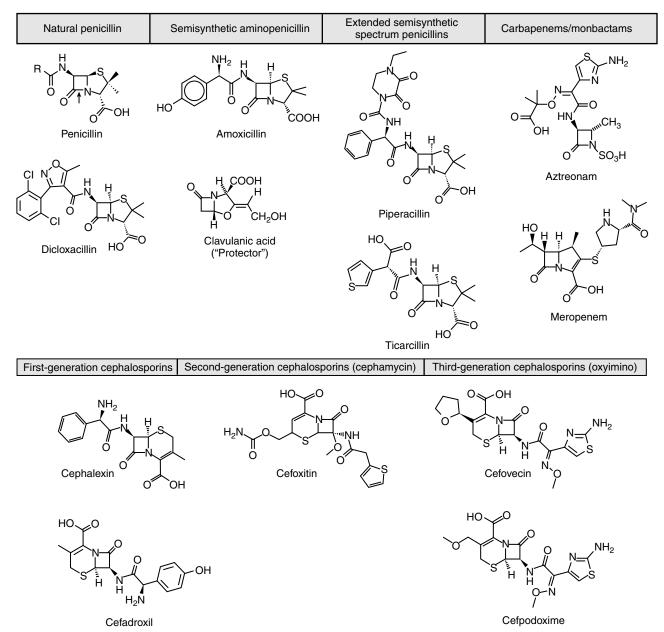

Figure 7-2 Beta-lactam antibiotics include the penicillins and cephalosporins. The four membered beta-lactam ring of each drug mimics the substrate of the transpeptidase enzyme (a penicillin-binding protein), and specifically the terminal portion of p-D-Ala-Asp-D-Ala (boxed inset). This ring structure also is the target of beta-lactamase enzyme destruction. Penicillins have an adjacent five-member ring, cephalosporins a seven-member ring. The addition of larger structures to the basic ring structure may help reduce emerging resistance by beta-lactamase rings but will not avoid methicillin resistance.

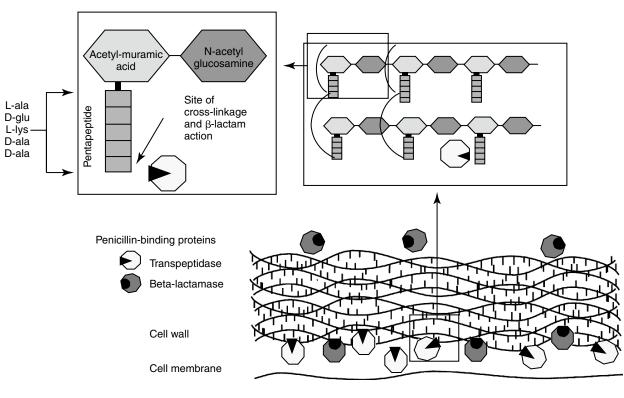

acting as a substrate and subsequently inhibiting the D-D transpeptidase enzyme (see Figure 7-3). In an actively growing cell, as peptidoglycan precursors increase in response to inhibition of synthesis, autolysins, particularly in gram-positive organisms, contribute to cell wall degradation. Degradation coupled with impaired cell wall synthesis causes the bacterial cell wall to lose rigidity. The cell becomes permeable to the surrounding environment, which, although isotonic to the host, is hypotonic to the organism. Influx of surrounding fluid into the hypertonic bacterial cell results in cytolysis, or

osmotic lysis, particularly in gram-negative organisms. Cell wall instability induces the secretion of autolysins, particularly in gram-positive organisms. Because organisms continually break down and rebuild cell walls, the efficacy of the beta-lactam antibiotic ideally is constantly present and, as such, this class of drugs is considered time-dependent (see Chapter 6). However, the duration that the plasma drug concentration (PDC) should be above the MIC varies with the drug, with the desired duration being 50% to 75% of the dosing interval for most drugs. However, T > MIC may be as little as 25% to 50%

Group	Drug	Generation	Route	Resistance to Beta-Lactamases	Potency (Dose)	Spectrum
1	Cefazolin Cephalothin	First	Parenteral	Staphylococcal, not enterobacterial	Moderate	High activity against gram +
2	Cefadroxil Cephalexin Cephradine	First Oral		Staphylococcal, some enterobacterial	Moderate	High activity against gram + Some gram –
3	Cefoxitin Cefotetan Cefuroxime Cefamandole	Second	Parenteral	Many	Moderate	High activity against gram– and anaerobes
4	Ceftiofur, Cefotaxime Ceftriaxone	Third	Parenteral	Many	High	Gram –, Some gram +
5	Cefpodoxime Cefixime	Third	Oral	Many	High	High activity against gram –, some gram +
6	Ceftazidime Cefoperazone	Third	Parenteral	Many	High	High activity against gram-including <i>Pseudomonas</i> gram+
7	Cefepime Cefpirome	Fourth	Parenteral	Many	High	High activity against gram-

+, Positive; -, negative.

Gram-positive organism

Figure 7-3 The antibacterial mechanism of action of the beta-lactams. The pentapeptide containing the D-Ala-D-Ala terminus (the structure mimicked and thus inhibited by beta-lactam antibiotics) provides the cross-linking of the strands of the cell wall, which are critical to rigidity. Two types of penicillin-binding proteins (PB) are located in the cell wall of bacteria. Transpeptidase enzymes are responsible for catalyzing the cross-bridging between the pentapeptides thus providing rigidity; changes in the structure of these proteins confers resistance to methicillin (PB-2) or other drugs. Beta-lactamase penicillin-binding proteins destroy susceptible beta-lactam antibiotics.

for carbapenems because they are characterized by more rapid bacterial killing.¹³ A longer T > MIC is indicated to decrease the risk of resistance.

Although all PBPs are able to covalently bind beta-lactam antibiotics, the numbers bound and subsequent activity vary among organisms. Up to nine PBPs are encoded by the genome of Escherichia coli; each PBP generally has subgroups. The diversity of PBPs is responsible, in part, for differences in the spectrum of activity of the beta-lactams. High-molecularweight PBPs (1, 2, and 3) are essential for microbial growth and survival in Staphylocccocus spp., whereas only PBPs 1 and 2 are critical for Streptococcus spp.; as such, these PBPs are the critical targets of antimicrobial therapy in these organisms.¹⁴ In E. coli PBP-2 is essential for cell elongation and PBP-3 for cell division. Because PB-3 appears to complex with PBP-1, -4, and -7 as well as with other proteins,¹² effective antimicrobial binding to PBP-3 might have a greater impact than binding to other PBPs in E. coli. The PBP targeted is known for some drugs (e.g, cefpodoxime targets PBP-1a and 1b and PBP-3 (see package insert).

KEY POINT 7-1 The mechanism of action of the beta-lactams necessitates the presence of the drug throughout most of the dosing interval.

Although beta-lactams are very effective antimicrobials, their unique mechanism of action increases the risk of therapeutic failure in certain conditions, independent of bacterial resistance. Efficacy, particularly toward gramnegatives, is reduced in a hypertonic environment (e.g., the renal intersitium of the normally functioning kidney, an abcess) because osmotic lysis may not occur. Slow growth impairs autolysin activity, which may result in the loss of the bactericidal effect of the beta-lactam antibiotic. Examples might include the combined use of a beta-lactam with a drug that slows growth of the organisms (i.e., a ribosomal inhibitor [see Figure 7-1]), or in a hypoxic environment (e.g., abscess).

Spectrum of Activity

The spectrum of activity of beta-lactam antibiotics varies (see Table 7-2). PD data are available for both the dog and cat for limited drugs (Table 7-9), with selected information provided on human pathogens associated with skin or soft tissue infections (Table 7-10). Penicillin G, a natural antibiotic, is effective against selected gram-positive cocci and both gram-negative and gram-positive anaerobes, but it is beta-lactamase sensitive.⁵ Selected enterococci are not susceptible to penicillin, and most staphylococci produce beta-lactamases. The gramnegative spectrum of penicillin G is limited but includes Pasteurella multocida. Penicillin V is an orally bioavailable natural penicillin, but its antimicrobial efficacy is reduced.⁹ Beta-lactamase-resistant isoxazolyl-derivative penicillins include dicloxacillin, cloxacillin, methicillin, and oxacillin. These drugs are effective against gram-positive organisms, including Staphylococcus spp., and gram-negative and anaerobic organisms.

The spectrum of the beta-lactams was expanded with the production of the semisynthetic aminopenicillins. Amoxicillin and ampicillin (aminopenicillins) are considered broadspectrum drugs; however, this classification has largely been muted by acquired resistance unless combined with clavulanic acid or sulbactam. They target PBP-1a. The anaerobic and gram-positive spectrum of penicillin G is maintained (although the aminopenicillins are slightly less efficacious against anaerobes). The aminopenicillins are generally effective against enterococci, although Enterococcus faecium often expresses resistance. In addition, many gram-negative organisms are added to the spectrum, including E. coli, Pasteurella, some Proteus species, Klebsiella, and selected others (e.g., Salmonella, Shigella). Serratia, Enterobacter, and Pseudomonas are not, however, included in the spectrum of the aminopenicillins. The spectrum of ampicillin is generally similar to that of amoxicillin, and it serves as the model drug for amoxicillin on culture and susceptibility (C&S) testing whereas amoxicillin-clavulanic acid indicates data for ampicillin-sulbactam. However, the potency of ampicillin generally is less than that of amoxicillin against enterococci and Salmonella but greater against Shigella and Enterobacter. The aminopenicillins are less effective compared with the penicillins against Bacteroides fragilis, although efficacy remains good to excellent.⁹ Like penicillin, the aminopenicillins are beta-lactamase sensitive. Combination with a beta-lactamase protector (e.g., clavulanic acid or sulbactam) improves efficacy and thus broadens the spectrum against susceptible organisms that have acquired resistance through beta-lactamase production. This includes Staphylococcus, E. coli, Klebsiella spp., and some Proteus spp.¹⁵ Pseudomonas spp. and other gram-negative organisms remain resistant.^{7,9} Further modifications led to the extended-spectrum penicillins characterized by a markedly enhanced spectrum, particularly against gram-negative organisms, including Pseudomonas aeruginosa, Serratia, Proteus spp., some Klebsiella spp. Shigella spp., and Enterobacter spp. Examples include the carboxypenicillins carbenicillin and ticarcillin, with ticarcillin having two to four times higher activity toward Pseudomonas spp. than carbenicillin, and the ampicillin-derived ureidopenicillin piperacillin, which has the highest antipseudomonal activity.^{5,7,16,17} The extended-spectrum penicillins are effective against anaerobic organisms, although they may be less effective than the natural penicillins. They maintain, however, good to excellent activity against B. fragilis.9 The extended-spectrum penicillins are beta-lactamase sensitive; however, a ticarcillin/clavulanic acid combination product is available.

The carbapenems (imipenem and meropenem) and monobactams (aztreonam) represent the most recent members of the beta-lactam penicillins.¹⁸ Imipenem targets PBP-1a, -1b, and -2, with its efficacy based on binding to PBP-2 and -1b. It is prepared in combination with cilastatin, which inhibits renal tubular degradation (metabolism by dehydropeptidase-1) of imipenem. As a result, drug half-life may be prolonged (although the clinical relevance of this effect in animals is questionable), and the formation of potentially nephrotoxic metabolites is reduced. Imipenem and meropenem have the broadest

Table 7-9 Susceptibility Data for Selected Beta-Lactams and Selected Feline and Canine Pathogens—cont'd

Amoxi-Clav, Amoxicillin–clavulanic acid; MIC, minimum inhibitory concentration; CLSI, Clinical and Laboratory Standards Institute; D, dog; C, cat; y, yes. All data (except cefpodoxime) is from Stegamenn et al ²⁰; data for cepfodoxime is from the package insert. All MIC are in µg/mL. Data is from dogs and cats considered to be antimicrobial free²⁰.

antimicrobial spectrums available against bacterial organisms with cell walls, including *Pseudomonas* spp. Imipenem and meropenem are relatively resistant to beta-lactamase destruction. However, an extended beta-lactamase enzyme has recently been reported, particularly in *Klebsiella pneumoniae*, emerging as a nosocomial pathogen.¹⁹ An advantage of the carbopenems has been their very low MICs (0.05 to 2 μ g/mL) for most

susceptible organisms. Meropenem is generally similar to imipenem for empirical treatment of serious infections.

Aztreonam is a monobactam (see Figure 7-2), with a high affinity for PBP-3 and lesser affinity for PBP-1a. It is particularly effective against gram-negative aerobes, including *Pseudomonas* spp. but is ineffective against gram-positive organisms and anaerobes.

MIC, Minimum inhibitory concentration.

Parantheses refer to the combination of piperacillin with tazobactam.

The spectrum of the cephalosporins is more diverse than that of the penicillins and is not as easily categorized. Although generalizations regarding the spectrum of activity of each successive generation might be made, variability in efficacy among the drugs within and certainly among generations may result in therapeutic failure if attention is not paid to differences.9 Thus either the package insert or C&S data should be consulted before selecting a cephalosporin, particularly beyond the first generation. In general, cephalosporins are ineffective against enterococci. With each successive generation, the cephalosporins become increasingly more resistant to beta-lactamase destruction, and all generations are generally more resistant as a class than are the penicillins. As such, they are often chosen as empirical first-choice treatment of Staphylococcus spp. Cephalothin (no longer commercially available) has been the drug designated by the Clinical Laboratory Standards Institute (CLSI; previously National Committee for Clinical Laboratory Standards [NCCLS]) as the model indicator for susceptibility for the first-generation cephalosporins. However, it does not represent the class equally. The aerobic spectrum of the first-generation cephalosporins is similar to that of the aminopenicillins,⁹ although efficacy is more similar to amoxicillin-clavulanic acid combinations. First-generation cephalosporins such as cefazolin, cephalothin, and cephalexin are active (although not equally so) against gram-positive and gram-negative organisms such as E. coli, K. pneumoniae, and Proteus mirabilis. Among the first-generation drugs, cefazolin has better efficacy than cephalexin against gram-negative organisms (e.g., E. coli) but poorer efficacy against Staphylococcus spp.5,9 Efficacy of cephalexin against E. coli is fair to poor. The anaerobic spectrum of the first-generation cephalosporins is fair but less than that of the aminopenicillins.

The second-generation cephalosporins, cefamandole, cefaclor, cefoxitin, and others, are characterized by enhanced activity toward Enterobacter spp., some Proteus spp., E. coli, and Klebsiella spp.5 Cefoxitin has an excellent anaerobic spectrum, particularly against Bacteroides spp.,^{5,8} although it is less effective than first-generation drugs against gram-positive organisms. Third- (cefotaxime, ceftazidime, cefpodoxime, cefoperazone, cefovecin, and the oxa-beta lactam moxalactam) and fourth-generation (cefepime; not approved in the United States) cephalosporins are generally reserved for serious gram-positive or gram-negative infections (e.g., P. aeruginosa, Enterobacter spp., and Serratia spp.). However, although the efficacy of most of the second-plus generation cephalosporins against E. coli tends to be good to excellent, efficacy against P. aeruginosa⁹ is variable, and cross-efficacy among members of these generations to any organism should not be assumed. For example, cefoperazone and ceftazidime are among the most effective drugs against P. aeruginosa, although efficacy is less than that of the newer extended-spectrum penicillins. Cefpodoxime and cefovecin are generally effective against *E*. coli but not effective against Pseudomonas spp. Selected thirdgeneration cephalosporins (e.g., cefotaxime) are effective against anaerobic organisms, whereas others (e.g., ceftazidime, ceftriaxone, and cefpodoxime) are not. Ceftiofur is a thirdgeneration cephalosporin approved for use for canine urinary tract infections. The antimicrobial spectrum of ceftiofur includes gram-positive (Streptococcus spp. and Corynebacterium spp.), gram-negative (Pasteurella, E. coli, and Salmonella spp. but not Pseudomonas spp.), and anaerobic organisms. Ceftiofur is effective against many staphylococcal organisms; however, selection against Staphylococcus spp. should be based on C&S data.9 The first-generation drug cefazolin has been inappropriatly promoted as a generic version of ceftiofur.^{19a} The spectrum of the third-generation drugs cefpodoxime and cefovecin (the former approved in dogs and cats, the latter approved in dogs but used in cats) includes *Staphylococcus* spp.; cefovecin is also approved for use in the treatment of *Strepto-coccus* spp. Both drugs are effective against a variety of gramnegative organisms, including *E. coli* and *Klebsiella*, but are not generally effective toward *Pseudomonas* spp. Stegemann²⁰ has provided PD statistics for a large number of organisms for cefovecin, as well as selected other beta-lactams, some of which are provided in Table 7-9.

KEY POINT 7-2 The spectrum of the penicillins becomes broader as the class "extends," whereas the spectrum of the later-generation cephalosporins varies with the drug.

Resistance

Bacteria develop resistance to beta-lactams through four major mechanisms: altered or different PBPs such that antibiotic binding does not occur (e.g., staphylococcal organisms and penicillins; enterococcal organisms and cephalosporins); efflux through specific pumps; loss of or changes in porins (especially P. aeruginosa); and inactivation by beta-lactamases. Inactivation by beta-lactamases is most common. Staphylococcus resistance to penicillin appeared as early as 1942; by the late 1960s, more than 80% of medically relevant isolates were resistant to penicillin as a result of beta-lactamase production. Today more than 90% of isolates (human) produce penicillinase.²¹ The approval of "protected" drugs (i.e., improved the efficacy of selected penicillins), but along with the cephalsoporins, is likely to have contributed to the emergence of altered PBP. This most notorious mechanism of resistance has yielded methicillin-resistant Staphylococcus aureus (MRSA) and vancomycin-resistant enterococci (VRE).

Beta-lactamases. Beta-lactamases are structurally and mechanistically similar to PBPs; indeed, certain PBPs are capable of beta-lactamase activity. Destruction of the betalactam (amide) ring reflects its hydrolysis (see Figure 7-2).²² Currently, more than 400 distinct beta-lactamase enzymes are produced by gram-negative, gram-positive, and anaerobic organisms.^{23,24} Selected examples are listed in Table 7-11. Altlhough clearly a major mechanism of resistance in gram-positive organisms, beta-lactamase production is also the major mechanism by which gram-negative organisms develop resistance.²² Beta-lactamase production occurs as a result of either chromosomal mutations, particularly in gram-positive organisms, or plasmid-mediated resistance in both gram-positive and gram-negative organisms. Beta-lactamases are either constitutive, already present in the cell wall (particularly in gram-negative organisms), or induced by the presence of the antimicrobial drug (in both gram-negative and gram-positive organisms).²⁵ Gram-negative bacteria have the added advantage of secreting beta-lactamases into the periplasmic space such that they are strategically placed before the antibiotic can penetrate the cell wall.⁹ The beta-lactams are variably susceptible to destruction by beta-lactamases; microbes vary in which enzyme they produce and whether the enzyme is constitutive or inducible (see Table 7-11).

Two major types of beta-lactamases exist: serine-based enzymes and the metallo-beta lactamases. The latter contain a zinc atom that activates water as the destructive site (see Table 7-11).²² Several schemes have been proposed to classify betalactamases. The most common scheme is based on the molecular structure (Amber Classification); however, classification according to the target substrate (Bush-Jacoby Classification) may be easier to follow (see Table 7-11). According to the Amber system, Class B enzymes contain the metallo-beta lactamases, but the other three classes are serine-based enzymes. These include classes A (TEM, SHV), C (ampC, targeting cephamycins [cefotetan, cefoxitin]), and D (OXA; targeting protected drugs, such as dicloxacillin, but also protectors such as clavulanic acid). The most prevalent beta-lactamases are class A penicillinases and cephalosporinases, including clinically relevant TEM-1 and 2 or SHV-1 enzymes found in E. coli and K. pneumoniae, and PC-1 enzymes produced by S. aureus.²²

KEY POINT 7-3 Microbes have been able to adapt to each pharmaceutical manipulation intended to decrease beta-lactamase activity.

TEM-1 and SHV-1 confer high-level resistance to penicillins and first generation cephalosporines but generally do not target the extended-spectrum (selected second- and third- or fourth-generation) cephalosporins or carbapenems. As such, the cephalosporins (cephalosporin C) are generally less impacted by beta-lactamases, particularly those produced by Staphylococcus species.¹⁰ However, only a few cephalosporins are stable against anaerobic beta-lactamases. Selected semi-synthetic beta-lactams also are less impacted by beta-lactamases, including most third-generation cephalosporins and imipenem. The semisynthetic dicloxacillin (and oxacillin) is beta-lactamase resistant, with the exception of class D (group 2d). The combination of beta-lactam antibiotics with drugs that inhibit beta-lactamase activity (e.g., clavulanic acid, sulbactam, and tazobactam) increases the potency of the beta-lactam antibiotic, (but not the spectrum) toward susceptible organisms (see Tables 7-2, 7-9 and 7-10). Clavulanic acid irreversibly binds to some but not all beta-lactamases (see Table 7-11).²⁶ Combinations of beta-lactams with beta-lactamase inhibitors are particularly useful against mixed infections and have shown efficacy against selected multiresistant pathogens such as Acinetobacter spp. Aztreonam is generally resistant to beta-lactamase destruction but is susceptible to extended-spectrum beta-lactamases (ESBLs). The presence and diversity of betalactamases in canine and feline staphylococcal organisms has been described. As in other species, production is encoded by the blaZ gene, with all four classes of enzymes (A to D) represented genes for classes A, C, and D being plasmid mediated and class B chromosomally mediated.²⁷

Microbes have adapted to each pharmaceutical manipulation intended to combat emergent resistance resulting from beta-lactamase destruction. Third-generation cephalosporins such as cefotaxime and ceftazidime initially were considered

indestructible by beta-lactamases.²⁵ However, high-level use has been accompanied by induction and selection for ESBLs in multiple-resistant coliforms,²⁸ particularly in those organisms that produce TEM and SHV enzymes. The genes encoding ESBLs are carried by large plasmids and are able to confer information between bacterial species and strains. The ESBLs are most commonly found in Klebsiella spp. (incidence in North America, 4.4%), E. coli (3.3% to 4.7%), or P. mirabilis (3.1-9.5%), but they also have been detected in other members of the family Enterobacteriaceae and in P. aeruginosa isolates.²⁹⁻³² The resistant gene codes for mutations in one or more amino acid (serine) substitutions in class A enzymes (TEM or SHV). The resultant change in configuration allows the enzyme to gain access to the drug despite the large oxyimino side chain of these newer-generation drugs.²⁴ Drugs amenable to destruction by ESBL include third-generation cefotaxime, ceftazidime and ceftriaxone, cefpodoxime, and (presumably) cefovecin.^{22,33} Selected fourth-generation drugs are also susceptible, including cefepime (no longer marketed in the United States).²⁸ Cephamycins (e.g., second-generation cephalosporins cefoxitin, cefotetan) do not appear to be destroyed (although they are destroyed by ampC). Monobactams (i.e., aztreonam) are destroyed. Carbapenems are generally not destroyed by ESBL, nor are beta-lactamase protectors such as clavulanic acid. The use of beta-lactamase protectors appears to reduce the clinical emergence of ESBLs and may reduce the emergence of other resistant pathogens such as Clostridium difficile and vancomycin-resistant enterococci.³⁴ However, the effect (e.g., of the beta-lactamase in the presence of ESBLs) is not always predictable. Decreasesd cephalosporin usage also reduces the advent of ESBLs.

Resistance to ESBLs often is incorporated in plasmids simultaneously conferring resistance to aminoglycosides and sulfonamides.²² Further, ESBL resistance may be associated with non–plasmid-mediated resistance mechanisms such as occurs for quinolones.²² An "inoculum effect" of ESBLs has been described for some drugs and may explain discrepancies among studies: the MIC of the organisms toward cephalosporins increases with a larger (10⁷) compared with smaller (10⁵) inoculum. Because susceptibility may depend on the size of the inoculum at the site of infection,²² ESBLs may not be detected on routine C&S testing.³¹ Lack of detection of ESBLs may also reflect different levels of activity against the different cephalosporins.

Detection of ESBLs has been based on double disk diffusion techniques. The susceptible cephalosporin (e.g., cefpodoxime, ceftazidime) is incubated with the isolate as the sole drug and in the presence of a beta-lactamase inhibitor; a substantial reduction in the MIC (e.g., fourfold to eightfold) with the combination drugs compared with the cephalosporin by itself indicates an ESBL.^{35,36} Not all clinical microbiology laboratories have incorporated tests for ESBLs in routine testing procedures.²² The presence of an ESBL should be suspected with organisms resistant to or with high MIC to cefotaxime but susceptible to beta-lactam/beta-lactamase combinations.²² The detection of an isolate with ESBL in a patient with a serious gram-negative bacillary infection should lead to the use of a carbapenem. However, a novel carbapenemase also has been described following isolation in *Serratia* spp., *K. pneumoniae* and *Enterobacter cloacae*.^{19,22,37} Alternatively, combination of the cephalosporin with clavulanic acid should be considered.

KEY POINT 7-4 Extended-spectrum beta-lactamases target later-generation cephalosporins but may be missed with susceptibility testing unless special tests are performed.

Altered pencillin-binding proteins. The advent of MRSA and multidrug-resistant Enterococcus spp. also has been associated with cephalosporins although it is likely that beta-lactamase inhibitors contributed to its emergence.²⁵ The approval of the cephalosporins in the 1980s was followed by the first MRSA epidemics in the mid-1980s in the United Kingdom; the use of second- and third-generation cephalosporins also was associated with an outbreak of MRSA in Japan.²⁵ In humans, mortality associated with S. aureus bacteremia is 20% to 40%; MRSA has become a leading cause of nosocomial infections in human medicine. The term MRSA was coined in the early 1960s, when these penicillinase-resistant drugs were relatively new, and refers to resistance expressed in vitro to methicillin.²¹ Although this discussion will focus on MRSA, increasingly, methicillin resistance is being recognized in other species and much of this information is relevant to all methicillin resistant staphylococci (MRS). Over the 30 to 40 years since MRSA was identified, MRSA infections have led to increased mortality and morbidity. The sequelae of MRSA are worse than those associated with beta-lactamase resistance because no alternative therapy remains that is predictably effective.²¹ In contrast to resistance resulting from penicillinase production which is generally considered low level, infection with MRSA is considered high-level resistance. Further, MRSA isolates are essentially multidrug resistant, that is, expressing resistance to classes other than beta-lactams.

MRSA and methicillin-resistant Staphylococcus pseudintermedius (MRSIG)³⁸ are indicated by the presence of the mecA gene. This gene encodes a mutation in penicillin-binding protein 2a, thus reducing its affinity for the beta-lactam ring, rendering the organism resistant to all beta-lactams. The mecA gene is carried on the staphylococcal chromosomal cassette (SCC); currently five SCCmec have been described.³⁹ Protectors such as clavulanic acid are also unable to bind and thus are ineffective.²¹ Detection of MRSA or MRSIG (or methicillinresistance in other staphylococci [MRS]) on C&S testing generally is based on resistance to oxacillin, which is more stable than methicillin in disks used for testing. However, variability in testing methods can profoundly alter results; therefore, cefoxitin might be a more appropriate indicator of multidrug resistance in these organisms.⁴⁰ Alternative procedures such as polymerase chain reaction or latex agglutination have been used to detect the gene responsible for the formation of penicillin-binding protein 2a (mecA) of MRSA, and other techniques such as pulsed-field gel electrophoresis or multilocus sequence typing identify the specific strain of MRSA (e.g., USA100 or USA300). It is likely that this area of diagnostics will be refined in the next decade and will be applied to other MRS.

KEY POINT 7-5 Changes in the penicillin-binding protein (PBP2) by *Staphylococcus* spp. renders the microbe resistant to all beta-lactams.

Antimicrobials are associated with induction, selection, and propagation of MRSA. The wide use of cephalosporins, in particular, may have contributed significantly to the advent of MRSA. MRSA in human patients has evolved from a hospital-acquired (HA-MRSA; nosocomial) infection (usually USA100) that occurs most commonly in patients whose immune systems are compromised by a community-acquired infection (CA-MRSA), in which otherwise healthy persons are infected, usually in the skin or soft tissue. Crowded conditions, shared items, and poor hygiene increase the risk of CA-MRSA. It is CA-MRSA strain USA300 that appears to be most commonly associated with increased colonization in dogs and cats. In contrast, it is HA-MRSA (USA-100) that is most commonly associated with infections in dogs and cats.^{40a} According to the Center for Disease Control, the incidence of MRSA doubled in human medicine between 1999 and 2006. The impact of MRSA (or other MRS) in veterinary medicine is increasingly problematic, not only because of its impact on the patient but also because of public health considerations. The mec gene has been detected in MRSA organisms infecting dogs,⁴⁰⁻⁴² and MRSA has been associated with infection in dogs.43 However, MRSA also has been found in up to 4% of healthy dogs, with identification complicated by the need for multiple sampling sites (nasal and rectal or perineal). Risk factors for the presence of MRSA in pets or working dogs (e.g., detection and aid dogs) include contact with human hospitals (particularly if patients fed the dogs treats or were licked by the dogs) and children.⁴² Infections have been isolated to family members and pets in the same household, but this is likely to reflect original transmission from humans to the pet.^{40-42,44} It is likely that colonization is transient in animals. However, healthy pets have been demonstrated to be potential reservoirs for transmission of MRSA to healthy handlers and a potential health risk to immunocompromised patients (humans and presumably other animals in the household). According to the American Veterinary Medical Association, colonization by MRSA is suggested to be an occupational risk for veterinarians, although the frequency of infection associated with MRSA in veterinarians compared with other health professionals has not been documented.

MRSIG⁴⁵ has a prevalence of 0.58% to 2% in healthy dogs and up to 4% in healthy cats,^{42,46} with the *mec* gene present in each canine MRSIG isolate in one study.⁴⁷ Human colonization with MRSIG is unusual.⁴² However, MRSIG has been reported as a cause of infection in human patients,⁴² and transmission from pets with pyoderma to humans has been confirmed.^{48,49} Although the true public health significance of MRSA and MRSIG (or other multidrug-resistant organisms) in pets is not clear, the fear of infection may be as important as true risk, necessitating proper hygiene and other proactive measures such that human or animal health (including unnecessary euthanasia) is not risked.

The American Veterinary Medical Association offers a website that includes a discussion of MRSA zoonoses, including sources of guidelines that might decrease the risk presented to susceptible humans.^{49a} Among the more important actions that can be taken is establishment of infection control policies and guidelines in each veterinary practice. In general, common sense approaches should prevail (e.g., minimizing intimate contact, maintaining good personal and environmental hygiene practices; see the three D's approach described in Chapter 6). This includes cleansing of hands of handlers and the paws (or body) of animals that might be exposed to MRSA, including those visiting human health care facilities. Immunocompromised patients are at most risk for MRSA infection acquired from an animal. In such cases the carrier or infected animal should be removed from the environment until successfully treated for MRSA. For dogs with skin infections, cultures are indicated to detect MRSA, particularly in animals for which infection does not resolve. Successful resolution of colonized or infected animals may require both topical (for skin infections) and systemic therapy. Evidence of successful treatment might be based on skin swabs of the ear, nose, and perianal region. Care must be taken to ensure that the laboratory providing culture procedures is well-versed in the diagnosis of MRSA, including speciation of coagulasepositive organisms.

KEY POINT 7-6 Methicillin-resistant *Staphylococcus aureus* likely originated with a human, whereas Methicillin-resistant *Staphylococcus pseudintermedius* likely originated from a dog or cat.

The multidrug resistance associated with MRSA is now evolving toward other (non-beta-lactam) antimicrobials. This reflects, in part, other resistance genes in the gene cassette carrying the *mec* gene.⁴² Drugs that are affected include fluorinated quinolones and aminoglycosides. Although newer fluorinated quinolones (e.g., levfloxacin) appear to be more effective than older drugs in vitro, particularly to *Staphylococcus*, whether this translates to better clinical efficacy is unclear.²¹ Glycopeptides such as vancomycin are the initial drugs used to treat MRSA in humans, although increasingly vancomycin-resistant *Staphylococcus aureus* (VRSA) infections have emerged. Linezolid and rifampin are alternative drug choices.

Multidrug resistant *Enterococcus* spp. also is an emerging issue; its emergence also appears to be correlated to use of cephalosporins. *Enterococcus faecalis* more so than *Enterococcus faecalis* is likely to develop resistance, and speciating *Enterococcus* spp. susceptibility testing might be prudent. Resistance reflects a change in penicillin-binding protein (PB-V), and the risk is increased when drugs effective against *Enterococcus* spp. are used.

Pharmacokinetics

The beta-lactams are weak acids, which favor oral absorption. Many of the beta-lactam antibiotics, however, are destroyed by the acidity of the gastrointestinal tract and thus cannot be given orally. Penicillin exceptions include penicillin V, dicloxacillin, the aminopenicillins (ampicillin and amoxicillin, including combinations with clavulanic acid), and carbenicillin (indanyl form only; effective concentrations can be achieved only in urine). Lack of stability also may affect the shelf-life of reconstituted products; expiration dates should be adhered to as indicated for the reconstituted product. Orally bioavailable cephalosporins include cephalexin, cefadroxil, and cefpodoxime (third or fourth generation). The oral bioavailability of the cephalosporins also varies among drugs and species.^{5,9}

Many beta-lactams are available as intravenous or parenteral preparations. Absorption from parenteral sites tends to be rapid and complete, with the exception of products that are specifically formulated to allow slow release (e.g., esterified penicillins). Although drug concentrations may persist in circulation longer than non-slow-release preparations (an appealing aspect for time-dependent antimicrobials), older dosing regimens were designed for efficacy against organisms considerably more susceptible to drugs at the time of approval compared with current microorganisms. Thus consideration should be taken to design the dose of these products to compensate for any increase in MIC that may have emerged since the approval of the labeled dose. Selected beta-lactams are highly bound to plasma proteins. Although binding limits distribution into tissues, it also contributes to a long disappearance half-life. Cefpodoxime and, to a greater degree, cefovecin are example of beta-lactams whose long half-life reflects slow release from intravascular protein.²⁰

KEY POINT 7-7 As water-soluble drugs, all beta-lactams distribute to extracellular fluid, do not penetrate sanctuary tissues well, and are renally excreted.

Distribution of beta-lactams is limited to extracellular fluid (volume of distribution [Vd or Vd_{ss}] of unbound drug generally ≤0.3 L/kg), but, barring a marked host inflammatory response, adequate concentrations of unbound drug can usually be achieved in the interstitial fluid (the site of most infections) in many tissues (see Table 7-5).^{5,9} Penicillins and cephalosporins are thus widely distributed throughout most extracellular body fluids, including kidneys, lungs, joints, bone, soft tissues, and bile^{5,8,11} Interstitial fluid concentrations in normal tissues generally can be predicted by, but are not necessarily equivalent to, the concentration of (unbound) drug in plasma. Comparisons of AUC frequently reveal interstitial fluids to be 30% or less than that in plasma. Among the first-generation cephalosporins, cefodroxil appears to have the better tissue-to-PDC ratio in humans (see Table 7-5). Neither penicillins nor cephalosporins traverse sanctuaries well, including mammary, prostatic, or blood-brain barriers. Imipenem, but generally not antipseudomonal penicillins such as ticarcillin and piperacillin, can reach effective concentrations in the brain. However, first- and second-generation cephalosporins should not be used for central nervous system (CNS) infections because many are destroyed by local enzymes or transported out of the CNS. Beta-lactams in general achieve 25% or less in bronchial secretions compared with PDCs (see Table 7-5).⁵⁰⁻⁵² Inflammation increases the penetration of many beta-lactams. For example, cefuroxime, cefotaxime, ceftriaxone, and ceftazidime can reach therapeutic concentrations when the cerebral spinal fluid (CSF) is inflamed.9 Acute inflammation may also increase beta-lactam penetration of abscesses and pleural, peritoneal, and synovial fluids because of changes in vascular permeability. However, those drugs characterized by high binding to plasma protein will likewise be bound to inflammatory proteins. As response to therapy decreases, resolution of inflammation may decrease distribution. Further, if inflammation does not resolve but progresses, efficacy of beta-lactams is likely to decrease as a result of poor penetrabiltity of lipid tissue. The beta-lactams do not significantly accumulate in phagocytic cells (see Table 7-5). Betalactams are concentrated in the urine, enhancing efficacy for cystitis; the clinician must not assume that the high concentration will be achevied in other tissues that also are infected (e.g. nephritis or other urinary tract sites, and even high urinary concentrations may be ineffective in the presence of biofilm (see Chapter 8).

The small Vd that characterizes the unbound beta-lactams contributes to their relatively short half-lives, which often are less than 1 to 4 hours (see Table 7-1). Slow release of highlyprotein bound drugs will prolong presence in the plasma. Because beta-lactams in general do not exhibit a long postantibiotic effect, dosing intervals for such drugs may be inconvenient; for critical patients, administering the drug as a constant-rate infusion may be appropriate. The attributes of constant-rate infusion for critical human patients receiving beta-lactams with short half-lives are well recognized and have been demonstrated in animal models.³ The advantages may reflect better steady-state concentrations of drugs in peripheral tissues. Exceptions occur for selected drugs that have a longer half-life, drugs characterized by metabolism to active metabolites, or slowly absorbed or released preparations. The former includes cefpodoxime (4- to 5-hour half-life and 80% to 90% protein bound) and cefovecin (approximate 4- to 5-day halflife and 90% to 99% bound to serum proteins in dogs or cats). Penicillins designed for slow release include slow-release esters (e.g., procaine or benzathine penicillins) or highly proteinbound drugs that may be slowly released from plasma to tissue (e.g., cefovecin). For the latter, generally either absorption or distribution, rather than elimination, half-life is prolonged, resulting in a "flip-flop" model (see Chapter 1). The beta-lactam antibiotics are eliminated, in general, by active tubular secretion in the renal tubules. Clavulanic acid, which is a beta-lactam antibiotic, albeit with poor efficacy by itself, is excreted primarily in the urine of dogs.⁵³ With the exception of hetacillin (no longer available), hepatic metabolism does not play a role in the elimination of the penicillins. Some cephalosporins are eliminated in the urine after deacetylation by the liver, often generate no active metabolites. Examples include cephalothin, cephapirin, cefotaxime, and ceftiofur. Imipenem is degraded to inactive metabolites in the kidney. Reabsorption from the urine is facilitated by an acid urinary pH. Deacetylation of ceftiofur results in an active metabolite; dosing regimens and C&S testing are

based on ceftiofur bioactivity.⁵⁴ Ceftriaxone and cefoperazone are eliminated in the bile in humans and appear to be at least partially eliminated in the bile in dogs.⁹

Disposition of selected beta-lactam antibiotics

Penicillins. Preparations of penicillin G intended for intramuscular use (e.g., procaine and benzathine) may be prepared as esters, which hydrolyze at variable rates and thus prolong absorption. Procaine penicillin is absorbed for at least 24 hours and benzathine penicillin for approximately 120 hours in some species.⁹

For the aminopenicillins the oral bioavailability of amoxicillin is greater than that of ampicillin and, unlike ampicillin, is not impaired by the presence of food.⁵ Clavulanic acid appears to be about 30% to 65% orally bioavailable.^{15,53,55} The absorption of both amoxicillin and clavulanic acid appears to occur through a saturable process. As with humans, a maximum rate may be reached in dogs at 10 mg/kg and 5 mg/kg, respectively. As the oral dose of amoxicillin reaches 25 mg/kg and clavulanic acid 6.25 mg/kg, amoxicillin may interfere with oral absorption of clavulanic acid. Thus ratios that favor clavulanic acid might be preferred to ensure sufficient absorption.²⁶ Other disposition paramenters of the aminopenicillins are summarized in Table 7-1. The disposition of amoxicillin is such that care should be taken to ensure that underdosing does not occur. This is likely to require administration beyond the label dose (12.5 mg/kg, alone or as clavulanic acid). For treatment of S. pseudintermedius, Stegemann²⁰ has reported an MIC₉₀ of $<0.5 \mu g/mL$ for amoxicillin-clavulanic acid (see Table 7-9). The MIC_{50} and MIC_{90} for amoxicillin-clavulanic acid and E. coli are 2 and 8 µg/mL, respectively. Integration of PK-PD for these organisms indicates that an alternative drug to amoxicillin with or without clavulanic acid might be considered; an exception might occur with UTI because higher drug concentrations will be achieved in the target tissue (urine). However, precaution is also suggested with this approach (see Chapter 8). Note that CLSI has recently re-set breakpoint MIC's such that many isolates considered susceptible before this change will now be considered resistant.

KEY POINT 7-8 The low C_{max} achieved for amoxicillin at the labeled dose coupled with its short half-life markedly increase the likelihood of therapeutic failure even for "susceptible" isolates.

Carbepenems. Both imipenem and meropenem have been studied in dogs.^{56,57} Imipenem is minimally protein bound in dogs.⁵⁶ Peak concentrations (see Table 7-1) occur at 30 minutes for intramuscular and 50 minutes for subcutaneous administration. Extrapolated PDCs after intravenous administration appear to approximate 40 mg/L. The volume of distribution of 0.32 L/kg indicates distribution to extracellular fluid; clearance (CL) is 0.26 L/hr/kg. The elimination half-life varies almost twofold with the route (see Table 7-1). Bioavailability is high after intramuscular or subcutaneous administration.⁵⁶ In dogs given 5 mg/kg subcutaneously, targeting a 12-hour interval and a T \geq MIC₂ (25%) (acceptable for carbapenems),

the highest MIC that might be treated is 2 μ g/mL. The dose should be increased (approximately 30%) to adjust for \leq 70% drug movement from plasma into normal interstitial fluid, particularly if the drug is given subcutaneously.

Meropenem has been studied in dogs after single dose⁵⁸ and constant-rate infusion.⁵⁷ As with imipenem, it is minimally (12%) protein bound in dogs. Clearance is 5.6 to 6.5 mL/min/kg. After a dose of 20 mg/kg, mean meropenem (µg/ mL) in interstitial fluid (using ultrafiltration techniques) was 24 ± 8 μ g/mL. After subcutaneous administration, C_{max} (μ g/ mL) in plasma and interstitial fluid, respectively, were 25 and 11 (ratio = 0.44), and AUCs were 63 and 43 μ g * hr/mL, (ratio 0.68) respectively. The better ratio for AUC reflects a longer mean residence time in intracellular fluid (ICF) compared with plasma (2, 4, and 0.9 hours, respectively). Although interstitial fluid concentrations correlated very well with PDC, the doses based on plasma C_{max} values might be increased at least 40% when basing dosing on PDC to compensate for differential distribution to extracellular sites of infection. The AUC in interstitial fluid after 20 mg/kg administered intravenously or subcutaneously was 73 μ g * hr/mL, and 43 μ g * hr/mL, respectively, indicating that intravenous administration might be preferred to subcutaneous administration from a cost standpoint. Note that the time to maximum concentration in interstitial fluid after subcutaneous administration was 3.7 hours (2 hours for intravenous administration), indicating a potential delay in response in the acute situation.⁵⁸ Based on plasma C_{max} after 20 mg/kg administered subcutaneously in dogs, a 12-hour dosing interval, and T > MIC of 25%, the highest MIC that might be treated is 4 μ g/mL. If concentrations are used to design the dosing regimen, the highest MIC that could be treated would be 1 µg/mL. Anuric renal failure in humans prolongs the half-life of meropenem fourfold.59

First-generation cephalosporins. Papich et al. described the tissue distribution of cephalexin.^{59a} The ratio of cephalexin C_{max} or AUC in plasma versus interstitial fluid were approximately 50% and 57%, respectively. The eliminaton half-life of cephalexin appears to be somewhat route dependent, being almost twice as long as after oral administration (150 minutes) compared with intramuscular or intravenous administration (80 minutes; see Table 7-1). However, Papich et al. reported a much longer half-life of 4.7 + 1 hours in dogs after oral administration of 25 mg/kg.59a Plasma clearance is 2.5 mL/min/kg.60 Bioavailability approximates 60% after either oral or intramuscular administration.⁶⁰ Oral bioavailability in dogs is affected by the time of day of administration, with C_{max} 22% lower in the evening; however, this is more than offset (as a timedependent drug) by a prolongation of half-life by 50%.⁶¹ The oral bioavailability of cephalexin also is affected by pretreatment with metaclopramide, which increases C_{max} and AUC, respectively, by 17% and 25%.⁶¹ Based on the original half-life reported for cephalexin, targeting T > MIC (50%), the maximum MIC that can be treated using an oral dose of 20 mg/ kg is 1 μ g/mL. This is equivalent to the MIC₅₀ but less than the MIC₉₀ (2 µg/mL) reported for S. intermedius and cephalexin in dogs.²⁰ A dose of 40 mg/kg is needed for twice-daily dosing, or the interval should be reduced to every 8 hours. Doses would need to be further increased to compensate for differential distribution to tissues or other host or microbial factors. However, if the half-life of 5 hours is used, then twice-daily dosing of cephalexin will result in drug concentration in both plasma and interstitial fluid above the MIC_{90} for *S. inter-medius*²⁰ for 12 hours or more.^{59a} Note that the MIC_{50} and MIC_{90} , respectively, for *E. coli* and cephalexin are 8 and 16,²⁰ indicating that this drug should not be used to treat infections associated with *E. coli*, including urinary tract infections.

Cephalothin (no longer available in the United States, although it remains the model drug for first-generation cephalosporins at the time of publication) has been studied in dogs after oral administration at 30 mg/kg. Food affects its absorption: C_{max} of 45 µg/mL is reduced to 28 µg/mL with food at a T_{max} of 1.7 and 2.8 hours, respectively. Elimination half-life is 1.8 and 2.6 hours without and with food, respectively.⁶²

Cefadroxil achieves a C_{max} of 35 µg/mL at a T_{max} of 20 minutes after an oral dose of 30 mg/kg. Food minimally affects rate or extent of absorption according to one study, but it does increase half-life from 1.7 to 4 hours.

Cefazolin has been studied in two separate groups of canine patients undergoing elective orthopedic procedures. In one study⁶³ clinical canine patients (n = 15) undergoing total hip replacement were administered 22 mg/kg intravenously over 2 minutes at the time of surgical positioning; animals were dosed 2 more times.⁶⁴ The distribution of the central compartment (Vc; before distribution) was 0.083 ± 0.008 L/kg. The distribution half-life approximated 5 minutes, and the elimination half-life approximated 45 minutes. Tissues from the coxofemoral joint capsule, acetabulum, and femoral cancellous bone were collected from each patient as the site was approached surgically; serum samples were collected at the same general time for each patient. Peak serum concentrations after the first dose were $178 \pm \mu g/mL$; tissue (homogenate) concentrations and mean time of collection were as follows: joint capsule, $58 + 5.7 \mu$ g/mL at 20 min, acetabulum 157 + 23 at 52 minutes and bone cancellous 227 + 29 at 68 minutes. Peak serum concentrations approximated 178 µg/mL (before distribution) and 119 µg/mL (after distribution). Based on simulations, ideal dosing was suggested to be either 22 mg/kg every 2 hours or 8 mg/kg every hour, to ensure drug concentrations remained above the MIC of Staphylococcus spp. (reported at 2 μg/mL).

Second- and third-generation cephalosporins. Cefuroxime is a second-generation cephalosporin approved for use in humans. Oral administration is in the form of the axetil ester; as a prodrug, desterification occurs before oral absorption. It has been studied both orally and parenterally in Beagles (n=6) as part of a toxicity study.^{64a} Intravenous doses up to 500 mg/kg every 24 hours were well tolerated for 1 week. Jung⁶⁵ compared cefuroxime in serum to that in cortical tissues in dogs. At approximately 1.25 hours, after 10 and 20 mg/kg administered intravenously, serum concentrations were 12.5 and 28.7 µg/mL, respectively. The elimination halflife was 2.9 hours. Spurling⁶⁶ reported limited PDCs after oral administration in Beagles. Concentrations (µg/mL) after oral administration of the axetil form at 100 or 400 mg/kg were approximately 28.7 \pm 5, and 77 \pm 17, respectively.^{66,67}

KEY POINT 7-9 The longer half-life of cefpodoxime renders it preferable to cephalothin for treatment of susceptible infections as long as a sufficiently high dose is used.

After a dose of 50 mg/kg ceftriaxone (third generation) was given to apparently healthy dogs, clearance was 3.61 ± 0.8 mL/kg/hr; T_{max} occurred at 30 minutes compared with 90 minutes after subcutaneous administration. Pain occurred at the injection site after both intramuscular and subcutaneous administration, whereas intravenous administration was not associated with any adversity.⁶⁸

Based on studies in dogs after an intravenous dose of 14 mg/kg, cefepime was distributed to a volume of 0.14 l/kg, suggesting that the drug might be protein bound. However, both the elimination half-life and MRT were short at 60 minutes. Clearance was 0.13 ± 0.04 l/kg/hr. The dose necessary to maintain the breakpoint MIC of 8 µg/mL for at least two-thirds of the dosing interval (above 2 µg/mL for the entire interval) (for humans) in dogs was recommended by the author to be 40 mg/kg every 6 hours.²⁸

Ceftazidime is a third-generation drug characterized by an elimination half-life of 0.8 hours in dogs. After subcutaneous injection, T_{max} occurs at 1 hour after administration of 30 mg/ kg. When given an initial dose of 4.4 mg/kg followed by a constant-rate infusion of 4.1 mg/kg/hr for 36 hours, C_{max} at steady state is 22.2 µg/mL. Total body clearance is 0.19 L/kg/hr.⁶⁹ The MIC₉₀ for clinical isolates (n = 101) of *P. aeruginosa* was \leq 4 µg/mL.⁶⁹ Using 4µg/mL as the basis for a subcutaneous dose of 30 mg/kg, only 3 half-lives can elapse for T = MIC, indicating a 6-hour dosing interval might be appropriate for *Pseudomonas* spp. Ceftazidime has been studied in cats (n = 5) after intravenous and intramuscular (30 mg/kg) administration.⁷⁰ After intravenous administration, the Vd was 18 ± 0.04 L/kg; protein binding was not described. Plasma clearance was 0.19 ± 0.08 L/hr/kg, and elimination half-life was 0.77 ± 0.06 hour. After intramuscular administration, bioavailability was 82.47 ± 4.37%, resulting in a C_{max} of 89.42 ± 12.15 µg/mL, at a T_{max} of approximately 30 minutes. The authors indicated that for an 8- to 12-hour dosing interval, T > MIC would range from 35% to 52% of the dosing interval for intravenous and 48% to 72% for intramuscular administration for isolates with an MIC $\leq 4 \,\mu g/mL$.

Ceftiofur is a third-generation drug approved for use in dogs for treatment of urinary tract infections. It has been studied at 0.22, 2.2, and 4.4 mg/kg administered subcutaneously in dogs (n = 9).⁷¹ PDCs increase proportionately (see Table 7-1). It has a relatively long half-life compared with other cephalosporins, reflecting, in part, its active metabolite. Accordingly, a longer dosing interval is likely to be more reasonable for ceftiofur compared with the first-generation drugs. When administered subcutaneously, peak PDCs (C_{max}) were 1.66 ± 0.2, 8.91 ± 6.42, and 27 ± 1 µg/mL at 0.22, 2.2, and 4.4 mg/kg, respectively.⁷¹ At the C_{max} of approximately 9 µg/mL at a dose of 2.2 mg/kg, targeting T > MIC of 50%, the highest MIC that can

be treated at 12-hour intervals is 4 µg/mL. At 4.4 mg/kg administered subcutaneously, the C_{max} disproportionately increases to 29 µg/mL, and the highest MIC that could be treated using the same targets is 16 µg/mL, which actually exceeds the MIC_{BP} (≥8 µg/mL). Urine concentrations were also reported for ceftiofur bioactivity in the dog. At 24 hours, urine concentrations at 2.2 and 4.4 mg/kg were 8.1 and 29.6 µg/mL, respectively. These concentrations surpassed the the MIC₉₀ for *E. coli* (4.0 µg/mL) and *P. mirabilis* (1.0 µg/mL).⁷¹

Cefpodoxime is a relatively new third-generation cephalosporin to be approved in dogs for treatment of canine pyoderma. Orally, it is administered as a prodrug, cefpodoxime proxetil, which is desterified in the gastrointestinal tract such that it is absorbed as cefpodoxime. According to the package insert and technical mongraphs, oral bioavailability in dogs is 63% and food does not impair absorption. At 10 mg/kg administered orally, C_{max} is variable at 16.4 ± 11 µg/mL, suggesting that dosing should err on the high side for higher MIC; T_{max} occurs at 2 to 3 hours. Plasma clearance is 23 mL/hr/kg. Cefpodoxime is excreted largely in the urine with more than 75% excreted as the parent drug. The elimination half-life of 5.6 hours (MRT 9 hours) is longer than that of many betalactams; therefore a longer dosing interval is possible (i.e., 12 to 24 hours, depending on the dose and MIC of the infecting microbe). PDCs after 10 mg/kg appear to approximate 1 µg/ mL at the end of a 24-hour dosing interval. Thus PDC will stay above the MIC₉₀ for *E. coli* (0.5), and for *S. pseudintermedius* (0.5) well beyond the targeted T>MIC of 50% to 75%. (assuming MIC does not change dramatically overtime). However, at 5 mg/kg administered orally in dogs, the highest MIC that can be treated with a 12-hour dosing interval is 4 µg/mL, and with a 24-hour dosing interval, 2 µg/mL, both of which are still above the MIC_{90} of the approved pathogens. Cefpodoxime is well tolerated in dogs at doses as high as 400 mg/kg/day for 6 months.

Tissue kinetics of cefpodoxime compared with cephalexin have been described in dogs.^{59a} The free and thus diffusible fraction of drug in plasma ranged from 9% to 34%. Maximum drug concentrations after administration of 8.5 mg/kg (single dose) in dogs (n = 6) was (extrapolated from plot) approximately 10 μ g/mL free drug (33±7 μ g/mL total) in plasma compared with 4.3 +1.9 in interstitial fluid, suggesting less than 50% of the drug in plasma reaches interstitial tissues. Unbound AUC in plasma was not provided, but the disappearance half-life of cefpodoxime from interstitial fluid was twice as long as that from plasma (10 + 3 hours versus 5.6 + 0.9)hours, respectively). The reason for this difference is not clear, although factors that influence diffusibility from tissue into serum might also influence antibacterial activity potentially precluding drug efficacy. Nonetheless, on the basis of these data, interstitial concentrations of cefpodoxime exceeded the MIC₉₀ of S. intermedius and E. coli as reported on the package insert for 24 hours.^{59a} This is in contrast to cephalexin, which is <20% bound to plasma proteins and for which interstitial concentrations exceeded the MIC₉₀ for S. pseudintermedius (as reported by Stegemann²⁰) for 12 hours but did not achieve the MIC_{90} for *E. coli*.

Cefovecin (third-generation) is the newest cephalosporin to be approved in dogs at the time of this publication. Its PD and PK have been very well described including either concentrations or bioactivity in interstitial fluid in dogs or cats in part because its disposition is complicated by extensive binding to plasma proteins.^{20,72,73} Accordingly, care must be taken when designing dosing regimens to base decisions on unbound, rather than total, drug. Based on protein-binding studies (microdialysis) at cefovecin concentrations ranging from 10 to 300 µg/mL in dog plasma, 96% to 98% is bound at concentrations below 100 µg/mL, with the fraction increasing to 72% at 200 µg/mL and 56% at 300 µg/mL. Avid protein-binding results in a slow release and a long elimination half-life of 136 or 133 hours when given intravenously or subcutaneously, respectively. Proteinbinding also affects T_{max}, which does not occur until 6 hours (based on total drug), and the apparent Vd (0.12 L/kg), which is higher than total blood volume but considerably lower than extraceullar fluid volume. C_{max} of unbound, active drug approximates about 5 µg/mL. Predicted unbound concentrations suggest that $T > MIC_{90}$ of, S. pseudintermedius (0.25 µg/mL) occurs at approximately day 12 after dosing 8 mg/kg subcutaneously; however, this is reduced to day 8 on the basis of the lowest unbound concentration predicted by the 95% confidence interval of 1 µg/mL, which is the more prudent statistic to follow (see package insert). For organisms with MIC $\geq 2 \mu g/mL$ (see Table 7-9) (e.g., S. aureus, not an approved indication), T > MIC of mean (predicted) unbound drug at approximately 1 to 2 days; however, if based on the lowest (95% confidence interval) predicted unbound concentrations, 2 µg/mL would not be reached in plasma. In contrast, the MIC₉₀ of Streptococcus *canis* (an approved indication) is much lower (< 0.06 μ g/ mL); thus T > MIC exceeds 14 days even when based on the lowest predicted unbound concentration in plasma. The same is true for *Pasteurella*, the approved indication in cats; the targeted $T > MIC_{90}$ is not reached until 12 days after treatment.

KEY POINT 7-10 The high fraction of cefovecin binding to plasma proteins prolongs its half-life, but less than 10% of total drug is active.

Studies of unbound cefovecin in tissue have been published using tissue cage models in dogs.⁷² The studies demonstrate that unbound cefovecin effectively moves from plasma into tissues, as indicated by antibacterial activity against *S. pseudintermedius* across time). After 8 mg/kg administered subcutaneously in dogs, cefovecin (total) C_{max} (total, µg/mL) was 116, 32, and 40 in plasma, transudate, and exudate, respectively, with elimination half-life from transudate similar to that in plasma (147 hours and 136 hours, respectively). Antibacterial activity was detectable in transudate at 4 hours; however, T_{max} of cefovecin antibacterial activity did not occur until approximately 2 days. Interestingly, antibacterial activity in transudate actually exceeded antibacterial activity in plasma at all time points after 8 hours and far exceeded it from day 5 forward. Peak antibacterial effects for *S. pseudintermedius* persisted in transudate until day 10 after injection, with log 2 reduction in CFUs still present at day 18; activity was gone by day 21.

Urine concentrations of cefovecin have been reported in dogs after subcutaneous administration of 8 mg/kg. Peak urine (presumably unbound) concentrations of 66 μ g/mL were achieved at 54 hours and approximated 2.9 μ g/mL at 18 days.

These data support the use of cefovecin for treatment of susceptible isolates causing urinary tract infections. Cefovecin also is approved for use in cats. Compared with the dog, cevovecin at 8 mg/kg reaches a higher total plasma C_{max}; however, it is 99% or more bound to plasma proteins in the cat. Although mean predicted unbound concentrations approximate 10 µg/ mL, the predicted variability is great, yielding as little as 0.2 if based on the lower 95% confidence interval (see package insert). The elimination half-life in cats is slightly longer at 166 hours (compared with 136 hours in dogs). The T_{max} for plasma is only 2 hours in cats (compared with 6 hours in dog). Peak concentrations of cefovecin in transudate (occurring at 1 day) were approximately 65 µg/mL (compared with approximately 30 µg/mL in dogs). However, 99% of the drug in transudate also was bound, despite the assumption that transudate is protein free. Antibacterial studies were not performed in the transudate of cats and it is not clear what impact, binding has on transudate bioactivity. The concentration of free drug in transudate in cats approximated or exceeded the MIC₉₀ $(T > MIC_{90})$ *P. multocida* (0.012 µg/mL; the approved target organism in cats) for 10 days.

The percentage of a radiolabeled dose of cefovecin recovered in urine of dogs (approximately 28%) was only slightly higher than that in feces (24%), indicating that the impact of cefovecin on normal gastrointestinal microbiota may not necessarily be less than that of orally administered drugs. Although urine contamination of feces may have occurred during the collection process, a second peak in PDCs occurs in cats, indicating that enteroheptic circulation may occur.

KEY POINT 7-11 Indiscriminate use of cefovecin must be avoided such that emergence of methicillin-resistant *Staphylococcus aureus* or methicillin-resistant *Staphylococcus intermedius* will not be facilitated.

Stegemann²⁰ has reported the PD activity of many anaerobic and aerobic gram-positive and gram-negative (potentially) pathogenic organisms collected from dogs and cats in the United States and Europe. Isolates were tested toward cefovecin, amoxicillin–clavulanic acid, cephalexin, and cefodroxil. The number of isolates in general for each organism exceeded 25, although exceptions exist (e.g, *Klebsiella*, coryneforms). *Acinetobacter* and *Enterococcus* spp. (n \geq 25) were characaterized by an MIC₅₀ of 16 or higher, well above the C_{max} of unbound drug; cefovecin should not be used to treat infections caused by these organisms. For the remaining isolates, integration of PD data with PK data (see Table 7-6) reveals that T > MIC for cefovecin that is superior to the other three drugs studied.

Several considerations should be made when selecting cefovecin as empirical choice for treatment of (presumed) susceptible infections in the dog or cat. First, recognizing the historical relationship between cephalosporins and MRSA might lead to judicious, if not limited, use. Second, not all organisms are equally susceptible to cefovecin. Caution is recommended when using cefovecin for treatment of organisms whose MIC₉₀ \ge 2 µg/mL. Third, if the decision is made to redose cefovecin, doing so probably should be considered at 2 to 4 days rather than 7 to 14 days for those organisms whose MIC is equal to or greater than 2 µg/mL. The need for redosing might be limited to those patients at risk for persistent and thus resistant infections. A final consideration for cefovecin therapy is the time that must lapse to detectable (4 to 8 hours in plasma or transudate) and peak (2 to 3 days) antibacterial activity of cefovecin in interstitial fluid.72 Cefovecin may not be a wise choice if rapid antibacterial efficacy is needed. This includes the surgical patient. Because of its long time to onset and persistence, cefovecin should not be used for surgical prophylaxis. Fourth, increasingly in human medicine, the duration of antimicrobial therapy is being shortened (e.g., to 5 days or less) for treatment of uncomplicated infections such that emergent resistance might be minimized (see Chapter 6); with cefovecin, "hit hard, get out quick" is not possible.

Drug interactions. The potential synergistic and antagonistic effects of beta-lactams with other antimicrobials was discussed in Chapter 6. Synergisim resulting from enhanced antimicrobial uptake associated with altered cell wall permeability has been demonstrated for a number of antimicrobials. Antagonism should be anticipated with drugs whose impact slows organism growth (i.e., single subunit ribosomal inhibitors); efficacy of beta-lactams may be reduced to bacteriostatic rather than bactericidal effects. An exception may occur for chloramphenicol and selected Enterobacteriaceae (see the discussion of chloramphenicol). As weak acids, the betalactams may chemically interact with and inactivate weak bases (see the discussion of aminoglycosides). Inactivation occurs at high concentrations, as might occur with mixing of medications, or potentially, in urine. High protein binding of beta-lactams may result in drug intractions with other highly protein-bound drugs because of competition for protein-binding sites, as is exemplified for cefovecin. Drugs for which higher concentrations have been demonstrated when combined with cefovecin and include carprofen, furosemide, doxycycline, and ketoconazole (PI). It should be anticipated that concurrent use of cefovecin with other highly proteinbound drugs will result in increased free drug concentrations. Beta-lactams will compete for active tubular secretion proteins in the proximal tubule with other organic acids (e.g., penicillins, cephalosporins, nonsteroidal antiinflammatory drugs, sulfonamides, diuretics). The prototypic example drug is probenecid, the combination of which with penicillins was used therapeutically to prolong elimination before implementation of mass production technology. According to the package insert accompanying probenecid, combined use with penicillin results in a twofold to fourfold increase in penicillin drug concentrations.

Adverse Effects

Mammalian cells lack a cell wall; therefore, the beta-lactam antibiotics are very safe. Diarrhea is a common side effect that may reflect altered intestinal microbial flora. Experimentally, co-oral administration with a recombinant betalactamase minimally altered fecal microflora but did not negatively influence PDCs.^{73a} Increasing the ratio of amoxicillin to clavulanic acid reduces gastrointestinal upset in humans (but may decrease the absorption of clavulanic acid; see previous discussion), but ratios less than 4:1 can only be accomplished using human-approved drugs, whose equivalent bioavailability has not been established in dogs and cats. The role of probiotics in preventing diarrhea has yet to be established but warrants consideration. Hypersensitivity is an infrequent reaction and occurs less often with cephalosporins. Penicilloic acid (results from breakdown of the beta-lactam ring) is the more likely mediator of hypersensitivity reactions; it is generated from the activity of several beta-lactamase or other enzymes from various sources. Thrombocytopenia has been reported to occur with some members of this class. With the exception of the carbapenems and selected later-generation cephalosporins, the betalactams may cause endotoxin release (see Chapter 6), which may prove detrimental to the patient, although relevance to dogs and cats is not clear.74 Penicillins, including imipenem, antagonize gamma-aminobutyric acid type A receptors and may thus lower the seizure threshold.⁷⁵ The risk may be greater in patients with renal disease.⁷⁶ Cephalexin can cause false glucosuria.77

Therapeutic Use

The broad spectrum and wide safety margin of the beta-lactam antibiotics lead to their common use. Caution is recommended, however, when they are used to treat complicated infections without the benefit of C&S data. For many drugs, because of the short half-life, C_{max} achieved at recommended doses often is not sufficient to allow a convenient dosing interval. Exceptions occur for those cephalosporins with a long half-life or carpabenems for which T > MIC of 25% is acceptable. Resistance develops to beta-lactams relatively rapidly, and the drugs are not characterized by an excellent distribution pattern, with interstitial fluid concentrations of active drug often being 50% to 30% or less of plasma concentrations, depending on the tissue and the drug. Caution should be taken with third- and fourth-generation cephalosporins despite indications of susceptibility on culture data because of inducible ESBLs that require special testing, especially in the presence of a high infecting inoculum. The spectrum of natural penicillins is relatively narrow, particularly when considered in the context of resistance that has emerged through decades of use. Resistance to aminopenicillins also limits their use as empirical drugs of choice. Exceptions might include anaerobic infections. Because the extended penicillins are susceptible to beta-lactamase destruction, combination with a beta-lactamase protector (e.g., ticarcillin and clavulanic acid) or use of imipenem-which is inherently more resistant to beta-lactamase destruction-should

be considered. Imipenem or meropenem should be considered before other beta-lactams for treatment of infections associated with endotoxemia because either drug is associated with the least endotoxin release. Constant-rate infusion should be considered for those penicillins with a short half-life to maintain effective concentrations in the critical patient; alternatively, and preferably, carbapenems should be considered in lieu of penicillins. Use of beta-lactamase– protected products should be considered even in uncomplicated infections. Indiscriminate use of beta-lactams, and particularly cephalosporins, should be avoided to minimize the advent of MRSIG.

The first-generation cephalosporins have been excellent first-choice antimicrobials for many infections, including urinary, skin, and respiratory tract infections. Their relative resistance to beta-lactamases produced by Staphylococcus spp. leads to their frequent empirical selection for infections in which Staphylococcus spp. are assumed to be involved. However, their empirical use increasingly is being limited, particularly at dosing regimens currently recommended. Their efficacy against Staphylococcus spp. as well as against many gram-negative organisms leads to their selection for surgical prophylaxis. Cefovecin should not be included in this category because of its long time to antibacterial effect and time to maximum effect and the persistence of drug concentrations well beyond the immediate postoperative period. Of the second-generation cephalosporins, cefoxitin, which is not impacted by ESBL, might be more safely considered for empirical therapy requiring a broad-spectrum antimicrobial and for anaerobic infections. With the exception of P. aeruginosa, cefoxitin is effective against most other organisms. The use of other second-generation and the third-generation cephalosporins is best based on C&S data because the spectra of these drugs are so variable. Caution should accompany use of second- through fourth-generation cephalosporins when based on in vitro data that may not reflect the production of ESBLs. Note also that the (over) use of cephalosporins has been associated with the emergence of multidrug-resistant microorganisms, including MRSA, Enterococcus spp., and P. aeruginosa.²⁵

Beta-lactams should be the first drugs considered for combination antimicrobial therapy (if used at appropriate dosing regimens). Their unique mechanism of action facilitates movement of other drugs into bacteria, which should facilitate efficacy of other antimicrobials. The risk of resistance should also be reduced as antimicrobial movement into the cell is improved. Beta-lactams are combined with drugs effective against gram-negative organisms when broad-spectrum therapy is needed, as in the case of life-threatening infections for which the causative organisms are not known, polymicrobial infections involving anaerobes and aerobes, or gram-positive and gram-negative organisms.

Vancomycin

Vancomycin has had an important role in the treatment of human patients infected with methicillin-resistant staphylococci (see Chapter 6), but the advent of penicillinase-resistant

beta-lactams and the incidence of adverse reactions have curtailed its use. Vancomycin is a large glycopeptide with three components, each of which may be responsible for its antimicrobial action on bacterial cell walls (Figure 7-4).78 The D-Ala-D-Alanine precursor of the pentapeptide fits into a pocket formed by the large molecule, sterically interfering with further cell wall elongation. The spectrum of activity of vancomycin is limited to Staphylococcus and Streptococcus spp. and anaerobes (see Table 7-4). Selected Enterococcus, Clostridium, and Corynebacterium spp. are also generally susceptible. With the exception of enterococcal organisms, the effects of vancomycin are generally bactericidal, although they act slowly. As with other cell wall-active antimicrobials, vancomycin exhibits time-dependent killing effects, with efficacy also related to AUC. Resistance has been impeded by the high specificity of the drug. Multiple mutations are required to change the enzymes currently targeted by vancomycin. Resistance that has developed by E. faecalis has resulted from synthesis of a new protein that interferes with vancomycin. More recently, vancomycin-resistant staphylococci have emerged. A strain of vancomycin-intermediate S. aureus (VISA) has been described, the mechanism of which includes thickening of the cell wall, coupled with "clogging" of the cell wall by vancomycin itself. 79

Although vancomycin is available as an oral preparation, this preparation is intended for topical (gastrointestinal) administration, most commonly indicated for pseudomembranous colitis caused by *C. difficile*. Systemic effects require intravenous administration. Vancomycin is distributed to most body tissues. The exception is the CNS, unless the meninges are inflamed; even then only 30% or less will penetrate. It is renally eliminated; drug concentrations may become toxic if doses are not modified for the patient with renal disease. The risk of nephrotoxicity is increased dramatically if the drug is given in combination with another nephrotoxic drug. Hypersensitivity in human patients warrants slow (60-minute) intravenous infusion of drug diluted in fluid. Ototoxicity has been reported in humans when concentrations reach 60 to $100 \ \mu\text{g/mL}$.⁸⁰ Its use for veterinary patients should be limited to treatment of organisms resistant to other drugs as based on C&S data.

Teicoplanin

Teicoplanin is a mixture of several molecules (teicoplanins A_2 1-5). The molecules compose a fused glycopeptide core ring structure (teicoplanin) to which are attached two carbohydrates (differing from those in vancomycin), mannose and n-acetylglycosamine, and an acyl (fatty acid). It is the latter structure that confers better lipid solubility compared with vancomyin. Its mechanism of action and impact on bacterial killing and spectrum is similar to those of vancomycin. Its use has largely been replaced by vancomycin or daptomycin.

Fosfomycin

Fosfomycin is a phosphonic acid that contains a carbonphosphorous bond (see Figure 7-12). It is a natural antibiotic produced by *Streptomyces fradiae*. Its in vitro spectrum is broad, and it expresses potential efficacy against isolates expressing multidrug resistance, including *E. coli* and gram-positive organisms. As a phosphoenolpyruvate analog, fosfomycin irreversibly inhibits phosphoenol pyruvate transferase, an enzyme that catalyzes the first step of cell wall peptidoglycan synthesis of microbial cell walls.⁸¹ As a cell wall inhibitor, fosfomycin is bactericidal when present at the site of infection at therapeutic concentrations. Its

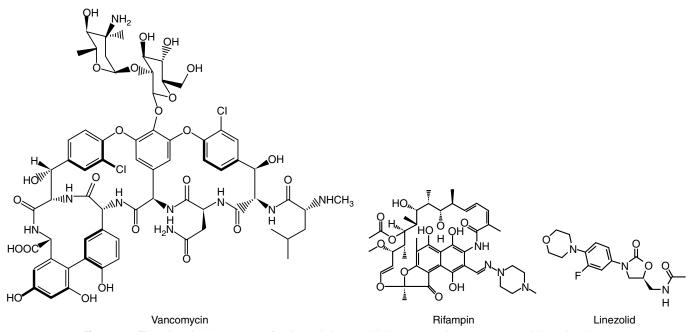

Figure 7-4 The chemical structure of selected drugs which target resistant gram-positive microbes.

irreversible nature contributes to a concentration-dependent effect. Fosfomycin exhibits in vitro activity against a broad range of gram-positive and gram-negative aerobic microorganisms associated with uncomplicated urinary tract infections. The MIC breakpoints reported for humans are 64 (S), 28 Intermediate (I), and 256 (R). Although its mechanism of action is similar to that of the beta-lactams, fosfomycin is not susceptible to destruction by any class of beta-lactamases. Rather, resistance to fosfomycin, which is unusual, reflects the FosX or FosA enzyme, which hydrolyzes the drug in a manner similar to that of glutathione S-transferases. The gene for this protein is chromosomally mediated. Thus when resistance does occur, it is usually only toward fosfomycin (single drug resistance) with cross-resistance not occurring between fosfomycin and other classes of antimicrobial agents. Therefore resistance is not associated with multidrug resistance.⁸¹ Further, compared with susceptible strains, fosfomycin-resistant mutants are impaired, exhibiting poorer growth rates and reduced adherence to uroepithelial cells. Fosfomycin appears to reduce bacterial adherence to uroepithelial cells, and decreased adherence is facilitated by N-acetylcystein⁸² and urinary catheters.⁸³ Studies in humans have demonstrated that fosfomycin distributes well to soft tissues, reaching therapeutic breakpoints.⁸⁴ Other attributes of fosfomycin that support its use for treatment of E. coli urinary tract infections include renal excretion, synergistic interaction with several other classes of antimicrobials,⁸⁶ and preparation as a 3-g sachet (granules), which is mixed with water to orally deliver approximately 40 mg/kg (in humans).

The disposition of fosfomycin disodium (pure substrate) has been described in dogs (n = 8)⁸⁸ after intravenous, intramuscular, subcutaneous, and oral administration at both 40 and 80 mg/kg day for 3 days. Plasma protein binding was negligible; drug concentrations increased in a dose-dependent manner and did not change during the study period, including across each 3-day treatment period. At 40 mg/kg, peak PDCs (µg/mL) were as follows: 51.8 ± 3.4 (extrapolated peak PDC; Co, intravenous) and 5.4 ± 0.04 (oral); and at 80 mg/kg, $113 \pm$ 12 (Co, intravenous) and 10.8 ± 0.5 (oral). Oral bioavailability (F) was 30%. Clearance was 14.9 ± 1.26 mL/kg/hr, elimination half-life was 1.3 ± 0.06 hours, and mean residence time was 1.62 ± 0.4 and 5.2 ± 0.7 (oral).

The PD and PK of fosfomycin have also been studied by the author. The distribution MIC for fosfomycin for clinical *E. coli* isolates, regardless of the presence of multidrug resistance, appears to be well below the susceptible breakpoint ($\leq 64 \ \mu g/mL$) for fosfomycin. In more than 100 clinical isolates collected from dogs and cats, the MIC range was 0.25 to 4 $\mu g/mL$; the MIC₅₀ and MIC₉₀ were, respectively, 1 and 1.5 $\mu g/mL$. Fosfomycin tromethamine was administered as a single oral dose of 80 mg/kg. After oral administration, C_{max} , elimination half-life and mean residence time were $66 \pm 21 (\mu g/mL)$, 2.5 ± 1.09 hours and 5.1 ± 1.7 , hours, respectively. Drug was detected at concentrations exceeding the MIC₉₀ of fosfomycin for multidrug-resistant *E. coli* (1.5 $\mu g/mL$) until 7 (2.5 $\mu g/mL$) and 12 hours (9 $\mu g/mL$) after intravenous and oral administration, respectively. Drug was present in urine at concentrations above 10 μ cg/ mL at 24 hr post dosing. Gastrointestinal upset manifesting as mild to moderate diarrhea was observed in 4 of the 12 dogs. Food decreased oral bioavailability: without food, 109 \pm 31% (95% confidence interal CI: 84%-135%) and with food, 66 \pm 16% (95% CI: 52%-79%). Gender had no impact on oral bioavailability. Kill studies in our laboratory indicate that for treatment of *E. coli*, the drug is not concentration dependent, as is suggested by other studies that indicate both time- and concentration-dependent effects.^{88,89} Further studies are warranted to establish efficacy for treatment of multidrug-resistant-associated urinary tract infections.

Although fosfomycin is appealing for treatment of urinary tract infections and potentially other infections caused by multidrug-resistant isolates, differences in bioavailability (oral) among different fosfomycin salts necessitates that PK be the basis, particularly of oral dosing regimens in the dog. Its efficacy appears to be both time and concentration dependent; if the latter, this should facilitate efficacy despite the short-half-life of the drug.⁸⁸ The drug appears to interact in an additive to synergistic fashion with a number of other antimicrobials.

DRUGS THAT TARGET RIBOSOMES (BACTERICIDAL)

Aminoglycosides

Despite their potential nephrotoxicity, aminoglycosides remain the cornerstone of aerobic gram-negative therapy in many complicated or serious infections. Minor differences in the chemical structures of these drugs lead to differences in efficacy and toxicity. Clinically useful aminoglycosides include neomycin, gentamicin, amikacin, netilimicin, streptomycin (or dihydrostreptomycin), and tobramycin.

Structure–Activity Relationship

Aminoglycoside compounds are composed of an amino sugar linked through glycosidic bonds to an aminocyclitol.5,90 They vary in the amino sugar and the specific number and location of the amine groups (Figure 7-5). The different name endings indicate the microbe of origin for the natural antibiotic: The suffix "icin" (e.g., gentamicin) originates from Micromonospora sp., whereas the "mycin" suffix (e.g., tobramycin) derives from Streptomyces. Amikacin is a semisynthetic derivative of kanamycin, and netilmicin, a semisynthetic derivative of sisomicin. Tobramycin is most similar to gentamicin in both spectrum and toxicity. The aminoglycosides are polycationic, depending on the number of amine groups. Kanamycin and gentamicin have two amino sugars, whereas neomycin has three amino sugars. The amine group of gentamicins is variably methylated, yielding three different gentamicins. Streptomycin has a different aminocyclitol sugar compared with the other drugs, whereas spectinomycin is an aminocyclitol that does not contain any amino sugars.

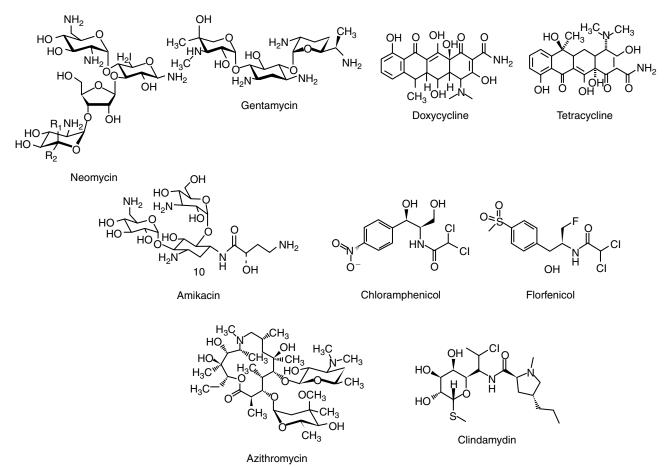

Figure 7-5 Chemical structures of ribosomal inhibitors.

Mechanism of Action

Aminoglycosides target bacterial ribosomes (Figure 7-6). The drugs enter gram-negative organisms initially through porins in the lipopolysaccharide layer. Subsequent penetration of aerobic bacteria at the level of the cell membrane appears to occur in three binding stages: the negatively charged moieties of phospholipids are first ionically attracted and bound by the positive moieties of the drug, followed by the lipopolysaccharides and finally membrane proteins. Energydependent uptake follows binding to lipopolysaccharides. An acidic environment external to the cell membrane has been associated with increased transport, perhaps because of an increase in the membrane potential differential. However, a lower pH more commonly has been associated with increased membrane resistance; the disparity may reflect the different molecules of each aminoglycoside. An alkaline environment consistently appears to facilitate transport as does movement of cations out of the cell membrane. Uptake depends on a membrane-bound respiratory protein that is lacking in anaerobic organisms, leading to inherent resistance. The system also is deficient in facultative anaerobes such as Enterococcus spp. Active transport depends on a high oxygen tension in the environment rendering obligate anaerobes inherently resistant, and facultative anaerobes resistant in an anaerobic environment.91 Cations such as calcium and magnesium in the lipopolysaccharide covering and cell membrane repel the aminoglycosides, impairing transport into bacterial cells (and renal tubular cells). Removal of calcium (e.g., through use of chelating agents such as ethylenediaminetetraacetic acid [EDTA]) or a decrease in serum calcium (i.e., hypocalcemia) facilitates aminoglycoside movement into the cell.^{5,90} Hyperosmolarity and decreased pH also decrease drug movement into the cell.⁸⁰

KEY POINT 7-12 Effiacy of aminoglycosides is dependent on active transport. Accordingly, efficacy is markedly reduced to absent in an anaerobic environment, and anaerobes are not susceptible.

Once inside the cell, aminoglycosides bind to ribosomes (see Figure 7-6). Although their mechanism of action is not completely understood, aminoglycoside antimicrobials bind to the 30S ribosomal subunit, which, as the initiator of protein synthesis, plays a crucial role in providing high-fidelity translation of genetic material.⁹² Binding is so effective that polyribosome formation is prevented, and protein synthesis is impaired because of altered synthesis and misreading. Thus, in contrast to most bacteriostatic drugs, which bind to 50S ribosomes, the aminoglycosides are more likely to achieve bactericidal concentrations safely in animals. Although only a small amount of aminoglycoside appears to penetrate the cell membrane, the initial impact on ribosomes is sufficient

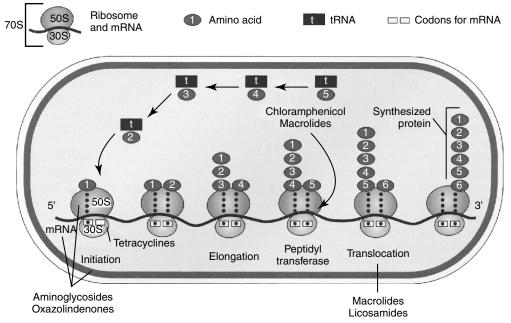

Figure 7-6 The mechanism of action of ribosomal inhibitors. The bacterial ribosome is a complex structure, composed of three RNA molecules (peptidyl and aminoacyl tRNAs and mRNA) and more than 50 proteins. The ribosome is formed as two subunits, 30S (including a 16S portion) and 50S (including a 5S portion; S referring to sedimentation rate), which join when protein synthesis is initiated and separate when completed. The process of initiation begins by the formation of a functional ribosome. The 30S subunit complexes with mRNA (which codes tRNA synthesis) and forms an initiation complex consisting of tRNA, the first amino acid (methionine), and three initiation factors (IF 1-3), one of which is an energy source, GTP. The initiation complex joins the 50S subunit, forming the (mature) 70S ribosome; it is the mature 70S ribosome that initiates protein synthesis. The mature ribosome is composed of an "A" or amino acid site (30S), the "P" or peptidyl site (50S), which contains a peptidyl transferase center; and an E or exit site adjacent to the P site. The aminoacyl tRNA carrying the amino acid binds to the A site, which then complexes to an elongation factor. Release of energy by GTP causes a conformational change or contracting motion, and the the peptide forming at the P site joins the amino acid at the A site. A nucleophilic attack initiated by the aminoacyl tRNA results in bonding of the amino acid to the growing peptide (transpeptidation); the growing peptide is then translocated to the P site. The elongation step is repeated until protein synthesis is completed.²⁷⁸ The aminoglycosides inhibit ribosomal initiation (as the 30S subunit becomes activated to 70S); binding is irreversible, contributing to a bactericidal effect. Tetracyclines bind to the 16S portion of the 30S subunit of ribosomes, preventing the translocation of the amino acid from transfer RNA (tRNA) to the codon of messenger RNA (mRNA). Chloramphenicol and erythromycin prevent the transfer of peptides by binding to the 50S subunit. Erythromycin and clindamycin prevent translocation of the peptide. Drugs that act at the same site should not be used in combination.

to alter cell membrane proteins and permeability such that additional drug is able to penetrate the cell. Irreversible saturation of the ribosomes results in cell death and accounts for the concentration-dependent killing effects of the drugs; the irreversible nature of binding contributes to bactericidal effects.⁹² Aminoglycosides are rapidly bactericidal, with efficacy and the postantibiotic effect of aminoglycosides correlating to peak concentrations, which ideally should be at least 10 times the MIC of the target organism.93-97 Drugs that target the 50S ribosomal unit (e.g., chloramphenhicol, linezolid) may interfere with intracellular movement and thus rapid killing effects of aminoglycosides.94 Because toxicity of aminoglycosides is correlated with trough concentrations (later discussed as adverse effects of aminoglycosides), treatment is implemented with once-daily therapy at high doses. This approach is both clinically^{85,97,98} and experimentally^{95,96,99} equal to or more efficacious and safer than the traditional frequency of administration (i.e., two to three times daily). The appropriateness of this dosing method may vary with the organism and the immunocompetence of the patient.

KEY POINT 7-13 The aminoglyosides exhibit a clinically important concentration-dependent postantibiotic effect.

Spectrum of Activity

The spectrum of activity of aminoglycosides (see Tables 7-2 through 7-4, 7-9 and 7-10) includes most aerobic gram-negative bacteria, particularly E. coli, K. pneumoniae, P. aeruginosa, Proteus spp. and Serratia spp.5,16,80,91,101 Newer aminoglycosides such as gentamicin, tobramycin, amikacin, and netilmicin have a wider spectrum compared with older compounds such as streptomycin and kanamycin. These drugs are also effective against selective aerobic gram-positive organisms, most notably Staphylococcus spp. However, they generally should not be used as sole agents against gram-positive organisms. Synergism against gram-positive isolates has been demonstrated when combined with penicillins or vancomycin.⁸⁰ Aminoglycoside activity against Enterococci spp. is adequate only when used synergistically with a cell wall-active antibiotic, such as beta-lactams or vancomycin.92 Among the aminoglyocsides, based on clinical isolates in humans, netilimicin has the lowest MIC₉₀ toward Enterococcus spp. and, along with tobramycin, Staphylococcus spp. Of the aminoglycosides most commonly used in dogs and cats, gentamicin has a much lower MIC_{90} than amikacin toward Staphylococcus spp., even accounting for differences in breakpoint MICs. Gentamicin is preferred to amikacin for treatment of Staphylococcus infections, based on a rabbit model of endocarditis.¹⁰¹ Further, a recent comparison of activity of 1000 isolates also found gentamicin to be more effective than amikacin toward Staphylococcus spp.¹⁰² In this same report, the authors noted that gentamicin also had lower MIC toward many enterobacteriacea but that amikacin achieved higher serum concentrations (and has a higher breakpoint MIC), thus negating this benefit.¹⁰² Gentamicin and tobramycin have a very similar spectrum toward gramnegative aerobes. They and amikacin are effective against P. aeruginosa, Proteus spp. and Serratia spp. Gentamicin is the least effective of the three against P. aeruginosa but most effective against Serratia marcescens.92 Amikacin generally is most effective against P. aeruginosa. With the exception of Pseudomonas species (usually an obligate aerobe, although exceptions have been reported), these organisms are facultative anaerobes and, if cultured aerobically from an anaerobic environment, may fail to respond to aminoglycoside therapy in the patient. The aminoglycosides are also effective against Nocardia and selected atypical mycobacterial organisms.

KEY POINT 7-14 In general, gentamicin may be more efficacious toward *Staphylococus*, spp. whereas amikacin may be more efficacious toward *Pseudomonas* spp.

Resistance

Besides the inherent resistance of anaerobic organisms (owing to decreased active transport), resistance to aminoglycosides is acquired as a result of decreased cell entry; altered porin size in the gram-negative organism is less important.⁹⁰ Resistance also includes altered ribosomal structure (uncommon except for *Enterococcus* spp.) and, more commonly, destruction by microbial enzymes inside the cell. Resistance to gentamicin involving altered ribosomal structure by *Enterococcus* spp. generally affects all aminoglycosides, as well as penicillins and vancomycin. An exception is streptomycin, which is destroyed by a different enzyme and may remain effective toward *Enterococcus*.⁹⁰

Enzymatic destruction is the most important mechanism of acquired resistance in clinical isolates, in part because it is acquired through conjugative plasmids. Resistance reflects enzyme modification of the amino or hydroxyl groups of the drugs. The modified drug can no longer bind to ribosomes. Impact on efficacy varies among the different aminoglycosides. For example, target sites of destruction by the enzymes are harder to reach with amikacin. Consequently, amikacin is less vulnerable to resistance than are other aminoglycosides and is frequently effective toward otherwise multidrug-resistant isolates.^{5,80,90} At least three different enzyme classes exist, classified by phenotypes as to phosphotransferases, acetyltransferases, and nucleotidyltransferases. Among the aminoglycosides used clinically in veterinary medicine, gentamicin and kanamycin more commonly act as substrates for phosphotransferases and acetyltransferases, wheraeas amikacin and tobramycin are more common substrates for the nucleotidyltransferases. Of the three enzymes, the phosphotransferases are more likely to be associated with high-level resistance.

Resistance to aminoglycosides by Staphylococcus spp. reflects chromosomal mutations in transmembrane potentials and thus drug uptake. Mutational resistance caused by changes in ribosome binding sites has been identified primarily against streptomycin, the use of which is limited. However, whereas the four gram-negative organisms most commonly causing (blood) infection in humans (Pseudomonas, Klebsiella, E. coli, and *Enterobacter*) remain susceptible (>95%) to the greatest number of aminoglycosides, up to 40% of S. aureus organisms are resistant to gentamicin. Current investigations are attempting to identify the mechanism by which enzymatic destruction of aminoglycosides might be inhibited, much the same as beta-lactamases have been used to prevent betalactam destruction.92 Low-level resistance caused by multidrug efflux mechanisms has been identified in P. aeruginosa, Burkholderia sp. (previously Pseudomonas), Acinetobacter, spp. and E. coli.92

KEY POINT 7-15 Enzymatic destruction of aminoglycosides is increasingly limiting efficacy, particularly for gentamicin toward *Staphylococus* spp.

Adaptive resistance has been described for the aminoglycosides (see Chapter 6). In humans up to 40 hours may need to elapse between doses for full bacterial susceptibility to commence.¹⁰³ This phenomenon supports the once-daily use of the aminoglycosides.

Pharmacokinetics

The aminoglycosides are polar, water-soluble weak bases, and as such they are poorly absorbed from the gastrointestinal tract. An exception might occur in very young animals that are still absorbing colostrum or in the presence of inflammatory gastrointestinal disease.^{90,91} Kanamycin, which is structurally very similar to amikacin, behaves similarly to amikacin.⁹¹ Aminoglycosides are administered topically (including aerosolization and incorporation in beads) or parenterally but can be used orally for local bacterial cleansing of the gastrointestinal tract. However, absorption from body cavities may be sufficiently rapid to cause neuromuscular blockade.⁹⁰ Absorption will also occur when applied topically to large wounds with subcutaneous exposure; absorption may be sufficient to cause toxicity.¹⁰⁴

Although aminoglycosides are distributed to extracellular fluids, their penetration into many tissues is considered poor (see Table 7-5). However, therapeutic concentrations can be attained in synovia and in pleural and peritoneal fluid, particularly if membranes are inflamed. Penetration of bronchial secretions is generally better than that of many beta-lactam antibiotics. However, therapeutic concentrations generally are not attained in CSF, ocular fluids, bile, milk, and prostatic secretions. Further, killing of intracellular (e.g., *Enterobacter* spp.) spp.) organisms may be limited.^{94a} Intrathecal administration has been indicated for CNS infections, but the advent of third- and fourth-generation cephalsoporins and carbapenems has preempted this need.⁹⁰ Aminoglycosides are actively accumulated by renal tubular cells, but this may be of more relevance to toxicity rather than efficacy. In addition to anaerobic environments, the efficacy of aminoglycosides is reduced in an acidic environment such as might occur in the urine, ascitic fluid, and abscesses.

KEY POINT 7-16 As water-soluble weak bases, aminoglycosides are not orally absorbed, do not penetrate tissues well, and are excreted in proportion to the glomerular filtration rate.

Drug elimination half-life of the aminoglycosides is generally less than 2 to 4 hours (see Table 7-1). The aminoglycosides are eliminated by glomerular filtration, which is a relatively inefficient process. Drug accumulates in acidic urine, and alkaline urine pH facilitates reabsorption. Urine concentrations have been described for selected aminoglycosides in dogs.¹⁰⁵ Dosing of gentamicin (6.6 mg/kg), tobramycin (3 mg/kg), and amikacin (15 mg/kg) subcutaneously in divided doses at 8-hour intervals (not recommended) for five consecutive doses and kanamycin at 11 mg/kg at 12-hour intervals (also not recommended) for 4 doses generated mean interval urine concentrations (μ g/mL) of 107 ± 33 for gentamicin: 66 ± 39 for tobramycin, 342 ± 153 for amikacin, and 473 ± 306 for kanamycin.¹⁰⁵

The disposition of aminoglycosides varies somewhat among animals, primarily because of differences in glomerular filtration rates. Elimination is slower in larger animals because glomerular filtration rate decreases with body size; this may be offset by differences in Vd. Dosing based on metabolic rate normalizes the rate of elimination and might be considered in patients predisposed to aminoglycoside nephrotoxicity, although estimates of glomerular filtration rate based on extracellular fluid volume may be more accurate.¹⁰⁶

A number of investigators have described the disposition of aminoglycosides in dogs or cats (Table 7-1). Gentamicin has been studied in dogs by multiple investigators. Riviere¹⁰⁷ described the disposition in 5-month-old Beagles (n = 11). Clearance was 4.1 ± 0.6 mL/min*kg and Vd (area) was $0.4 \pm$ 0.04L/kg. Elimination half-life was 61 ± 8 minutes. Wilson¹⁰⁸ studied gentamicin (3 mg/kg) in dogs (n = 6) after intravenous, intramuscular, and subcutaneous administration. After intravenous administration, clearance was 2.29 ± 0.48 mL/ min*kg and Vdss was 0.172 ± 0.025. Bioavailability approximated 95% for both intramuscular and subcutaneous routes, yielding a C_{max} of approximately 10 µg/mL for either route, with time to peak concentration for intramuscular administration being 27 minutes compared with 43 minutes for subcutaneous administration. The elimination half-life was 54 ± 15 minutes. Albarellos²⁰⁴ studied gentamicin after intramuscular administration of 6 mg/kg for 5 days. After day 1, assuming 100% bioavailability, clearance was 1.24 ± 0.6 mL/min*kg $(1.10 \pm 0.4 \text{ by day 5})$, and Vd (area) was $0.084 \text{ L/kg} (0.1 \pm 0.05 \text{ cm})$ day 5). Mean residence time was 1.48 ± 0.54 hour (1.77 ± 0.48) by day 5; significantly prolonged) and half-life ranged from 0.55 to 1.46 hours. For IV administration, the Vd_{ss} after intravenous administration was 0.23 \pm 0.04 L/kg and clearance was 2.64 \pm 0.24 mL/min*kg.

Jernigan and coworkers¹⁰⁰ have described the disposition of several aminoglycosides in cats (see Table 7-1). After intravenous administration of gentamicin (3 mg/kg) in cats (n = 6), Vd_{ss} was 0.12 \pm 0.02 l/kg and clearance was 1.1 \pm 0.25 mL/ kg*min. Bioavailability after subcutaneous administration was $83 \pm 14.8\%$. Gentamicin was also studied in cats (n = 6) after intravenous, intramuscular, and subcutaneous administration of 5 mg/kg.¹¹⁰ After intravenous administration, Vdss was 0.14 ± 0.02 L/kg and clearance was 1.38 ± 0.35 mL/min*kg; mean residence time was 1.8 ± 43 hour. Bioavailability after intramuscular and subcutaneous administration was 67.8 and 76.2%, respectively. Tobramycin was studied in six cats after 5 mg/kg.¹¹¹ After intravenous administration, Vd_{ss} was 0.19 \pm 0.03 l/kg and clearance was 2.21 \pm 0.6 mL/min*kg; mean residence time was 90 ± 16 minutes. Bioavailability after intramuscular and subcutaneous administration was 103% and 99% respectively; bioavailability was also measured at greater than 150% for both routes in one set of studies, perhaps indicating decreased clearance owing to nephrotoxicity. Finally, amikacin (5 mg/kg) was studied in cats (n = 6) after intravenous, intramuscular, and subcutaneous administration.¹¹² After intravenous administration, Vdss was 0.17 ± 0.02 L/kg, and clearance was 1.46 ± 0.26 mL/min*kg; mean residence time was 118 ± 14 minutes. Bioavailability after intramuscular and subcutaneous administration was 95 \pm 20% and 12.3 \pm 33%, respectively.

Disposition of the aminoglycosides appears to vary among breeds. Kukanich¹¹³ has compared the PK of amikacin (10 mg/kg, administered intravenously) in Greyhounds and Beagles (n = 6 each). The volume of distribution (L/kg) was smaller (0.18 versus 0.23), but clearance was less (2.1 versus 3.3 mL*kg/min) in Greyhounds, thus elimination half-life did not differ (0.8 and 0.9 hour for Greyhounds and Beagles, respectively). The bioavailability of amikacin in Greyhounds after subcutaneous administration was approximately 90%. Although extrapolated time 0 PDC was reported for both species after intravenous administration (86 and 70 µg/ mL, respectively, for Greyhounds and Beagles), this is not an appropriate target on which to base C_{max}/MIC (i.e, the C_{max} should be measured after distribution has occurred). However, compartmental analysis yielded concentrations extrapolated from the terminal curve (presumably reflecting postdistributional concentration; see Table 7-1). On the basis of these data and a target C_{max}/MIC of 8 (rather than 10), the respective subcutaneous doses (mg/kg) of amikacin recommended by the authors to target an MIC of 2, 4, and 8 μ g/mL, respectively, were for the Greyhound 6, 12, and 24 and for the Beagle, 11.5, 22, and 40.

The influence of endotoxemia on gentamicin disposition has been described in cats.^{114,115} Elimination half-life was shorter (77 \pm 13 minutes before and 65 \pm 14 after), but this change is not likely to be significant, in part because neither Vd_{ss} nor clearance was significantly different.

The disposition of aminoglycosides also differs among ages. PDCs are less in the neonate and pediatric patient because greater total body water and extracellular fluid compartments increase the Vd of the drugs from 0.25 to 0.35 L/kg (see Table 7-1). Renal clearance of aminoglycosides is less. Thus for young animals the dose of aminoglycosides should be increased; although elimination half-life may be longer, the current use of a 24-hour interval should preclude the need to lengthen it further in the pediatric patient. Disposition is also altered by disease. Dehydration and obesity increase PDCs, which may be of benefit for these concentration-dependent drugs. Intensive fluid therapy or other syndromes associated with accumulation of fluid at a site to which aminoglycosides distribute and endotoxemia decrease plasma aminoglycoside concentrations.⁹¹ Ascites also will increase the Vd and halflife of aminoglyocosides.¹¹⁶ Aminoglycosides may accumulate and cause nephrotoxicity in the fetus and should not be used during pregnancy.⁹⁰ Elimination is impaired in the patient with renal disease; dosing regimens are usually modified by lengthening the interval on the basis of serum creatinine concentration (see the section on therapeutic use).

Adverse Effects

The aminoglycosides induce a glomerular and (principally) tubular nephrotoxicity; however, because of the regenerative capacity of the proximal tubule, toxicity is largely reversible unless allowed to progress to an irreversible state (i.e., destruction of basement membrane). Toxicity results from active uptake into the renal tubular cell and disruption of cellular lysosomes (Figure 7-7). Impaired cellular respiration and synthesis of protective vasodilatory renal prostaglandins by the aminoglycoside may be important in the development of nephrotoxicity.

KEY POINT 7-17 Aminoglycoside nephrotoxicity can be minimized if kidneys are allowed a drug-free period such that drug that has been actively accumulated in the kidney can be eliminated.

Reversible renal impairment occurs in up to 25% to 55% of human patients receiving aminoglycosides for more than 3 days, although the better-designed studies indicate a rate of 10% to 20%.^{90,117} In humans aminoglycoside-induced nephrotoxicity is defined as an increase in serum creatinine concentration of 0.5 mg/dL in patients for which baseline concentration is < 3 mg/dL, or an increase in 1 mg/dL if the baseline is at or above 3 mg/dL.¹¹⁷

The exact mechanism of aminoglycoside-induced nephrotoxicity is not known. Toxicity begins as the anionic phospholipids of the renal tubular cell membranes attract and bind the cationically charged drugs. The relative nephrotoxicity of the different aminoglycosides reflects differences in their renal

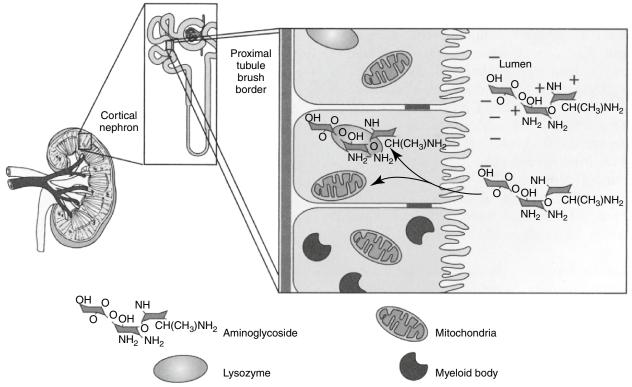

Figure 7-7 Nephrotoxicity of aminoglycosides occurs primarily in the proximal tubular cells. The cationic charge of the drugs is attracted to the anionic charge of the phosopholipids in the cell membrane. The drug is actively accumulated in the cell by pinocytosis. Inside the cell the drugs accumulate in lysozymes, causing lysosomal disruption and release of myeloid bodies. Intracellular movement into lysozymes also limits intracellular efficacy. Mitochondrial function is also impaired. The effects of prostaglandin on renal blood flow may contribute to the toxicity of aminoglycosides. A number of factors increase or decrease the risk of toxicity (see text).

accumulation.⁹⁰ Nephrotoxicity may be related to the number of positively charged amino groups on the drugs; hence, neomycin is expected to be among the most nephrotoxic of the drugs.5 An acidic local pH may enhance uptake by ionizing the aminoglycoside and thus increase the risk of toxicity. Of the clinically used aminoglycosides, neomycin is the most nephrotoxic and dihydrostreptomycin, the least. The nephrotoxicities of the other aminoglycosides are between these two extremes. Several studies have compared tobramycin and gentamicin (the latter is more concentrated), but controlled clinical trials in humans have failed to find a clinical difference in the nephrotoxicity potential between the two.90 Studies comparing the nephrotoxic potential of amikacin with other aminolgycosides (but not gentamicin) also have been inconclusive.⁹⁰ A number of drugs increase the risk of nephrotoxicity (see the section on drug interactions).

The attraction of aminoglycoside cations to the renal tubular cell membrane can be competitively inhibited by divalent (e.g., magnesium or calcium) cations (e.g., ethylenediaminetetraacetic acid [EDTA]) or decreased in an alkaline urine (unionizing amine groups). Hypocalcemia or hypomagnesemia may increase the risk of aminoglycoside toxicity; in contrast, dietary calcium loading may protect against toxicity. Uptake of aminoglycosides also may be related to the amount of phosphatidylinositol in the cell membrane; the amount is disproportionately higher in renal cortex and cochlear tissues.⁹¹

Once the renal tubular cells are entered, aminoglycosides are then actively accumulated in the cell by pinocytosis; intracellular accumulation may result in concentrations greater than fiftyfold of that in plasma. Inside renal tubular cells, probably in part because of ion trapping, aminoglycosides are sequestered in lysosomes, which subsequently appear morphologically as myeloid bodies. The drugs are slowly eliminated in the urine as myeloid bodies, which contain drug, RNA, and DNA after the tubular cell dies.

The cause of tubular cell death induced by aminoglycosides remains unclear, although a number of cellular functions (in addition to lysosomal damage) are impaired; examples include phospholipases, sphingomyelinases, and ATPases. Mitochondrial respiration is decreased, impairing energy resources of the cell. Again, this may reflect interaction between the drug and mitochondrial cell membrane. Proximal tubular permeability may be impaired both directly as drugs interact with the cell membrane and indirectly as a result of impaired Na⁺,K⁺-ATPase activity. Aminoglycosides also alter glomerular function, perhaps by reducing the number and size of glomerular endothelial cells.91 Finally, phospholipases important for renal prostaglandin synthesis are among the enzymes impaired by aminoglycosides. The initial decrease in glomerular filtration that accompanies aminoglycoside therapy may reflect the inability of the kidney to vasodilate in response to vasoconstrictor actions such as that signaled by angiotensin II.⁹¹ This may reflect altered prostaglandin synthesis. As glomerular filtration declines, so may clearance of the aminoglycoside, thus increasing the risk of toxicity.90

The half-life of renal cortical aminoglycosides is approximately 100 hours. This and the fact that a critical

Box **7-1**

Minimization of Aminoglycoside Nephrotoxicity

- 1. Use once-daily therapy when appropriate.
- 2. Ensure adequate hydration status. If any doubt, or in a patient at risk, treat with sodium isotonic.
- 3. Maximize peak plasma drug concentration to ensure that $C_{max}/MIC > 10$ and trough plasma drug concentration is < 2 $\mu g/mL$.
- 4. Monitor peak and trough concentration aminoglycoside concentration such that half-life and clearance can be followed.
- Monitor urinary renal enzyme (γGT) to creatinine ratios, urine sediment, and serum creatinine.
- 6. Use the least nephrotoxic aminoglycoside (possible amikacin versus gentamicin).
- Use the most effective aminoglycoside for the target organism (e.g., gentamicin for *Staphyloccocus*, amikacin for *Pseudomonas*).
- Use combination antimicrobial therapy, particularly with synergistic antibiotics and always for gram-positive organisms
- 9. Avoid use of other nephrotoxic or nephroactive drugs, including antiprostaglandins, ACE inhibitors, and furosemide.
- 10. Administer during periods of activity (e.g., early morning in dogs, possibly evening in cats).
- 11. Treat with N-acetylcysteine.

aminoglycoside concentration must be reached before nephrotoxicity emerges generally preclude renal cortical nephrotoxicity before the first 3 days of therapy (Box 7-1).¹¹⁷ No study has demonstrated a threshold of dosing or interval that ensures or predicts toxicity. Studies that have focused on aminoglycoside toxicity in dogs and cats have used dosing interval that ranges from 12 hours to constant intravenous infusion. Studies regarding aminoglycoside nephrotoxicity in cats have focused on doses of 35 mg/kg or more at intervals of 12 hours or less.⁹¹ A bimodal course of aminoglycoside-induced nephrotoxicity has been described in the dog, with an initial subclinical phase characterized by a concentrating defect and an azotemic phase; different disease states might be predictable based on changes in pharmacokinetics.¹⁰⁸ Under experimental conditions, gentamicin at 4 mg/kg every 12 hours in dogs changes urine osmolarity within 7 days and an increase in serum creatinine by 17 days. Urinary prostaglandin E activity decreases before azotemia, which may be responsible for the state of nephrogenic diabetes insipidus. Whereas a single dose of 15 mg/ kg gentamicin was associated with subclinical and morphologic changes in the kidney of young Beagles,¹¹⁹ higher doses of 30 mg/kg administered at 8-hour intervals in dogs result in increases in urine gamma-glutamyltransferase within 2 days and serum creatinine within 9 to 12 days. Interestingly, a study that describes the disposition of gentamicins C1, C1a, and C2 in dogs found clearance of C1 to be twice as fast and Vd to be twice as high as for the other two gentamicins.¹²⁰ The investigators found that the renal binding of C1 is likely to be greater, suggesting that it is more likely to be nephrotoxic compared with C1a and C2. tamicin renal medullary accumulation in cats but does not appear to be associated with increased renal pathology.¹¹⁵ Tobramycin was associated with increased serum creatinine and/or BUN in 9 of 12 cats dosed twice with tobramycin despite washout periods,¹¹¹ suggesting that it may be more nephrotoxic than other aminoglycosides, at least in cats.

No indicator of renal damage induced by the aminoglycosides is sufficiently sensitive to prevent damage; indeed, damage will continue beyond detection with current methods. Changes in urine osmolality or sodium fractional clearance typical of the initial subclinical phase may detect a concentrating defect. However, this should be preceded by a release of renal tubular enzymes such as gamma-glutamyltransferase into urine. Measurement of the enzyme has been used experimentally to measure aminoglycoside toxicity. The enzymes increase within several days after damage has begun. However, 24-hour sample collection for these procedures is impractical. Measurement of the urine creatinine to gammaglutamyltransferase ratio in spot samples of urine have proved useful in experimental models of aminoglycoside toxicity.¹²³ Ratios may not, however, change until several days after toxicity has begun.⁹¹ A change in aminoglycoside clearance may be the most sensitive indicator of aminoglycoside toxicity (see Chapter 5.81,114,115 In humans serum creatitine may increase up to 1 week after therapy is discontinued, indicating the potential for continued damage once the drug is discontinued,¹¹⁷ presumably because accumulated drug remains in the tubules. Accordingly, nephrotoxicity is best avoided (see Box 7-1 and the section on therapeutic use).

The presence of renal disease is not a contraindication for aminoglycoside use, although it certainly raises the risk. Normograms have been designed in human medicine to reduce the risk of further damage (see the section on therapeutic use). The risk of nephrotoxicity is greater if any condition of the patient depends on renal prostaglandin formation, such as hypotension, shock, endotoxemia, renal or cardiac disease, or with concurrent drug therapy that impairs prostaglandin synthesis, such as nonsteroidal antiinflammatory drugs.^{5,126} Metabolic acidosis (or an acidic urine pH) also predisposes the patient to aminoglycoside nephrotoxicity because drugs are ionized and attracted to the anionic changes of cell membranes.¹²⁷ Consequently, if the source of infection is in the urinary tract, maintaining an alkaline pH will enhance the efficacy of the aminoglycosides by facilitating their diffusion back into infected tissue (and bacteria), while decreasing renal tubular cell uptake of aminoglycosides, presumably because of decreased ionization of the drugs. Aminoglycoside toxicity was demonstrated to be temporal in rats,¹²⁸ being worse when rats were resting and least when active. Accordingly, dosing in the morning may be prudent for dogs; dosing at night might be considered for cats. Some patients (e.g., pediatric dogs <14 days of age, patients with diabetes mellitus or hypothyroidism) are protected against aminoglycoside- (gentamicin)-induced

nephrotoxicity because renal accumulation in the cortical tissues is limited.^{130,131} Symptomatic hypomagnesemia, hypocalcemia, and hypokalemia associated with inappropriate urinary excretion of potassium despite low serum concentrations has been reported in humans after gentamicin therapy.¹³² The magnitude correlated with the total cumulative dose of gentamicin. Risk factors included older age and long duration of therapy.¹²³ Note that hypomagnesemia and hypocalcemia may increase the risk of aminoglycoside toxicity by increasing the ease with which drugs enter the renal tubular cell.

KEY POINT 7-18 The presence of renal disease is not a contraindication for aminoglycoside use, although it certainly raises the risk of adverse effects.

Studies have attempted to identify therapies that might treat or prevent aminoglycoside-induced nephrotoxicity. The role of prostaglandin analogs (e.g., misoprostol) in the prevention or treatment of aminoglycoside toxicity has not yet been established. Melatonin administered simultaneously to rats receiving gentamicin was associated with reduced nephrotoxicity.124 Rate receiving L-Carnitine (40 to 200 mg/kg/day, injected) beginning 4 days before receiving doses of gentamicin ranging from 50 to 80 mg/kg had less nephroxicity (based on serum creatinine and histology) compared with untreated rats. Renal gentamicin concentrations were not different, suggesting that decreased aminoglycoside uptake by the renal tubular cell was not the mechanism of prevention. Proposed mechanisms were promotion of fatty-acid oxidation, increased mitochondrial ATP, and decreased formation of oxygen radicals.¹³⁵ Again, in rats, N-acetylcystein (10 mg/kg intraperitoneally [IP]) protected against gentamicin (100 mg/ kg subcutaneously/day \times 5 days) induced nephrotoxicity.¹³⁶ This treatment apparently also has also been demonstrated to be otoprotective in human patients undergoing hemodialysis that are treated with gentamicin.¹³⁷ A federally funded human clinical trial is currently underway to validate the beneficial effects of N-acetylcysteine in patients with or at risk to develop aminoglycoside nephrotoxicity.

Aminoglycosides can cause an irreversible ototoxicity, although this is not likely to occur at therapeutic doses as long as trough concentrations are lower than 2 to 5 μ g/mL (lower should be targeted for gentamicin, higher for amikacin). However, a single dose of tobramycin was associated with ototoxicy in humans.⁸⁰ Like nephrotoxicity, ototoxicity reflects active uptake of the drug by hair cells of the cochlea. Both auditory and vestibular toxicity may occur. As with nephrotoxicity, the ototoxic potential of each drug varies. The drugs typically should not be given to a patient with a perforated eardrum. Aminoglycosides can cause neuromuscular blockade owing to impaired calcium release at myoneural junctions. The risk appears to be dose dependent and is greater with intravenous administration, in the presence of hypocalcemia, or when combined with other agents active at the myoneural junction (e.g., anesthetics, skeletal muscle relaxants). Neuromuscular blockade can be reversed by cholinesterase inhibitors and (cautiously) calcium.

Drug Interactions

The risk of aminoglycoside ototoxicity and nephrotoxicity is increased when aminoglycosides are used in combination with one another or with nonsteroidal antiinflammatory drugs, diuretics (particularly loop-acting), angiotensin-converting enzyme inhibitors, amphotericin B, and other nephrotoxic (or nephroactive) or ototoxic drugs. The risk of neuromuscular blockade is increased with the combination of aminoglycosides and intravenous calcium, calcium channel blockers, and gas anesthetics and other neuromuscular blocking agents, including atacurium. Edrophonium will reverse the latter, whereas calcium supplementation can reverse any neuromuscular blockade.²

As weak bases, the aminoglycosides may chemically inactivate weak acids; inactivation has been documented in vitro¹³⁸ and in vivo¹³⁹ between tobramycin and extended-spectrum penicillins but not carbapenems.¹⁴⁰ Tobramycin appears more amenable to inactivation than does amikacin.¹³⁹ In vivo inactivation is more likely to occur in patients with renal disease for which PDC may be higher than in normal patients. Chemical inactivation might also occur in urine as higher concentrations are achieved. In general, the aminoglycoside is inactivated rather than the penicillin simply because the penicillin is present at much higher concentrations compared with the aminoglycoside.

Synergism between aminoglycosides and cell wall-active antimicrobials has been documented against *Enterococcus* spp. as well as some strains of Enterobacteriaceae, *P. aeruginosa*, staphylococci (including MRSA), and other microorganisms. However, these organisms are not always inhibited by the combination of aminoglycoside and cell wall-active compounds. Indeed, antagonism has been described between aminoglycosides and beta-lactams against a MRSA, presumably owing to induction of an aminoglycoside-modifying enzyme.⁹²

Therapeutic Use

Despite their ability to cause nephrotoxicity, the aminoglycosides remain the most effective drugs for the treatment of serious gram-negative infections. They are also effective (combination therapy recommended), against Staphylococcus, Nocardia, Mycoplasma, and selected Mycobacteria spp. Caution is recommended in their use for infections in tissues that are difficult to penetrate and infections that may be located in an anaerobic environment. Combination therapy and topical therapy (in concert with systemic therapy) should be considered whenever possible for serious or complicated infections or in the presence of intracellular infections. Aminoglycosideimpregnated calcium hydroxyapatite or methyl methacrylate beads and methyl methacrylate cement have been used with apparent success in orthopedic procedures (see Chapter 6). ^{140a} Aminoglycosides cannot be given orally with the intent of systemic effects, and their use might be limited to hospitalized patients. However, once-daily therapy increases the convenience and safety of outpatient aminoglycoside therapy.

The pharmacologic rationale for once-daily (also called extended-interval) dosing of aminoglycosides includes their concentration-dependent bacterial killing, minimization of the adaptive resistance, the presence of a postantibiotic effect, and avoidance of renal cortical drug accumulation (i.e., providing a drug-free period to facilitate excretion) such that trough concentrations reach a low target.¹¹⁷ As early as 1984,¹⁴¹ a fixed-dose, prolonged interval was known to be safer than a reduced dose and fixed interval in regard to nephrotoxicity in dogs. Recent studies in dogs, humans, and experimental models have supported a 24-hour dosing interval (administering the total daily dose once a day) for aminoglycoside therapy. The once-daily dose of an aminoglycoside necessary to impair renal function has not been determined, in part because different drugs are studied at different doses and intervals. Because clinical patients are likely to be characterized by changes that predispose to toxicity, studies in normal animals may not be relevant. Once-daily administration of gentamicin was concluded to be safe for 5 days in dogs at a single daily dose of 6 mg/kg. 108 Maximum concentration (C_max (µg/mL), was 9.2 at a T_{max} of 0.48 hours. Mean trough gentamicin serum concentrations were 0.1 µg/mL. Although deemed safe, serum creatinine and urea nitrogen were increased and specific urine gravity decreased in one dog and granular casts were evident in two dogs.

Many clinical trials have been performed in humans to assess the safety and efficacy of once-versus multiple-daily dosing of aminoglycosides. Differences in objectives, patients, methodologies, and conclusions have led to confusion. Several meta-analyses have been performed in humans that focuses on clinical efficacy and either nephrotoxicity or ototoxicity in patients treated with aminoglycosides once versus multiple times daily. The number of trials included in each meta-analysis ranged from 21 to 26; the number of persons studied by each meta-analysis was 2100 to more than 3000. Barza's group¹⁴² found that once-daily administration of aminoglycosides in patients without preexisting renal failure was as effective as multiple-daily dosing and was associated with a lower risk of nephrotoxicity and no greater risk of ototoxicity. Further, once-daily dosing was more convenient and less costly. A second (22 studies)¹⁴³ and third meta-analysis (26 studies)¹⁴⁴ found the rates of efficacy and toxicitity were similar and convenience and reduced cost justified the once-daily approach. Another study found that gentamicin (once or multiple times daily) and ticarcillin-clavulanic acid, either alone or combined with gentamicin, was associated with the same efficacy and nephrotoxicity renal function was better preserved with either once-daily gentamicin combined with ticarcillin-clavulanic acid or ticarcillinclavulanic acid alone.145 However, in humans, experts continue to advise that extended-interval aminoglycoside dosing not be used in patients with endocarditis, mycobacterial infections, or burns. Further, a simple once-daily approach to aminoglycoside therapy should not be used if the patient's creatinine clearance is less than 20 mL/min or in patients in hemodialysis because of marked alteration of PK in these patients. Rather, monitoring should be the basis of dosing in these patients.¹⁴⁶ Further, for obese patients (actual body weight > 20% above ideal body weight [IBW]), the dose should be reduced using the following formula that adjusts weight: obese dosing weight = IBW + 0.4 (actual weight - IBW).147 A number of normograms have been developed for use in humans to support the design of aminoglycoside dosing regimens that will be effective yet safe in patients with renal disease. Generally, the normograms are based on creatinine clearance and other patient factors. However, in general, the normograms underestimate the dose necessary to achieve a therapeutic maximum drug concentration. Methods using probabilistic or deterministic methods are currently being investigated.¹⁴⁸ However, therapeutic drug monitoring continues to be the preferred method to allow calculation of individual patient PK.117,146 Indeed, a meta-anlysis that compared once-daily multiple-dosing therapy and dosing based on PK found that basing doses on individual PK was the safest approach to dosing with aminoglycosides.¹¹⁷ AUC based on two time points has enhanced prediction of dosing regimens for aminoglycosides in children with cystic fibrosis.¹⁴⁹ However, the distribution phase of aminoglycosides is sufficiently slow that the first sample probably should be collected no earlier than 1 hour after dosing is complete. Monitoring peak (no earlier than 1 hour, to ensure complete distribution) and detectable trough concentrations (no later than 2 to 3 half-lives after the peak to ensure concentrations are still detectable) will allow estimation of half-life, and (if given intravenously) Vd and clearance (see Chapter 5). Pretreatment and posttreatment comparisons may be useful in the early detection of significant changes in renal function, which will also help guide safe therapy. The clinical pharmacologist offering recommendations will be able to determine these parameters regardless of the actual timing (i.e., 1 versus 1.5 hours for peak, 4 versus 8 hours for trough); however, accuracy in reporting the time that samples were collected is critical for proper recommendations when the samples are collected for determination of half-life.

Maintaining hydration is probably the single most important means by which the risk of aminoglycoside-induced nephrotoxicity can be minimized. Ototoxicity also can be minimized by hydration and avoidance of topical administration, particularly in the presence of a perforated tympanum. Although gentamicin is the most economical aminoglycoside, amikacin should be considered for serious infections because of its improved resistance to antimicrobial destruction and better efficacy against some organisms, including *P. aeruginosa*. The aminoglycosides are often used in combination with other antimicrobials that have a less comprehensive gramnegative spectrum. As with imipenem, the aminoglycosides cause minimal endotoxin release in patients suffering from gram-negative infections associated with a large inoculum.⁷⁴

DRUGS THAT TARGET NUCLEIC ACIDS

Fluorinated Quinolones

The fluorinated quinolones (FQs) are among the most recent classes of antimicrobials to be developed for treatment of bacterial infections. These synthetic drugs are minimally toxic yet have been effective in the treatment of many aerobic gramnegative organisms and selected gram-positive organisms. The desire to expand their spectrum of activity and the advent of resistance has led to innovated structural changes.

Structure–Activity Relationship

A review of the development of FQs is worthwhile, not only to facilitate understanding of their actions but also to provide insight regarding the advantages of so-called designer drugs. Two decades elapsed between the development of nalidixic acid, the progenitor of the FQs, and norfloxacin, the first of the FQs to be approved for use. Among the FQs currently used for treatment of susceptible infections in dogs and cats, ciprofloxacin was first approved for use in humans in 1986, with its veterinary counterpart, enrofloxacin, rapidly following in 1991. Extensive use of these drugs has exposed the need for improvements and newer clinical indications; pharmaceutical companies have been attentive to addressing these needs.

Nalidixic acid is the progenitor of the FQs (Figure 7-8). Synthetic manipulations, including but not limited to the addition of a fluorine atom, have broadened the antibacterial spectrum; enhanced tissue penetrability; reduced (some) side effects (perhaps while contributing to others); and, most recently, decreased the risk of resistance. Currently marketed FQs generally consist of a quinolone ring nucleus, the target of most initial structural manipulations (Figure 7-9), or a napthyridone ring structure, which replaces the nitrogen at carbon 8 on the quinolone structure (enoxacin, tosufloxacin, trovafloxacin, and gemifloxacin). The quinolone nucleus contains a carboxylic acid group at position 3 and an exocyclic oxygen at position 4 (hence the term "4-quinolones"); these are the active DNA gyrase binding sites, and thus these sites generally are not chemically manipulated. The structures yield two pKas for most FQs, rendering them amphoteric; they can act as weak bases, weak acids, or neutral compounds. For example, the carboxylic acid of enrofloxacin has a pKa of 6 and the amine group a pKa of 8.8. The side chain attached to the nitrogen at position 1 affects potency. The ethyl group at this position on nalidixic acid and the first of the clinically used FQs, norfloxacin, was replaced with a bulkier group (e.g., the cyclopropyl group of ciprofloxacin), which enhanced both gram-negative and -positive spectra. Substitution at position 5 also improved the gram-positive spectrum; however, it was the addition of a fluorine atom at position 6 that profoundly enhanced the gram-positive spectrum. The addition of a piperazyl ring, containing a heterocyclic nitrogen, at position 7 also was a critical improvement. This addition improved bacterial penetration (potency) and added P. aeruginosa to the gram-negative spectrum. The combination of the fluorine atom with a piperanyl ring produced the "breakthrough" class of FQs used today; norfloxacin was the first of these FQs to be approved in the United States.

Chemical manipulations continue to improve the FQs in terms of spectrum, potency, and avoidance of resistance. Substitutions on the piperazyl (e.g., ofloxacin, its L isomer, levofloxacin, and sparfloxacin) enhance the gram-positive penetration, whereas substitutions at position 8 enhance anaerobic activity (e.g., sparfloxacin, pradofloxacin, moxifloxacin). Substitutions at these sites with halogens such as chlorine or fluorine (e.g., 8-chloroquinolones or 8-fluoroquinolones [sparfloxacin]) result in ultraviolet unstable compounds (particularly the chloro substitution), which can cause phototoxicity. In contrast, substitution of a methoxy-group at the 8 position

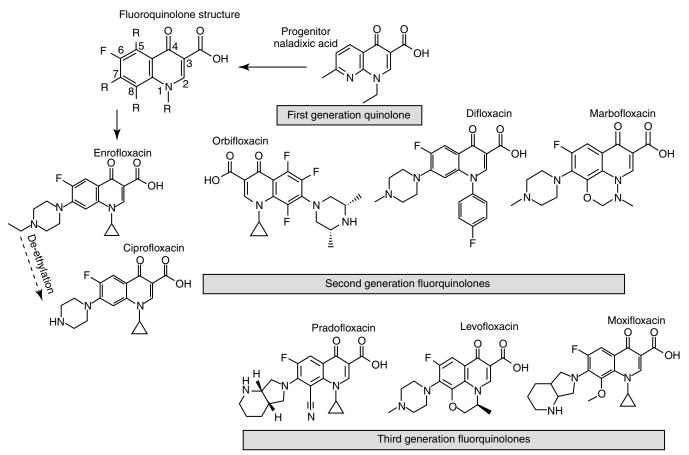

Figure 7-8 Various substitutions of the core chemical structure of the fluorinated quinolones have improved their spectrum, efficacy, and tissue penetration. The efficacy of the fluorinated quinolones depends on the ketone group at position 4 and on the carboxylic acid at position 3 (necessary for inhibition of DNA gyrase). The combination of the fluorine at position 6 (which markedly expanded the gram-positive spectrum) and the substitution of a piperyl ring at position (which enhanced efficacy towards *Pseudomonas aeruginosa* as well as increased tissue penetrability) represented a "breakthrough" for the fluorinated quinolones (e.g., enrofloxacin and its active metabolite, ciprofloxacin). Substitutions at position 8 increase the anaerobic spectrum (e.g., pradofloxacin). The addition of larger side chains may impair microbial resistance mechanisms.

(e.g., moxifloxacin, gatifloxacin) confers good anaerobic activity but without risk of phototoxicity. Recent improvements (in human medicine) focus on increasing the efficacy of FQs toward pneumococci and MRSA, as well as other gram-positive cocci, Enterobacteriaceae, *Pseudomonas*, and anaerobes, and methods by which resistance might be minimized.

KEY POINT 7-19 Chemical manipulations of fluorinated quinolones improve potency, broaden the spectrum, and decrease resistance.

Four drugs are currently approved for oral use in small animals in the United States: enrofloxacin (the first approved, for both dogs and cats, also approved for injectable [SC] use in dogs), followed rapidly by orbifloxacin (dogs and cats), difloxacin (dogs), and marbofloxacin (dogs and cats) (see Figure 7-8). Pradofloxacin may be undergoing consideration for approval for use in dogs in the United States. Variations in the chemical structures of these drugs may result in subtle differences in potency, efficacy, and tissue distribution. Humanmarketed FQs, particularly ciprofloxacin and increasingly levofloxacin, continue to be prescribed by veterinarians. Care should be taken to ensure that differences in disposition between humans and dogs or cats are considered when using these drugs. In their guidance to industry, the FQs have been indicated by the Food and Drug Administration (FDA) as "drugs of interest"; as such, veterinary use of these or newer FQs approved for use in humans is likely to draw scrutiny by allied health professions, including regulatory agencies. Note that use of drugs intended for human use (including cheaper generic drugs) instead of veterinary drugs solely because the former are less expensive is likely to be a disincentive for veterinary manufacturers with regard to future approvals of drugs for animals. Further, Animal Medical Drug Use Clarification Act stipulates that the conditions underwhich extra-label drug use is allowed include the lack of availability of a veterinary approved drug that meets the patient's needs. Extra precautions should be taken when prescribing human-medicine drugs to ensure judicious use.

Because enrofloxacin was the first of the veterinary FQs to be approved for use in dogs and cats, it often is the gold standard on which subsequent drug approvals are based and

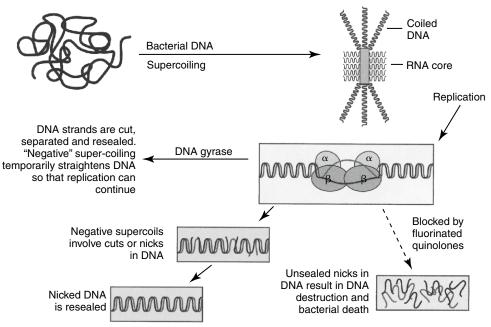

Figure 7-9 The mechanism of action of fluorinated quinolones. During DNA synthesis, the double strands of circular bacterial DNA are in a tightly (negatively) coiled state (negative referring to the direction of the coils). The DNA strands are "unzipped" to allow either messenger RNA or a new DNA strand to be synthesized. The unzipping induces stress and the subsequent formation of positive supercoils, that ultimately must be removed. DNA gyrase, a topoisomerase, directs double-stranded breaks in the DNA. After DNA synthesis, the daughter chromosomes are unlinked by topoisomerase IV. Both DNA gyrase and topoisomerase IV are essential to bacteria and either or both are targeted by the fluorinated quinolones. Drugs that target both enzymes may require multiple mutations for resistance to emerge.

upon which clinical trials evaluating FQ efficacy are based. Because it is structurally similar to ciprofloxacin and because it is metabolized (up to 50% of the AUC of bioactivity) to ciprofloxacin in many species, much of the PD information in the human literature regarding efficacy for ciprofloxacin is applicable to enrofloxacin. However, exceptions occur, particularly with regard to PK considerations. Further, some differences exist in regard to pharmacodynamics between ciprofloxacin and enrofloxacin. Although marbofloxacin has been approved for a shorter period in the United States compared with enrofloxacin, it has been used since 1994 in Europe, and a considerable amount of information is available regarding this drug. In contrast, less information is available for orbifloxacin and particularly difloxacin.

Mechanism of Action

The FQs currently are the only veterinary-approved antimicrobials that directly inhibit DNA synthesis. Bacterial DNA, is circular and can be up to 1.3 mm long, necessitating a negatively supercoiled state surrounding the RNA core (see Figure 7-9).^{150,151} During DNA synthesis, the double strands of DNA must be uncoiled or "unzipped" to allow either messenger RNA to interpret or a new DNA strand to be synthesized. The unzipping of the double strands induces positive supercoiling, which leads to undue stress in the individual strands. Accordingly, DNA gyrase (topoisomerase II), directs double-stranded breaks in the DNA, thus inducing a negative supercoil configuration, balancing the positive supercoils. Once DNA polymerase passes through a break in the strand, the break is repaired. Topoisomerase IV separates the daughter DNA molecules produced by DNA replication.¹⁵² Both DNA gyrase and topoisomerase IV are essential to bacteria replication; both are targeted by FQs either individually or sequentially, depending on the drug and organism.¹⁵¹

Bacterial topoisomerases are ATPase-dependent enzymes. Each exists as a tetramer consisting of two A and two B subunits. For DNA gyrase, the subunits are encoded by the genes gyrA (2517 bp) and gyrB (2060 bp), respectively, and for topoisomerase *parC* and *parA*, respectively. The primary enzyme responsible for activity varies with the organism and influences the target of the FQ. DNA gyrase is the primary target in E. coli, other gram-negative organisms, and Mycobacterium tuberculosis, whereas topoisomerase IV is the primary target of S. aureus and (probably) other gram-positive organisms.151,153 The efficacy of the FQs against various microbes can be explained, in part, by the presence or absence of the target enzymes, as well as drug preference for different enzymes (which in turn can be related to chemical structure [see above]). For example, unlike most other bacteria, M. tuberculosis lacks topoisomerase IV and might be less susceptible than other microbes that have both targets. Ciprofloxacin prefers topoisomerase IV, whereas moxifloxacin prefers DNA gyrase. Accordingly, bactericidal activity of moxifloxacin might be (and clinically appears to be) better compared with ciprofloxacin against M. tuberculosis. Efficacy of FQs is related to the number of molecules that interfere with the target topoisomerase; interference is irreversible, resulting in concentrationdependent effects.

KEY POINT 7-20 Differences in efficacy of the fluorinated quinolones reflects, in part, the preferred topoisomerase targeted by the drug.

The MICs of the FQ for susceptible organisms tend to be low compared with most other antimicrobial drugs. DNA gyrase actions are inhibited at concentrations of 0.1 to 10 μ g/mL. The precise mechanisms by which FQs kill are not fully understood, but strand breakage, autolysis associated with SOS DNA repair systems, and blockade of replication by the gyrase FQ complex may cause bacterial inhibition without bacterial killing.¹⁵⁴ However, the concentration of FQs necessary to inhibit the growth of organisms (MIC) is very close to that necessary to kill the organism (MBC). Although mammal DNA replication also depends on a topoisomerase, its function is somewhat different. More important, affinity of host topoisomerases is less than 0.001 of that of bacterial DNA gyrase. Thus the unique mechanism of action of the FQs renders rapid bactericidal activity with minimal effects on the host. The time to effect for FQs is very short (30 minutes); their rapidity of action often is the reason for preference of these drugs compared with other equally but more slowly effective antimicrobials (e.g., amoxicillin-clavulanic acid combinations for the treatment of selected pyodermas). Interestingly, cellular factors such as intracellular magnesium concentration, salt, and ATP may influence the affinity of FQs for their target enzymes; the clinical implications of this observation are not clear.¹⁵¹

KEY POINT 7-21 The irreversible interaction between drug and topoisomerase results in a concentration-dependent effect for the fluorinated quinolone.

The efficacy of the FQs occurs, in part, because of a long postantibiotic effect, which also is concentration dependent. Depending on the organisms, drug, and concentration, the postantibiotic effects can approximate 5 to 8 hours.¹⁵⁵⁻¹⁵⁹ The efficacy of the FQs appears to correlate more closely with peak concentrations (i.e., concentration dependent) than with duration of PDC above the MIC.^{160,161} Consequently, efficacy is more likely when C_{max}/MIC exceeds 10 or more. However, duration of time that PDCs are above the MIC (AUC/MIC) also is an effective predictor of efficacy, and may be better than C_{max}/MIC for selected organisms.¹⁶² Analysis of multiple studies focusing on the best predictor of successful bacterial killing indicated that the area under the inhibitory curve (AUIC), an index that is similar to AUC/MIC (see Chapter 6) was the best predictor of efficacy. If AUIC is greater than 100 but less than 250, bacterial killing is slow (evident by day 7 of therapy), whereas an AUIC greater than 250 produced rapid killing, with eradication occurring within 24 hours. The effect occurred for both gram-negative and gram-positive organisms.¹⁵³ These data suggest that the most effective use of the FQs is to administer at a dose that will achieve rapid killing. A comparison of C_{max}/MIC or AUC/MIC may be helpful in comparing relative efficacy among the FQs used to treat feline or canine pathogens¹⁶⁴ (see Table 7-12).

Spectrum of Activity

The (human-medicine) FQs have been categorized into 3 to 4 generations based on their spectrum of activity (see Figure 7-8).¹⁶⁵ Athough not often used, the classification is helpful for perspective on the development of the FQs. The spectrum of nalidixic acid, the first-generation drug, is narrow. However, it was improved through pharmaceutical manipulation, yielding the second-generation drugs. This generation is exemplified by the human-marketed drug ciprofloxacin and the current veterinary FQs approved for use in dogs and cats. Their spectrum includes a broad gram-negative and less broad gram-positive spectrum. Third-generation drugs include levofloxacin, the L-isomer of ofloxacin, sparfloxacin, gatifloxacin, and moxifloxacin. This generation is characterized by enhanced potency, improved spectrum (which includes anaerobes), and reduced resistance. The fourth-generation drugs are characterized by the broadest spectrum and are exemplified by trovafloxacin. Each generation has been designed such that drug molecules target specific molecules of the target enzymes, thus increasing efficacy, and for some reducing the emergence of resistance.

The second-generation veterinary FQs have been referred to as broad in spectrum, but this term is appropriate only when referring to the gram-negative spectrum; the term broad is more appropriate for third-generation drugs, for which their currently is no veterinary approved example in the United States. The gram-positive spectrum is more selective, and anaerobes, in general, are not susceptible. However, other microbes are targeted, including cell wall-deficient microbes and mycobacterium. Organisms particularly susceptible to FQs include Pasteurella (among the lowest MICs), E. coli, Klebsiella spp. E. cloacae, P. mirabilis, Citrobacter freundii, and S. marcescens. Pseudomonas spp. also is included in the spectrum but generally is characterized by the highest MICs, with efficacy toward Pseudomonas spp. varying with the individual drugs (Table 7-12; see also Tables 7-3 and 7-4).¹⁵⁴ Among the drugs used in dogs or cats, ciprofloxacin, enrofloxacin, and marbofloxacin tend to have the lowest MICs. Ciprofloxacin is most potent toward gram-negative isolates, particularly for E. coli and P. aeruginosa.^{164,166} The gram-positive spectrum includes Staphylococcus spp. and some Corynebacterium. The FQs have exhibited variable efficacy against Streptococcus species and E. faecalis.^{156,167} Other susceptible organisms generally include Campylobacter, Salmonella, Shigella, and Yersinia. Efficacy of the FQs toward leptospirosis is supported by limited studies. Some rickettsial organisms may be susceptible; in vitro data and limited in vivo data indicate potential efficacy against organisms causing ehrlichiosis and Rocky Mountain spotted fever.168

KEY POINT 7-22 The second-generation fluorinated quinolones have a broad gram-negative spectrum and a more limited gram-positive spectrum and are generally not effective toward anaerobes.

Integration of PK and PD of the FQs reveals some differences in predicted efficacy among the FQs used in cats and dogs toward organisms within the spectrum (see Table 7-12).

MIC, Minimum inhibitory concentration; *MPC*, mutant prevention concentration.

Г

Based on PK reported either in the literature or on the package insert, two PDIs were determined: the C_{max}/MIC (target 10) or AUC/MIC (target 125). The PDIs were compared among drugs for the susceptible isolates of each organism at the lowest and highest labeled dose for each drug. In general, at the low dose the only organism for which the target PDIs were reached for all drugs was *E. coli*. For all other organisms, even at the high dose, targets were reached consistently only for ciprofloxacin, enrofloxacin, and marbofloxacin.¹⁵⁴ The authors concluded that the highest dose of the FQ is generally recommended when possible and that enrofloxacin, marbofloxacin, and ciprofloxacin performed in vitro better than difloxacin and marbofloxacin.

Levofloxacin is a human-marketed third-generation FQ that increasingly is being used in dogs and cats. It is twice as potent against gram-positive isolates (topoisomerase IV) and equally potent against gram-negative isolates (DNA gyrase) compared with ciprofloxacin, although more recent data suggest that this is not consistent (see Table 7-4).¹⁶⁹ For example, the MIC_{50/90} (μ g/mL) for human organisms isolated from skin or soft tissue infections are as follows: S. aureus (0.25, > 4), *E. coli* (≤0.03, 4), or *P. aeruginosa* (0.5, >4).¹⁷⁰ The potential efficacy of levofloxacin cannot be assessed for dogs because PK have not been established and neither C_{max} nor AUC is available. Kinetics have been reported for levofloxacin in the cat, but at 10 mg/kg, the C_{max} does not reach the MIC₉₀ for Staphylococcus or Pseudomonas spp. The C_{max}/MIC_{90} is only 1 (rather than the target ≥ 10) for *E. coli*. The target ≥ 10 would be reached based on the MIC₅₀ for *Staphylococcus* spp. and E. coli but not for Pseudomonas spp. The safety of levofloxacin in cats at doses that will be necessary to reach the target PDI has not been established. These data suggest that PK and PD studies are needed in the dog before levofloxacin is used and that the organisms against which levofloxacin is used in cats at the dose of 10 mg/kg should be characterized by an MIC of 0.5 µg/mL or less. Once-daily administration was demonstrated to be more effective against Staphyloccus spp., including an MRSA isolate, compared with twice-daily dosing.169

Anaerobic organisms have been considered generally resistant to the FQs. However, the spectrum of the newer drugs, particularly those substituted at position 8, has been expanded to include anaerobes. Levofloxacin, sparfloxacin, grepafloxacin, and pradofloxacin each has greater activity against anaerobes compared with older drugs. This includes the *B. fragilis* group, as well as *Clostridium, Peptostreptococcus, Prevotella*, and *Fusobacterium* spp.¹⁷¹

The FQs are effective against mycobaterial organisms. However, using *M. tuberculosis* as an example, the MIC (μ g/mL) for the newer FQs are lower compared with the second-generation drugs: 1 μ g/mL for levofloxacin, 0.1 to 0.5 for sparfloxacin, 0.2 to 0.25 for gatifloxacin, and 0.12 to 0.5 for moxifloxacin, compared with 0.5 to 4 for ciprofloxacin.¹⁵⁴ Of the FQs, gatifloxacin and moxifloxacin have been demonstrated to exceed the mutant potential concentration (MPC; see Chapter 8) for *M. tuberculosis*. Like other organisms, and despite their slow growth, the activity of FQs against *Mycobacterium* spp. is concentration dependent. However, tubercular organisms are able to enter a dormant, persistant, and antimicrobial-resistant phase, necessitating long-term therapy.

Each of the veterinary FQs has been approved with a "flexible" dosing regimen, indicating low to high doses, with the choice depending on the MIC of the infecting organism. However, as previously discussed, increasing evidence suggests that the highest concentration should be targeted whenever possible. The concept of the MPC emerged in the context of emerging FQ resistance in mycobacteria. Targeting simply the MIC is likely to select for stepwise mutants (see Chapter 6).¹⁶² Flexibility also occurs for the interval: for enrofloxacin and orbifloxacin, the label allows once- or twice-daily dosing, whereas for marbofloxacin and difloxacin, the dose is limited to once a day. Because FQs are concentration dependent, administration of the total daily dose as a once-daily dose is generally preferred, as has been demonstrated for ciprofloxacin¹⁷³ and levofloxacin.¹⁶⁹ P. aeruginosa is an example of an organism whose tendency toward resistance suggests the higher, oncedaily dose.174 Because efficacy of an FQ is based on AUC/MIC as well as C_{max}/MIC, a second dose (not half the dose twice) might be considered, particularly for selected organisms (e.g., S. aureus).

KEY POINT 7-23 Failure to achieve the mutant prevention concentration (MPC) may allow emergence of multistep mutants.

The amphoteric nature of the FQs complicates the impact of pH on efficacy. For example, difloxacin was shown to be most potent (based on MIC differences) at a pH of 7.1 compared with 5.9 or 7.9, with a fourfold increase in the MIC at the alkaline pH occurring for *E. coli*, *K. pneumoniae*, *P. mirabilis*, and *S. intermedius*.¹⁵⁹

Resistance

A major advantage of the FQs promoted during marketing, was the lack of clinically relevant plasmid-mediated quinolone resistance. Rather, the major mechanism of resistance reflects genetic mutations in the target topoisomerase enzymes (e.g., DNA gyrase [topoisomerase II] and topoisomerase IV). However, several observations dampen the importance of the predominance of mutational, rather than plasmid-mediated, resistance. First, history has demonstrated that resistance of any antimicrobial (plasmid or otherwise) may take several decades of intense antimicrobial use, suggesting that, as with other antimicrobials, the use of FQs ultimately was to be limited by resistance. Secondly, resistance to norfloxacin emerged as little as 3 years after its approval, regardless of the mechanism. This rapid development of resistance foretold a similar problem with other second-generation FQs. Thus, as the medical community enters the third decade of ciprofloxacin use in human medicine and the second decade of FQ use in veterinary medicine, increasing resistance, albeit not necessarily plasmid mediated, has emerged and is limiting the widespread effective use of these drugs in both human and veterinary medicine. Finally, plasmid-mediated resistance has appeared and plays a role in horizontal transmission of FQ resistance.¹⁶⁵ The development of FQ resistance by human bacterial organisms has influenced the decision to ban extralabel use of FQs in food animals or use as food additives (i.e., growth promotants). Clinically, the increasing pattern of resistance for veterinary FQs and ciprofloxacin has emerged toward several organisms, including S. aureus, P. aeruginosa, E. coli, and other gram-negative organisms (see Chapter 6). In chronic otitis of dogs, 14% of S. pseudintermedius cultured from the middle ear and more than 65% of Pseudomonas spp. cultured from the external and middle ear were resistant to enrofloxacin.¹⁷⁵ A prospective study of more than 300 organisms submitted to commercial laboratories found nearly 30% of E. coli resistant to all veterinary FQs, as well as ciprofloxacin. The MIC₉₀ for Pseudomonas surpassed the CLSI MIC breakpoint for all drugs except ciprofloxacin, and for E. coli and Staphylococcus spp. (not including S. intermedius) exceeding it for all drugs by fourfold to eightfold.¹⁵⁴ A subsequent prospective study of more than 350 E. coli isolates (collected from all body tissues, with the vast majority associated with urinary tract infections) found that 30% demonstrated an MIC₉₀ greater than 32 μ g/ mL (MIC breakpoint $\geq 4 \,\mu g/mL$), with regional geographical differences demonstrated.¹⁶⁶ Resistance to FQs is associated with FQ use; in humans a single dose of ciprofloxacin lead to FQ-resistant microorganisms.¹⁶⁷ That FQ resistance can be associated with FQ use in dogs was demonstrated by Debavalya et al.:178 Close to 100% of fecal E. coli developed high level resistance to FQs (associated with multi-drug resistance) within 3 to 9 days of therapy of enrofloxacin in dogs (5 mg/kg every 24 hours).

Susceptibility data from laboratories that test both ciprofloxacin and enrofloxacin may report susceptibility to ciprofloxacin but resistance to enrofloxacin. Interpretive standards on culture reports for ciprofloxacin are based on human data and may not take into account differences in oral bioavailability, just as standards for enrofloxacin do not include bioactivity contributed by ciprofloxacin. Although ciprofloxacin is more potent toward E. coli and Pseudomonas aeruginosa compared to enrofloxacin, the difference is usually within 1 tube dilution. A prospective study compared the proportion of resistance and the relative susceptibility (efficacy) among ciprofloxacin, difloxacin, enrofloxacin (alone or with ciprofloxacin), marbofloxacin, and orbifloxacin FQs toward six organisms collected from canine and feline patients.¹⁵⁴ The proportion of resistant isolates, which was based on CLSI interpretive criteria, did not differ among drugs, suggesting that expression of resistance by an isolate to one (second-generation) FQ might be prudently interpreted as resistance to all, despite the not uncommon finding of susceptibility to ciprofloxacin and resistance to another FQ (e.g., enrofloxacin).

Three major mechanisms of FQ resistance have been identified,^{55,167} with the most studied being changes in the structure of the target topoisomerase enzymes. However, mutations, which impart resistance within the FQ class of drugs, are often accompanied by decreased expression of porin membranes and increased activity of efflux pumps, which imparts multidrug resistance.^{155,169} Thus far, resistance

to FQs acquired through changes in DNA gyrase has been documented clinically only after chromosomal point mutations; at least 10 different mutations have been identified so far. Resistance is stepwise, with the first step occurring primarily through mutations that reduce FQ affinity for the preferred topoisomerase target, which varies with the organism. Gram-negative bacteria tend to more commonly target DNA gyrase; changes occur more often in the GyrA subunit compared with GyrB.141 The primary target of gram-positive organisms tends to be changes in topoisomerase IV, targeting parC and parE followed by changes in DNA gyrase. Recent evidence suggests that the drug (and its primary target) select for the mechanism of resistance.141 High-level resistance generally reflects a second step mutation that leads to additional changes in the amino acid sequence of either (the alternate) topoisomerase target, thus further decreasing affinity, or the generation of efflux pump mechanisms. The MIC of the organisms progressively increases with each step. The role of reduced porin membranes and efflux pumps in FQ resistance was more recently discovered. Gram-negative isolates are associated with both mechanisms of reduced drug accumulation (i.e., porins and pumps), as well as decreased lipids in the lipopolysaccharide covering, impeding drug transport; gram-positive isolates (S. aureus) have been associated with increased drug efflux.145,147,167 The efflux pumps affect multiple drugs, contributing to multidrug resistance, including resistance to drugs structurally unrelated to FQs.^{167,169, 169a} These include tetracyclines, phenicols, and macrolides. Betalactams may also be involved; resistance to antiseptics and disinfectants may occur. Expression of the pump is chromosomally mediated. For example, mutations in the mar operon may induce the acrAB proteins of a stress-induced efflux pump, resulting in high-level resistance, even for isolates with no or single mutations in topoisomerase.¹⁵⁵ Plasmid-mediated quinolone resistance (PMQR), associated with the *qnr* gene, has recently been identified in clinical bacterial isolates, generally associated with class I integrons. However, while initially rare, in 2003, several strains of E. coli and Klebsiella spp. were found to transmit qnr resistance, and isolates have since been identified in the United States. The author has reported a high incidence of PMQR in clinical canine and feline E. coli isolates.^{165a} Resistance mediated by PMQR and qnr tends to be low level and thus may be difficult to detect on C&S testing. Mechanisms include production of a protein that prevents quinolone binding to the target, and enzymatic destruction of the drug. Its impact appears to be related to its ability to increase the incidence of spontaneous mutations and facilitation of altered porin or efflux protein activity. Despite its low level, PMQR resistance associated with qnr appears to affect other drug classes, including cephalosporins (including second- and third-generation), aminoglycosides, and potentiated sulfonamides.

The emergence of stepwise resistance is generally indicated by an increase in the MIC of the organism toward the drug. In human medicine, isolates characterized by an MIC greater than 0.125 μ g/mL for ciprofloxacin are treated as "reduced susceptibility," indicating that a first step toward mutation (or

resistance) has occurred, whereas isolates greater than 2 µg/ mL are considered to have "high-level" resistance.¹⁶⁵ These reports are likely, in part, to be the basis of "susceptible" MIC breakpoint promulgated by CLSI. However, it is important to note that despite a susceptible designation for some isolates, reduced susceptibility is an indication that resistance has begun and use of a FQ should be done cautiously and judiciously. Actions such as using a second dose or using the drug in combination with a second, synergistic drug should be strongly considered. Current clinical microbiology laboratories often do not perform susceptibility testing at concentrations below 0.125 to 0.25 µg/mL for FQs, thus precluding the identification of isolates that are characterized by reduced susceptibility. Thus it is important to note that reduced susceptibility to an FQ of intererest may characterize a "susceptible" isolate, and use of FQs should be done judiciously.

The term MPC was coined after substantial evidence emerged that resistance to FQs reflects multistep or stepwise selection of mutants when the FQ is used therapeutically at a dose that targets the MIC of a cultured infecting microble (see Chapter 6).¹⁷² At drug concentrations below the MPC, first step mutants will continue to grow in the absence of effective host response, and may replace the wild-type (nonmutant) population.¹⁸⁰ Consequently, the MPC, rather than the MIC, ideally is targeted with drug therapy. Predicting the MPC on the basis of MIC is not possible; the relationship between the two appears to be larger for gram-positive than gram-negative isolates, and varies among the FQs (see Table 7-12).¹⁸⁰ Among the veterinary FQs, using quality assurance isolates, the ratio of MPC to MIC seems to be similar for gram-negative isolates, being less than 10, and the MPC might be reasonably targeted with doses that are within recommendations based on a C_{max}/ MIC ratio of 10. However, Pasquali¹⁸¹ demonstrated that the MPC/MIC for E. coli was fourfold to sixteenfold higher for enrofloxacin compared with ciprofloxacin. In this study the authors found that targeting the MPC for P. aeruginosa was not effective, postulating that the reason reflects efflux pump activity rather than point mutation (the basis of the MPC theory) as the major mechanism of resistance. Enrofloxacin and pradofloxacin have the lowest MPC/MIC ratio for grampositive isolates; concentrations necessary to target the MPC for gram-positive isolates may be achievable with these drugs but may not be achievable at recommended doses, particularly for difloxacin and orbifloxacin. Use of the highest dose of any FQ is recommended because of the risk of resistance. If reduced susceptibility is suspected (e.g., MIC > $0.25 \ \mu g/mL$), then the addition of a second dose or use as part of combination therapy might be prudent. Combination therapy has been described as a mechanism to reduce emergent resistance to FQs. For example, in an in vitro model, rifampin prevented emergence of resistance to ciprofloxacin.¹⁶⁹ The addition of a FQ decreased the advent of resistance to cephalosporins in another study.182

Newer drugs, including gemifloxacin, trovafloxacin, gatifloxacin, and pradofloxacin, may target both DNA gyrase and topoisomerase IV. Thus for these drugs, multistep resistance may be necessary to neutralize their antibacterial effects. Newer FQs appear to avoid resistance because their stereochemistry interferes with altered porin sizes and efflux mechanism. For example, for pradofloxacin the cyclopropyl ring at N1 provides bacterial killing, but the diazabicyclononyl moiety at C7 appears to physically block porins.¹⁵⁴ Wetzstein¹⁸⁰ compared the MPCs for older and newer FQs. That resistance may be more likely with older compared with newer drugs was suggested by an in vitro study,¹⁶⁹ in which resistance could be induced for ciprofloxacin but not levofloxacin. However, surveillance studies in humans infected with Streptoccocus spp. as well as other isolates, report variable findings, including lower, similar, or higher rates of resistance for levofloxacin, compared with ciprofloxacin.^{169,183,184} Because resistance is likely to emerge even to the newer FQs, use based on C&S testing and design of a dosing regimen that targets the MPC as much as possible is prudent.

FQ resistance by *Mycobacterium* spp. occurs primarily as part of multidrug-resistant tuberculosis, which develops when an FQ is used as the only active agent in a failing multidrug regimen.¹⁵⁴ Thus combination with traditional antitubercular drugs (isoniazid, rifampin) enhances antimicrobial efficacy.¹⁵⁴

Pharmacokinetics

The PK of the veterinary FQs are largely comparable among the drugs, particularly if structurally similar, although individual differences may become important for some infections. Maximum drug concentrations of the FQs do not always increase linearly with dose (see Table 7-1) This may reflect, for some drugs, variability in peak concentrations measured among different investigators, including different analytical methods. In particular, attention must be paid to the method of drug detection, with those based on bioactivity (i.e., bioassay) frequently yielding higher concentrations if an active metabolite is present (e.g., enrofloxacin and ciprofloxacin).

KEY POINT 7-24 The fluorinated quinolones are characterized by good to excellent tissue distribution because of their lipid solubility and accumulation in phagocytic white blood cells.

The only injectable preparation approved for dogs is for enrofloxacin, although an injectable preparation is available for human FQs, including ciprofloxacin. All remaining veterinary FQs approved in dogs or cats are available for oral administration. Enrofloxacin is available as a topical combination preparation. Marbofloxacin, enrofloxacin, difloxacin, and orbifloxacin are characterized by close to 100% oral bioavailability in young adult animals. A number of factors, however, influence absorption of FQs in general, and several drugs specifically. Magnesium and aluminum decrease oral absorption, and food may also, which may be undesirable for concentration-dependent drugs. The oral bioavailiabity of FQs may not be predictable, with extrapolation among species not recommended. For example, norfloxacin is characterized by 60% or less oral bioavailability in dog, and ciprofloxacin, generally less than 60%. Extrapolation of levofloxacin between humans and cats appears to be more appropriate than that of

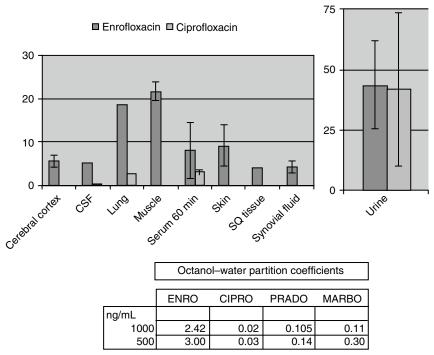

Figure 7-10 Selected tissue homogenate concentrations of enrofloxacin 2 hours after intravenous administration of 20 mg/kg. Concentrations in fluids are most relevant to bacterial exposure. Ciprofloxacin concentrations reflect metabolism of enrofloxacin to ciprofloxacin. Octanol–water partition coefficients suggest that enrofloxacin would distribute best into fluids at physiologic pH.

ciprofloxacin. Oral absorption also may be impaired in neonates, as has been demonstrated for enrofloxacin.¹⁸⁵

As a class, the FQs are well distributed to most body tissues (see Table 7-5). Protein binding of enrofloxacin, ciprofloxacin, and marbofloxacin in dogs is $34 \pm 2\%$, $18.5 \pm 2\%$, and 21 \pm 6%, respectively.¹⁷⁶ Although the Vd of the drugs ranges from a low of 1.12 (marbofloxacin) to a high of 3.2 (difloxacin), the clinical relevance of these differences is not likely to be a sufficient cause to select one over another. The respective PCs for selected FQs have been variably reported, with enrofloxacin characterized by the highest lipophilicity of the three: 2.4, 0.02, and 0.11;187 and 3.54, 0.07, and 0.08, for enrofloxacin, ciprofloxacin, and marbofloxacin, respectively (Figure 7-10).¹⁷⁶ However, as with Vd, predicting tissue distribution based on PC is difficult. This reflects, in part, the common use of homogenate data for solid tissues. Homogenate data include both interstitial fluid and ICF. As such, drugs that penetrate cell membranes and accumulate in cells, not necessarily in active form, may be characterized by higher concentrations compared with drugs that distribute to interstitial fluid only. Intracellular trapping of drugs may limit access to microbes in interstitial fluid, although movement from the cell back into interstitial fluid may prolong the presence of drug in interstitial fluid by slow release from the cell. The relevance of the data is then influenced by the location of the infection (i.e., intracellular versus extracellular) and host (e.g., inflammation) or microbial (e.g., biofilm) factors that might affect efficacy. Fluid tissue concentrations (based on homogenate data) are generally greater in organs of elimination compared with plasma for all FQs. Solid tissue concentrations are often higher (e.g., if drug is trapped in the cells), particularly for

the liver and kidney (organs of elimination) but also spleen and lung (perhaps reflecting phagocytic cell accumulation), prostate (perhaps reflecting ion trapping), and muscle^{161,188} Homogenate tissue data are available on the package inserts of several of the veterinary approved FQs. Interestingly, the concentration of difloxacin in cortical bone (but not bone marrow), exceeds that in plasma by threefold, but did not change across a 24-hour period. This might suggest that FQs (or difloxacin) bind to bone, which may preclude activity. Frazier and coworkers¹⁸⁹ compared the disposition and homogenate tissue concentrations of difloxacin (5 mg/kg), enrofloxacin (5 mg/kg; ciprofloxacin also measured), and marbofloxacin (2.75 mg/kg) after multiple dosing (5 days) in the same dogs using a randomized crossover design (21 day washout period); drugs were detected using HPLC. Their studies demonstrate that the FQs accumulate in tissues with multiple dosing. Concentrations increased in the skin to reach a 4-day peak that exceeded the 1-day concentration by at least threefold. The concentrations in skin (µg/mL) at 1 and 4 days were, respectively, as follows: marbofloxacin (1.87 and 4.9), enrofloxacin (1.38 and 5.99), ciprofloxacin (0.2 and 0.5 for a total bioactivity of 1.59 and 6.9), and difloxacin (1 and 3.8). Urine concentrations also were higher at day 4 compared to day 1, with the magnitude varying for each drug. The concentrations in urine (µg/mL) were at 24 and 98 hours, respectively: marbofloxacin (14 and 50), enrofloxacin (0.14 and 1.83) plus ciprofloxacin (5.61 and 33.3 for a total bioactivity of 5.9 and 39), and difloxacin (0.56 and 1.8).

Homgenate data has been reported for enrofloxacin in anesthestized dogs (n = 4) receiving 20 mg/kg of enroflxoacin IV dogs.¹⁸⁸ The 1- and 2-hour serum concentrations

Table 7-1 3	Serum Ra	Concentrations and Tissue to Serum Ratio for Enrofloxacin and Ciprofloxacin*													
	Enrofloxacin	.	Ciprofloxacin	-											
Tissue	(μg/mL)	Ratio	(μ g/mL)	Ratio

Serum	1433	1.0	230.85	1.0											

*3 hours after 4 days of oral and 1 day of intravenous 5 mg/kg enrofloxacin.

were 8.2 and 6.4 µg/mL (ciprofloxacin 3.1 and 2.8 µg/mL), respectively. Homogenate tissue to plasma ratios at 2 hours from lowest to highest were, in order, tracheal cartilage (0.2), aqueous humor (0.3), synovial fluid and subcutaneous tissue (0.4), peritonenal fluid and CSF (0.5), and brain (0.6).¹⁷⁸ For fluids located in sanctuaries, at 1 hour aqueous humor (n = 2)achieved 2.5 µg/mL enrofloxacin and 0.5 µg/mL ciprofloxacin; peak CSF concentration of 5.3 µg/mL occurred at 2 hours (one dog). For aqueous humor a second study documented, 0.23 µg/mL of enrofloxacin and 0.064 µg/mL of ciprofloxacin 3 hours after 4 days of oral and 1 day of intravenous dosing at 5 mg/kg.¹⁸⁰ The ratio of tissue to plasma concentrations were similar for ciprofloxacin and enrofloxacin (see Table 7-13). Another study documented that marbofloxacin (2 mg/kg, administered intravenously) achieves 0.41 µg/mL in aqueous humor at 3.5 hours in dogs.¹⁹¹ Other ratios of plasma to tissue enrofloxacin after 20 mg/kg administered intravenously¹⁹² included ligament (0.6), ear cartilage (0.7), and bone marrow (0.8). Concentrations in the prostate were 2.5fold higher and urine 4.5-fold higher than in plasma (urine concentration of 45 µg/mL). Interstitial fluid concentrations of enrofloxacin (and formed ciprofloxacin) and marbofloxacin have also been measured using ultrafiltration. After 10 mg/kg enrofloxacin administered intravenously, the ratio of C_{max} in interstitial fluid (2.41 µg/mL) compared with plasma (5.54 μ g/mL) was 0.47; the ratio for AUC, however, was 1.3, indicating that the drug appears to stay longer in interstitial fluid compared with plasma.¹⁷⁷ A second study¹⁷⁶ determined plasma to interstitial fluid ratios after 5 mg/kg, administered orally, for marbofloxacin (approximating the highest labeled dose) and enrofloxacin (the lowest once-daily dose). Plasma to interstitial fluid C_{max} ratio was 0.75 for marbofloxacin and 0.7 for enrofloxacin plus ciprofloxacin and for AUC was 1.11, for marbofloxacin and 1.3 for enrofloxacin and ciprofloxacin. The higher AUC for marbofloxacin reflected in part the higher C_{max} but also a longer elimination half-life (8.5 hours) compared with enrofloxacin (3 hours). All FQs that have been studied thus far (enrofloxacin, marbofloxacin, pradofloxacin, and ciprofloxacin) accumulate in phagocytic WBCs; concentrations may be up to 140-fold higher compared with plasma

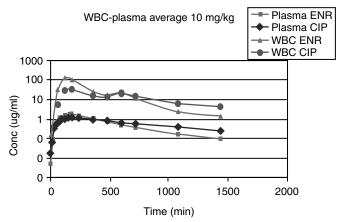

Figure 7-11 Enrofloxacin is metabolized by de-ethylation to ciprofloxacin. The two compounds will act in an additive fashion. The dotted line in the top graph indicates the predicted amount of bioactivity resulting from both enrofloxacin and its active metabolite, ciprofloxacin, after administration of 10 mg/kg. The longer half-life of ciprofloxacin can contribute to a longer duration. The graph demonstrates the accumulation of both enrofloxacin and ciprofloxacin in white blood cells (top two plots).

(see Table 7-5).^{164,193–196} Drug in phagocytes will be distributed to sites of inflammation, thus increasing concentrations at the site of infection.¹⁹⁶ Impact on intracellular killing is controversial. Whereas some studies have demonstrated that FQs retain intracellular killing effects compared with macrolides,¹⁹⁷ another in vitro study demonstrated reduced intracellular killing ability for a variety of FQs.¹⁸⁴

KEY POINT 7-25 The bioactivity of enrofloxacin can be doubled by formation of its more potent metabolite, ciprofloxacin.

The organ of elimination varies among the FQs. Difloxacin is eliminated almost exclusively by hepatic metabolism to inactive metabolites. Orbifloxacin is 40% eliminated unchanged in the urine. Marbofloxacin (clearance of 1.6 L/min) is largely excreted into the urine. However, up to 15% is metabolized in the liver to inactive metabolites,198 with the proportion changing in the presence of renal disease.¹⁹⁸ Enrofloxacin also is eliminated in the urine as the unchanged drug, although approximately 25% of the drug is metabolized to ciprofloxacin, which subsequently achieves concentrations severalfold higher than enrofloxacin (Figure 7-11; see also Figure 7-8 and Table 7-13). Therapeutic concentrations of ciprofloxacin can be achieved in other tissues after administration of enrofloxacin, depending on the target organism.^{161,193,199} The parent and metabolite should act in an additive fashion.¹⁶⁰ Because ciprofloxacin is characterized by a longer half-life than enrofloxacin in dogs (see Table 7-1), as a metabolite, ciprofloxacin can double the AUC of enrofloxacin bioactivity (see Table 7-1 and Figure 7-11).¹⁹³ Longer elimination half-lives also characterize difloxacin and marbofloxacin compared with orbifloxacin and enrofloxacin, contributing to higher AUC for these drugs (see Table 7-1). Elimination half-lives are somewhat dose dependent,193 at least for enrofloxacin and ciprofloxacin (see Table 7-1). Alkaline urine increases the passive reabsorption of FQs from the renal tubules and may also prolong the elimination half-life. The longer half-lives should increase efficacy by increasing the likelihood that the drug will achieve the target AUC/MIC. Heinen²⁰⁰ compared PDIs among the FQs after oral administration, using a bioassay that detects both parent compound and active metabolites (see Table 7-1). Based on MIC_{90} determined for E. coli and Staphyloccoccus spp. (from isolates before 1999), for no drug was the targeted AUC/MIC achieved for Staphylococcus spp. and only enrofloxacin achieved the C_{max}/MIC for Staphylococcus spp. Enrofloxacin (5 mg/kg) had the highest C_{max}/MIC toward E. coli, followed by marbofloxacin (2 mg/kg) and orbifloxacin (2.5 mg/kg); difloxacin (5 mg/kg) did not reach the targeted C_{max}/MIC or AUC/MIC for either organism. A similar pattern of efficacy was found among the veterinary FQs by Boothe using isolate MIC and reported C_{max}^{164} with enrofloxacin plus ciprofloxacin > ciprofloxacin > marbofloxacin > orbifloxacin > difloxacin being the general pattern of magnitude in PDI. However, the higher dose was generally needed to reach desired targets for PK/PD indices; isolates had been collected from 1998 to 2000 suggesting the likelihood of achieving targeted PDI with current isolates is less likely.

The disposition of enrofloxacin in neonatal kittens differs from that in adults, appearing to be age dependent even in the pediatric patient.¹⁸⁵ Administration of 5 mg/kg to 2- to 8-week-old kittens¹⁸⁵ revealed a shorter half-life at all ages but a Vd_{ss} that was less at 2 to 4 weeks and greater at 6 to 8 weeks compared with that of adults. Accordingly, C_{max} was lower in the 6- to 8-week-old kittens. Enrofloxacin was generally poorly bioavailable at all ages.

Pradofloxacin. Pradofloxacin is a newer-generation FQ that may be undergoing approval in animals in the United States and the European Union. Structurally, it is characterized by a cyclopropyl ring at N1 (see Figure 7-8) that increases bacterial killing. A diazabicyclononyl moiety at C7 appears to physically block drug efflux through porins and targets both topoisomerases such that mutation must be multistep.¹⁵⁴ Its spectrum includes P. aeruginosa. However, many anaerobes also will be effectively targeted. At 3 mg/kg orally for 5 days in dogs, C_{max} was 1.7 ± 0.9 µg/mL and 6.2 ± 2.3 μ g/mL in dogs (n = 6); half-life was 10 ± 7 hr at 3 mg/kg and 5.9 \pm 1.5 hr at 12 mg/kg.¹⁹⁰ The long half-life results in an AUC/MIC that is favorable compared with the other FQs. Pradofloxacin also has been studied in anesthetized dogs. It appears to be well distributed among the tissues.¹⁹⁰ Aqueous humor concentrations achieved 0.32 µg/mL after 5 days of administration (4 oral followed by 1 IV) at 5 mg/kg of pradofloxacin.

Ciprofloxacin. Although ciprofloxacin has been studied in dogs following intravenous and oral²⁰² administration (Table 7.1), the studies used different animals, and limited information is available on its oral bioavailability in dogs. However, reports provided by the manufacturer indicate that ciprofloxacin is only 33% to 40% bioavailable in dogs²⁰³ compared with nearly 80% to 100% in humans. Oral absorption

of ciprofloxacin in dogs involves a dose-dependent nonlinear component that may affect its oral absorption.²⁰² Oral and bioavailability of ciprofloxacin in cats (using pure powder in gelatin capsules) appears to be less than that in dogs, being $20\% \pm 11\%$ following single dosing and $33\% \pm 12\%$ after multiple dosing.²⁰⁵ Oral absorption was characterized by marked interanimal variability, suggesting that oral absorption may be minimal in some cats.²⁰⁵ This suggests that oral ciprofloxacin should be avoided in cats, and oral dosing in both cats and dogs should err on the side of higher doses to compensate for unpredictable oral bioavailability. More than several human-marketed generic preparations of oral ciprofloxacin are now available at a greatly reduced cost compared with oral enrofloxacin. However, whereas bioequivalence of a generic product must be proved to the pioneer product, this proof is generated only in the species in which the drug is approved. That the PK behavior of an orally administered generic drug will behave the same way in a nonapproved species should not be assumed.

The disposition of ciprofloxacin has been described in cats after intravenous administration of 10 mg/kg (see Table 7-1). In cats Vd_{ss} of ciprofloxacin is 3.85 ± 1.34 L/k, and plasma clearance is 0.64 ± 0.28 L/hr/kg, which exceeds the normal feline glomerular filtration rate (0.15-0.25 L/h/kg), suggesting that active tubular secretion occurs.²⁰⁶ AUCs after intravenous and oral administration are 17 ± 5 and $3 \pm 1.2 \mu$ g*hr/mL, respectively, in cats. Drug accumulation was not significant after seven oral administrations.²⁰⁵ Ciprofloxacin is metabolized into active (in humans) and inactive metabolites (N-oxide [the primary metabolite in dogs] and N-desmethyl). However, high concentrations of unchanged drug are achieved in urine, as is demonstrated after administration of enrofloxacin (see Figure 7-10).

Levofloxacin. Levofloxacin is the optical S-isomer of the racemic drug substance ofloxacin (see Figure 7-8). Compared with older FQs, its spectrum includes mycoplasma and gramnegative organisms, but the spectrum is broader toward grampositive organisms and includes anaerobes.²⁰⁷ Ofloxacin is marketed as the levo isomer (i.e., levofloxacin) rather than the racemic mixture because the L-isomer is much more active against bacterial pathogens than the R-isomer. In humans levofloxacin is well absorbed orally, is distributed to a volume of 1.1 L/kg, and is renally excreted. Concentrations in the CSF approximate 16% of that in plasma, suggesting that the drug may not be well distributed into sanctuaries. Excretion is correlated with creatinine clearance, and half-life is prolonged with renal disease, requiring dose adjustments in patients with significant renal dysfunction.²⁰⁸

Because of its spectrum and improved antibacterial activity compared with veterinary FQs, levofloxacin has been used anecdotally in dogs but does not appear to have been studied in dogs. However, ofloxacin (but not its isomers) has been studied after oral administration in young and mature Beagles.²⁰⁹ Peak concentrations (measured by HPLC) at 20 mg/kg were $14.2 \pm 0.4 \mu$ g/mL. The dispositions of the L-and D-isomer are likely to differ, precluding prediction of the proportion of the C_{max} represented by levofloxacin. However, even if 100% of the drug is the L-isomer, concentrations are still well below the MIC_{90} of levofloxacin. The disposition of levofloxacin has been well described in cats on the basis of a bioassay after intravenous and oral administration,²¹⁰ and it does not appear to be substantially different from that in humans. In cats the drug is well, albeit slowly, absorbed orally (T_{max} 1.6 hours), with bioavailability at 87%. The drug is rapidly distributed, reaching a Vd_{ss} of 1.75 L/kg; clearance is 0.14 L*hr/kg, and mean residence time is 13 hours (see Table 7-1). The C_{max} following oral administration was 4.7 µg/mL, indicating that the drug should be used in cats only for organisms with an MIC of 0.5 µg/mL or less.

Drug Interactions

The FQs inhibit selected hepatic drug-metabolizing enzymes and are known to prolong the elimination of selected drugs. Theophylline toxicity has been documented in humans and dogs (see Chapter 2) simultaneously receiving theophylline and ciprofloxacin or enrofloxacin.²¹¹ Marbofloxacin also impairs the elimination of theophylline in dogs, but the effect is dose dependent, being absent at 2 mg/kg. However, at 5 mg/kg, theophylline clearance is decreased by 26% (compared with 50% reduction by enrofloxacin at 5 mg/kg IV once a day for 5 days), resulting in a change in theophylline halflife from 3.6 to 5.4 hours and a change in C_{max} from 32 (no marbofloxacin) to 44 µg/mL (5 mg/kg marbofloxacin).²¹² Ciprofloxacin has been associated with increased cyclosporine concentrations, prolonged anticoagulant effects of warfarin, and enhanced hypoglycemic effects of oral hypoglycemics and insulin. Presumably, enrofloxacin and other FQs might have similar effects. Because of chelation by magnesium, calcium, and other cations, drugs such as antacids, sucralfate, and multiple vitamins should not be administered orally at the same time as a FQ. Because FQs competitively inhibit gamma-aminobutyric acid receptor binding, drugs that act similarly (e.g., selected nonsteroidal antiinflammatory drugs) when used in combination may increase the risk of seizural or other CNS activity. Enrofloxacin has been associated with false glucosuria.77

KEY POINT 7-26 Fluorinated quinolones can impair the metabolism of selected drugs.

The use of FQs in combination with other antimicrobials may result in synergistic activity (e.g., aminoglycosides for gram-negative organisms; beta-lactams for gram-positive or gram-negative organisms) (see Chapter 6) or antagonistic (e.g., ribosomal inhibitors).

Adverse Effects

Adverse reactions to the FQs do not reflect interaction with mammalian topoisomerases. Most adverse reactions are predictable and can be prevented with proper administration. Gastrointestinal upset manifested by vomiting, nausea, and possibly diarrhea may occur after any route of administration but particularly oral administration. The intramuscular administration of enrofloxacin frequently causes pain on injection. Nausea and vomiting have been reported when the intramuscular solution is given intravenously and may reflect mast cell degranulation and histamine release. The intramuscular solution also is very alkaline (pH 10). Diluting the drug in saline and administering it over a 30-minute period may reduce nausea and clinical signs consistent with an anaphylactoid response. FQs have been associated with allergic reactions; however, the lack of previous exposure in some (human) patients (and in the author's experience with ciprofloxacin) suggests an anaphylactoid rather than anaphylactic reaction.²¹³Acute cardiovascular toxicity (hypotension, decreased left ventricular function) has been described for levofloxacin (Freedom of Information [FOI]) after an intravenous bolus (≥ 6 mg/kg) or intravenous infusion (≥ 20 mg/kg, but not ≤10 mg/kg). Increased circulating histamine concentrations accompanied the high-dose intravenous infusion, indicating a potential anaphylactoid reaction at 10, 15, 30, and 60 mg/kg intravenous bolus. Death occurred in dogs in association with neurologic and cardiac signs at 200 mg/kg, administered intravenously. Enrofloxacin also is available as a more concentrated solution (100 mg/mL) approved for use in cattle. However, it is prepared an an arganine-based vehicle, which is painful on injection and will cause perivascular inflammation if given parenterally by any route other than intravenous. Ulcers may occur if the large animal prepration is given orally.

Cartilage deformities and ligament and tendon repair. The FQs are associated with cartilage damage in dogs (and other species) (see package inserts). Enrofloxacin's original package insert cited clinical signs indicative of cartilage damage in Beagle puppies within 3 days of treatment at 12.5 mg/kg. Lesions have been documented in dogs treated with other FQs. For levofloxacin, arthropathies occurred in juvenile dogs at $\geq 10 \text{ mg/kg/day}$ for 7 days (FOI). Lesions in adult dogs require much higher concentrations, as was demonstrated for levofloxacin: the no-observed-effect level was 3 mg/kg/day in normal 7- to 8-month-old dogs compared with 30 mg/kg/day in normal 18-month-old dogs. The arthropathic potential of ofloxacin (the racemic mixture of levo and the R-isomer of ofloxacin) also has been studied in dogs.²⁰⁹ At 20 mg/kg for 8 days, eight out of eight 3-month-old animals developed histologic lesions, whereas only two developed clinical signs; the associated serum ofloxacin concentration was 14 µg/mL. The mechanism of cartilage damage is not known, although the most likely mechanism appears to be chelation of magnesium ions leading to dysfunction of integrins. These cell membrane proteins regulate a variety of cellular functions, including chondrocyte adherence to extracellular matrix and proteoglycan synthesis.²¹⁵ Magnesium-deficient diets in juvenile rats led to cartilage damage similar to that caused by FQs.²¹⁶ Indeed, magnesium supplementation may reverse the effects of FQs on canine chondrocytes.²¹⁷ Dogs may be among the most sensitive and the most likely to exhibit clinical lameness caused by FQ-induced cartilage damage.²⁰⁴ Note that cartilage lesions as a result of FQs might be considered when FQs are used in any situation that involves growing or repairing cartilage, such as septic or immune-mediated arthritis and potentially osteoarthritis. Lesions have also been reported in other The FQs appear to negatively affect healing in damaged ligaments.²¹⁹ Connective tissue proteins decreased by up to 73% in dogs treated with as little as 30 to 200 mg/kg ciprofloxacin orally. Lesions were similar to those produced in magnesiumdeficient dogs, suggesting that FQs induce tendon or ligament damage by antagonizing magnesium effects in the affected tissues.

The impact of FQs on bone repair also may be of concern. Based on experimental fracture healing in rats receiving placebo, cefazolin, or ciprofloxacin (50 mg/kg every 12 hours subcutaneously for any of the aforementioned drugs), fracture callus healing appeared to be impaired by FQs.²¹⁸ In vivo studies in dogs of the effects of ciprofloxacin at 30 to 200 mg/kg/day orally (equivalent to approximately 15 to 65 mg/kg bioavailable drug) in dogs on either a normal or magnesiumdeficient diet found a number of proteins were decreased in both groups at all doses, including collagen, elastin, and fibronectin.²¹⁹ Of these effects, the authors concluded that magnesium deficiency increases the risk of impaired healing in the presence of FQs.

Seizures and other central nervous system disorders. Seizures and other CNS disorders have been precipitated in human and veterinary patients²²⁰ and animal models receiving FQs;²²¹ predisposing factors include a preepileptic state, high doses, and concurrent use of nonsteroida1 antiinflammatory drugs.²²⁰ Newer drugs may be more likely to cause CNS side effects.²²² FQs (and imipenem) inhibit GABA release, leading to hyperexcitability;⁷⁶ inhibition of N-methyl-D-aspartate or adenosine may also be involved.¹⁴³ FQs also lower seizure threshold and impede neuromuscular transmission. Peripheral neuropathies are a recognized side effect of FQs in humans.^{13,223} Clinical signs in humans have been described as severe, involving multiple organs. Onset is described as rapid (within 24 hours of onset of therapy; 84% afflicted within 1 week) and long term in duration, with symptoms lasting more than 3 months in 71% of afflicted patients and more than 1 year in 58%. The majority of cases involved levofloxacin (64%), despite ciprofloxacin (21%) being the most commonly prescribed drug. The most frequent complaints included both sensory (tingling, burning, or numbness) and motor (musculoskletal, cardiovascular, skin, gastrointestinal [cramping]) abnormalities; symptoms were described as severe in 80% of the patients.

Dose-dependent retinal degeneration. Dose-dependent retinal degeneration has been associated with use of FQs in cats. The incidence of ocular toxicity is very rare, occurring in 1 of 125,000 cats receiving enrofloxacin. The incidence at high doses is sufficiently low that toxicity was not detected in preapproval toxicity studies. During preapproval in cats, 25 mg/kg/ day for 30 days and 125 mg/kg for 5 days were not associated with detectable toxicity. It is not clear whether ocular toxic specific outcomes were addressed. Doses in clinical reports²²⁴ in which ocular toxicity occurred (retrospective study) ranged

from 4.6 to 54 mg/kg/day, with duration of dosing ranging fom 4 to 120 days. Clinical signs began with mydriasis, rapidly followed by acute blindness. Age may be a factor, with cats younger than 9 years seemingly requiring a higher (>20 mg/ kg) dose. Diseases associated with changes in disposition that might result in high plasma enrofloxacin concentrations (e.g., renal disease, heart disease) may also increase the risk. Intravenous administration may increase the risk, further supporting the concentration dependence of toxicity.

Experimental studies by Bayer Animal Health in young, apparently healthy cats at 5, 20, and 50 mg/kg/day for 21 days found electroretinography changes in one of six cats at 20 mg/kg and severe changes in six of six cats within 1 week at 50 mg/kg. Manufacturers of other veterinary FQs have likewise performed follow-up ocular toxicity studies. Marbofloxacin was not associated with lesions in young cats treated with up to 27 mg/kg/day for 6 weeks or 55 mg/kg/day for 14 days. Orbifloxacin was not associated with lesions at 15 mg/kg/day orally for 30 days, but changes occurred at 45 and 75 mg/kg.²²⁵

KEY POINT 7-27 Among the fluorinated quinolones currently approved for use in cats in the United States, marbofloxacin appears to be the least likely to cause retinal degeneration in cats.

The mechanism of ocular toxicity appears to reflect a mutation in four amino acids of an efflux protein in the blood-retina barrier, rendering it ineffective. Effective protein activity is absent in all cats. (personal communication, Dr. Katrina Mealey, Washington State University). The FQs are structurally similar to compounds known to cause accumulation in lysosomes of retinal pigment cells and subsequent ocular toxicity. Additionally, FQs have a predilection for pigmented cells of the eye. The FQs also have been associated with phototoxicity. The combination of FQs with ultraviolet radiation produces both a time- and concentration-dependent ocular toxicity, with a methyl group at position 8 of the quinolone ring reducing the risk.²²⁶ Reducing exposure to sunlight (dosing at night, or keeping cats indoors) might be prudent for cats receiving FQs.

Induction of bacteriophage supergenes. Induction of bacteriophage supergenes has been associated with the use of FQs, and in dog bacterial isolates, specifically enrofloxacin. Shortly after approval of enrofloxacin in Canada, seven canine cases of streptococcal toxic shock syndrome (STSS) and/or necrotizing fasciitis (NF) were reported; four of the dogs had been treated with enrofloxacin in the early stages of infection. Treatment was not only ineffective, but the syndrome appeared to be worsened by the antimicrobial therapy.²²⁷ Further investigation has provided some insight into the possible relationships between STSS and NF and bacteriophage supergenes in S. canis. Using polymerase chain reaction analysis, 22 of 23 S. canis isolates in one study exhibited a bacteriophageencoded streptococcal superantigen gene. Under culture conditions, induction of the bacteriophage by enrofloxacin at therapeutic concentrations resulted in a 58-fold enhancement of expression of the gene.²²⁸ Apparently, the FQ stimulates autoingestion of a repressor protein that otherwise would prevent the bacteriophage from becoming lytic. FQs apparently also can induce bacteriophage lysis and enhanced Shiga toxin production in *E. coli*. For example, ciprofloxacin-treated mice experimentally colonized by Shiga-toxigenic *E. coli* died while their untreated colonized cohorts did not; increased Shiga toxin was demonstrated in their feces. However, induction requires ideal conditions, being dependent in part on stage and rate of growth and ideal drug concentration; conditions favoring bacteriophage induction in clinical patients have not yet been described.

Therapeutic Use

The FQs originated from nalidixic acid, itself a by product of chloroquine.¹⁵⁰ Nalidixic acid is characterized by a narrow spectrum, and its use was limited to treatment of urinary tract infections. Modifications of chemical structures increasingly have improved the drugs, yielding drugs that have among the broadest of antibacterial spectrums. However, caution should be exercised with selected drugs because efficacy toward specific organisms (e.g., Pseudomonas, spp. anaerobes) varies. The FQs also are characterized as a class among those with the greatest tissue and antimicrobial distribution patterns. However, differences in tissue distribution (e.g., enrofloxacin versus ciprofloxacin, bone distribution of difloxacin) does indicate prudence when comparing FQ use. The rapid bactericidal effect of FQs is of clinical benefit in life-threatening situations or immune-suppressed patients; concentration dependence allows once-daily dosing that improves owner compliance. Intracellular accumulation of these drugs supports use for recurrent infections caused by intracellular organisms or at sites characterized by marked inflammation. Plasmid-mediated resistance has been slow to develop, although increasingly resistance, particularly that associated with multidrug resistance, is limiting FQ use. Oral bioavailability allows prolonged administration on an outpatient basis. However, bioavailability of the different drugs varies among the species, and good oral bioavailability should not be assumed. Rather, extrapolation of oral doses should be based on scientific studies. The unique mechanism of action of these drugs renders them appealing for combination antimicrobial therapy.

However appealing these numerous attributes of the FQs, common use of these drugs is discouraged. Widespread use and abuse—of these drugs in the past 2 decades has proved that antimicrobial resistance can and will occur. Resistance, when it does occur, is often associated with multidrug resistance affecting chemically unrelated drugs. The emergence of of MDR with newer FQs needs to be assessed. Confirmation of the need for the drug and attention to MPCs (see Chapter 6) in the design of the dosing regimen should be two hurdles that are consciously addressed each time these drugs are considered. The metabolism of enrofloxacin to ciprofloxacin and the reduced oral bioavailability of ciprofloxacin as a human-medicine drug call for extra caution to be taken. Once the decision is made to use an FQ, strict adherence to the principles of antimicrobial therapy, with a special focus on proper dosing regimens, is paramount to protecting this class of antimicrobial drugs, which is so critical to the medical community.

Rifamycins

Rifamycins are macrocylic antibiotics produced by Amycolatopsis mediterranei. Several semisynthetic derivatives) of natural rifamycins (rifamycin SV, Rifampin, rifampicin, rifamiderifamide) have been used as extended-spectrum antibiotics.¹⁵⁰ Rifampin is among them. A large molecule (MW 823; see Figure 7-4) as with all rifamycins, it inhibits the B subunit of DNA-dependent RNA polymerase, suppressing RNA synthesis. Because mammalian RNA polymerase does not bind to rifamycins, its inhibition requires much higher concentrations. Rifampin can achieve bactericidal concentrations in some tissues. Effects are concentration-dependent for mycobacterium but unclear for other organisms. However, resistance develops very rapidly, markedly curtailing its use, and in general, rifampin should be used only in combination with other effective antimicrobials. Resistance may develop in as little as 2 days when it is used as the sole antimicrobial; rifampin is used experimentally to study mutation frequencies in some organisms. The use of rifampin as sole agent for treating pyoderma is addressed in Chapter 8. Resistance generally reflects a single mutation that changes the affinity of the target enzyme for the drug. Resistance (and efficacy) can be decreased with combination therapy with a number of drugs, including erythromycin, most beta-lactam antibiotics, chloramphenicol, doxycycline, and selected aminoglycosides. Rifampin has shown some efficacy against fungal microorganisms.

Spectrum

The spectrum of activity of rifampin includes primarily grampositive (especially Staphylococcus spp.) organisms (see Table 7-4). However, it also is effective against Mycobacterium, Neisseria, and Chlamydia spp. and has been used to treat Clostridium and Bacteroides species. Rifampin has limited activity against gram-negative organisms (including Brucella). Resistant gram-negative organisms include E. coli, Enterobacter spp. K. pneumoniae, Proteus spp. Salmonella spp., and P. aeruginosa. However, an Internet search reveals a number of papers that indicate efficacy toward P. aeruginosa when combined with a number of other drugs. Highly susceptible grampositive organisms are considered to have an MIC of 0.25 µg/ mL or less; MICs are often less than 0.1 µg/mL. In contrast, the MIC of gram-negative organisms is generally 8 to 32 μ g/mL; the higher MICs reflect limited penetration of gram-negative organisms. A dose of 10 mg/kg in the dog achieves a C_{max} of 40 µg/mL (see Table 7-1); accordingly, its use for gram-negative isolates (and ideally, all isolates) should be based on C&S testing.

KEY POINT 7-28 Rapid resistance to rifampin limits its use to combination therapy only.

Pharmacokinetics

Rifampin may be administered intramuscularly, intravenously, or orally with systemic effects. Oral absorption of rifampin is incomplete in humans (~40%) with peak plasma concentrations occurring in 2 to 4 hours. Concurrent feeding may reduce or delay absorption. Because it is a substrate for P-glycoprotein,²²⁹ oral absorption may be much higher in dogs exhibiting P-glycoprotein deficiency. Approximately 75% to 80% of rifampin is bound to plasma proteins. Rifampin is very lipid soluble, distributing well to most body tissues. It concentrates in white blood cells and is characterized by immunmodulation.²³⁰ Because rifamycins penetrate tissues and cells to a substantial degree, they are particularly effective against intracellular organisms. Rifampin is rapidly eliminated after acetylation to a metabolite (desacetyl rifampin) that is equal in efficacy to the parent compound. Whether the dog is a deficient acetylator of rifampin is unclear. Both the parent and metabolite are excreted in the bile (supporting its use for cholangitis in humans); the parent compound and metabolite undergo enterohepatic circulation. The elimination half-life of rifampin is dose dependent, being about 8 hours in dogs.

Adverse Effects

Rifampin is usually well tolerated and produces few side effects. However, gastrointestinal disturbances and abnormalities in liver function (icterus) have been reported in humans and may lead to discontinuation of therapy. Hypersensitivity reactions can also result from rifampin administration, and renal failure is a possible consequence when intermittent dosage schedules are followed. Partial, reversible immunosuppression of lymphocytes occurs. Urine, feces, saliva, sputum, sweat, and tears are often colored red-orange by rifampin and its metabolites; urine may stain. Plasma will also be orange and may be misinterpreted as hemoglobinemia. CNS depression after intravenous administration and temporary inappetence may occur. Interestingly, intermittent administration (less than twice weekly) increases the risk of side effects in humans, resulting in a flulike syndrome that is associated with clinical signs indicative of a drug reaction (eosinophilia, thrombocytopenia, hemolytic anemia [note potential for orange discoloration of plasma] and renal disease).¹⁵⁰ In a limited number of dogs, marked increases in serum alkaline phosphatase have been observed by the author. No other liver enzyme or function tests were affected, and dogs did not become clinically ill. The increase may reflect induction of the enzymes (much the same as glucocorticoids or phenobarbital), but monitoring of hepatic function may be prudent in at-risk dogs receiving rifampin.

Drug Interactions

Rifampin is a broad, potent inducer of microsomal enzymes, including CYP1A2, 2C9, 2C19, and 3A4;¹⁵⁰ as such, it will shorten the elimination half-life of a number of drugs and may increase the risk of toxicity associated with drug metabolism.²²⁹ Therapeutic failure may occur for other drugs metabolized by the liver if modifications in dosing regimens are not made. Rifampin PDCs will decrease after multiple dosing

because of induction, with plasma elimination half-life of rifampin progressively shortening by approximately 40% during the first 2 weeks of treatment in humans. Other affected drugs include the imidazoles, cyclosporine, digoxin, and several sodium channel- and beta receptor-blocking cardiac antiarrhythmics. Endogenous substrates of hepatic metabolism also may be affected; several steroids will be more rapidly catabolized.¹⁵⁰ Withdrawal syndromes have been reported in humans receiving opioid analgesics.¹⁵⁰ Because rifampin is a substrate for P-glycoprotein, dogs with the MDR-1 (ABC) deletion will have an increased risk of adverse reactions; the risk is increased if rifampin is used in combination with other drugs that interact with this protein. Finally, rifampin also has decreased biliary secretion of some compounds, notably contrast imaging media.¹⁵⁰ Rifampin has been used in combination with a number of drugs to enhance efficacy (and reduce resistance; see the section on resistance) for treatment of MRSA, VRE, and Mycobacterium spp. and others. Use in combination with doxycycline has been recommended for canine brucellosis, although clinical efficacy has not been demonstrated.2

KEY POINT 7-29 Rifampin is a potent inducer of drugmetabolizing enzymes.

Two other rifamycins are approved for use in humans. Rifabutin is a derivative of rifampin that is characterized by less induction of drug-metabolizing enzymes. Used for the treatment of Mycobacterium spp., it is characterized by unique side effects, including polymyalgia, anterior uveitis, and others. Rifapentine is used to treat tuberculosis associated with human immunodeficiency virus infections in humans. Its longer half-life allows once-weekly dosing, and its impact on drug-metabolizing enzymes has been described as intermediate.150 Rifaximin is a semisynthetic derivative of rifamycin that is not orally absorbed. It is indicated for treatment of enteric pathogens, including Campylobacter, C. difficile, E. coli, Helicobacter pylori, and Salmonella and Shigella.²³¹ A potential advantage of rifaximin is an apparent minimal long-term effect on the gastrointestinal flora: both E. coli and Enterocococcus spp. were minimally affected after 3 to 14 days of therapy. Resistance to rifaximin seems to emerge only slowly, compared with systemic use of rifampin.²³¹ Indications in humans have been a variety of (nonbloody) diarrheas, including small bowel overgrowth, intestinal gas, and inflammatory bowel disease.

Metronidazole

Metronidazole is deriviative of the antibiotic azomycin (2 nitro-imidazole) secreted by a streptomycete (Figure 7-12).²³² A number of other nitroimidazoles were developed from azo-mycin.²³² Among the other closely related imadazoles used outside the United States are tinidazole, and benznidazole, the latter being used to treat acute Chagas disease. Metroni-dazole impairs microbial RNA and DNA synthesis but must first undergo nitrous reduction in the organism. As such, metronidazole is a prodrug, with efficacy depending on the

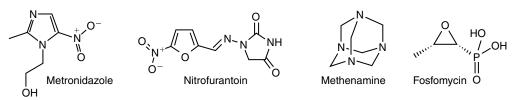

Figure 7-12 Chemical structure of miscellaneous antimicrobials.

nitrous group and a low redox potential that can be achieved only in an anaerobic environment.²³³ Only organisms that live in a low-oxygen environment have developed anaerobic energy or electron-generating pathways (e.g., ferredoxins) capable of generating single electrons. Transfer of the electron to the nitrous group of metronidazole results in a highly reactive nitro radical ion. Although DNA is the primary target, other macromolecular structures may be targeted. Metronidazole will be regenerated on death of the microbe, thus facilitating its efficacy. Efficacy appears to be predominantly bactericidal, although actions may be bacteriostatic toward some organisms (e.g., Eubacterium spp.). Metronidazole acts as a concentration-dependent drug against trichomoniasis, and, although this is not always clear, it also appears to be concentration dependent when treating other microbes. However, time dependence has also been ascribed²³⁴ (e.g., *Clostridium* and its efficacy appear to be similar if administered once or twice daily).235

KEY POINT 7-30 Metronidazole is effective only against anaerobic bacteria.

Spectrum

Metronidazole is rapidly bactericidal against all gram-negative (e.g., *B. fragilis*) and most gram-positive (e.g., *Clostridium* spp.) anaerobic bacilli, generally at MIC equal to or less than 8 μ g/mL. Microaerophilic microbes such as *Helicobacter* and *Campylobacter* spp. are susceptible. Metronidazole is effective toward a number of protozoa, with efficacy dependent on the nitro group at position 5 and enhanced with substitutions at the 2 position.²³⁶ Susceptible infections include trichomoniasis (MIC of 0.05 μ g/mL if anaerobic conditions), amebiasis, and giardiasis (1 to 50 μ g/mL).

Resistance

Aerobes and facultative anaerobic bacteria lack electron transport systems necessary to generate single electrons and thus are resistant to metronidazole. Further, in higher oxygen environments, oxygen will compete for the electrons generated by anaerobic organisms, thus decreasing efficacy of metronidazole. Higher doses are necessary if the infection occurs in an environment of 1% or more oxygen.²³² Interestingly, protozoa may develop resistance ot metronidazole in patients with impaired oxygen-radical scavenging abilities.²³² Microbes also acquire resistance by decreasing proteins that generate the electrons (e.g., ferredoxin). The mechanism of bacterial resistance is not totally clear, but increased production of interfering enzymes is likely. Resistance by *Helicobacter* spp. can be rapid.

Pharmacokinetics

Metronidazole is well distributed to all body tissues and can penetrate the blood-brain barrier. It is minimally protein bound (in humans). Elimination is dose dependent and occurs primarily by hepatic metabolism. At least one metabolite has 50% of the activity of the parent compound toward trichomonads. Intestinal microbes can produce a small amount of the reduced (active) metabolites. Peak concentrations in dogs after 44 mg/kg reached 42 μ g/mL. Vd is 0.95 \pm 0.1 L/kg, and clearance is 2.5 ± 0.54 mL/kg/min.²³⁷ Oral bioavailability is variable, ranging from 59% to 100%. Elimination half-life in one study was 4.5 ± 9 hours (see Table 7-1). Metronidazole disposition has been described in the cat after single intraveous (5 mg/kg) administration as the salt-free product and then at 20 mg/kg orally of the benzoate salt (12.4 mg/kg active drug).²³⁸ Extrapolated plasma concentration after intravenous administration at time 0 averaged 7.8 \pm 2 µg/mL; Vd was 0.7 \pm 0.3 L/kg, and plasma clearance was 91 mL/kg/hr. Elimination half-life and mean residence time were 5.3 ± 0.7 and 7.6 ± 1 hours, respectively. The benzoate salt was fairly well absorbed but was characterized by clinically significant variability, with a bioavailability of 65% \pm 27% (range 28% to 80%). The C_{max} also varied, with a mean of 8.8 + 5.4, reflecting a range of 4.9 to 17.8 μ g/mL; T_{max} also varied from 1 to 8 hours (mean 3.6 ± 2.9 hours). Elimination half-life and mean residence time after oral administration were 5.2 ± 0.5 and 8.7 ± 1.3 hours, respectively.

Adverse Effects

Metronidazole may discolor urine (red-brown).232 More problematic adverse reactions include gastrointestinal upset (including hepatotoxicity when given at high doses) and CNS adversities, including seizures.^{237,239} The risk of neurotoxicity is increased with intravenous administration; as such, oral administration is the preferred route whenever possible. The caustic nature of the intravenous solution also necessitates slow intravenous administration. The mechanism of neurotoxicity is not known, but in mice degenerative lesions have been demonstrated in the Purkinje cells, vestibular tracts, and several nuclei associated with equilibrium and fine motor control. These areas are also the site of the majority of gamma-aminobutyric acid-minergic receptors. In humans, characteristic lesions seen on magnetic resonance imaging indicate that the cerebellum may be most sensitive to damage; because interstitial edema was evident, with axonal swelling was suggested as a cause.²⁴⁰

In dogs, seizures are indicative of toxicity. One study in dogs (n = 21) induced seizures at doses of 60 to 110 mg/kg for a total of 10 to 110 days.²⁴¹ The most common clinical signs were vertical nystagmus, ataxia, inability to walk (≥50% each), and paraparesis (30%); less frequent neurologic signs included tetraparesis, hypermetria, tremors, head tilt, torticollis, and opisthotonus. Treatment with diazepam proved effective based on a shorter response time (resolution of debilitating clinical signs; 13 hours versus 4.5 days) as well as recovery time (return to normalcy; 11 versus 36 hours). The dose of diazepam was approximately 0.5 mg/kg, administered intravenously followed by oral administration every 8 hours for 3 days. Neurologic reaction to metronidazole has also been reported in cats (n = 2). The dose and duration associated with clinical signs were 111 mg/kg body for 9 weeks followed by 222 mg/ kg/day for 2 days in one cat and 58 mg/kg for 6 months in the second.²⁴² Clinical signs in cats included ataxia, altered mentation, and progression to seizures. Neurologic signs resolved within days of discontinuation of the drug and supportive therapy. Histologic lesions have also been described in another 14-year-old cat that developed fatal presumed metronidaozle toxicity after treatment for inflammatory bowel disease at 73 to 147 mg/kg/day. Among the neurologic clinical signs was acute tetraparesis; lesions included diffuse, multifocal areas of necrosis throughout the brainstem.²⁴³

Metronidazole as either the free form or when administered as the benazoate salt was genotoxic (disruptive of lymphocytic DNA) but not cytotoxic to feline polymorphonuclear cells. Genotoxicity resolved within 7 days after the drug was discontinued.

Preparations

Metronidazole is available as either a hydrochloride (used in the approved product) salt (oral or intravenous) or, in pure drug substrate form (i.e., for compounding), the benzoate salt. It can be administered as a loading dose infused over 30 to 60 minutes in fluids, followed by an intravenous drip. It also can be given intermittently as an 8- to 12-hour maintenance dose as long as the infusion takes place slowly. For intravenous administration the dose should be neutralized with sodium bicarbonate and mixed with lactated Ringer's solution, saline, bacteriostatic water, or 5% dextrose in water (see package insert). Because intravenous administration of metronidazole is complicated, oral administration is preferred whenever possible.

The benzoate salt of metronidazole, which is not commercially available, is less bitter tasting and more tolerable than the commercially available hydrochloride salt. The oral disposition of the benzoate salt was previously described.²³⁸ However, the benzoate moiety is larger than the hydrochloride moiety, representing 38% of the drug product. As such, when dosed on total drug weight, the dose of metronidazole benzoate should be 1.6 times the dose of metronidazole hydrochloride.²⁴⁴ Further, the benzoate must be removed by desterification before its absorption; it is not clear if oral administration of the benzoate form will be as effective against gastrointestinal microbes compared with a nonbenzoate form. Metronidazole (not studied as a salt) has been demonstrated to be stable in solutions when stored at 40° C for 90 days.²⁴⁵ However, it reacts with the aluminum of needles or other canulas. Metronidazole is subject to drug interactions associated with inhibition (e.g., cimetidine) or induction (e.g., phenobarbital, prednisone, rifampin) of drug-metabolizing enzymes.

Metronidazole is available as a topical gel, which provides wound odor control. Although it can be prepared as a transdermal PLO gel, studies by the author demonstrated minimal absorption when applied to the pinna of the ear for 3 weeks at 15 mg/kg.

Metronidazole is a drug of choice for treating infections caused by obligate anaerobes, particularly those associated with gastrointestinal flora. Increasingly, it is used in lieu of oral vancomycin to treat *C. difficile*. Frequently, it is cited as a treatment for inflammatory bowel diseases in animals or humans (particularly Crohn's disease). Its efficacy may reflect, in part, immunomodulatory properties (see Chapter 19) or its ability to target those microbes most likely to produce inflammatory mediators.

DRUGS THAT TARGET FOLIC ACID

Inhibitors of Folic Acid Synthesis:/Sulfonamide/ Trimethoprim or Ormetoprim Combinations

The sulfonamides are the oldest group of antibiotics used therapeutically. All sulfonamides that are currently used were derived from the first clinically relevant sulfonamide, sulfanilamide, itself a derivative of the azo dye prontosil. The discovery of its efficacy in vivo but not in vitro indicated that metabolism by the host was necessary for efficacy and contributed to the understanding of the role of drug metabolism in bioactivation. Once the metabolite was identified as the active drug, a number of manufacturers produced hundreds of different sulfanomide antimicrobial preparations. The FDA had not yet been empowered by Congress to evaluate drug safety, resulting in the lack of safety limitations. Among the vehicles in which drugs were prepared was a product containing ethylene glycol. The subsequent death of more than 100 persons, including children, ingesting the product contributed to congressional approval of the Food Drug and Cosmetic Act of 1938. It was this act that empowered the FDA to evaluate drugs for safety before marketing.

The sulfonamides were the first group of commercially available antimicrobials used systemically.²⁴⁶ Their use was somewhat curtailed by the advent of the penicillins, only to increase again in the 1970s with their combination with the diaminopyridine trimethoprim. Not surprisingly, long-term use of these drugs has contributed to the development of resistance that has limited their clinical use.²⁴⁶ However, a decline in their use, in part because of concerns regarding drug allergies, probably has contributed to a decline in resistance. Sulfonamides generally are used in combination with diaminopyrimidines for treatment of bacterial infections, with use of sulfonamides as sole agents generally limited to treatment of coccidiosis.

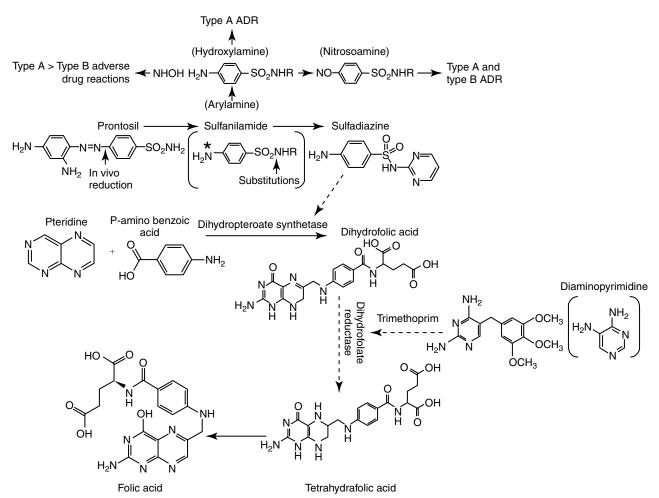

Figure 7-13 The mechanism of action of the sulfonamides and the diaminopyrimidines. By itself, either type of drug is bacteriostatic, but the two-point sequential inhibition of folic acid synthesis results in bactericidal effects. The progenitor of the sulfonamides is sulfanilamide *(inset)*. As such, all are arylamines. Metabolism of the arylamine to a hydroxyalamine and nitroso compound contributes to the toxicities, including drug allergies, associated with sulfonamides.

Structure Chemistry Relationship

As derivatives of sulfanilamide, all sulfonamides have the same nucleus. Functional groups have been added to produce compounds with varying physical, chemical, pharmacologic, and antibacterial properties, but the active amine is in position 4 and any substitutions at this position must be freed in vivo (Figure 7-13). Although amphoteric, sulfonamides generally behave as weak organic acids and are much more soluble in an alkaline than in an acidic environment. Those of therapeutic interest have pK_a values between 4.8 and 8.6. Water-soluble sodium or disodium salts are used for parenteral administration. Such solutions are highly alkaline, somewhat unstable, and readily precipitate out with the addition of polyionic electrolytes. In a mixture of sulfonamides (e.g., the sulfapyrimidine group), each component drug exhibits its own solubility; therefore, a combination of sulfonamides is more water soluble than a single drug at the same total concentration. This is the basis of triple sulfonamide mixtures used clinically (primarily in large animals). The N-4 acetylated sulfonamides, except for the sulfapyrimidine group (sulfadiazine), are less water soluble than their nonacetylated forms. Highly insoluble

sulfonamides are retained in the lumen of the gastrointestinal tract for prolonged periods and are known as "gut-active" sulfonamides. Most sulfonamides used clinically for treatment of bacterial infections are "potentiated." The "potentiator" of sulfonamides is a diaminopyrimadine; examples include trimethoprim, ormetoprim, and pyrimethamine (the latter being the preferred drug for toxoplasmosis) (see Figure 7-13).

Mechanism of Action

Folic acid is an essential bacterial substrate necessary for protein and nucleic acid metabolism. Bacterial synthesis of folic acid is accomplished in several sequential steps (see Figure 7-13). The sulfonamides are structurally similar to PABA and act as competitive substrates (antimetabolites) for the synthetase enzyme. Among the many sulfonamides used clinically are sulfadiazine, sulfamethoxazole, sulfachlorpyridazine, sulfadimethoxine, and sulfasalazine; sulfisoxazole is the model drug upon which C&S testing is based.

Because folate metabolism is required for many cellular functions, bacterial growth is inhibited; consequently, the antibacterial effects of sulfonamides as sole agents are bacteriostatic. The diaminopyrimidines trimethoprim and ormetoprim also impair folic acid synthesis but at a different point in the metabolic pathway. They prevent the conversion of dihydrofolate to tetrahydrofolate by inhibiting the reductase enzyme. By themselves, these drugs also are bacteriostatic. It is the combination of a sulfonamide antimicrobial with a diaminopyrimidine antimicrobial ("potentiated") that results in subsequent two-point inhibition of bacterial folic acid synthesis and thus bactericidal rather than bacteriostatic activity (see Figure 7-13). ^{5,246} Mammalian cells are not affected by these drugs because they are dependent on dietary sources of folic acid; in contrast, microbes cannot use external sources of the substrates. Further, the affinity of bacterial enzymes for the drugs is much higher than the mammalian enzymes. The competitive nature of the mechanism of killing activity of potentiated sulfonamides leads to a time-dependent effect. High inoculums may require higher doses for efficacy.

KEY POINT 7-31 The combination of the sulfanomide and the diaminopyrimidine results in bactericidal effects.

Spectrum of Activity

The spectrum of activity of sulfonamides is considered broad, but efficacy is variable because of acquired resistance. However, a decline in their use during the last decades (due to concerns regarding allergies) appears to be associated with an increased in susceptibility for a number of organisms. The spectrum of combined products includes gram-positive, gram-negative, and anaerobic organisms. The sulfonamides exhibit good to moderate activity against E. coli; Enterobacter spp.; Klebsiella spp.; Proteus spp.; Pasteurella spp.; and anaerobic organisms such as Actinomyces, Bacteroides, Fusobacterium spp., and selected clostridia.²⁴⁷⁻²⁴⁹ The spectrum of these drugs does not include Serratia spp., P. aeruginosa, Rickettsia, or Mycoplasma spp. The sulfonamides exhibit good efficacy against Brucella spp., Actinomyces spp., and selected protozoal organisms such as Pneumocystis carinii and Cryptosporidium spp. Some Chlamydia spp. are susceptible to sulfonamides, whereas others are not. The difference appears to be based on whether the organism can obtain folic acid from the host.249a Mycoplasma organisms are not susceptible to sulfonamides. By itself, trimethoprim has a potency that is twentyfold to 200-fold less than that of sulfonamides.²⁴⁶ Potentiated sulfonamides are generally useful for uncomplicated infections of many body systems.

Resistance

Inherent resistance to sulfonamides reflects, in part, the ability of the microbe to make use of host folic acid. Resistance to the sulfonamides and to trimethoprim or ormetoprim occurs relatively rapidly. Chromosomal resistance results in impaired drug penetration, reduced affinity of the enzyme for the substrate, or increased bacterial production of PABA. Plasmid-mediated resistance occurs rapidly because of altered drug penetration and decreased affinity of the enzyme for the substrate. Resistance to one sulfonamide generally results in resistance to all sulfonamides.²⁴⁶ The increasing emergence of resistance has sharply curtailed the use of these drugs. The role of trimethoprim/sulfonamide combinations for the critically ill patient or for chronic infections should be based on C&S information because of the incidence of resistance.

Pharmacokinetics

The sulfonamides are generally rapidly and completely absorbed after oral administration, although there are exceptions (see the discussion of structure and chemistry). Trimethoprim and ormetoprim are well absorbed after oral administration. Sulfasalazine is poorly absorbed as an intact molecule and is used primarily for gastrointestinal diseases. After oral administration sulfasalazine is partially absorbed in the small intestine. It undergoes enterohepatic circulation and ultimately is eliminated in the urine. Most of the drug (70%) is metabolized by colonic bacteria to its component parts: sulfapyridine and 5-aminosalicylic acid. Sulfapyridine is rapidly absorbed and subsequently eliminated in urine. The 5-aminosalicylic acid may provide the major therapeutic benefit for chronic inflammatory bowel disease.²⁴⁶

Solutions intended for parenteral administration must be buffered to prevent pain and irritation caused by the alkalinity of the compounds. Topical administration is not recommended because of the effects of these drugs on wound healing. An exception is made for silver sulfadiazine and mafenide, which are used primarily for burn patients in human.²⁴⁶ Sulfadiazine is combined with silver in a topical otic preparation approved for use in dogs. Protein binding of the sulfonamides varies from 15% to 99%. Examples include sulfadiazine at 30% to 50% bound, sulfadiamethoxine, at greater than 75%, and sulfasalazine up to 99% bound. Protein binding contributes to a relatively long half-life, allowing for convenient dosing intervals.

KEY POINT 7-32 The disposition of the sulfonamides, which are time dependent, is markedly variable among members of this drug class.

The tissue penetrability of the sulfonamides varies. All are distributed at least to extracellular fluid. Sulfamethoxazole (the model drug for susceptibility testing) is limited to interstitial fluid, whereas sulfadiazine is distributed to total body water.²⁴⁶ Sulfadiazine penetrates most body tissues extremely well, including the prostate.²⁵⁰ The penetration of these drugs varies with the sulfonamide component. Prostatic penetration is facilitated by a high pK_a . Sulfadiazine (pK_a 6.4) is among the best distributed sulfonamides but only achieved 11% of serum concentration in the prostate of dogs in one study (the original reference for this study could not be found). Drugs with a more basic pK_a may appear to better penetrate the prostate, although this may reflect ion trapping in prostatic fluids. Sulfadiazine can attain therapeutic concentrations in CSF, particularly if given intravenously, and is the preferred sulfonamide for CNS infections.²⁴⁶ Trimethoprim achieves tissue concentrations four times higher than that in plasma. The combination of a sulfonamide with a diaminopyramidine at a ratio of 1:5 trimethoprim/sulfonamide results in a bactericidal effect and a tissue distribution ratio of 1:20 in most tissues.⁵ This ratio, however, is described in humans, and information in dogs or for sulfadimethoxine and ormetoprim does not appear to be available.

Sulfonamides that undergo hepatic metabolism are generally acetylated. All sulfonamide antimicrobials are arylamines. The dog lacks some genes that encode for N-acetyltransferases responsible for metabolism of arylamines.²⁵¹ Thus metabolism in the dog may involve other pathways, facilitating the formation of potentially nitroso metabolites that are responsible for allergic or other idiosyncratic reactions (see the section on adverse reactions) (see Figure 7-13).²⁵² Drugs are renally excreted as either the parent compound or the conjugated metabolite by either glomerular filtration or active tubular secretion. Both passive reabsorption and enterohepatic circulation can prolong the elimination half-life of selected sulfonamides.²⁴⁶ Acetylated metabolites of sulfonamides are often less soluble than the parent compounds, which increases the risk of renal damage should drug precipitate and form crystals. However, this is unlikely in dogs because of deficient acetylation. The risk is reduced in other species because of the use of combination products, which reduces the total amount of dose needed for efficacy. The elimination half-lives of the drugs vary with the sulfonamide component and among the species. The duration at which sulfonamides remain in the body leads to classification as short-acting (12 hours or less: sulfacetamide, sulfathiazole, and sulfisoxazole), intermediate-acting (12 to 24 hours: sulfadimethoxine, sulfisoxazole, sulfamethoxazole, sulfapyridine, sulfamethazine, and sulfadiazine), and long-acting (longer than 24 hours).²⁴⁶ In the dog, according to the package insert, sulfadimethoxine concentrations are 39 µg/mL 24 hours after dosing. Peak ormetoprim at 2 hours was 1.09 µg/ mL in dogs but was 0.09 µg/mL at 24 hours, indicating a halflife of about 6 hours. It is not clear whether the differences in half-life between sulfadimethoxine and ormetoprim "match" in terms of ideal proportion throughout the labeled 24-hour dosing interval.

Adverse Effects

Reactions to sulfonamide antimicrobials reflect the greatest proportion of antimicrobial adversities in the dog.²⁵² The adversities to sulfonamide antimicrobials but not other sulfonamides (e.g., nonsteroidal antiinflammatories, zonisamide, furosemide) probably reflect the basic structure of the sulfanilamide molecule, which is an arylamine, in which the amine group is directly attached to the benzene ring (see Figure 7-13). The susceptibility of dogs to sulfonamide toxicity may reflect the species' deficiency in acetylation and specifically N-acetylation. The proposed mechanism of toxicity reflects shunting of the sulfanilamide arylamine to an oxidative phase I pathway (see Figure 7-13). Oxidation of the arylamines yields hydroxylamine, a metabolite that can be cytotoxic at high concentrations; the metabolite also is somewhat allergenic. Hydroxylamine can be further metabolized (often spontaneously) to a nitroso compound, which is somewhat cytotoxic but is more immunogenic

than the hydroxyarylamine. The potential role of the arylamine as a cause of sulfonamide toxicity is supported by the lack of apparent toxicity by other sulfonamide drugs used in dogs, which, lacking a primary arylamine, are not converted to hydroxylamine. The likelihood of adversity may be related to the type of metabolites formed and the rate of acetylation. As such, the likelihood of toxicity occurring may vary among the sulfonamide antimicrobials. The mechanism of hypersensitivity may reflect haptenization of the metabolite and a subsequent T-cell response, although other mechanisms (e.g., humoral response or cytotoxicity) may contribute.²⁵² Deficiencies in glutathione, ascorbic acid, or other radical scavengers may increase the risk of either type A or B reactions; the role of supplementation in preventing or treating adversities apparently has not been addressed scientifically but may be prudent. Controversy exists as to whether the parent sulfonamide might be immunogenic.²⁵² The "potentiator" may also be responsible for some reactions; for example, trimethoprim has been associated with skin eruptions or hepatopathy in humans; further, use of sulfadiazine as the sole coccidiostat in dogs has not been associated with drug allergies.

KEY POINT 7-33 Adversity to the sulfonamides probably reflects their metabolism to toxic or allergenic metabolites.

Type A (1) Adverse drug reactions. With the exception of thyroid-gland suppression, sulfonamides, and sulfadiazine in particular, appear to be free of type A or I adverse drug reactions at doses higher than those used therapeutically. For example, suppression of the thyroid gland was the only adverse effect evident in dogs treated with sulfadiazine at 300 mg/kg a day for 20 days. Any sulfonamide, including antimicrobial drugs, may profoundly alter thyroid physiology at high doses (25 mg/kg twice daily). The sulfonamide is a reversible substrate inhibitor of thyroid peroxidase, preventing the iodination and coupling of tyrosine residues necessary for formation of thryoxine and thyronine.²⁵³ Whereas labled doses of sulfadiazine and trimethoprim do not appear to cause thyroid suppression at least for 4 weeks, clinical hypothyroidism has occurred in one dog treated with trimethoprim sulfadiazine at 48 mg/kg/day for 10 weeks. Experimentally induced suppression of thyroid hormone (T₄) synthesis occurred in 57% of dogs treated for pyoderma at 60 mg/kg/day for 6 weeks. Decreased thyroid hormone synthesis generally will be clinically relevant by 3 weeks of therapy but may take 6 to 8 weeks or longer and will return to normal within 3 weeks after therapy is discontinued.

Aplastic anemia has been reported in dogs receiving 30 to 60 mg/kg of sulfadiazine a day,²⁵² although the role of allergy versus folic acid deficiency was not documented. Because mammalian cells can use dietary folic acid, supplementation might be considered, particularly for patients that develop anemia (normocytic rather than megaloblastic)²⁵² consistent with folic acid deficiency while receiving a sulfonamide. Cats appear to be more sensitive to the effects of trimethoprim/ sulfonamide combinations. Doses of 300 mg/kg per day for 10 to 30 days orally resulted in lethargy, anorexia, anemia, leukopenia, and increased blood urea nitrogen. Before the advent of

triple and potentiated sulfonamide preparations, crystalluria was a common type I side effect, with subsequent renal damage. Nonetheless, with high doses of any sulfonamide product, prudence dictates that the hydration status of the animal be normal, particulary if urinary pH is acidic.

Type B (II) Adverse drug reactions. Although the sulfonamides are generally safe drugs, the advent of hypersensitivity drug reactions (immunologic) has limited their use. Immunemediated diseases of the skin, kidney, liver, and eye are not dose dependent.

Sulfonamide antimicrobial toxicity in animals has been reviewed.^{252,254} The incidence of systemic sulfonamide toxicity in dogs has been reported as 0.25%. In a study of dogs (n = 40), inclusion criteria included clinical signs consistent with a drug allergy and treatment with a sulfonamide antimicrobial for at least 5 days.²⁵⁴ The breeds most often represented were Golden Retrievers, Miniature Schnauzers, German Shepherd Dogs, Labrador Retrievers, and Samoyeds, with Miniature Schnauzers and Samoyeds being overrepresented. The lack of representation by Doberman Pinschers was suggested to reflect decreased treatment of this breed with sulfonamides. Ages ranged from 6 months to 14 years (mean 5.7 ± 3.2), and neutered female dogs were overrepresented (60%). Three sulfonamides were represented, with 64% of afflicted dogs receiving sulfamethoxazole, 23% sulfadimethoxine, and 13% sulfadiazine; either trimethoprim or ormetoprim also were administered. No information was available regarding the proportion of sulfonamides prescribed to dogs. The frequency of each drug being administered was not determined. Doses ranged from 23 to 81 mg/kg/day, and time of onset ranged from 5 to 36 (mean 12) days. The most common clinical signs and the proportion of animals afflicted were fever (55%), thrombocytopenia (54%), hepatopathy (28%), neutropenia (27%), keratitis sicca (25%), and hemolysis (22%). Facial palsy was an unusual clinical sign. Other clinical signs included arthropathy, uveitis, skin and mucosal lesions, proteinuria, facial palsy, hypothyroidism, pancreatitis, facial edema, and pneumonitis. Dogs with hepatopathy or thrombocytopenia had a significantly lower recovery rates.²⁵⁴ Dogs with hepatopathy also tended to have received the highest doses, suggesting that a toxic metabolite might be responsible and the adversity might be, in part, type A rather than type B (i.e., dose dependent and thus predictable). The fact that some animals developed adversities in as little as 5 days might also support a type A or idiosyncratic type B reaction, rather than allergy. Large breeds, with Doberman Pinschers overrepresented, appear to be at greater risk for developing arthropathy (as reviewed by Trepanier).252

Keratoconjunctivitis sicca is a more common side effect of sulfonamides in dogs, occurring in as many as 15% of animals receiving sulfonamides.²⁵⁴ It has been reported in dogs after treatment with sulfasalazine, sulfadiazine, and sulfamethoxazole. The reaction may reflect direct cytotoxicy to the lacrimal gland rather than an allergic reaction, but nonetheless, time of onset may be months to years after therapy is initiated. Female dogs may be at greater risk. Resolution of clinical signs is more likely if the inciting drug is discontinued early; otherwise,

normal function may not recur once the drug is discontinued. Prognosis is more favorable for younger dogs receiving the drug for a short period of time.

Drug Interactions

The sulfonamides have been associated with a number of drug interactions in humans.² Inhibition of elimination with subsequent prolonged or increased effects have been reported for oral hypoglycemic agents, dapsone when combined with trimethoprim, folate antagonists (increased risk of megaloblastic anemia), methanamine (increased risk of crystalluria), procainamide (decreased metabolism when combined with trimethoprim), and warfarin (increased anticoagulant activity with trimethoprim). In contrast, increased elimination has been reported for cyclosporine when combined with either sulfonamides or trimethoprim.²

Therapeutic Use

Because of the advent of resistance, the use of sulfonamides is limited to uncomplicated infections of most body systems. The concentration in urine supports the use of potentiated sulfonamides for urinary tract infections. Trimethoprim/sulfonamide combinations are indicated for treatment of infections caused by susceptible bacteria in difficult-to-penetrate tissues such as the prostate and CNS.²⁴⁶ These drugs are among the drugs of choice for treating *Nocardia* and *Actinomyces* spp. Synergistic effects have been cited toward these organisms when used in combination with beta-lactam antibiotics.

DRUGS THAT TARGET RIBOSOMES (BACTERIOSTATIC)

Tetracyclines

Tetracyclines historically have been widely used, but development of resistance has largely curtailed empirical use in the last decade. However, the decline in use appears to have led to a decrease in resistance, and susceptibility increasingly is demonstrated through C&S data, potentially leading once again to more common use of these drugs.

Structure–Activity Relationship

Three naturally occurring tetracyclines are obtained from Streptomyces: chlortetracycline (the prototypic drug but no longer available in human-medicine preparations), oxytetracycline, and demethylchlortetracycline (see Figure 7-5). Several tetracyclines have been derived semisynthetically (tetracycline from chlortetracycline, rolitetracycline, methacycline, minocycline, doxycycline, lymecycline, and others). Elimination half-lives permit a further classification into short-acting (tetracycline, oxytetracycline, chlortetracycline), intermediateacting (demethylchlortetracycline and methacycline), and long-acting (doxycycline and minocycline) formulations. All of the tetracycline derivatives are crystalline, yellowish, amphoteric substances that, in aqueous solution, form salts with both acids and bases. They characteristically fluoresce when exposed to ultraviolet light. The most common salt form is the hydrochloride, except for doxycycline, which also is available as doxycycline hyclate. The tetracyclines are stable as dry powders but not in aqueous solution, particularly at higher pH ranges (7-8.5). Preparations for parenteral administration must be carefully formulated, often in propylene glycol or polyvinyl pyrrolidone with additional dispersing agents, to provide stable solutions. Tetracyclines form poorly soluble chelates with bivalent and trivalent cations, particularly calcium, magnesium, aluminum, and iron. Doxycycline and minocycline exhibit the greatest liposolubility and better penetration of bacteria.

Mechanism of Action

Tetracyclines bind bacterial ribosomes and impair protein synthesis (see Figure 7-6). Bacterial ribosomal activity was described in the section on aminoglycosides. The tetracyclines bind to the 16S portion of the 30S ribosomal subunits, preventing access of the amino-acyl tRNA to the acceptor site on the mRNA ribosome complex⁸⁰ (see Figure 7-6). Because tRNA binding is prevented, amino acids cannot be added to the peptide chain, and protein synthesis is impaired. Tetracyclines are bacteriostatic in action and should not be used in the immunocompromised patient, whether disease or drug induced (i.e., glucocorticoids or anticancer drugs). Their effects are described with other bacteriostatic ribosomal inhibitors as time dependent but are probably related to AUC. The tetracyclines also inhibit matrix metalloproteinases, an action separate from their antibacterial properties.

Spectrum of Activity

Tetracyclines enter cells either through porins or active transport pumps.⁸⁰ They are considered broad spectrum (see Table 7-2), being effective against gram-positive, gram-negative, anaerobic organisms, as well as cell wall-deficient and rickettsial organisms and others. Their spectrum includes gramnegative organisms, particularly Pasteurella spp., and often E. coli, Klebsiella, and Salmonella spp. P. aeruginosa is generally not included; although susceptibility may be indicated on C&S data, caution should be exercised when selecting tetracyclines. They generally are intrinsically more effective against gram-positive organisms (see Tables 7-3 and 7-4). As such, Staphylococcus and Streptococcus spp. generally are included in the spectrum. However, the broad general use of these drugs has led to resistance by many organisms and use against gram-positive organisms should be based on C&S testing. The spectrum of action also includes Chlamydia, Mycoplasma, Rickettsia, and Hemobartonella organisms. Spirochetes (Borrelia, Leptospirosis spp. also are generally susceptible, and several mycobacterial organisms are susceptible. Tetracyclines target Brucella spp.) although in human medicine generally they are combined with rifampin or gentamicin. Tetracyclines generally are effective toward actinomycosis and are generally considered more effective than chloramphenicol.80

Tigecycline is a glycylcycline, a class of drugs that are synthetic analogs of the tetracyclines. Specifically, it is a glycolamide derivative of minocycline. The spectrum of this class is similar to that of the tetracyclines; however, they often remain effective against strains that have developed resistance to tetracyclines through increased efflux transport mechanisms.⁸⁰

Resistance

Resistance to tetracyclines is plasmid mediated and inducible.⁸⁰ Most resistance to tetracyclines results from either decreased influx or increased transport of the drug out of the microbial cell. Other mechanisms include altered binding site (which may reflect a mutation) and enzymatic destruction. Cross-resistance does not necessarily occur and depends on the mechanism. Drugs that minimize the impact of efflux pumps have been developed, including the glycylcyclines.²⁵⁵ These drugs also have a higher binding affinity than tetracyclines.

Pharmacokinetics

The oral absorption of tetracyclines is variable, with chlortetracycline being the least bioavailable, oxytetracycline more so, and doxycycline the most lipid soluble of the tetracyclines, being 100% bioavailable. Absorption is decreased in the presence of divalent and trivalent cations such as those present in milk products or antacids; exceptions occur for doxycycline and minocycline. Tetracyclines, particularly doxycycline, are widely distributed to most body tissues, and theoretically, inflammation need not be present for distribution into the brain⁸⁰ (see Table 7-5). Drugs will distribute through the placenta into the fetus and into milk. Doxycycline is able to penetrate cell membranes and thus gain access to intracellular organisms. Doxycycline is 99% protein bound, which prolongs its elimination half-life; note that concentrations in body fluids (see Table 7-5) are likely to reflect unbound drug, whereas that in plasma may reflect bound drug, decreasing ratios. Tetracyclines, with the exception of lipophilic tetracyclines such as minocycline and doxycycline, do not penetrate the CSF. The latter drugs are thus preferred because of better tissue penetrability for treatment of infections caused by susceptible bacteria in difficult-to-penetrate tissues, reaching 30% to 40% of plasma concentrations. Minocycline is characterized by a larger Vd in people than is doxycycline, suggesting the potential of better tissue penetrability, but may also be more bound to bone or other tissues containing cations. Tetracyclines accumulate in reticuloendothelial cells.⁸⁰ Tetracyclines are incorporated into forming bone and the enamel and dentin of teeth and cause discoloration of teeth upon eruption. The age at which this occurs in dogs and cats is not clear.

KEY POINT 7-34 Among the tetracyclines, doxycycline and minoclycline stand out for their lipid solubility and biliary excretion.

Doxycycline (PC 0.68 and pKa 3.09)⁵⁷ was studied in the dog in both plasma and interstitial fluid (using ultrafiltration) after intravenous and constant-rate influsion (to allow establishment of steady-state concentrations). The drug is 91% bound to plasma proteins in dogs, resulting in a total AUC difference sixfold higher in plasma compared with interstitial fluid. Further, the interstitial fluid C_{max} (of unbound drug) was only 0.14 µg/mL at steady-state conditions; in contrast, PDCs extrapolated from the terminal component of the elimination curve was 1.6 µg/mL. The concentration of interstitial fluid

drug was equivalent to the concentration of unbound drug in plasma.⁵⁷ Vd of unbound drug was 0.65 ± 0.08 L/kg; clearance was 1.66 ± 2.21 mL*kg/min.

With the exception of doxycycline and minocycline, the tetracyclines are eliminated by both renal (approximately 60%) and biliary (40%) excretion. Presumably, minocycline is eliminated essentially in the bile, whereas the route of elimination of doxycycline is less obvious. In humans it is eliminated by both renal (41%) and biliary (59%) mechanisms. In dogs intestinal elimination of the unchanged drug appears to be the predominant route, with only about 16% of a given dose being excreted unchanged in the urine. Tetracyclines undergo enterohepatic circulation. Toxic concentrations may accumulate in patients with renal disease. Differences that justify use of minocycline instead of doxycycline are difficult to ascertain. Adverse reactions to minocycline may, however, be more likely.

The tetracyclines are available as intravenous, parenteral, and ocular preparations. Tetracyclines should not be given intramuscularly because of local tissue damage and irritation. For the same reason, tetracyclines are not indicated for topical treatment other than the eye.

Adverse Effects

Tetracyclines cause several adverse effects in small animals. Toxicity may be worsened in patients with renal disease because of decreased elimination. Gastrointestinal upset follows direct irritation of the gastrointestinal mucosa after oral administration; administration of doxycycline with food will reduce gastrointestinal side effects. Rarely, hepatotoxicity may occur. Rapid intravenous administration may result in collapse. Although the likelihood of this occurring in small animals is not clear, prudence dictates slow administration of a diluted solution (i.e., 1:10) when tetracyclines are administered intravenously. Although the mechanism is not certain, calcium binding may be important. Intravenous administration of tetracycline has caused anaphylactic shock in dogs. Diluting fluids should not contain calcium or other cations to which tetracylines might chelate. Hypersensitivity has also been reported in a dog after intramuscular administration of tetracycline. Minocycline may be more likely to cause allergic drug reactions in drugs. Lesions characterized by erythema of the skin and mucous membranes occurred in dogs after administration of most doses of minocycline. Anemia may also occur (10 mg/kg, administered intravenously). Brown to gray discoloration of teeth may occur because of chelation of tetracyclines in calcium deposits of dentin and, to a lesser degree, enamel. Tetracycline and oxytetracycline cause a yellow discoloration, whereas chlortetracycline produces a gray-brown discoloration; of all the tetracyclines, oxytetracycline causes the least tooth discoloration. Because chelation might occur in forming dentin as well as enamel, tetracyclines should be avoided from 3 weeks' gestation to at least 1 month after birth. Among the lipid-soluble tetracyclines, doxycycline may be less likely to cause discoloration. In humans minocycline may stain teeth regardless of tooth development because of chelation with iron; the drug probably has not been used

sufficiently in animals to determine whether a similar effect will occur. Other side effects caused by tetracyclines include drug fever (in cats), an antianabolic effect, and a Fanconilike syndrome in the kidneys, with the latter more likely with expired or degraded tetracyclines.²⁵⁵

Doxycycline has been associated with esophageal erosions in cats (and humans).⁸⁰ In a study of 30 cats, no orally administered tablets had passed in 30 seconds; only 40% had entered in 5 minutes. In contrast, 90% of tablets passed within 30 seconds when followed with 6 mL of water, with 100% passage at 90 seconds. For capsules only 17% had passed by 30 seconds, but 93% had passed by 60 seconds.²⁵⁶ The impact of esophageal damage is not unique to doxycline; other drugs are ulcerogenic because of local effects. Indeed, the cat has been used as a model to assess the ulcerogenic potential of orally administered drugs.²⁵⁷ For doxycycline, the risk may be decreased with use of the monohydrate salt. In the event that erosions do occur, among the treatments to consider would be pentoxifylline.²⁵⁸

KEY POINT 7-35 Doxycycline is only one of many drugs that might cause esophagitis in the cat.

Drug Interactions

Because of chelation with cations (magnesium, calcium, aluminum, and so on), tetracyclines should not be simultaneously administered with cation-containing drugs (e.g., antacids, sucralfate, buffered aspirin, calcium-containing supplements, fluids). Cholestyramine may also bind to tetracyclines. Tetracyclines, with the exception of doxycycline, should not be administered with food.

Because tetracyclines bind to the 30s ribosomal subunit, combination with antimicrobials that target the 50s subunit might be considered (e.g., the phenicols, macrolides, and lincosamides) with scientific support. One study indicates an in vitro synergistic effect of the combined use of doxycycline and azithtromycin against *P. aeruginosa*.²⁵⁹

Therapeutic Use

The therapeutic indications for tetracyclines are many but have decreased in recent years because of the advent of resistance. Treatment of microbial infections is best based on C&S data. Doxycycline is the preferred tetracycline because of its ability to move intracellularly compared to other tetracyclines. Doxycycline generally is indicated among first-choice therapies for obligate intracellular organisms, including ehrlichiosis, Rocky Mountain spotted fever, chlamydiosis, mycoplasmosis, and hemobartenellosis. Doxycycline also has been used to treat canine brucellosis. Other potential indications include leptospirosis and Lyme disease.

Phenicols

Chloramphenicol has been widely used in the past, but the development of resistance and human toxicity to chloramphenicol have severely curtailed its use and commercial availability. Florfenicol is a commercially available thiamphenicol derivative approved for treatment of bovine respiratory diseases complex. A sulfonyl group replaces the aromatic ring nitro group that is otherwise associated with chloramphenicol's irreversible bone marrow suppression in humans (see Figure 7-5). As chloramphenicol increasingly is difficult to obtain commercially, florfenicol may find a niche for use in small animals, particularly cats, in which the disposition is more predictable than with dogs.

Mechanism of Action

Like tetracyclines, chloramphenicol and florfenicol bind bacterial ribosomes and impair protein synthesis (see Figure 7-6). However, binding occurs at the 50s subunit with inhibition of peptidyl transferase. Actions are bacteriostatic in action, and these drugs should not be used in immunocompromised patients. As with other bacteriostatic ribosomal inhibitors, the effects of chloramphenicol and florfenicol should be considered time dependent. As with tetracyclines, although host ribosomes do not bind as effectively as do bacterial ribosomes, some host ribosomal activity will be impaired. Binding sites for chloramphenicol are close to those for clindamycin, which it competitively inhibits.⁸⁰ Chloramphenicol also inhibits mitochondrial protein synthesis in mammalian cells, with erythropoietic cells particularly sensitive.

Spectrum of Activity

Chloramphenicol is considered broad spectrum (see Table 7-1), being effective against gram-positive, gram-negative, and anaerobic organisms. *P. aeruginosa* is generally not included. The spectrum of action also includes *Chlamydia*, *Mycoplasma*, *Rickettsia*, and *Hemobartonella* organisms. As previously noted, tetracyclines are considered more effective than chloramphenicol for the latter organisms, but chloramphenicol tends to be more clinically effective for other organisms. The spectrum of activity of florfenicol is similar to chloramphenicol; although the anaerobic spectrum has not been described, it is assumed to be similar. The MIC for florfenicol of small animals generally reflects 1.0 to 8.0 µg/mL.

Resistance

Resistance to chloramphenicol is caused by destruction (acetylation) of the drug by microbial enzymes. The fluorine ring of florfenicol may impair bacterial acetylation, and thus florfenicol is more resistant to bacterial deactivation;²⁶⁰ selected organisms resistant to chloramphenicol may be susceptible to florfenicol.²

Pharmacokinetics

Chloramphenicol is very well absorbed after oral administration in its crystalline form. Many of the originally-approved preparations are no longer available in the United States. The liquid form is less well absorbed, so much so that the palmitate form should not be used for cats because of variability in oral absorption. The chloramphenicol succinate ester is the water-soluble form intended for injection (see Table 7-1). The succinate must be hydrolyzed by plasma, hepatic, pulmonary, or renal esterases before activity. Chloramphenicol palmitate is a suspension for oral administration. Its ester is hydrolyzed by small intestinal lipases; the freed chloramphenicol is then orally absorbed. The freed chloramphenicol is among the most lipid soluble of the clinically used drugs and achieves moderate to high concentrations in most body tissues, including the CSF. It is, however, unlikely to achieve bactericidal concentrations in most tissues, including the CNS. Most of the drug is eliminated by hepatic metabolism. Glucuronidation is a major route of elimination of chloramphenicol. Cats eliminate chloramphenicol more slowly because of deficiencies in both phase I and phase II metabolism. Greater concentrations may occur in cat urine than in dog urine as a result.²⁶¹ Pediatric patients also may not eliminate chloramphenicol as efficiently as young adult dogs.

KEY POINT 7-36 Although chloramphenicol is bacteriostatic, its excellent tissue distribution and relatively long half-life render it potential appealing choice in immunocompromised patients.

Chloramphenicol was studied after single oral dose as the commercially available Chloromycetin (50 mg/kg) in dogs.²⁶² Although pharmacokinetics were not reported, the C_{max} (μ g/mL) at T_{max} were, respectively, for Greyhounds with feeding, 21.6 ± 4.8 at 1.5 hours, or without feeding, 18.6 ± 6.7 at 3 hours; large dogs (22-26 kg), 20.0 ± 4.8 at 1.5 hours; and small dogs (11.4 to 15.5 kg), 27.5 ± 7.0 at 3 hours. Peak concentrations were notably higher in small dogs than large dogs. Half-life in Greyhounds was 3.2 hours in fasted dogs versus 1.9 hours in fed dogs; the elimination half-life (based on noncompartmental anaylsis of published data) in large dogs was 2.3 hours compared with 3.4 hours in small dogs. Average half-life among all groups was 2.7 ± 0.7 hours; mean residence time was 4.6 ± 0.67 hours. Neither oral bioavailability nor clearance was determined.

During approval for use in humans, chloramphenicol was studied in dogs.²⁶³ Chloramphenicol was measured on the basis of an analytic procedure that detected chloramphenicol and its metabolites; therefore the relevance of the data must be considered. Homogenate tissue concentrations were described after subcutaneous administration of 35 mg/kg for 2 dogs: at 1.5 and 3 hours, plasma concentrations were 21 and 13, respectively, yielding an elimination half-life of 2.9 hours. Concentrations in the brain and CSF at the same time were 15 and 8 µg/mL (brain) and 7 and 9 µg/mL (CSF), yielding a 3-hour plasma:tissue ratio of 0.7. A second study measured chloramphenicol using a bioassay. However, only a single dog was studied after oral administration of 150 mg/kg of the crystalline powder form. The C_{max} was 45 µg/mL at 4 hours and approximately 15 µg/mL at 8 hours, yielding a disappearance half-life of 2.5 hours. This should extrapolate to a C_{max} of approximately 14 µg/mL when 50 mg/kg is administered. Although 54% of the drug was eliminated in the urine, only 6.3% of the drug in the urine was pharmacologically active. Intravenous administration of 50 mg/kg yielded an initial plasma concentration of approximately 39 µg/mL and a concentration of approximately 5 µg/mL at 8 hours, yielding a half-life of about 1.5 hours.²⁶³

Chloramphenicol has been studied in cats (n = 5). Oral administration of the crystalline powder in capsules yielded C_{max} (µg/mL) of 43 to 62 at 40 mg/kg, 25 to 42 at 20 mg/kg tid, and 8 to 25 at 50 mg bid.²⁶⁴ Cats were also dosed with succinate intravenously, intramuscularly, subcutaneously, or orally (crystalline powder in capsules).²⁶⁵ Concentrations at 30 minutes (T_{max} for each route except oral) were, respectively ($\mu g/mL$) 19.5 ± 1.5 (intravenous), 18.6 ± 2.6 (intramuscular), 14.8 ± 2.9 (subcutaneous) and 9.8 ± 2.61 (oral) after administration of 20 mg/kg (n = 5). The mean half-life of all three routes was $4.4 \pm$ 1.38; range was 3.3 hours for subcutaneous and 6.9 hours for intravenous. AUC for each route was similar (lowest at 55 \pm 7 μ g*hr/mL for intravenous, highest at 67 ± 9 for subcutaneous). Finally, the bioavailability of the palmitate salt suspension is poor in cats, particularly in the fasted state.²⁶⁶ Peak concentrations of the crystalline form following 100 mg/cat was 25 ± 5 (fasted) or 31 ± 3 (fed) versus 6.5 ± 1.3 (fasted) and 16 ± 3 (fed) for the succinate form.

Florfenicol has been studied in dogs and cats.^{260,267} In dogs, although predictable PDCs (1.64 µg/mL) are achieved at 20 mg/kg after intramuscular administration, concentrations are unpredictable after subcutaneous administration. The drug appears to follow a "flip-flop" model, with the elimination half-life in dogs following intramuscular administration much longer (9 hours) compared with intravenous administration (<1 hour). A second study determined the oral bioavailability and described in more detail the PK of florfenicol (based on HPLC) in dogs (n = 6) after intravenous and oral administration (20 mg/kg).²⁶⁷ Florenicol clearance was 1.03 ± 0.49 l*kg/ hr, and the Vd_{ss} 1.45 \pm 0.82 L/kg.The elimination half life is 1.11 + 0.94 hour after intravenous and 1.24 \pm 0.64 after oral administration. Oral bioavailability was 95 \pm 11%, with C_{max} reaching 6.18 μ g/mL at a T_{max} of 0.94 hour. Florfenicol amine is a major metabolite of florfenicol, with a longer half-life in dogs (2.26 hours), but it has only 1/90 the activity of the parent compound, and its contribution to microbiological activity is considered negligible. Dogs showed no evidence of side effects after either intravenous or oral administration. The disposition of florfenicol by the intramuscular route appears to be more predicatable in cats than dogs, with C_{max} (22 mg/kg) reaching 20 µg/mL after IM administration and 27 µg/mL after oral administration (see Table 7-1).²⁶⁷ Oral administration was based on a solution of 100 mg/mL. The elimination half-life was 8 hours in cats after oral administration, supporting a 12-hour dosing interval. The distribution volume in cats is supportive of a lipid-soluble drug. Adverse reactions were not noted in the six cats studied.

Adverse Effects

A major toxic concern with chloramphenicol for humans is both reversible dose-dependent and irreversible doseindependent (rare) bone marrow suppression. Reversible bone marrow suppression can also occur in animals. Dosedependent bone marrow effects may reflect suppression of bone marrow precursor cells after mitochondrial damage. Irreversible bone marrow suppression may reflect reduction of the NO₂ group to a toxic metabolite that causes stem cell damage. Irreversible suppression should be avoided with florfenicol, which lacks the NO₂ group. Although cats appear more sensitive to chloramphenicol-induced reversible bone marrow suppression than do dogs, toxicosis appears rapidly reversible once the drug is discontinued. Toxicity to chloramphenicol occurs in cats after 7 days of therapy at 50 mg/kg, administered intramuscularly. The drug can, however, be used for 7 to 10 days safely in cats after oral administration of the crystalline form (capsules) at the rate of 50 mg/cat.^{265,266} The antianabolic effects of chloramphenicol may result in impaired protein synthesis in the patient; however, despite earlier concerns, impaired immune response to vaccines does not appear to occur.

KEY POINT 7-37 Irreversible bone marrow suppression has resulted in limited availability of chloramphenicol products.

Drug Interactions

Because they compete for the same ribosomal binding site, chloramphenicol should not be used in combination with macrolides. Because they target two different ribosomal sites, the combination of chloramphenicol with tetracyclines is appealing. Interestingly, the combined use of chloramphenicol with penicillins has been demonstrated to enhance penicillin (bacteriostatic) activity in Enterobacteraceae that are otherwise resistant to penicillins because of beta-lactamase production. Chloramphenicol inhibits product of beta-lactamases in these organisms.^{267a} Chloramphenicol is a potent inhibitor of drugmetabolizing enzymes and inhibits the hepatic metabolism of other drugs, potentially causing toxicity should drug concentrations increase. Prolonged sleeping times have been documented after administration of pentobarbital to dogs and cats also receiving chloramphenicol;²⁶⁸ chloramphenicol has markedly prolonged phenytoin half-life²⁶⁹ and phenobarbital half-life (see Chapter 2) in dogs. Phenobarbital-induced sedation and ataxia have occurred in as few as 3 days of chloramphenicol therapy. Chloramphenicol decreases the rate of elimination of digoxin.²⁷⁰

KEY POINT 7-38 Chloramphenicol is a potent inhibitor of drug-metabolizing enzymes.

Therapeutic Use

Chloramphenicol has been commercially available as a palmitate (oral) salt and a sodium succinate injectable preparation. Florfenicol is commercially available only as solution intended for (intramuscular) injection, which has been studied in dogs and cats.

Lincosamides: Lincomycin and Clindamycin

The lincosamides, including lincomycin and its congener, clindamycin, are large glycosidic antimicrobials that contain an amino side chain (see Figure 7-5). They are often used in humans as penicillin substitutes to minimize the risk of penicillin hypersensitivity. The lincosamides inhibit the 50s subunit of the bacterial ribosomes but at a site distinct from that bound by the macrolides or chloramphenicol (see Figure 7-6). Peptidyl transferase is subsequently inhibited. Efficacy

is reduced when the lincosamides are used concurrently with macrolides. The ribosomal action of the lincosamides results in a bacteriostatic action against susceptible organisms at recommended doses. Clindamycin is generally bacteriostatic but can be bactericidal at concentrations that can be achieved in some tissues. As with other bacteriostatic drugs, the lincosamides are classified as time dependent, implying that plasma or tissue drug concentrations should exceed the MIC of the infecting organism for the majority of the dosing interval; efficacy also may be related to the AUC/MIC.

The spectrum of the lincosamides varies with the drug. Clindamycin is more effective against susceptible bacteria compared with lincomycin and also has greater activity toward anaerobes. The spectrum of clindamycin includes aerobic grampositive cocci, including Staphylococcus and Streptococcus spp. as well as Nocardia spp. and anaerobic organisms including B. fragilis, Fusobacterium spp., Clostridium perfringens, Peptostreptococcus, and Actinomyces spp. Clindamycin also is effective against cell wall-deficient organisms such as Mycoplasma spp. Plasmid-mediated resistance reflects changes in the ribosomes and appears to be increasing against *Staphylococcus* spp. and Bacteroides spp. Resistance to one lincosamide generally results in resistance to others. Occasionally, resistance to macrolides may confer resistance to clindamycin if the mechanism reflects methylation of the ribosome.⁸⁰ Clindamycin is not a substrate for the macrolide efflux pump.

Because of its anaerobic and gram-positive spectrum, clindamycin often is chosen as one component of combination antimicrobial therapy. This combination also has been used to target *P. aeruginosa*; although generally ineffective as a sole agent, clindamycin may alter adherence of the microbe to epithelial cells, facilitating killing by the alternative drug.

Pharmacokinetics

Only oral preparations of clindamycin are approved in the dog and cat; an injectable preparation is approved for use in humans. Both clindamycin and lincomycin are bioavailable after oral administration, although clindamycin is more so. Food does not impair the absorption of clindamycin but does appear to impair absorption of lincomycin. Clindamycin is available as the hydrochloride, palmitate, or phosphate salts. The palmitate form is an oral prodrug, with the ester being rapidly hydrolyzed to yield free drug. The phosphate form is intended for parenteral administration, including subcutaneous, intramuscular (although it is painful), and intravenous routes. In the cat administration of 5.5 and 11 mg/kg orally generates serum concentrations above the MIC of most S. pseudintermedius organisms and previously S. aureus, but it is likely that resistance has resulted in less favorable PDI. Higher doses (11 to 20 mg/kg) will generate concentrations above the MIC of most susceptible anaerobes (see Table 7-1). In dogs oral administration of 11 mg/kg every 12 hours has been sufficient for treatment of most Staphylococcus spp. infections, but current MIC₉₀ for clindamycin and susceptible Staphyloccocus spp. have not been reported. As a time-dependent drug, decreasing the interval to 8 to 6 hours may increase efficacy. Clindamycin is highly (>90%) protein bound. Distribution of the lincosamides includes most body tissues, with excellent concentrations being achieved in the skin and bones. However, it does not substantially penetrate the brain or CSF, although it can achieve concentrations effective for toxoplasmosis.⁸⁰ Its Vd in both dogs and cats approximates 1.5 L/kg. Clindamycin has been cited for its efficacy in the treatment of chronic gingivitis or periodontal disease. Unlike many other drugs with a favorable spectrum, it is able to penetrate the biofilm that protects the causative organisms. Accumulation of clindamycin in white blood cells up to fortyfold or more may increase the probability of reaching bactericidal concentrations at some sites of infection. The lincosamides are eliminated primarily by biliary excretion.

After administration of 10 mg/kg intravenously, intramuscularly, and subcutaneously in dogs, in addition to C_{max} and elimination half-life (see Table 7-1), the following were achieved: T_{max} occurred at 73 ± 16 min (intramuscular) or 47 ± 20 min (subcutaneous) and CL (mL/min/kg) 6.1 \pm 1.1. The elimination half-life may vary with the route (see Table 7-2), as does mean residence time at 143 ± 34 , (intravenous), 700 \pm 246 (intramuscular), or 364 \pm 147 (subcutaneous) minutes. Bioavailability was 115% after intramuscular and 310% after subcutaneous administration. The long half-life coupled with the highest C_{max} suggests that the subcutaneous route of administration is the preferred parenteral route for clindamycin.²⁷² The reason for the very high bioavailability after subcutaneous administration is not clear, although enterohepatic circulation is anticipated to increase bioavailability regardless of route of administration.

Clindamycin disposition has been reported in cats after oral administration of either a capsule or aqueous solution (see Table 7-1). ²⁷¹ Peak PDCs are equivalent for both preparations, but a longer half-life for the capsule may contribute to a (not statistically significant) greater AUC for the capsule (42.6 ± 12.2) compared with the solution (35 ± 9.2). The lack of statistical difference may reflect the marked variability in half-life mean residence time for both preparations, which was approximately 6.5 hours.

Adverse Reactions, Drug Interactions, and Indications

Pseudomembranous colitis is a reported side effect in humans caused by overgrowth of C. difficile. The negative impact on the intestinal microbiota may persist for more than 2 weeks.⁸⁰ Because of similar mechanisms of action, this drug should not be combined with chloramphenicol or erythromycin. It has been combined with aminoglycoside treatment of polymicrobial infections involving gram-negative and anaerobic organisms. The use of clindamycin as combination antimicrobial therapy was addressed in the preceding section. Because of its ability to impair pili formation and thus adherance to tracheal epithelium, clindamycin has been associated with treatment of cystic fibrsosis associated with P. aeruginosa in humans, generally in association with antipseudomonadal antimicrobials.²⁷³ However, the macrolides are more generally accepted for this use. The use of clindamycin as part of combination chemotherapy targeting protozoal disease (toxoplasmosis) is addressed in Chapter 12).

Macrolides and Azalides

Structure-Activity Relationship

The macrolides are named for their chemical structure, composed of a very large lactone (MW >750 to >1000) ring attached to a number of sugars.²⁷⁴ They include the azalides, which contain a nitrogen in the ring structure (see Figure 7-13). No macrolide derivative is approved for use in dogs or cats at the time of this publication. Human-medicine drugs include the14member rings erythromycin and clarithromycin and the 15-member ring azithromycin (an azalide semisynthetic derivative of erythromycin), spiramycin, and dirithromycin (a prodrug converted to the active erythromycylamine). The methyl group that distinguishes clarithromycin from erythromycin and the additional methyl group on azithromycin increases acid stability and enhances tissue distribution. Telithromycin is a ketolide macrolide (discussed later). Tylosin, a drug approved for use in food animals, is used to treat intestinal disorders, largely in dogs. Of the human drugs, erythromycin (firstgeneration), azithromycin, and to a lesser extent, clarithromycin (second-generation) are used in dogs and cats.²⁷⁴ Tilmicosin is approved for use in selected food animals, but toxicity precludes its use in the injectable form in dogs and cats; information is not available regarding safety of other preparations. The second-generation macrolides differ from erythromycin only by the addition of a methyl group substitution. However, this simple change improves acid stability and tissue penetration. Further, because the methyl group enhances interaction with bacterial ribosomes, the spectrum also is improved.274

KEY POINT 7-39 Efficacy of the very lipid-soluble macrolides and clindamycin is facilitated further by accumulation in phagocytic white blood cells.

Mechanism of Action

Macrolides inhibit bacterial ribosomal action by binding to the 50s subunit of susceptible organisms (see Figure 7-6), and impairing the translocation step of protein synthesis. The azalides macrolides bind the ribosome at two sites.²⁷⁵ Although macrolides are classified as bacteriostatic in vitro, they are bactericidal against very susceptible organisms. Further, selected drugs (e.g., azithromycin) accumulate in selected tissues at bactericidal concentrations. All macrolides generally accumulate in phagocytic white blood cells, which may facilitate distribution to the site of infection. Efficacy is enhanced in an alkaline pH, probably because of increased diffusion of the nonionized drug into organisms; as such, intracellular activity may be decreased in phagocytic cells. The antibacterial effects of the macrolides vary with the drug and are time dependent for erythromycin; antibacterial effects for azithromycin and clarithromycin are time dependent for some organisms and concentration dependent for others.

Spectrum of Activity

Like the lincosamides, the macrolides are often used in humans as penicillin substitutes to minimize the risk of penicillin hypersensitivity. Organisms are considered susceptible to the

macrolides at an MIC below 2 µg/mL. For the first-generation drugs, gram-positive organisms accumulate erythromycin at concentrations that exceed that of gram-negative organisms by a hundredfold. As such, erythromycin is most effective against gram-positive organisms. Streptococcus spp. are susceptible at a range of 0.015 to 1 μ g/mL, although resistance is increasing. Many Staphyloccocus organisms have remained susceptible to erythromycin, but MIC ranges of 0.12 to > 128 μ g/mL for S. aureus indicate an increasing trend of resistance. Among the staphyloccoci, S. pseudintermedius remains the most susceptible. P. multocida, Bordetella pertussis, and Mycoplasma spp. are among the organisms susceptible to erythromycin. However, use should be based on C&S testing. Erythromycin generally is effective against anaerobic organisms, with the exception of Bacterioides spp. Macrolides are generally effective against Campylobacter spp.

The azolides were designed to overcome barriers presented to penetration of gram-negative organisms. Thus the spectrum of azithromycin and clarithromycin increases, particularly in terms of gram-negative bacteria, although efficacy toward selected gram-positive microbes may decrease, requiring higher MIC.²⁷⁵ The actions of the azolides are bactericidal for Streptococcus pyogenes and S. pneumoniae but bacteriostatic toward staphylococci and most aerobic gram-negative organisms. Clarithromycin is effective at lower concentrations than erythromycin against Streptococcus and Staphyloccus spp. but is similar to erythromycin in efficacy against other organisms. Azithromycin has less activity against gram-positive organisms compared with erythromycin and greater activity against selected gram-negative organisms and Mycoplasma spp.80 Although the spectrum of the macrolides generally includes Actinomyces spp., efficacy is generally less for Nocardia spp. Clarithromycin and azithromycin are effective against the Mycobacterium avium complex, Mycobacterium leprae, and Toxoplasma gondii. Compared to erythromycin, azithromycin and clarithromycin have enhanced activity against selected protozoa (e.g., T. gondii, Cryptosporidium spp.).

Controversy surrounds the classification of macrolides as either concentration or time dependent. The macrolides do exhibit a postantibiotic effect, with that of clarithromycin and azithromycin being longer than that of erythromycin. Azithromycin appears to be bacteriostatic against *Staphylococcus* or *Streptococcus* spp.; in vitro killing did not increase in a dose-dependent manner, suggesting that the drug is a timedependent antimicrobial.²⁷⁶

Resistance

Acquired mechanisms of resistance to macrolides include pump-driven drug efflux from the cell (particularly in staphylococci, group A streptococci, and *S. pneumoniae*) and altered ribosomal targets (methylase enyzme; MLSB phenotype) that also confer resistance to lincosamides, which bind at the same ribosomal site. Efflux pumps contribute to resistance in *E. coli* as well.¹⁷⁹ Chromosomal mutations in *Bacillus subtilis*, *Campylobacter* spp., and gram-positive cocci alter the ribosomal binding site. Resistance of *S. aureus* to erythromycin generally is indicative of resistance to azithromycin and clarithromycin as well. The Enterobacteriaceae produce an esterase that hydrolyses the drug.

Pharmacokinetics

The macrolides and azolides are largely water insoluble and are unstable in the acidic gastric environment.²⁷⁴ However, each of the macrolides is available as an oral preparation. Erythromycin also is available as a topical and ophthalmic preparation. Erythromycin base preparations generally are coated to prevent gastric degradation. Oral absorption of entericcoated or delayed-release products designed for humans may be unpredicatable in animals.² Oral salts include the estolate and ethylsuccinate salts, which must be de-esterified after oral absorption, and the stearate (octadecanoate) and phosphate salts. The former (and possibly the latter) dissociate in the duodenum to be absorbed as the free base. The disposition of selected erythromycin salts has been described in dogs.²⁷⁷

After oral administration, the erythromycin base is incompletely but adequately absorbed. Food may increase acidity and thus delay absorption. Esters (stearate, estolate, ethylsuccinate) improve stability and absorption but do not appear to increase PDCs. Among the salts, estolate appears to be best absorbed orally and minimally affected by food. For the azolides, clarithromycin is characterized by greater acid stability compared with erythromycin. Clarithromycin is more rapidly absorbed (in humans), but food delays absorption and first-pass metabolism (to an active metabolite) further reduces oral bioavailability of the parent compound to 50%. Azithromycin also is absorbed rapidly, but, again, food decreases bioavailability to 43% (in humans). Erythromycin is approximately 75% protein bound; binding is as high as 96% (in humans) for the estolate salt. Protein binding for clarithromycin is concentration dependent and ranges from 40% to 70%. Despite their large moleculer size, macrolides are sufficiently lipid soluble that they diffuse through membranes, albeit slowly. With a Vd of 2 L/kg in dogs, erythromycin will reach effective concentrations in all tissues except the brain and CSF. In general, the macrolides act as weak bases and, as such, trapped in an acidic environment, including acidic intracellular organelles. Consequently, tissue concentrations will exceed plasma in many tissues. Although accumulation occurs in selected tissues (e.g., bile, bronchial secretions, phagocytic white blood cells), concentrations reach only 50% of plasma in the prostate and aqueous humor and less than 15% in the CSF. Concentrations in the middle ear will approximate 50% of those in plasma. Clarithromycin and its active metabolite are well distributed, achieving higher concentrations than erythromycin in both the middle ear and CNS. Among the macrolides, azithromycin distributes the most extensively, with a Vd that exceeds (in humans) 30 L/kg. Fibroblasts act as a reservoir, with transfer to phagocytic cells. Whereas erythromycin and azithyromycin are eliminated principally in the bile, clarithromycin is extensively metabolized to an active (14 hydroxy derivative) metabolite. Excretion is primarily by biliary secretion into the feces; enterohepatic circulation of active drug might be anticipated. Urine excretion is not significant (3% to 5%), with concentrations in urine being low (approximately 50% of plasma); an exception is clarithromycin, for which the active metabolite might achieve high concentrations in urine. The elimination half-life for azithromycin has been reported at 1 to 1.5 hours in dogs^{279, 280} and cats.

The disposition of erythromycin as the estolate tablet and ethylsuccinate suspension and tablet has recently been described in dogs.²⁷⁷ Intravenous administration revealed a Vd of 4.8 L/kg (see Table 7-1) and a clearance of 2.64 ± 0.84 L/hr/kg. Oral absorption of all three products was poor: the ethylsuccinate tablets did not yield predictably detectable concentrations, whereas, based on mean AUC adjusted for differences in dose, the bioavailability of the estolate tablet was only 11% (T_{max} 1.7 hr) and the ethylsuccinate suspension only 3% (T_{max}, 0.7 hr). Absorption of the suspension, in particular, was described by the authors as erratic. Peak concentrations did not reach MIC₉₀ for susceptible Staphylococcus spp. of 0.5 µg/mL (reported by the authors) for any of the oral preparations. The apparent efficacy of erythromycin, despite poor absorption, may reflect accumulation of drug in tissues such that higher concentrations are achieved at the site of infection.²⁷⁷ All dogs vomited after dosing, regardless of route of administration, with vomiting apparent 5 to 10 minutes after intravenous administration, approximately 45 minutes after oral succinate preparations, and 1 to 2 hours after the estolate tablet administration.

Limited information is available for the second-generation macrolides in animals. Azithromycin and clarithromycin absorption is influenced by uptake transporters in the intestinal epithelium. Whereas efflux transporters, such as P-glycoprotein, decrease absorption, others (organic anion-transporting proteins) facilitate uptake.²⁷⁸ Azithromycin has been studied in cats and dogs (see Table 7-1).^{279, 280} Bioavailability in the dog is greater than 97%. Serum protein binding is less than 25%.

Clearance is 6.0 mL*min/kg. In dogs 67% of the drug is eliminated in the bile and 33% in the urine.²⁷⁹ The majority of the drug (75%) is eliminated unchanged. The remaining portion is metabolized by cytochrome P450s into a number of metabolites, which, with one exception, are inactive. Tissue concentrations (based on homogenate) at 24 hours after 20 mg/kg orally were over 101, 20, and 39 µg/mL, respectively, for liver, kidney, and lungs. After 5 days of dosing, 23 µg/mL was achieved 24 hours after the last dose in the eye but only 1.2 μ g/mL in the brain (at 30 mg/kg for 5 days). In cats the maximum drug concentration (C_{max}) of 0.97 ± 0.65 µg/mL occurs at T_{max} of 0.85 ± 0.72 hr. Plasma concentrations (µg/ mL) range from approximately 8 at 1 hour to 0.1 at 12 hours after intravenous administration of 5 mg/kg and approximately 1 µg/mL to 0.1 µg/mL during the same times after oral administration of 5 mg/kg. Although the elimination half-life is long, concentrations in plasma are below 0.1 µg/mL after 12 hours. However, concentrations of azithromycin approximate 0.75 to 1 μ g/mL in the femur, skin, and muscle versus 10 μ g/mL in tissues characterized by reticuloendothelial cells (liver, spleen, and to a lesser degree lung) and the kidney with concentrations persisting for 72 hours or more. Because tissue concentrations were based on homogenate, it is not clear how much drug is available to interstitial fluid. Clearance is 0.64 ± 0.24 L*hr/kg. Oral bioavailability is $52 \pm 22\%$. The elimination halflife is 35 (range 29 to 51 hours).²⁸⁰ The Clinical Laboratory and Standards Institute susceptible breakpoint for azithromycin (human pathogens) is 4 µg/mL. Because concentrations decline to less than 0.1 µg/mL by 12 hours, daily dosing should be considered in both cats and dogs; because time to steady state will approximate 3 to 5 days, a 15 mg/kg loading dose should be considered followed by once-daily dosing at a minimum of 5 mg/kg. Although cats do metabolize azithromycin, the unchanged drug is the predominant form in tissues. Biliary excretion is a major route of clearance in the cat.²⁸⁰ Kinetics of clarithromycin become zero order (saturated) at higher doses. The large Vd of the macrolides contributes to their long elimination half-life. The half-life in cats exceeds 72 hours in some tissues.²⁸⁰ In contrast to azithromycin, urinary concentrations of clarithromycin can be signifcant: up to 40% of the parent drug or its metabolite are eliminated in the urine. The mean half-life in plasma is 35 hours but varies in tissues from a low of 13 hours (fat) to a high of 72 hours (cardiac muscle).

Adverse Effects

Side effects of the macrolides are limited. With injectable products, pain may occur with intramuscular injection and thrombophlebitis with intravenous injection. Reversible cholestatic hepatitis accompanied by jaundice has been reported in humans 10 to 20 days into erythromycin therapy, especially with the estolate preparation.

Gastrointestinal upset is the most common adverse effect of the macrolides. Up to 50% of animals treated with erythromycin may exhibit vomiting. Erythromicin is motilin-like in action and characterized by marked prokinetic effects on gastrointestinal motility. This effect is dose dependent in humans and may occur more commonly in younger animals. Abdominal cramping, epigastric pain, and increased gastric emptying resulting from increased gastric motility also may occur. However, because contraction is not coordinated, efficacy as a prokinetic is limited. Gastric emptying may decrease gastric maceration of ingested food, although the impact on digestion is not likely to be significant. Azithromycin and clarithromycin do not appear to have the same gastrointestinal side effects of erythromycin. In humans allergic reactions occur rarely and are manifested as fever or skin eruptions, which resolve once therapy is discontinued. Cholestatic hepatitis is an infrequent side effect in humans.

Drug Interactions

Antacids decrease the rate (and thus peak) but not extent of absorption of azithromycin, whereas food decreases the extent by close to 50%. The macrolides may inhibit cytochrome P450 enzymes, and CYP 3A4 in particular, impairing the metabolism of other drugs.^{280a} Among the macrolides, erythromycin followed by clarithromycin is most likely to be involved in significant drug interactions, although all three drugs inhibit drug-metabolizing enzymes. The effects of drugs metabolized by the liver, including selected anticonvulsants, cardiac drugs, and theophylline, are likely to increase. Drugs affected in humans include glucocorticoids, digoxin, theophylline, and warfarin. The macrolide antimicrobials (clarithromycin, roxithromycin) also increase the risk of digoxin toxicity, although this effect may be more reflective of competitive interactions with P-glycoprotein transport proteins.²⁸¹ Azithromycin is a substrate; others may be as well.²⁸² Among the P-glycoprotein interactions with azithromycin in cats is cyclosporine; peak cyclosporine concentrations exceeded 4500 ng/mL in a cat receiving 5 mg/kg while being treated with azithromycin.

Because they are ribosomal inhibitors, care must be taken not to combine the macrolides with drugs whose efficacy requires rapid bacterial growth, unless scientific support exists, or "-cidal" concentrations of the macrolide are achieved at the target site for both drugs. For example, synergistic effects have been documented against B. fragilis when erythromycin is combined with cefamandole and against Nocardia asteroides when combined with ampicillin. The use of erythromycin in combination with other antimicrobials is limited in small animals. Erythromycin has been used in combination with rifampin to treat Rhodococcus equi in horses; a similar application has not been identified in dogs or cats. Synergistic antimicrobial actions also have been reported against P. aeruginosa for either azithromycin or clarithromycin when combined with sulfadiazine/trimethoprim or doxycycline. In humans azithromycin has been combined with antipseudomonadal drugs, particularly for treatment of cystic fibrosis-associated P. aeruginosa infections. This may reflect an apparent immunomodulatory effect of azithromycin or its ability to inhibit adherence of pseudomonad organisms to respiratory epithelium. Less commonly, synergism has been demonstrated for azithromycin when combined with ticarcillin/clavulanic acid, piperacillin/ tazobactam, ceftazidime, meropenem, imipenem, ciprofloxacin, travofloxacin, chloramphenicol, or tobramycin.²⁵⁹

Although not included in their spectrum, the macrolides, like clindamycin, impair the ability of *P. aeruginosa* to adhere to tracheal epithelium, the first step in respiratory tract infection. The effect occurs at least at subinhibitory concentrations and reflects decreased ability to form pili.²⁷³ Decreased adherence to human mucins also has been demonstrated for azithromycin.²⁸³ Other proposed effects of azithromycin include decreased alginate formation and decreased biofilm. Azithromycin has been demonstrated to impede, but not prevent, biofilm formation by *Pseudomonas* spp.²⁸⁴ These attributes have led to its long-term use for treatment of cystic fibrosis in humans, generally in association with some level of antipseudomonadal antimicrobials. Antiinflammatory effects have also been attributed to azithromycin's apparent long-term efficacy for treatment of cystic fibrosis.^{285,286}

Tylosin

Tylosin is a classified as a macrolide, but it is structurally somewhat different from erythromycin, leading to differences in its mechanism and spectrum. Like erythromycin, it targets the 50s ribosomal subunit, but with different sequelae. It is stable in the gastric environment and does not require enteric coating for oral administration. Like erythromycin, tylosin is distributed well to most body tissues and is eliminated by hepatic metabolism and biliary excretion. Approved for use in the United States for treatment of swine dysentery and other large animal syndromes, tylosin also has been used in small animals to treat infections of the gastrointestinal tract (associated with chronic inflammatory bowel disease) and bacterial pyodermas. Its spectrum is not clear but includes selected gram-positive and gram-negative organisms.

Ketolides

Like the azolides, the ketolides are semisynthetic modifications of erythromycin designed to minimize barriers to penetration in gram-negative organisms.²⁷⁵ Telithromycin is the first ketolide approved for clinical use in humans; the drug was developed specifically for treatment of upper and lower respiratory tract infections caused by organisms resistant to the macrolides.²⁸⁷ Like the macrolides and azalides, the ketolides are well distributed into tissues, with concentrations being maintained in humans sufficiently long to allow a 24-dosing interval. Thus far, the ketolides have not been used or studied in veterinary medicine, perhaps because azithromycin currently meets the needs of infections that might otherwise be treated with ketolides.

MISCELLANEOUS ANTIMICROBIALS

Oxazolidinones

Oxazolidinones are a new group of synthetic antimicrobials effective against gram-positive bacteria, including methicillin- and vancomycin-resistant staphylococci, vancomycinresistant enterococci, penicillin-resistant pneumococci, and anaerobes.288 Linezolid is the first of this class of drugs to be approved for use in the United States (see Figure 7-4). Oxazolidinones inhibit the initiation of protein synthesis by binding at the P site of 50S ribosomal subunit; it also binds to the 70S subunit. Oxazolidinones compete with chloramphenicol and lincomycin for binding of the 50S subunit, which indicates that they have close binding sites, even though oxazolidinones do not inhibit peptidyl transferase as do chloramphenicol and lincomycin. Oxazolidinones may inhibit formation of the ribosomal initiation complex, similar to aminoglycosides. The mechanism is sufficiently different from other 50S binders that resistance to other protein synthesis inhibitors does not cross over to the oxazolidinones. Efficacy against Staphylococcus spp. is characterized by an MIC₉₀ between 1 and 4 µg/mL in humans; methicillin resistance does not appear to affect susceptibility. Linezolid also is effective against enterococci; even intermediate isolates appear to be susceptible at 1 µg/mL.288 Streptococci also are susceptible. Anaerobic activity is comparable to clindamycin.²⁸⁹ Linezolid is effective toward atypical mycobacterium²⁹⁰ and both Actinomyces and Nocardia sp. Activity toward S. pneumoniae is generally bactericidal but bacteriostatic against staphylococci and enterococci. 291, 292 Antibacterial effects appear to be time dependent, with efficacy related to AUC/MIC. Resistance thus far is rare.

Disposition includes good oral absorption and good tissue penetration. Linezolid accumulates in bone, lung, vegetations, hematoma, and CSF. Concentrations in sanctuaries are lower than those in plasma.²⁹³ Linezolid has been approved by the FDA for treatment in humans of complicated skin infections or nosocomial pneumonia caused by MRSA, concurrent bacteremia associated with either vancomycin-resistant *E. faecium* or CA pneumonia caused by penicillin-resistant *S. pneumoniae*.²⁸⁸ It has become the drug of choice for treatment of resistant gram-positive infections. The oxazolidinones have been minimally used in dogs and cats, and their use is discouraged unless warranted on the basis of C&S testing and until kinetic studies are available in the target species (e.g., cats).

Linezolid PK has been described in the dog after oral and intravenous administration (see Table 7-1).²⁹³ Oral absorption is rapid and complete, allowing intravenous and oral dosing to be the same. The drug is minimally protein bound. Clearance is 2.0 ± 0.3 mL*min/kg. The drug appears to undergo limited metabolism to inactive metabolites that are extensively enterohepatic recycled. Renal excretion occurs for parent compounds and metabolites. In humans renal disease causes accumulation of metabolites that may contribute to adverse effects.²⁹⁴

Linezolide appears to be well tolerated in humans. Myelosuppression has occurred in humans. Additionally, it is an inhibitor of monoamine oxidases, and care should be taken in patients also receiving serotonergic or adrenergic drugs or dietary supplements. Peripheral neuropathies have been associated with long-term use. Drug interactions involving cytochrome P450 do not appear to occur. Linezolide inhibits mitochondrial protein synthesis, causing hyperlactatemia in humans.²⁹⁴ Linezolid may decrease intracellular movement of aminoglycosides, affecting rapid killing. ⁹⁴ Based on in vitro killing curve studies, linezolid efficacy against MRSA was enhanced most by rifampin, compared with vancomycin or gentamicin; indeed, efficacy of the latter was reduced by linezolid, with activity antagonistic toward gentamicin.

MISCELLANEOUS ANTIBIOTICS

Daptomycin. Daptomycin is a lipopeptide derived from Streptomyces that was discovered several decades ago but has been reconsidered for treatment of vancomycin-resistant gram-positive organisms. Its spectrum includes gram-positive and anaerobic microbes. However, its mechanism involves binding to the cell membrane, and although bactericidal, daptomycin is associated with an increased risk of toxicity. It acts in a concentration-dependent fashion.⁸⁰ Vancomycin-resistant drugs require higher concentrations. Daptomycin is minimally orally bioavailable, requiring intravenous administration for systemic effects. It cannot be given intramuscularly because of direct toxicity. It is not involved in any clinically relevant drug interactions. Although largely renally excreted, it is approximately 92% bound to plasma proteins in humans. The result is a longer half-life that allows once-daily dosing in humans. Daptomycin causes skeletal muscle damage in dogs at doses that exceed 10 mg/kg and peripheral neuropoathies at higher doses.⁸⁰ Dispostion has been described for Beagles after onceand twice-daily dosing.²⁹⁵ When given at 5, 25, or 75 mg/kg intravenously, peak serum concentrations were 58, 165, and 540 µg/mL, respectively (total drug); concentrations extrapolated from the terminal component of the curve approximated **Fusidic Acid.** Fusidic acid is a steroidlike antimicrobial that interferes with ribosomal translocation (peptidyl tRNA). Efficacy is limited to gram-positive bacteria. It is bactericidal at high concentrations against both coagulase-positive and coagulase-negative staphylococci. It is available as oral, intravenous, topical, and ocular preparations. In humans it is characterized by 90% oral bioavailability. Adverse reactions include granulocytopenia, rash, and hepatotoxicity; thrombophlebitis; and venospasm, which may accompany intravenous infusion. Resistance develops rapidly when used as a sole agent. Drugs with which it has been combined include the aminoglycosides, quinolones, rifampin, and vancomycin. However, combination therapy has not precluded development of MRSA.

Topical Antimicrobials

The advantage of topical antimicrobials is achievement of very high concentrations at the site of infection and avoidance of side effects that otherwise might occur with systemic therapy.

Bacitracin

Bacitracin is a complex polypeptide isolated from *B. subtilis*. It inhibits peptidoglycan synthesis in bacteria by interfering with the enzyme responsible for movement of cell components through the membrane. Its spectrum of activity includes gram-positive and very few gram-negative organisms. Systemic use causes nephrotoxicity, and use is limited to topical administration. The drug is not absorbed after oral administration and can be used to treat gastrointestinal infections caused by susceptible organisms.^{5,297}

Polymyxins

Polymyxins are a group of large acetylated decapeptides produced by *Bacillus* spp. At least six compounds have been identified, of which only two, polymyxin (polymyxin B) and colistin (polymyxin E), are used clinically. Polymyxins are cationic detergents that interact and interfere with the phospholipid of the bacterial cell membrane, resulting in increased permeability. The polymyxins are thus bactericidal. However, a number of compounds can interfere with their activity, including divalent cations, purulent exudate, fatty acids, and quaternary ammonium compounds. The spectrum of activity of the polymyxins includes most gram-negative organisms, including *P. aeruginosa*. Two exceptions include *Proteus* spp. and most *Serratia* spp. The drugs are weak bases ($pK_a \ 8 \ to \ 9$) and are not orally bioavailable. As such, they have been used to "sterilize" the gastrointestinal tract.

Elimination is principally by way of the kidneys, which are also the primary sites of toxicity. Glomerular and tubular epithelial damage has limited their usefulness. Other side effects include respiratory paralysis (after rapid intravenous administration), CNS dysfunction, fever, and anorexia. Use of the polymyxins is primarily limited to topical administration. However, pemphigus vulgaris has been reported in association with topical use for otitis externa in the dog.²⁹⁶ Polymyxin protects against gram-negative endotoxemia by binding to the anionic lipid component of the lipopolysac-charide at concentrations much lower than those associated with toxicity. Relevance to treatment in dogs or cats is not established.

Novobiocin

Novobiocin is derived from coumarin and is effective against both gram-positive and gram-negative organisms. The drug is particularly efficacious against *Staphylococcus* spp. Its mechanism of action is not certain but involves both cell membrane and cell wall synthesis. Novobiocin causes a number of toxic effects when used systemically, including bone marrow suppression, nausea, vomiting, and diarrhea. Its use is limited to topical application.^{5,297}

Mupirocin

Mupirocin (pseudomonic acid) is a naturally occurring fermentation product of Pseudomonas fluorescens. It is available as a cream or ointment, and its use has been largely limited to topical application. Although it acts to inhibit protein synthesis, its mechanism is novel in that it prevents incorporation of isoleucine into proteins by binding to isoleucyl transfer-RNA synthetase.²⁹⁷ Its unique mechanism precludes crossresistance with other antibacterials. Resistance is unusual, low level, and generally overcome by higher concentrations. The spectrum of mupirocin includes aerobic gram-positive cocci (high efficacy toward S. aureus, S. epidermidis, and betahemolytic streptococci) and selected gram-negative cocci. An advantage to mucopirin is that it minimally affects normal flora. Its indications in human medicine include prophylaxis in ulcers, operative wounds, and burns and treatment of skin infections. In humans mupirocin has proved efficacious as an oral antibiotic. In addition, mupirocin has proven useful in the management of secondary pyodermas or superinfection of chronic dermatoses. Mupirocin is generally not associated with side effects; local burning, stinging, itching, or pain has been reported in about 1% of human patients.²⁹⁷

Silver Sulfadiazine

Silver sulfadiazine (see the discussion of sulfonamides) is approved for use in humans in a polypropylene glycol vehicle and in a water-soluble gel. It is approved for use in dogs combined with enrofloxacin as an otic preparation. The synergistic coupling of the silver with sulfadiazine results in efficacy against *P. aeruginosa* as well as a broad range of gram-positive and other gram-negative organisms. The silver component interferes with the cell wall. Silver sulfadiazine has been approved for use in the treatment of human burn patients, but other antimicrobials have proved more efficacious (e.g., iodophors; combinations of povidone iodine with neomycin, polymyxin, and bacitracin [Neosporin]; and silver sulfadiazine–cerium nitrate cream). However, the low toxicity, low hypersensitivity, and low level of resistance warrants its continued use in veterinary patients.²⁹⁷

Urinary Antiomicrobials

Nitrofurans. The nitrofurans are synthetic compounds whose antimicrobial activity occurs through the 5-nitrofuran group (see Figure 7-12).^{5,297} Nitrofurantoin and furazolidone are examples. They are weak acids. These drugs block oxidative reactions necessary for formation of bacterial acetyl coenzyme A. They are bacteriostatic in action. The spectrum of activity of nitrofurantoin includes a number of gram-positive or gram-negative organisms, but its use should be based on C and S testing. The spectrum also includes selected protozoa. Nitrofurans are orally bioavailable but require an acidic environment to cross cell membranes. Use is limited to urinary tract infections, and ideally those associated with an acidic pH. Because 50% of nitrofurantoin is eliminated in urine in an active form, the drug is appropriate for treatment of urinary tract infections. Its use is, however, limited by gastrointestinal and systemic toxicity. Systemic toxicities in humans include peripheral neuropathy at therapeutic doses. The time to onset ranges from 3 weeks to over 12 months (median: 2 to 3 months). Although not common, peripheral neuropathy can be both severe and irreversible. Old age and renal disease increased the risk of toxicity.²⁷¹ Albeit rare, pulmonary pneumonitis and fibrosis have been associated with long-term (6 months or more) use in humans and may be insidious in onset. The use of nitrofurantoin is limited to infections of the urinary tract that are not susceptible to other drugs. However, a current advantage to this drug is limited resistance among those organisms considered susceptible, including E. coli and selected other organisms.

Methenamine. Methenamine (hexamine; hexamethylenetetramine is the name for commercial uses) is a chemical that releases formaldehyde and ammonia on hydrolysis (see Figure 7-12). It is usually sold as the hippurate salt. The degree of hydrolysis, and thus antibacterial efficacy, is pH dependent, requiring an acidic pH. The drug is bactericidal in an acid environment and bacteriostatic in a more alkaline environment. Therefore it is less effective in the presence of urease-producing bacteria that alkalinize the urine. Its spectrum of activity includes both gram-positive and gram-negative organisms. Methenamine is orally bioavailable and reaches high concentrations in urine.²²⁰ The chemical is used primarily to treat urinary tract infections in dogs. Generally, it is used in combination with urinary acidifiers to enhance antibacterial actions. Its safety in cats could not be verified.

This chapter focuses on the treatment of bacterial infections on a systems basis. In addition, selected organisms are discussed because of their unique nature and the difficulties encountered when treating such infections. In general, the ease with which microbes appear to become resistant requires dosing regimens that are based on scientific studies demonstrating both efficacy toward the microbe and pharmacokinetics in the target species; if the latter is not available, extrapolated doses should be promulgated by persons with expertise (e.g., a veterinary clinical pharmacologist). Because of limited evidence-based information in veterinary medicine, data from the human-medicine literature may serve as a basis for recommendations. Information supporting the judicious use of antimicrobial drugs is found in Chapters 6 and 7. This includes but is not limited to data referring to drug concentrations achieved in the plasma at recommended doses (see Table 7-7), and other pharmacokinetic data (see Table 7-1) and tissue-to-drug ratios of antimicrobial drugs (see Table 7-5). In addition, population pharmacodynamic data are available that indicate the concentration of drug necessary to inhibit the microbes (minimum inhibitory concentration [MIC]) for selected drugs: See Table 7-3 (*Escherichia coli*), Table 7-4 (human data for selected microbes for which veterinary information could not be consistently found), Tables 7-9, and 7-10 (data for beta-lactams), and Table 7-12 (fluoroquinolones). Selected pharmodynamic data are also provided in this chapter for infections associated with specific body systems. This includes an example of regional cumulative antimicrobial susceptibility antibiograms that might help guide empirical therapy, which is increasingly discouraged as resistance emerges (Figure 8-1). The clinician is encouraged to consider the approach to individualized antimicrobial therapy presented in Chapter 6. This includes Figure 6-1, which is an algorithm for antimicrobial therapy that is intended to minimize the risk of antimicrobial resistance, particularly in the at-risk patient. Algorithms have also been offered for infections of selected body systems. Preventing resistance is among the more important considerations that must be made by veterinarians using antimicrobials. (Box 8-1). A three "Ds" approach includes "detergent" (address hygiene at multiple levels), "de-escalating" drug use, and "design" dosing optimal regimens. Hygiene, which goes beyond simple hand washing, also is a critical component of preventing emerging resistance. Resistance is also minimized by de-escalating drug use. This includes simply decreasing the number of antimicrobial drugs prescribed and dispensed. However, de-escalating also entails moving to a lower tier of drug classes (i.e., one that is less broad in its actions and less "effective" toward microbes that tend to develop multidrug resistance). Although it is critical to use the best drug possible such that the infecting population is killed, once this is accomplished, de-escalation to a less-important lower tier class of drugs should be possible. First-tier drugs might include both narrow and broader spectrum beta-lactams (amoxicillin with without clavulanic acid), clindamycin, tetracyclines, and potentiated sulfonamides. Second-tier drugs might include those drugs characterized by spectra purposefully extended to target organisms not generally susceptible to first-tier drugs. Newer drugs such as third-generation cephalosporins, extended-spectrum penicillins, and fluoroquinolones might be included in this category. Therapy should be based on culture and susceptibility testing data, whenever possible, and population pharmacodynamic statistics if patient MIC data are not available. Third-tier drugs include those that tend to be reserved for treatment of microbes associated with either inherent or acquired resistance. Their use should be based on culture and susceptibility testing data and should be de-escalated to a lower-tier drug as soon as possible. Examples might include drugs that target multidrug-resistant gram-negative (aminoglycosides, carbapenems) and gram-positive (glycopeptides, linezolids) organisms. The American College of Veterinary Internal Medicine¹ and the International Society of Companion Animal Infectious Disease (publications pending) have promulgated guidelines intended to minimize emerging resistance.

KEY POINT 8-1 A three-pronged approach is indicated for preventing antimicrobial resistance: escalating hygiene, de-escalating antimicrobial drug use, and optimizing dosing regimens such that the infecting inoculum is eradicated, not simply inhibited.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM AND SPECIAL SENSES

Meningitis

Meningitis serves here as the prototypic infection of the central nervous system (CNS).

Physiology and Pathophysiology

Infections of the CNS are uniquely problematic for three reasons: cellular components reflect functional specialization, a major portion of the CNS is sequestered from the rest of the body by physiologic barriers, and tissues of the CNS are closely confined within rigid skeletal structures such that swelling cannot occur without subsequent and potentially lethal damage. Cellular specialization is of diagnostic benefit in the identification and localization of infections of the CNS because clinical signs are often referred to a specific region of the brain.

The course of CNS infection is affected by the relationship of the brain and spinal cord to the vasculature, meninges, and skeletal structure. The brain is suspended in cerebrospinal fluid (CSF) and is surrounded by the meninges (pia mater and arachnoid [together forming the leptomeninges] and the dura mater). Infections of the leptomeninges tend to involve their entire surface that surrounds the brain and spinal cord. In contrast, infections of the dura mater tend to be limited and sharply circumscribed. With persistent infection of the meninges, increased intracranial pressure results from extensive cerebral edema and hydrocephalus. Infections of the spinal cord meninges are less limited and often extend longitudinally the length of the cord.¹

About 85% of CSF is produced by the choroid plexus of the lateral, third, and fourth ventricles. The CSF flows into the subarachnoid space, circulates around the brain and spinal cord by bulk flow, and is reabsorbed through the arachnoid. The CSF is totally recirculated in 3 to 4 hours. The choroid plexus is physiologically similar to renal tubules, even containing similar secretory mechanisms. Indeed, specialized transport systems allow the movement of organic acids (including many beta-lactams) against a concentration gradient out of the CSF. In cases of infections involving the ventricles, because of the flow pattern of CSF, intrathecal administration of drugs does not result in predictable drug concentrations in the ventricles. Rather, drug must be directly instilled into the ventricles. Infections of the CNS can impair CSF reabsorption across the arachnoid villi, resulting in hydrocephalus.¹

Capillaries of the brain and spinal cord (with the exception of the choroid plexus) differ from other capillaries. First, the vascular endothelium is characterized by tight junctions rather than intracellular clefts. Second, they are surrounded by the foot processes of astrocytes (see Figure 29-1). Both form a barrier to passive diffusion of drugs and their compounds. Only compounds that are actively transported or are of sufficient lipid solubility can pass out of the capillaries into the brain. The barrier affects the movement of antimicrobials. In addition, impaired movement of immunoglobulins, complement, and other mediators of the immune response affects antimicrobial selection in that bacteriostatic drugs are much less desirable.^{1,2}

Continued

Figure 8-1 Cumulative antimicrobial susceptibility reports for canine (top) and feline (bottom) organisms isolated from samples collected during the years 2007 to 2010 at a veterinary teaching hospital. The data are geographically restricted to Alabama and are from a teaching hospital that has a wide referral base. Accordingly, the data may not be relevant to other areas of the United States nor to patients with first time infections. No attempt has been made to separate data according to history, including previous antimicrobial exposure. Ideally, each practice would generate a cumulative report at frequent intervals (e.g., yearly or every other year). The report might serve as a basis for empirical selection of antimicrobials. However, the number of isolates must be sufficient to represent the population; ideally, at least 100 isolates of each organism should be sampled. Drugs that are not included in the antibiogram for each organism generally are not included because the use of the drug for that organism is inappropriate. Each cell indicates the percentage of the tested isolates that were considered susceptible to the drug on the basis of Clinical and Laboratory Standards Institute (CLSI) guidelines promulgated in 2008. The first row lists the drugs to which susceptibility was determined for the organisms. The far left column names the genus and species of the organisms isolated and for which susceptibility was determined. The second from the left column indicates the total number of isolates tested. For some drugs not all isolates were tested; in such instances the total number of isolates tested is indicated in parentheses in that cell. New CLSI interpretive criteria for selected drugs (approved in 2010), including amoxicillin-clavulanic acid cephalexin and its model drug, cephalothin, are likely to result in a marked decrease in the percentage of susceptible isolates. Cephalothin continues to act as a class drug, representing first-generation cephalosporins (see Chapter 6 for a discussion of limitations of model drugs; e.g., cephalexin should not be used to treat E. coli, as a general rule). Staphylococcus intermedius represents what is currently referred to as S. intermedius group. (Data provided by Terri Hathcock, MS, Diagnostic Veterinary Microbiologist, Infection Control Officer, College of Veterinary Medicine, Auburn University.)

Box 8-1

Treatment of Multidrug-Resistant Microorganisms

- 1. Avoid emergent resistance.
 - A. Address hygiene both in the hospital and at home. Clean bedding. Reduce exposure to environment or family members that might carry resistant organisms.
 - B. Base drug on culture and susceptibility data. Wait for data if possible. If not, base empirical therapy on local cumulative antimicrobial susceptibility data (see Figure 8-1).
 - C. De-escalate antimicrobial use. Avoid using antimicrobials when possible. De-escalate to lower-tier drug as soon as possible. Decrease duration of therapy.
 - D. Use drug with a spectrum that is as narrow as possible, minimizing selection pressure.
 - E. Optimize dosing regimens (see 4) such that all infecting colony-forming units (including colony-forming units with mutant prevention concentration) are killed (not inhibited), especially in at-risk patients.
 - F. Consult experts (e.g., specialists, including clinical pharmacologists, veterinary diagnostic microbiologists).
- 2. Treat underyling cause of recurrent infections.
- 3. Implement adjuvant therapies.
- 4. Base design of dosing regimen on culture data, including minimum inhibitory concentrations.
 - A. Pharmacodynamic indices should surpass that recommended for efficacy; for example, concentration-dependent drugs, $C_{max}/MIC > 12$, AUC/MIC > 250 (AUC/MPC \geq 22); time-dependent drugs T > MIC more than 75%.
 - B. Intravenous dosing should be considered to ensure that the highest concentrations of drug will be obtained. If the site can be topically reached, topical administration should accompany systemic therapy.
- 5. Use drug combinations known to produce either additive or synergistic effects. Use full dose of both drugs. De-escalate as soon as possible.
- 6. Gram positive:
 - A. Methicillin-resistant *Staphylococcus*, spp., non–Vanconmycinresistant *Enterococcus* spp.

- i. Rifampin combined with any other drug to which the organism is susceptible
- ii. Vancomycin (not Vancomycin-resistant *Enterococcus*). Vancomycin must be given intravenously for systemic therapy (oral drug is for gastrointestinal therapy only).
- iii. Linezolid
- Aminoglycosides should not be used as sole agents for treatment of multidrug-resistant gram-positive infections. In general, gentamicin is more efficacious against-*Staphylococcus* spp. than amikacin.
- v. Choramphenicol is a bacteriostatic drug; care must be taken to ensure that killing effects are achieved.
- vi. Potential alternatives include fusidic acid or fosfomycin (evidence needed).
- vii. Some evidence exists that the combination of vancomycin with a carbapenem may enhance efficacy.
- B. For vancomycin-resistant *Enterococcus* spp., use betalactams with known susceptibility.
- 7. Gram-negative:
 - A. Combination therapy is based on culture and susceptibility testing data.
 - B. The laboratory should test specifically for presence of extended-spectrum beta-lactamases, particularly for third-generation cephalosporins. Testing may be indicated for carbapenem targeting extended-spectrum beta-lactamases in *Klebsiella pneumoniae*. Otherwise, the presence of AMP-C indicates the use of carbapenems.
 - C. The most effective drug or drug combination should be used initially, with de-escalation to a lower-tier drug when possible (i.e., within 5 days).
- 8. Clostridium difficile
 - A. Discontinue antimicrobial therapy that may be contributing to overpopulation.
 - B. If therapy is indicated, treat with metronidazole; alternative is oral vancomycin.

Vascular damage associated with infection can affect the course of infection. Hypertrophy of the endothelium (as might occur with persistent bacterial infection) or infection of the endothelial cells (as occurs with Rocky Mountain spotted fever, for example) can cause thrombosis or embolization to arteries or veins. Loss of capillary integrity contributes to cerebral edema and movement of microorganisms into the brain. At the same time, capillary permeability facilitates movement of antimicrobials that normally cannot cross the cerebral or meningeal capillaries into the site of infection.^{1,2}

The inflammatory response of the CNS also differs from that in other body tissues. The response tends to be less intense and is characterized by infiltration of microglial cells and proliferation of astrocytes. Abscessation is slower and involves gliosis rather than fibrosis. Host response to infection in the CNS involves antibody, cell-mediated immunity, and complement-mediated immunity. Normally excluded from the CNS, antibody in the CNS indicates damage to the bloodbrain barrier or synthesis of immunoglobulin from cells that have been able to penetrate the brain parenchyma. Antibody protection is important in bacterial meningeal infections and may determine the outcome. Cell-mediated immunity, on the other hand, is the predominant host response to fungal or intracellular parasites. Infections by selected organisms, such as Mycoplasma spp., may lead to a host response to both the infecting organism and host proteins (e.g., myelin). Despite the role of the immune system in bacterial infections of the CNS, host defenses remain inadequate for control of the infection. Indeed, the relative lack of opsonization, complement, and immunoglobulins may allow bacterial survival in the subarachnoid space.1,2

Bacterial products can contribute to the development of cerebral edema. Release of cytokines and tumor necrosis factor is mediated by materials such as endotoxin of gramnegative organisms and teichoic acid produced by *Staphylococcus aureus*. Whereas changes in capillary permeability may increase antimicrobial movement across the blood-brain barrier, antimicrobial therapy may initially worsen cerebral edema, as bacterial death causes release of more mediators of inflammation. Inflammation, hemorrhage, hydrocephalus, and edema may cause displacement of the brain or spinal cord. Herniation may be a life-threatening sequela.¹ The potential release of endotoxin may be an important consideration in the initial selection of an antimicrobial; drugs that minimize endotoxin release yet still penetrate the blood-brain barrier include meropenem and the fluoroquinolones.

Antimicrobial Selection

Successful antimicrobial therapy of CNS infections is facilitated by use of a bactericidal drug and maximization of plasma drug concentrations such that bactericidal concentrations are achieved in the CNS. The CNS is relatively immunoincompetent, thus increasing the concentration of drug necessary for effective therapy. Studies in animal models have shown that the rapid bactericidal killing in the CSF requires drug concentrations that exceed the minimum bactericidal concentration (not MIC) by tenfold to twentyfold.² To maximize drug concentrations at the site of infection, drugs that can be given intravenously are preferred to oral preparations. Antimicrobials to treat the CNS are often selected empirically because of difficulties encountered when collecting culture and susceptibility data. Most infections reach the CNS by a hematogenous route. Organisms most likely cultured from or infecting the CNS are delineated in Table 6-1; however, the lack of predictability of the infecting organism mandates the need for a properly collected culture sample. After the most likely infecting organism and drugs effective against the organism have been selected, antibiotics should be selected next on the basis of movement into the CNS. Drug penetration of the blood-brain barrier is particularly challenging because the barrier not only prevents movement of antimicrobials into the CNS but also actively transports out or destroys some antimicrobials (i.e., selected beta-lactams) (see Table 7-5).

KEY POINT 8-2 Doses of antimicrobials, particularly those that are water soluble, may have to be increased tenfold or more to achieve effective concentrations in the brain.

To enter the CNS, antimicrobials must penetrate the epithelium of either the choroid plexus or the cerebral endothelium; both are characterized by tight junctions. Antimicrobials generally are not metabolized in the CNS; concentrations thus reflect a balance between penetration and elimination via the blood-brain or blood-CSF barrier.³ Passive diffusion is the major mechanism of drug movement. Drugs that are more likely to penetrate the barrier are characterized by high lipid solubility, small molecular weight, and low protein binding.² Whereas lipid-soluble drugs enter the CNS through transcellular pathways, water-soluble drugs must move through paracellular pathways and thus depend on the opening of tight junctions. Several transport mechanisms facilitate influx (as well as efflux; see below and Chapter 27) of selected drugs (e.g., penicillins, ceftriaxone), but this accounts for only a low concentration of drug movement. Antimicrobial movement into the CNS thus is generally slow, with peak concentrations often not occurring until several hours after drug administration. Methods intended to increase permeability of and thus antimicrobial movement into the CSF (e.g., hyperosmotic solutions, receptor-specific antibodies, inflammatory mediators) have not been well evaluated.³ Once selected drugs successfully penetrate the CNS, drug efflux may decrease intracellular concentrations. Penicillins (but not ceftriaxone, carbapenems, nor ampicillin) are actively transported from the CNS; active transport can be inhibited by probenicid.⁴ Interestingly, the action of this pump is inhibited by meningeal inflammation. Therefore inflammation will increase inward movement of several antimicrobial, including many beta-lactams and vancomycin. However, as treatment is effective, increased influx declines such that within 5 days of therapy, penicillin CSF half-life and drug concentrations in humans markedly decrease. This is in contrast to drugs with a low affinity for active transport system; for such drugs concentrations tend to remain clinically relevant throughout CNS infection. Active transport mechanisms do not appear to affect CSF concentrations of fluoroquinolones or aminoglycosides.³

Antimicrobial therapy also is likely to be affected by the presence of purulent material. As in all body systems, the microenvironment can negatively affect antibacterial therapy. In the presence of meningitis, lactate accumulates in the CSF, causing the pH to decrease. Antibacterial activity of weakly basic antimicrobials may decrease, particularly for the aminoglycosides and potentially for the fluoroquinolones.² The dynamics of CSF are altered by disease and drugs. At best, CSF production is unaltered, although several studies have demonstrated decreased CSF production. Gluocorticoids may further decrease CSF production; however, rather than prolonging the half-life of the drug in the CNS, glucocorticoids appear to decrease or not change CSF antimicrobial concentrations.⁵

Drug movement into the CNS was summarized in Box 6-4 and Table 7-5. Because of the impact of normal physiology and drugs, dosing regimens designed for treatment of CNS infection tend to differ from traditional therapy, in that doses often are much higher. The risk of toxicity that might accompany such increases must be weighed against the need to penetrate the CNS in concentrations sufficient to cause bactericidal effects (see Table 7-5). In general, selected beta-lactams (meropenem more than imipenem; cefoxitin, ceftazidime and cefotaxim), trimethoprim/sulfonamide, fluorinated quinolones, rifampin, and metronidazole can achieve bactericidal concentrations for some infections in the CNS; chloramphenicol and doxycycline or minocycline achieve bacteriostatic concentrations.⁶ Amikacin may achieve effective concentrations as well. Drugs that should be avoided or whose doses should be further markedly increased for treatment of CNS infections because of poor penetration include many beta-lactams, including carbenicillin, cephalothin, cefazolin, cefotetan; and clindamycin, erythromycin, and tetracycline. Drugs recommended for treatment of meningitis in humans are increased by at least 50% to 100% or more when safety is not an issue, with intervals being reduced for timedependent drugs, to ensure that adequate concentrations reach the CNS. For other drugs, doses for treatment of CNS infections are increased several-fold compared with other infections. For example, beta-lactam doses in particular are increased as follows: penicillin normally dosed at 1 million U is increased 1 to 4 million U to 24 million U/person; aztreonam is increased threefold, and several third-generation cephalosporins (cefotaxime, ceftazidime, ceftriaxone) are increased sevenfold to twentyfold. Aminoglycoside doses are either not increased or increased twofold (e.g., amikacin). Doxycycline is increased twofold, and sulfonamides are increased fourfold to fivefold. Because of local immunoincompetence, duration of therapy for patients with infections of the CNS should be at least 10 to 14 days and up to 21 days.² The need for 4 to 6 weeks of therapy, as has been suggested in dogs, is not clear; it may not be necessary.⁷ Intrathecal administration of antimicrobials that might be systemically toxic at concentrations necessary to be effective in the CNS might be a reasonable alternative. However, this method has not been well studied, particularly in animal patients. Further, because distribution of intrathecally administered drug into the CSF is uneven, drug concentrations may not be adequate at some sites.

Adjuvant therapy. Because of the harm associated with inflammation in a closed system, antiinflammatories should be considered when treating CNS infections (e.g., meningitis). Corticosteroid therapy may be indicated during initial stages of treatment of meningitis to minimize the effects of inflammation and loss of capillary integrity.^{2,7} Experimentally, methylprednisolone decreases leukocyte accumulation, CSF outflow resistance, and brain water content in animals with bacterial meningitis.² Dexamethasone also reverses the development of brain edema and, compared with methylprednisolone, has the added advantage of decreasing CSF pressure and lactate. Note that these studies did not include comparisons with antimicrobial therapy. Nonetheless, glucocorticoid therapy may be beneficial early during the course of therapy; indeed, treatment before antibacterial therapy may minimize the effects of mediators of inflammation released by dying bacteria.² A study of infants with bacterial meningitis treated with ceftriaxone and either a placebo or dexamethasone found the duration of infection and degree of inflammation in the latter group to be shorter and less, respectively, although mortality or long-term neurologic sequelae did not differ between the two groups.8 In an analysis of five clinical trials in adult humans with bacterial meningitis, the incidence of side effects was the same in the group treated with glucocorticoids (dexamethasone), but both mortality and persistence of clinical signs were improved in the group treated with steroids, leading the authors to conclude that a single dose is justified if given at the beginning of antimicrobial therapy.9,10 Dexamethasone can be used (0.1 to 0.15 mg/kg every 6 hours up to 4 days), particularly in the presence of cerebral edema.²

KEY POINT 8-3 A well timed but limited duration of treatment with glucocorticoids may be indicated in the patient with bacterial meningitis to prevent organ-threatening inflammation.

Treatment of cerebral edema should also include mannitol. If intensive monitoring is available, high-dose barbiturate therapy might be useful for these patients. Barbiturates decrease cerebral metabolic demands and cerebral blood flow and provide protection against oxygen radicals.

Adverse reactions. Because of altered permeability of the blood–brain barrier, the infected CNS is more likely than the normal CNS to respond adversely to antimicrobials. Seizures are the most likely manifestation. The antimicrobial most likely to cause seizures include selected beta-lactams (see Chapters 6 and 7), most notably imipenem (but not meropenem), metronidazole, and fluoroquinolones, particularly in patients also receiving nonsteroidal antiinflammatories. In general, seizures that develop as a result of drug therapy should be treated as with any acute seizural manifestation, with diazepam the preferred anticonvulsant of choice.

Ocular Infections

The principles of ocular therapy are discussed in Chapter 27.

Microbial Targets

Whitley¹¹ has provided a review of isolates cultured from ocular tissues of clinically normal dogs and dogs with ocular disease (Table 8-1). The most common organism associated

with bacterial conjunctivitis in dogs is *Staphylococcus* spp. (*aureus* [68% of infections] or *epidermidis* [27% of infections]). A variety of other organisms, including *Corynebacterium* spp. and gram-negative rods, make up the remaining infections. Most of the infecting organisms are considered normal ocular flora.¹¹ Bacterial infection complicating keratoconjunctivitis sicca generally is caused by *Staphylococccus* spp. (32% to 69% of dogs) and *Streptococccus* spp. (9% to 25%); *Pseudomonas* spp. (5% to 18% of infections) is the most common gram-negative isolate. In cats *Mycoplasma felis* and *gatea* are the more common isolates associated with conjunctivitis; however, they also are commonly isolated in normal cats, calling into question the role of the organism

in disease. *Chlamydia (Chlamydophila felis)*¹² may be a concurrent pathogen, although both it and *Mycoplasma* spp. may reflect infection secondary to primary feline herpesvirus infection.

Like conjunctival infections, corneal infections (including ulceration) are most commonly caused by *Staphylococcus* spp., followed by *Streptococcus* spp. (together making up approximately 65% of infections). Other causes include *Corynebacterium* spp. and gram-negative rods (including *Pseudomonas* spp.).

Drug Preparations

Characteristics of topical ophthalmic antibacterial drugs to consider are the spectrum, and their lipid versus water solubility, with lipid solubility being more important if tissue penetration is of importance. Because of the ability to administer high concentrations of antimicrobials with topical administration, traditional classification of bacteriostatic versus bactericidal (fungal or viral -static or -cidal) may not be relevant to antiinfective drugs, and susceptibility data might underestimate topical efficacy. Ophthalmic drugs indicated for treatment of ocular infections are available as single or multiple antimicrobial agents (Table 8-2a and Table 8-2b). Generally, either gram-negative or gram-positive organisms are targeted using individual agents; mixed infections can be targeted with combination products or drugs characterized by a broad spectrum. Whereas few drugs are approved for use in animals, multiple human products are commercially available. Others can be compounded, which might include "fortification" of commercial products. However, the nuances of ocular preparations mandate that extreme caution be taken when formulating or modifying a product intended for topical ocular therapy (see Chapter 23).¹¹

KEY POINT 8-4 Whereas high concentrations of drugs might be achieved with topical ophthalmic drug administration, lipid solubility remains important if deeper tissues are to be penetrated with systemic antimicrobials.

Drugs that target gram-negative organisms include the water-soluble, weakly basic aminoglycosides. At the high concentrations achieved topically, they are generally also effective against Staphylococcus spp. and include tobramycin (0.3%; drug of choice for treatment of Pseudomonas spp.), gentamicin (available with the glucocorticoid betamethasone), and neomycin (less effective toward Pseudomonas spp. and generally available only in combination with other antimicrobials). Polymyxin B, whose systemic use is precluded by nephrotoxicity, is a water-soluble drug, characterized by limited intraocular distribution. The fluoroquinolones also target gram-negative organisms, including Pseuodmonas spp. as well as Staphyloccoccus spp. In contrast to the aminoglycosides, the fluoroquinolones are lipid soluble. Drugs include ciprofloxacin, and ofloxacin and its L-isomer, levofloxacin. Systemic fluoroquinolones have been associated with retinal degeneration in cats (see Chapter 7). The adversity reflects accumulation due to a missing transport pump in the blood-retinal barrier (personal communication,

Drug	Effect	Target	Solubility	Trade Name	Manufacturer

 Table 8-2a
 Selected Topical Preparations for Treating Ophthalmic Infections

Katrina Mealey, Washington State University). It is not clear if the adversity may occur with topical use, but prudence suggests that safety not be assumed.¹³ Drugs that target gram-positive organisms include the lipid-soluble erythromycin (0.5%; bacteriostatic), whose efficacy is limited by resistance, and the water-soluble bacitracin, which, like polymyxin B, is most known for its nephrotoxicity associated with systemic therapy. An example of a triple-antibiotic combination is one containing neomycin, polymyxin B, and bacitracin (see Table 8-2a). Broad-spectrum topical antimicrobials include chloramphenicol (prohibited for use

in food animals), tetracyclines (drugs of choice for ocular *Mycoplasma* or *Chlamydia*), and the sulfonamides. Each is lipid soluble. Whitley¹¹ has described a preparation of vancomycin (3.1%) and cefazolin (3.3%) compounded from injectable products., although the combination might be improved by replacing cefazolin with a drug with a broader gram-negative spectrum.

Topical antifungal are limited and include the polyene natamycin. Its spectrum includes all fungal agents except dermatophytes. The imidazoles must be compounded from intravenous solutions (i.e., miconazole, fluconazole, and

Chloramphenicol	40-100	Mixed					

itraconazole). Their spectrum includes opportunistic, dimorphic fungi and dermatophytes.

Treatment of Selected Infections

Use of systemic antimicrobials for treatment of ocular infections is complicated by poor drug penetration. Therefore topical therapy is indicated for external ocular infections, and subconjunctival administration is recommended for serious corneal or anterior chamber infections. For bacterial endophthalmitis, intravitreal antimicrobial therapy is indicated, although extreme caution is indicated for this route.¹³ Treatment of intraocular infections can be supported with systemic therapy of lipid-soluble drugs that can achieve bactericidal concentrations. In addition to antibacterials, collagenase inhibitors such as *N*-acetylcysteine, sodium citrate, bacitracin, and tetracycline compounds have been recommended for treatment of corneal infections.

Treatment with tetracycline is indicated for control of *Mycoplasma* and *Chlamydia* spp. Cats may develop hypersensitivity manifested as acute conjunctivitis with topical treatment.¹⁴ Oral therapy with tetracycline (5 mg/kg bid) stops shedding within 6 days. Azithromycin starting at 7 to 10 mg/kg qd for 2 weeks, followed by 5 mg/kg qd for 1 week, followed by 5 mg/kg qd for 1 week, followed by 5 mg/kg qd for 1 week, followed by 5 mg/kg qd for the complicated dosing regimen or the long duration is not clear. The presence of sneezing may indicate infection with feline calicivirus (FCV), for which supportive therapy is indicated. Conjunctivitis, often accompanied by ulcerative keratitis, can be a manifestation of feline herpesvirus (FHV-1), In addition to supportive therapy, topical preparations are available for its treatment (see also Chapter 10).¹⁵ Antivirals include vidarabine, trifluridine, and idoxuridine (the latter

must be compounded). These are generally virustatic, requiring frequent application (every 1 to 2 hours is preferred, but every 4 to 6 hours is acceptable).

Systemic treatment of experimentally induced Chlamydia psittaci with 19 days of amoxicillin-clavulanic acid (12.5 to 25 mg/kg bid) has been compared with doxycycline (10 to 15 mg/kg qd; positive control) in 5-month-old cats (n = 24; 8 per group) using a randomized, placebo-controlled, blinded design.^{15a} Outcome was based on clinical scoring, including respiratory signs or corneal changes; other clinical signs were not described. Both treatments were associated with rapid clinical improvement and reduced chlamydial isolation, with amoxicillin-clavulanic acid being associated with less isolation. However, five of eight of the cats treated with amoxicillin-clavulanic acid, but no doxycycline-treated cats, became positive 3 weeks after treatment. These cats became negative again with 4 weeks of retreatment with amoxicillin-clavulanic acid and remained negative 6 months later.

Systemic therapy was described in cats experimentally infected with *C. felis*. Once the organisms was detected, cats were treated with azithromycin (10 mg/kg qd for 3 days followed by twice weekly) (n = 9; two untreated negative controls, two doxycycline-treated positive controls [10-15 mg/kg qd]).¹⁶ At the end of the 21-day treatment period, untreated control cats were also treated. Despite an initial response to treatment (negative isolation to day 14), infection was eradicated in only one of five cats treated with azithromycin compared with both cats receiving doxycycline. However, it is not clear if the dosing regimen for azithromycin resulted in effective drug concentrations.

Otic Infections

Otitis Externa

Pathophysiology. Inflammation of the ear canal and the proximal pinna affects up to 20% of dogs, whereas fewer (up to 6% of) cats are affected.¹⁷ A number of causes can be identified in otitis externa, and their resolution is paramount to successful therapy. Possible causes include foreign bodies, allergies, parasites (e.g., mites, chiggers), skin disorders of a keratinous or sebaceous origin, and autoimmune disorders. Structural characteristics of the ear also can predispose the animal to otitis externa, including pendulous ears, higher number of ceruminous glands, the vertical and horizontal paths of the canal, hair in the ear canal, stenotic ear canals, or neoplasm. Environmental factors also can contribute to the difficulty in treating otitis externa, including external conditions that perpetuate excessive moisture (e.g., humidity, bathing) or heat or irritants (e.g., irritating medicaments or shampoos). The presence of yeast or bacteria that are part of the normal flora perpetuates the inflammatory process, and, with time, the inflammatory process itself will cause proliferative changes that complicate therapy. One of the more important predisposing factors to otitis externa is inappropriate treatment, including undertreatment and overtreatment.¹⁷ Ultimately, in some animals surgical treatment will be indicated (Figure 8-2).

Figure 8-2 Otitis externa associated with proliferation and inflammation may fail to respond to topical and systemic antimicrobial therapy despite intensive cleaning. (Photo courtesy Harry W. Boothe, Jr, DVM, MS, DACVS, Auburn, AL.)

Microbial Targets. Bacterial organisms found in normal ears include S. epidermidis and Staphylococcus intermedius (Staphylococcus pseudintermedius; see Chapter 6) and Micrococcus spp. Coliforms are found less commonly. Infection usually can be distinguished from colonization by the presence of large numbers of organisms, particularly if the culture is pure. Infection also is indicated by the presence of inflammation and phagocytized bacteria. Inflammation reflects, in part, the breakdown of fatty materials by organisms into irritating byproducts. S. intermedius is the most common organism (30% to 50%) associated with otitis externa, followed by Pseudomonas aeruginosa, Proteus spp., Streptococcus spp., E. coli, and Corynebacterium spp. The infecting organism also appears to be time dependent in that acute otitis is generally associated with Staphylococcus, whereas chronic otitis more commonly involves Pseudomonas spp. This may refelect, however response to chronic antimicrobial therapy.

Petersen¹⁸ reported on the frequency and susceptibility of *S. intermedius* and *P. aeruginosa* in canine ear samples (n = 553) submitted to a state diagnostic laboratory between 1992 and 1997. Sampling methods varied. *S. intermedius* was isolated from 50% of ear samples but was the sole isolate in only 32% of the samples positive for *S. intermedius*. *P. aeruginosa* was isolated from 28% of ear cultures and was the sole isolate in 33% of *P. aeruginosa* samples.

The susceptibility of both *S. intermedius* and *P. aeruginosa* isolated from canine skin and ears appears to be changing across time (Table 8-3). A number of investigators have described their susceptibility. A review of the data suggests that the incidence of methicillin resistance is increasing, with a decrease in susceptibility of *Staphylococcus* spp. in general emerging in isolates collected during the period between 2003 to 2006. Morris¹⁹ focused on the susceptibility of *Staureus*,

and S. intermedius), as well as Staphylococcus schleiferi (including both coagulase-negative and positive subspecies; see also the discussion of Pyoderma). Of the total number of resistant isolates found in skin or ear, 28% of the methicillin-resistant S. aureus (MRSA), 40% of the methicillin-resistant S. intermedius (MRSI), and 33% of the methicillin-resistant Staphylococcus schleiferi (MRSS; presumed to be coagulase-positive subspecies schleiferi) were in the skin, and 5% MRSA, 26% MRSI, and 47% MRSS were located in the ear. Rubin²⁰ described the susceptibility of 106 canine P. aeurginosa isolates cultured from soft tissue infections, including otitis externa and interna (see Table 8-3). No information was available regarding previous antimicrobial therapy in these animals. The limited amount of data precludes assessment across time; however, Pseudomonas is an organism recognized for its inherent resistance to multiple drugs, with an increasing tendency of resistance toward drugs to which it is normally considered susceptible (e.g., fluoroquinolones).

The combined data, particularly from Staphylococcus spp. isolates, demonstrate the limited susceptibility of these organisms to drugs most often used systemically or topically to treat organisms infecting the skin or ear. Culture and susceptibility data might increasingly become the basis for drug selection and dose design. Although the applicability of culture and susceptibility testing to the topical treatment of otitis externa may be controversial, the incidence of resistance is sufficient to justify culturing even in the earliest stages of infection, particularly in those patients at risk for recurrence, such that emergent resistance can be detected. Susceptibility testing is clearly recommended if gram-negative organisms are expected or in the face of severe or chronic otitis, failed antimicrobial therapy, and the presence of inflammatory cells. Testing is also recommended if systemic therapy is anticipated. Care should be taken to appropriately prepare and collect cultures from infected ears. Frustratingly, the accuracy of susceptibility testing may be questioned simply because of differences in laboratories. Schick²¹ compared the results of cultures simultaneously submitted from dogs with otitis. Swabs were rubbed together to ensure similar samplings. Labs agreed regarding the presence of Pseudomonas spp. only 83% of the time. Susceptibility of the isolates to amikacin varied in 13 of 16 samples, for gentamicin 10 of 16, and for enrofloxacin 9 of 16.

In cats *Pasteurella multocida* joins *Staphylococcus* and *Streptococcus* spp. as a commonly infecting organism; the coliforms and *Pseudomonas* spp. are less common causes. *Malassezia pachydermatis* is an opportunistic yeast that occurs in up to 49% of normal dogs and 23% of normal cats. The numbers increase in dogs with otitis, however, being present in 80% or more of dogs. Although it is likely that *Malassezia* spp. contributes to otitis externa, its role is not clear. Nonetheless, therapy should target this organism as well.

Antimicrobial and Adjuvant Options. The public health implications of treating methicillin-resistant *Staphylococcus* spp. in dogs or cats are addressed in the discussion of *Pyoderma*. Because successful treatment of otitis externa is critically dependent on proper cleaning, it is difficult to separate antimicrobial therapy from adjuvant therapy. The goals of

therapy for otitis externa are to identify and resolve the primary factors, reduce inflammation, and control or eradicate infection. Sedation or anesthesia may be necessary for proper cleansing. Cleansing should remove irritating oils, waxes, and other debris that might serve as a nidus of infection by providing a microenvironment favorable to the growth of microorganisms. Ear cleaning should be less aggressive in the presence of severely swollen or proliferative canals; in such patients initial therapy might begin with antiinflammatory doses of glucocorticoids and antimicrobials, both systemically and topically.

KEY POINT 8-5 The goals of therapy for otitis externa are to identify and resolve the primary factors, reduce inflammation, and control or eradicate infection. Repetitive sedation or anesthesia may be necessary for proper cleansing.

Ceruminolytics contain various surface active agents or emulsifiers (dioctyl sodium sulfosuccinate, carbamide peroxide, squalene, propylene glycol, glycerin, oil) that dissolve wax accumulation and associated debris. They should be used as an initial flush. Less messy water-soluble agents (dioctyl sodium sulfosuccinate, propylene glycol) are often preferred.²² Carbamide peroxide, a common ingredient of human preparations that is seldom found in veterinary preparations, releases nascent oxygen, causing a bubbling action that softens and removes debris. Combination products may contain drying agents such as isopropyl alcohol, silicone dioxide, and alpha hydroxy acids (lactic, malic, or salicylic acid). In addition to their drying effects, these materials may also have mild antimicrobial effects.²²

Flushing solutions facilitate removal of debris. Although water and saline are the safest, some products contain germicidal ingredients. Chlorhexidine can be diluted to a 0.05% solution and used topically. Although ototoxicity should lead to cautious use in the presence of a perforated eardrum, one study failed to provide evidence of damage after 21 days of therapy in dogs with experimentally traumatized membranes; the power of the study to detect a significant difference is not stated.²² Povidone-iodine at 0.1% to 1% can provide bactericidal activity in flushing solutions, although it can cause contact irritation. Because of ototoxicity, solutions with less than 0.5% iodine are preferred if the eardrum is ruptured. Iodine might also be administered as a polyhydroxidine complex (Xenodine). Because it contains 0.5% of titratable iodine, it is less irritating and provides a longer duration of activity. Efficacy against Pseudomonas spp. has been established with this product. It must be used in an aqueous environment and therefore should be used within 2 hours after cleaning to maximize its effects.²² Acetic acid is a relatively inexpensive agent, available as white or brown vinegar in a 5% solution. Antimicrobial effects occur because of direct damage as well as acidification of the local environment. The acidic pH may also facilitate removal of necrotic debris. Pseudomonas spp. succumbs to a 2% solution within 1 minute of contact,²² whereas a 5% solution is effective against Staphylococcus spp. Streptococcus spp., E. coli, and Proteus spp. The preparation is irritating at 2% to 5% concentrations, however, and inhibition of wound healing and ototoxicity may occur at concentrations

of 2.5%. Dilutions of 1:1, 1:2, or 1:3 in water daily or every other day have been recommended.

Topical antimicrobial treatment of otitis externa is generally indicated regardless of whether systemic therapy is implemented. Topical products intended specifically for treatment of otitis externa (Tables 8-4 and 8-5) generally contain various drugs intended to target bacteria, yeast, and inflammation. Vehicles are designed to maximize drug solubility (only dissolved drug will passively diffuse) but must also allow drug movement from the vehicle into tissues. Antibacterial agents often include products that are associated with severe systemic toxicity when given orally or parenterally; topical administration generally is not associated with systemic adversities.

On the basis of a MEDLINE search and review of the literature in human medicine, the ototopic use of antimicrobials does not appear to be associated with an increased risk of antimicrobial resistance.²³ However, the relevance to canine or feline ear, for which the pathophysiology is substantially different, is not clear. Ototoxicity is, however, likely for many antimicrobial drugs when administered in the ear canal, especially in the presence of a perforated tympanic membrane (see later discussion).

KEY POINT 8-6 Topical treatment of otitis externa is generally indicated regardless of whether systemic therapy is implemented.

Topical antimicrobials generally are selected on the basis of cytology and potentially Gram staining. A number of products are commercially available (see Table 8-4). For selected drugs, ophthalmic (directly or diluted) or injectable (diluted) products may also be used. Vehicles used in topical products represent a balance between drug solubility and drug delivery. It may be necessary for vehicles to be pH balanced to maximize solubility. Demulcents (polyethylene or propylene glycol or glycerin) act to suspend non-water-soluble drugs; the glycol agents may irritate an already irritated ear. DMSO is included in some otic preparations as a vehicle, although it also has significant antiinflammatory effects. The agent is very hygroscopic and as such is an effective carrier agent for other drugs included in an otic preparation. In addition, DMSO provides mild antibacterial and antifungal actions as well as antiinflammatory and antifibroplastic effects. Other vehicles used to administer drugs useful for otic disorders include solutions, lotions, ointments, and other oil-based products. Occlusive oils may be undesirable for exudative lesions. Ointments and oil-based products can, however, be used in cases of chronic otitis externa that are dry. Generally, topical preparations should be applied twice daily. A number of home remedies have been recommended for treatment of otitis externa (see Table 8-5). Caution is recommended when making new preparations or modifying old preparations. A number of drug interactions between drugs and their vehicles can inhibit the efficacy of any of the drugs. In addition, drugs must be dissolved to be effective, and the addition of solid drugs (i.e., as powders or crushed tablets) to ointment vehicles (e.g., petrolatum jelly) is likely to yield an occlusive but minimally effective agent. Some acceptable modifications of commercially available products are noted in Table 8-5.

	ACTIVE INGREDIENT

*Represents a modification.

+Addition of 0.3 g Gentocin/L has been recommended; see text for precautions.

Note that modification of a product may alter the stability, and a shelf-life of 1 week or less might be prudent unless data exist to support a longer beyond-use date. Several in-practice compounded preparations have been described elsewhere.²⁴

Examples of antibacterials used in otic preparations to target gram-negative organisms include the aminoglycosides gentamicin (0.3%), tobramycin (0.3%), and neomycin (0.33%) and the cell membrane-active agents colistin (0.3%) and polymyxin B (5000 IU/mL). Topical aminoglycosides also target

Staphylococcus spp. whereas systemically, amikacin is more effective toward *Pseudomonas* spp., and gentamicin is more effective toward *Staphylococcus* spp., systemic use of an aminoglycoside as sole therapy for treatment of *Staphylococcus* spp. is discouraged. An otic preparation for amikacin can be compounded from the commercially available injectable product by adding 30 to 50 mg/mL to sterile saline or Tris-EDTA. Because aminoglycosides are more effective in an alkaline environment, they should be used either before or 1 or more

hours after acidifying agents. Silver sulfadiazine (0.5%) is an ointment approved for humans to prevent or treat infection in burn patients. Its spectrum also includes *Pseudomonas* spp. However, the product, as approved in humans, may cause skin irritation. Silver sulfadiazine (1%) is available in commercial products combined with enrofloxacin (0.5%) or as a micronized powder (e.g., www.spectrumrx.com) that can be reconstituted in sterile water to a 0.5% to 1% solution (5 and 10 mg/mL, respectively). An otic preparation containing orbafloxacin and posaconazole as an antifungal drug with mometasone as an antiinflammatory has recently been approved for dogs (Table 8-4). A number of other antimicrobials have been administered topically, including the narrow-spectrum fusidic acid for treatment of Staphylococcus spp., antipseudomonadals such as colistin or polymyxin B (10,000 U/mL of Neosporin GU,²⁴ fluoroquinolones (discussed later), and ticarcillin (which also targets Staphylococcus spp.). Ciprofloxacin and ofloxacin are available as human otic preparations. Ciprofloxacin is generally more potent than enrofloxacin against *Pseudomonas* spp.

Trothmethamineethylenediamine-tetraacetate (EDTA, Tris-EDTA, or commercial Triz/EDTA) is a topically applied compound that chelates cations, thus rendering the cell wall and membrane of both gram-positive and gram-negative organisms more permeable to antimicrobials. Penetration of antibacterials subsequently is facilitated. Treatment should be timed such that microorganisms are exposed to Tris-EDTA before peak concentrations of antimicrobials reach the site of infection. Direct addition of antibiotics such as gentamicin to the buffer solution may be less desirable than pretreatment with Tris-EDTA, followed later by antimicrobials (to allow time for chelation of cations). Because cations are also removed from the lipopolysaccharide covering, EDTA may be particularly effective for treatment of gram-negative organisms. Aminoglycosides in particular are facilitated because cations that otherwise would repel positively charged drugs such as aminoglycosides are removed. Synergisim has been demonstrated with Tris-EDTA and aminoglycosides (amikacin and neomycin) against S. intermedius, Proteus mirabilis, P. aeruginosa, and E. coli. Combination solutions appear to be stable for at least 3 months.²⁵

KEY POINT 8-7 Pretreatment of an infected site with *tris*-EDTA has the potential to enhance efficacy of many antimicrobials against many bacteria.

However Tris-EDTA synergisim also has been demonstrated, albeit in vitro, for other drugs. These include fluoroquinolones and amoxicillin. Tris-EDTA also appeared to have a synergistic effect with 0.15% chlorhexidine digluconate in an open, unblinded clinical trial in dogs (n = 11) with chronic otitis externa associated with both gram-negative and grampositive infections. Enrofloxacin was also used in these dogs.²⁶

A common otic preparation compounded by veterinarians for treatment of otitis externa combines 12 mL of 100 mg/mL enrofloxacin in 8 oz (240 mL) of T8 (alcohol combined with the spermicide nonoxynol-9), 4-8 mg of dexamethasone phosphate, and 1 to 2 mL of DMSO, yielding a final product of 0.5% enrofloxacin and 0.0016 to 0.0032% dexamethasone. Because T8 can be irritating, Tris-EDTA might be substituted, although the advantages of pretreatment with Tris-EDTA will be lost.

Topically applied antifungal otic agents generally target *M. pachydermatis* and include the imidazoles clotrimazole (1%), miconazole (1%), and the benzimidazole thiabendazole (1%) and the polyene macrolides nystatin and amphotericin B. Among these, those containing thiabendazole might be considered first line.^{17,22} Ketoconazole is available as a topical preparation that can be reformulated into solutions that can be used topically.²⁴ The allylamine, terbinafine, is also effective against *Malassezia* spp. and is available as a 1% solution.

Antiinflammatories often are included in topical otic solutions. Examples include DMSO (60%) and glucocorticoids. Among the glucocorticoids used topically, the order of potency (which should not be confused with efficacy) is fluocinolone > betamethasone or dexamethasone > isoflupredone > triamcinolone > prednisolone (prednisone should not be administered topically) > hydrocortisone. Note that sufficient drug may be absorbed with topical therapy that the hypothalamic-pituitary-adrenal axis will be affected.²⁷

Several clinical trials have addressed the topical treatment of otitis externa. A preparation containing marbofloxacin (0.3%), clotrimazole (1%), and dexamethasone (0.09%) (10)gtt/ear/day) was prospectively compared with one containing polymyxin B (5.5 IU/mL), miconazole (2.3%), and prednisolone acetate (0.5%) (5 gtt/ear/bid) in dogs (n = 140; ages 4 months to 16 years) with clinical signs indicative of acute or subacute otitis externa.²⁸ Treatments were randomized. Exclusion criteria included treatment within the previous 10 days with topical or systemic antimicrobials (including antifungals), nonsteroidal antiinflammatories, glucocorticoids (previous 14 days), or a long-acting steroidal antiinflammatory drugs (previous 60 days). The presence of concurrent auricular disease, including ear parasites, foreign bodies, and neoplasia or hyperplasia were also a basis for exclusion. Pregnant or nursing dogs were excluded. Culture (swab) revealed disease was associated with Staphylococcus spp. (39.5%; 82% S. intermedius), Pseudomonas spp. (12.9%; P. aeruginosa predominant), Enterobacteraceae spp. (17%; Proteus, spp. E. coli), and Malassezia spp. (58%). Streptococcus spp. and other gram-positive isolates represented another 11.4%, whereas 10.5% were infected with other gram-negatives; 8.6% of ears were cultured as no growth. Susceptibility testing indicated that 85% of isolates were susceptible to marbofloxacin. Interestingly, 43.5% were susceptible to polymyxin B, a drug generally considered ineffective against Staphylococcus spp. and other gram-positive as well as selective gram-negative organisms (e.g., Proteus spp.). Ears were scored for severity of otitis (0-3, with 3 most severe) and cultured (in addition to baseline) before, in the event of failure, or 2 weeks into therapy if the cause was Pseudomonas spp. Approximately 75% of yeast were susceptible to both antifungals studied. Owners and investigators were blinded to the treatment groups. Ears were cleaned according to a predefined schedule, based on the underlying classification scheme (erythematous [EO] or suppurative [SO]) approximately 2 to 3 times per week (with physiologic saline on days 0, 2, 4 (EO) or days 1 and 6 (SO).

Response was assessed on days 7 and 14, with treatment continued to day 14 if indicated on day 7 assessment. The preparations were found to be equivalent with regard to success (58% for the marbofloxacin preparation compared to 41% for the polymyxin-based preparation; failure to identify this difference as significant may have reflected the sample size), but the marbofloxacin preparation was considerd superior in terms of control of pain, pus, appearance, and odor on day 14. The differential response apparently was not statistically significant, although better efficacy would be expected for marbofloxacin based on the limited spectrum of polymyxin B.

Systemic therapy is indicated for severe infections but should be coupled with topical therapy and should be based on culture and susceptibility testing. Doses should be designed with the site of infection in mind; distribution is likely to be limited to the site, particularly with marked inflammation. Water-soluble drugs might be administered topically, and lipid-soluble drugs systemically. No data support selection of the same versus different but complementary antimicrobials when both topical and systemic therapy are used. The advantage of using the same antimicrobial topically as administered systemically is increased likelihood of effective drug concentrations at the site of infection. The advantages of combination therapy have been discussed previously (see Chapter 6) and are particularly appealing for the treatment of chronic, minimally responsive otitis externa. Oral antifungals such as ketoconazole or itraconazole may be indicated for control of infection caused by Malassezia spp. (see Chapter 9). Glucocorticoids may be necessary for rapid control of inflammation regardless of the cause or duration of infection. General principles of glucocorticoid therapy should be followed (see Chapter 30).

Treatment of Specific Causes of Otitis Externa

Acute otitis externa. Although ultimately the normal ear is clean and dry, severe swelling or proliferation indicates less aggressive therapy initially and the potential need for glucocorticoid therapy (topical or systemic). Once swelling is decreased, cleaning will be more effective. If the tympanic membrane is intact, initial cleaning begins with an application of a ceruminolytic, which can then be rinsed with water, or an antimicrobial solution such as chlorhexidine, povidone, polyhydroxidine iodine, or acetic acid. If the tympanic membrane is ruptured, only water or saline should be used for cleansing because many of the cleansing agents are ototoxic. Cleansing can be accomplished at home, although initial cleaning might be more thorough if performed under general anesthesia, particularly in intractable patients. For ears in which a large amount of debris has accumulated, removal of material may require alligator forceps through an otoscope and flushing with either an open-ended Tomcat catheter or a 3.5 to 5 French feeding tube and syringe or an in-house vacuum system. Hair that might obstruct drainage of the ear canal or facilitate collection of debris should be removed.

Because otitis externa tends to be associated with similar pathogens, regardless of the underlying cause, topical medication applied after cleaning generally contains an antimicrobial,

antifungal, and glucocorticoid. Glucocorticoids decrease not only swelling and proliferation but also apocrine and sebaceous secretions. Note that topical administration does not preclude suppression of the hypothalamic-pituitary-adrenal axis, and the long-term use of these products is discouraged. In the event of moderate to marked swelling of the ear canal and pinna, short-term use of systemic glucocorticoids may be indicated. Note that care should be taken not to use glucocorticoids in combination with nonsteroidal antiinflammatories (including treatment intended for control of osteoarthritis). To minimize the risk of antimicrobial resistance, products that contain commonly used first-line antimicrobial and antifungals directed toward Malassezia spp. might be chosen for acute (nonrecurring) otitis externa. Culture and susceptibility data are the best basis for selection of the most appropriate secondline antimicrobial. In the event of moderate swelling of the ear canal and pinna, topical antimicrobial therapy probably should be accompanied by systemic therapy. Therapy for acute otitis externa should be followed through rechecks at 10- to 14-day intervals. Resolution generally requires 2 to 4 weeks.

Chronic otitis. Resolution of chronic or recurring otitis includes treatment of specific diseases of the ear that allow perpetuation of infection or inflammation. Culture and susceptibility data collected during cleansing of the ears under general anesthesia should be the basis of antimicrobial selection, particularly systemic. Thorough visual examination accompanied by cytologic examination can help identify other underlying causes. Antiinflammatories (e.g., oral prednisolone at 0.5 mg/kg every 12 hours, tapered when indicated) are indicated in the presence of marked inflammation and when proliferation precludes effective examination. Topical therapy with intense cleansing should be implemented; several months of topical therapy may be indicated. Systemic therapy should accompany topical therapy if deeper infection is suspected (i.e., marked proliferation or ulceration).²³

Bacterial otitis. The need for antimicrobial therapy for bacterial otitis externa should be based on cytologic evidence of inflammatory debris and intracellular organisms supports bacterial infection. A first-line product containing neomycin or chloramphenicol might be appropriate. Severe inflammation may indicate the need for a lipid soluble systemic antimicrobial therapy. Among the more commonly selected systemic antimicrobials are amoxicillin-clavulanic acid, a fluorinated quinolone, or a first-generation cephalosporin.²² Failure to respond to first-line medicaments may indicate the need for culture. Some authors recommend discontinuing antimicrobial therapy for 3 to 5 days before culture; however, while a false negative might be ignored, a false positive is a clear indicator that therapy may fail. Otic preparations containing gentamicin or tobramycin might represent the second line of medicaments for infections resistant to neomycin or chloramphenicol.

Otitis caused by *Pseudomonas* spp. can be among the more frustrating problems to treat and often is the incentive behind the formation of homemade otic products. Flushing with an acetic acid–based solution is indicated. Commercially available otic products have been modified by the addition of drugs effective against *P. aeruginosa* (amikacin, enrofloxacin, polymyxin B, or colistin sulfate) or the addition of antiinflammatory drugs. Several alternatives can be considered for refractory cases. Enrofloxacin has been added to commercially available otic solutions, but it (or ciprofloxacin or marbofloxacin) also may be the oral antimicrobial of choice. Note that ciprofloxacin is more potent against *Pseudomonas* spp. and may be preferred topically; oral enrofloxacin will result in ciprofloxacin exposure, as well as enrofloxacin. The maximum end of the fluoroquinolone dosing regimen should be considered when treating a refractory case of *Pseudomonas*-induced otitis externa (i.e., 20 mg/kg once daily for enrofloxacin, 30 to 40 mg/kg orally for ciprofloxacin in dogs). Other products to be used in resistant cases include silver sulfadiazine, xenodine, and chlorhexidine (1.5%).

Malassezia pachydermatis. *Malassezia pachydermatis* is an opportunistic organism that, in large numbers, causes proliferatory changes in the ear. Its presence may contribute to bacterial otitis, and thus its control may be important in the treatment of otitis. Because control of inflammation may be paramount to controlling infection by *Malassezia*, spp. glucocorticoids such as those provided in otic preparations may be indicated. Ketoconazole appears to be among the most efficacious antifungal drugs, followed by miconazole, nystatin, clotrimazole, and amphotericin B.²² Thiabendazole (the active antifungal in Tresaderm), however, may be sufficiently effective, allowing other antifungals to be reserved for resistant cases. Routinely used cleaning and drying solutions should be used on a daily to alternate-day basis to facilitate control.

Ear mites generally occur in young animals, and their presence is determined by direct examination. Carbaryl and pyrethrin-based products should be used for at least a 3-week cycle to ensure killing of adults and immature mites. Products containing thiabendazole should be selected because the product probably kills all stages of mites, including eggs. Polyhydroxidine iodine may also be effective when administered once weekly for 4 weeks. *Otodectes* can be treated with ivermectin given orally once a week for 4 weeks or subcutaneously every 10 to 14 days. With severe infestations ivermectin should be combined with other topical miticides. Because other portions of the body may harbor mites that infest the ear, affected animals should be dipped.

Seborrheic otitis or ceruminous otitis usually accompanies endocrinopathies. Secondary bacterial and Malassezia spp. infections are not uncommon with this disorder. The first-line medications should be effective for management of most cases, but longer-term management may require a combination of cleansing, drying, and glucocorticoid products applied once to thrice weekly. Cocker Spaniels and other breeds occasionally develop what appears to be a local hypersensitivity to cerumen, resulting in a progressively inflammatory, proliferative disease that ultimately may result in calcification of auricular cartilages. Control of inflammation initially may require oral glucocorticoids accompanied by topical application of a potent (e.g., dexamethasone or fluocinolone) glucocorticoid. Topical antimicrobials (antibacterial and antifungal) probably are also indicated; systemic antimicrobial therapy may also be necessary. The ears should be frequently flushed with cleansing and drying agents. For some animals long-term, low-dose glucocorticoid therapy may be necessary.

Swimmer's ear generally occurs because frequent swimming encourages low-grade inflammation and subsequent maceration. Ears should be kept clean and dry. Topical antiinflammatory therapy and, in some cases, topical antimicrobial therapy may be necessary. Products should be used on the day of swimming and for several days after.

Otitis Media

Otitis media associated with infection of the middle ear generally results from extension of otitis externa through a perforated eardrum.^{17,29} A perforated eardrum may be hard to detect and must be distinguished from a "false" eardrum. Indications that infection of the external ear has extended into the middle ear include persistence of otitis externa, pain, swelling or narrowing of the ear canal, and evidence of neurologic involvement such as facial palsy (ptosis or paralysis of the lip or ear) or vestibular abnormalities. Less commonly, infection may follow extension from the pharynx by way of the auditory tube or hematogenous spread. Radiographs and surgical exploration may be necessary for both diagnosis and treatment. Debris should be cytologically examined for evidence of predisposing conditions. Fungal infections (e.g., aspergillosis, infection caused by Malassezia) spp., foreign bodies such as grass awns, neoplasia, inflammatory polyps, and tumors, including cholesteatoma, are among the more common causes of otitis externa. Calcification of auricular cartilage may also predispose subjects to the development of infection. Breeds apparently predisposed to otitis media include Cocker Spaniels and German Shepherd Dogs.

Medical management of otitis media is often unsuccessful unless accompanied by surgical management, particularly if inflammation is severe and chronic or if the ear canal is stenotic. Surgical intervention may be the most cost-effective means of management and should provide the most accurate diagnosis. Treatment includes removal of debris and topical application of an antimicrobial with or without an antifungal preparation until the infection appears resolved. After debris is cleaned from the external canal, myringotomy (under general anesthesia) may be necessary to clean debris, collect a sample for culture and cytologic examination, and relieve pain associated with the infection. Intraoperative infusion of the bulla may be an effective means of providing higher concentrations of an antimicrobial,²⁹ but duration of exposure is not clear and residual effects should not be anticipated. However, flushing the bulla is an effective means of reducing the microbial flora.³⁰ In a retrospective study of 34 dogs afflicted with otitis media, the most likely causative organisms were Enterococcus and Streptococcus spp., Pseudomonas spp., Proteus spp., and E. coli.³⁰ The varied population among animals limits empirical prediction of either the organism or, as was demonstrated in the study, susceptibility. Disconcertingly, empirical antimicrobial selection was inappropriate on the basis of culture and susceptiblitity data in nearly 60% of the patients. This probably reflects, in part, previous antimicrobial therapy.³⁰ This study also demonstrated that the

preflushing and postflushing cultures often did not match, and postflushing culture was recommended.

Systemic antibacterial therapy should begin in conjunction with topical therapy; current recommendations are to continue therapy for at least 4 to 6 weeks. For fungal infections (e.g., one caused by Malassezia spp.), oral therapy with an imidazole antifungal (e.g., thiabendazole, ketoconazole, itraconazole) should be implemented. For severe inflammation glucocorticoids may be given topically or, if indicated, systemically for the first 1 to 3 weeks of treatment. Topical glucocorticoid therapy can be continued if inflammation persists after resolution of infection. When used as a vehicle, DMSO may also impart antiinflammatory effects. Daily flushes of 5% acetic acid in water (1:1 to 1:3) may further control symptoms. Therapy must be continued until the tympanic membrane is repaired (generally 21 to 35 days). Control of the inflammatory process may be necessary before tympanic healing is complete. Should the tympanum not heal, debris may once again accumulate, and the ear must be flushed again.

Topical therapy of otitis media is complicated by the risk of ototoxicity, which is complicated by inflammation.²⁹ Although response to inflammation may decrease the risk of ototoxins reaching the inner ear, assessing the degree of protection is difficult. Ototoxins can affect either the vestibular apparatus or the cochlea; subtle changes in response to ototoxins may be difficult to detect. Either the active ingredient or the vehicle of a topical preparation may be ototoxic. Among the known ototoxins that might be used to treat the ear topically are chlorhexidine, fluoroquinolones, aminoglycosides, polymyxins, eruthromycin, detergents, and alcohols.³² The lack of data regarding the ototoxic potential of a given product does not necessarily mean that the product is safe. In general, direct application of any antimicrobial to the external ear in the presence of a perforated eardrum is discouraged.

Otitis interna

Otitis interna or labyrinthitis resulting from infection of the inner ear also occurs as a result of extension from otitis externa and media (see discussion of otitis externa), movement of organisms through the auditory tube, or hematogenous spread. Foreign bodies, tumors (including cholesteatoma), or other occlusive or inflammatory objects may predispose the subject to infection.³¹ Clinical signs vary with the extent of vestibular dysfunction, which in turn reflects the extent of infection and accompanying inflammation. Continuation of infection into the meninges is more likely in cats than in dogs.

Cultures that reflect infecting organisms might be obtained by sampling the middle ear; alternatively, myringotomy may be necessary. Both topical and systemic antimicrobial therapy should be implemented. Because yeast is often present, topical therapy should include antifungal drugs (e.g., nystatin). A number of antimicrobials can be used for treatment of otitis interna, although distribution is likely to be limited for many (see Table 7-5). A lipid-soluble drug is preferred, and combination therapy should be considered to minimize the risk of resistance. Examples include the fluoroquinolones and chloramphenicol; the latter, however, is not likely to reach killing concentrations at the site of infection. Ototoxicity of antimicrobial drugs must be considered.³²

INFECTIONS OF THE SKIN

Pyoderma

Pathophysiology

Pyoderma is defined as a bacterial infection in skin associated with pus. Both the normal organ (skin) and the diseased local environment (pus) present barriers to drug movement and therefore efficacy.³³ As such, pyoderma is a complex disease that may be difficult to treat effectively. The location of the infection in the skin, and particularly the depth (surface infection to cellulitis), confounds therapy.^{34,35} Consequently, one of the goals of therapy for pyoderma is to prevent the progression of clinical signs. Whereas a surface infection (e.g., intertrigo) is generally amenable to topical antimicrobial therapy, superficial skin structures (e.g., impetigo, superficial folliculitis) may be less responsive; however, even these infections may yet respond to proper topical therapy in lieu of systemic therapy. Certainly, as infection becomes more deep-seated, systemic antimicrobial therapy becomes more important (Figure 8-3, A).³³⁻³⁵ Lesions of deep pyoderma begin in the distal portion of the hair follicle, often extend below the follicle, and may be accompanied by furunculosis and a granulomatous response. As the disease worsens, antimicrobial penetration becomes more limited, and successful therapy is more difficult to achieve, requiring higher doses and, for time-dependent drugs, shorter intervals .³³⁻³⁵ Cellulitis is the most severe manifestation of pyoderma and involves infection of the dermis and adjacent subcutaneous tissues. Although uncommon, infection at this depth can become life threatening if sepsis develops.

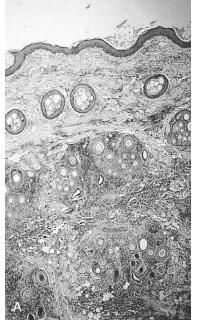

Figure 8-3 A, Histologic section of deep pyoderma. Scarring and accumulation of inflammatory debris present both mechanical and functional barriers to drug penetration.

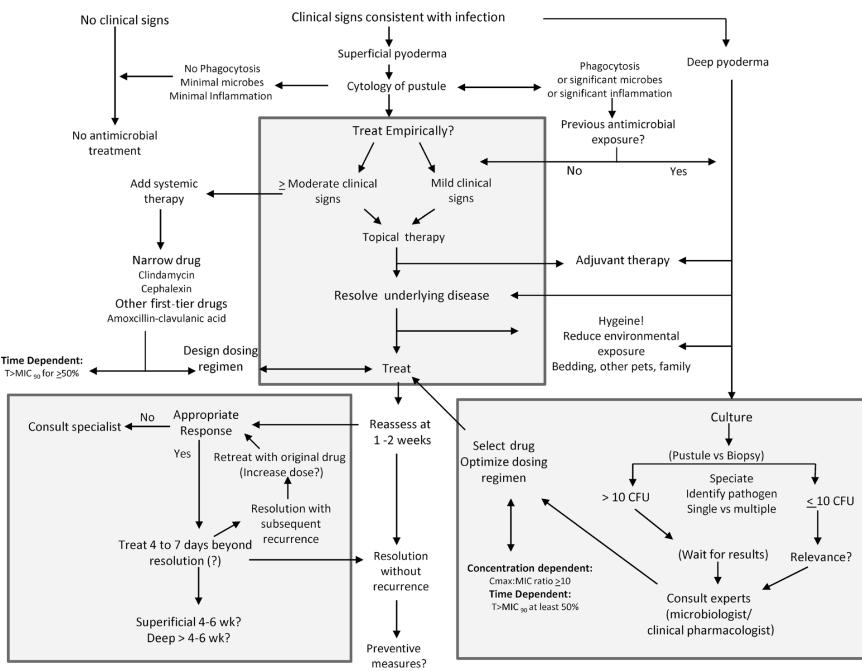

Figure 8-3, cont'd B, A suggested algorithm for treatment of canine pyoderma. Note empirical therapy of superficial pyoderma begins with topical rather than systemic therapy (*center*); treatment of deep pyoderma begins with culture and susceptibility testing (*lower right*). Once the decision is made to use systemic therapy, narrow spectrum, first-tier drugs should be chosen first (*upper left*). Topical therapy is a part of all therapies. Removal of underlying disease may be paramount to therapeutic success. Dosing regimens should be designed to minimize the advent of resistance; if successful, subsequent recurrences may continue to respond to first-tier drugs. Initial therapy should be reassessed within 7 to 10 days; failure to respond at this time should lead to alternate therapies, which may involve reculture and consultation with specialist. In responders, evidence regarding the duration of therapy is not clear and until such data exist, current recommendations focus on 4 to 6 weeks. (*A*, Photograph courtesy Bayer Animal Health.)

в

287

KEY POINT 8-8 Focusing on topical therapy as the sole method of delivery of antmicrobial therapy should minimize the need for systemic antimicrobial therapy, which might contribute to resistance.

Not all pyodermas are difficult to treat; indeed, most will respond to initial therapy. Therapy with superficial pyodermas should begin with topical therapy only (see Figure 8-3, B) However, some patients that initially respond to antimicrobial therapy experience recrudescence after therapy is discontinued. The most likely cause for recrudescence is failure or inability to control underlying skin diseases that predispose the skin to persistent or recurrent infections. Examples include ectoparasitism, seborrhea (cornification disorders), allergies (atopic dermatitis, flea or food allergies), and endocrinopathies (hyperadrenocorticism or hypothyroidism).33-35 Anatomic abnormalities such as skin folds (intertrigo) also predispose the patient to bacterial infection.³³⁻³⁵ Failure or inability to correct these underlying factors increases the risk of therapeutic failure, and emergent resistance if multiple courses of antimicrobials are implemented. In addition to the physiologic barriers presented by the normal animal, a number of other factors complicate treatment of pyoderma. These include the effects of the infecting microbe; mechanical, functional, and structural sequelae of progressive disease; and limitations of the drugs themselves. Although the sequelae of these interacting factors are difficult to predict in the individual patient, their impact can be minimized by decision making that is based on these interactions.

The surface of the skin normally presents several barriers to bacterial invasion and colonization. Cells of the stratum corneum desquamate from the surface of the skin and hair follicles, and the lipid-rich environment between the cells impedes bacterial movement.34,35 Epithelial proliferation follows injury to the skin, decreasing the likelihood of bacterial invasion. Sebum and sweat contain antibacterial chemicals such as inorganic salts^{34,35} and lipids.³⁶ Finally, resident microflora may be important by helping to keep invading microflora in check. Differences in the incidence and ease of treatment of pyoderma in dogs versus cats and other species may reflect anatomic and physiologic differences in their skin.^{34,35} Canine skin may be predisposed to pyoderma because the stratum corneum is thin and compact and contains less lipid material. Therefore canine stratum corneum may present a less efficient barrier to bacterial invasion compared with that of other species. Canine hair follicles lack a lipid-squamous "plug," which may facilitate bacterial penetration into the hair follicle.^{34,35,37} Finally, the pH of canine skin is higher than that of other species, perhaps providing an environment more conducive to bacterial proliferation.^{34,35}

Skin also has a well-developed immune response, composed of proteins, immunoglobulins located in the basement membrane, cells of the immune system located in the dermis and epidermis, and regional lymphoid tissue.^{34,35} However, materials released from microbes facilitate invasion, impair cellular phagocytosis, and damage host tissues. Under normal circumstances components of bacteria that penetrate the skin stimulate a humoral response (immunoglobulins G and M), which in turn activates effector mechanisms leading to an acute inflammatory response.^{34,35} Soluble mediators released by organisms (e.g., hemolysin, epidermolytic toxin, leukocidin) may damage host tissues or alter host response.^{34,35} Staphylococcus spp. in particular plays a role in perpetuating the inflammatory response. Cutaneous mast cells triggered by antistaphylococcal immunoglobulin E may increase epidermal permeability and facilitate bacteria or bacterial antigen penetration in patients with allergic skin disease.³⁴⁻³⁶ Most staphylococci associated with canine pyoderma produce "slime," a material that facilitates bacterial adhesion to cells. Staphylococcal organisms contain protein A, which impairs antibody response, activates complement, and causes chemotaxis.³⁸ Some staphylococcal organisms release superantigens (enterotoxin), which may cause interleukin release and an inappropriately large T-lymphocyte response in the skin.^{34-36,39} Finally, selected Staphylococcus spp. suppress or prevent intracellular killing once phagocytized by leukocytes.⁴⁰ Viability of the organisms will be maintained inside the phagocyte, allowing not only survival but perhaps also continued replication inside the cell. Subsequent release of the organism on the death of the phagocyte allows reinfection, leading to persistent or recurrent infections.

The phagocytic white blood cells (initially neutrophils) that respond to inflammatory mediators use a number of oxidative (e.g., myeloperoxidase) and nonoxidative (e.g., bactericidal permeability-increasing protein) mechanisms to kill phagocytized invading bacteria.⁴¹ Unfortunately, host responses to bacterial invasion may become deleterious and can negatively affect therapy. The inflammatory response to infection may facilitate bacterial penetration, is responsible for clinical signs associated with the disease, and may preclude antimicrobial penetration of the skin. The severe and persistent inflammatory response leads to pruritus, and self-trauma further aggravates bacterial penetration. The disease may develop an autoimmune component.^{34,35} These long-term changes, in conjunction with inflammatory disease, predispose the patient to recurrent pyoderma.

As bacterial skin disease progresses, pathologic changes become barriers to drug distribution at the site of infection, and dosing regimens should be modified accordingly. The barriers vary with the site of infection, ranging from very superficial structures (epidermal and hair follicle) to deep structures below the hair follicle. Hair follicles may rupture, leading to furunculosis. Granulomatous changes and keratinaceous debris may act as foreign bodies, perpetuating the inflammatory response.^{34,35} These deeper structures may become isolated by fibrous tissue as disease progresses unchecked. Foci of organisms located in these isolated beds of scar tissue are a likely cause of recurrent infections with deep pyoderma (see Figure 8-3, *A*), as can intracellular survival of phagocytized organisms (see Figures 6-17 and 6-18).^{34,35}

KEY POINT 8-9 As bacterial skin disease progresses, pathologic barriers impede drug distribution to the infecting organism. Dosing regimens should be modified accordingly.

Microbial Flora

The microflora of the skin is composed of both resident and transient organisms. Resident organisms in the skin of dogs include Micrococcus spp. beta-hemolytic streptococci, aerobic diphtheroids, Propionibacterium acnes, and Staphylococcus spp. Pseudomonas, Proteus, and Corynebacterium organisms have also been cultured from normal dogs. Among the resident organisms cultured from the skin of normal dogs, only S. intermedius is a likely initial cause of pyoderma. S. intermedius has recently been reclassified to Staphylococcus pseudintermedius; however, the original terminology will be used throughout this text until the newer terminology has been accepted and is in general use. S. aureus and other Staphylococcus spp. are much rarer causes of superficial pyodermas in dogs.^{34,35,37} S. intermedius is involved in approximately 90% of canine pyodermas.³³⁻³⁵ The resident status of S. intermedius in the skin is debatable. Although cultured frequently from either the skin or hair of normal dogs, S. intermedius may simply be a contaminant or a transient organism, acting as a "nomad," proliferating only when environmental circumstances are supportive of growth.⁴² The microflora of dogs with pyoderma differs from the microflora of the skin in normal dogs. Even skin not clinically affected by pyoderma is characterized by increased staphylococcal colonization.34,35 Eventually, Staphy*lococcus* spp. become the predominant organism in the skin. It can change the local environment, allowing proliferation of other organisms. Thus, even when disease has progressed to the point that gram-negative infections (e.g., E. coli, Proteus spp., and Pseudomonas spp.)^{34,35} are involved (generally deep pyodermas), S. intermedius is likely to be involved. In fact, if S. intermedius is not cultured from the skin lesion, the laboratory or culture technique may be questioned.³³ When pyoderma is treated, concomitant infection with S. intermedius should be assumed, and control of infection by S. intermedius in such cases should facilitate treatment of other organisms, including gram-negative bacteria.

Several studies have addressed microbes causing skin infections, including prevelance of methicillin-resistant Staphylococcus spp. (MRS) in dogs and cats. Among the caveats to the studies will be differences in methodology, particularly as it pertains to sample collection. Ideally, samples are based on tissue samples following adequate cleansing; more often than not, however, samples are collected by swabs. Diagnostic aids can be useful to discriminate infection from colonization in the skin. Gram staining and cytology are particularly helpful. The presence of rods indicates a mixed infection (with gram-negative organisms); intracellular organisms indicate phagocytosis and thus infection rather than colonization. Cytology may help stage or identify the cause of disease: Mononuclear infiltrations indicate deep, chronic infections; large numbers of Staphylococcus spp. in pustules may indicate hyperadrenocorticism.34,35

Petersen and coworkers¹⁸ reported on the frequency and susceptibility of *S. intermedius* and *P. aeruginosa* in samples collected between 1992 and 1997 from canine skin and ears (n = 497) and submitted to a state diagnostic laboratory (see Table 8-3). The method of sample collection was not provided

but reflects methods used by practitioners. S. intermedius was isolated from 89% of skin samples and was the only isolate cultured from 47% of samples. P. aeruginosa was isolated from 7.5% of skin samples, with the frequency of collection from the skin increasing during the 6-year period of the study. Of the isolates yielding P. aeruginosa, it was the only isolate in 33% of samples. Although Staphylococcus isolates were susceptible to drugs generally chosen empirically as first-choice treatment for pyoderma, as in the author's institution, MRS appears to have begun increasing in the early 2000s. This is indicated by the difference in isolates collected from 2003 to 2005, versus 2006 and 2007 (Table 8-3). These data demonstrate that initially the proportion of susceptible isolates collected from skin, and other tissues was nearly 100% for drugs traditionally selected empirically, only to decrease to nearly 65% susceptible during this period. These data underscore the limitations that appear to be emerging regarding empirical selection of antimicrobials even for those conditions traditionally considered safe, such as pyoderma. They also underscore the importance of appropriate dosing regimens to minimize the advent of resistance.

KEY POINT 8-10 Methicillin-resistant *Staphylococcus* increasingly is being identified in association with pyoderma.

The public health significance of treating MRS is addressed in greater depth in Chapter 7. The role of previous antimicrobial therapy facilitating multidrug-resistant *Staphylococcus* spp. has been well established (see Chapter 6). A report from Sweden demonstrated that *S. intermedius* isolates from dogs with recurring pyoderma were more likely to be characterized by resistance than isolates of first-time infections.⁴³ Approval and subsequent use of betalactamase inhibitors and cephalosporins are particularly well associated with MRSA and MRSI. Overproduction of beta-lactamases coupled with changes in penicllin-binding proteins contribute to oxacillin/methicillin-resistant *Staphylococcus* spp., whether *aureus* (MRSA) or *intermedius* (MRSI).

KEY POINT 8-11 The role of previous antimicrobial therapy facilitating emergence of multidrug resistant *Staphylococcus* has been well established.

Abraham⁴⁴ prospectively studied the frequency of *Staphy*lococcus spp. as a cause of infection in cats. No cat had received antimicrobials within the previous 7 days. The prevalance of coagulase-negative isolates was higher than coagulase-positive isolates in all cats, and the proportion of each was similar in healthy cats compared to cats with inflammatory skin disease (ISD). For healthy cats (n = 50); 21 were coagulase-positive isolates (n = 17/50, or 34% of all healthy cats) and 49 were coagulase-negative (n = 49/50 cats or (98% of all cats). This compares to ISD cats (n = 48) of which 25 were coagulasepositive isolates (n = 24/48 or 50% of cats) compared to 46 coagulase-negative isolates (n = 46/48 or 96% of cats). Of the coagulase-positive isolates, approximately 50% were S. aureus and S. intermedius, respectively, in both groups. Specifically, in healthy cats 10 and 11 of 21 coagulase-positive (48% and 52%) isolates were S. aureus and S. intermedius, respectively.

From the ISD cats, 14 and 11 of 25 (56% and 44%) were S. aureus and S. intermedius, respectively. The proportions of staphylococci infections differ between dogs and cats.⁴⁵ In a separate study by the same group, 74% of healthy dogs (n = 37/50) were positive for growth compared with 88% of dogs with ISD (n = 52/59).⁴⁵ The total number of isolates (from different body regions) cultured was greater in ISD dogs compared with healthy dogs. For both healthy and ISD groups, coagulase-positive isolates far outweighed coagulasenegative isolates, and S. intermedius outnumbered S. aureus. For coagulase-positive isolates in the 52 ISD dogs, the frequency of isolation of S. aureus, intermedius, and schleiferi subsp. coagulans (SSc) (all coagulase positive isolates) was, respectively, 10, 134, and 6 isolates each, compared with 8, 69, and 0 isolates, each respectively, in the 37 healthy dogs (2 coagulase-negative isolates). In the healthy dogs, 9 isolates of coagulase-negative S. schleiferi subsp. schleiferi [SSs] were identified, indicating the possible importance of subspeciated S. schleiferi. Methicillin resistance occurred in both coagulasepositive (MRSA, MRSI, MRSSc) and -negative (MRSSs) isolates and was more frequent for MRSI and in ISD (n = 4 MRSI, n = 1 MRSA, MRSC = 1, MRSS = 1) compared with healthy (MRSI = 1, MRSA = 0, MRSC = 1, MRSS = 0) dogs.

Other staphylococci are being recognized for their increasing role in canine pyoderma. S. schleiferi has recently been recognized for its increasing role, particularly in recurrent infections;45,47,48 it was the second most common Staphylococcus organism cultured in one study. The increasing recognition of this organism is important because multiple antimicrobial resistances can occur with S. schleiferi, 45,49 whereas the incidence of multiple drug resistance (meaning resistance that includes drug classes other than beta-lactams) by S. intermedius remains low (see the discussion of antimicrobial resistance below). Concern might heighten if laboratories cannot or do not distinguish between S. schleiferi and S. intermedius, much as S. intermedius was confused with S. aureus in the 1970s. Further S. schleiferi exists as either coagulase-negative (schleiferi subspecies), which generally indicates contaminants, or coagulase-positive (coagulans subspecies), which has a greater clinical significance. The increasing prevalence of S. aureus infections coupled with the emergence of S. schleiferi warrants more caution and vigilance in the prevention of zoonosis.⁵⁰

The role of *P. aeruginosa* as the sole infectious organism in canine pyoderma (n = 20) was retrospectively studied in 66 dogs with mixed or pure infections associated with pyoderma.⁴⁶ As with Petersen,¹⁸ the incidence of *Pseudomonas* as the sole agent of pyoderma was observed to be increasing. Seven of the dogs presenting with deep pyoderma had not been previously presented for skin disease; these dogs responded well to 3 to 4 weeks of fluoroquinolone therapy. The remaining 13 dogs had a protracted history of skin disease that had been treated with antimicrobials, immunomodulatory drugs, or both. Of these dogs, 11 had been previously treated with antimicrobials effective against *Staphylococcus* spp. Antimicrobials to which isolates should potentially have been susceptible but were resistant included enrofloxacin (40%; half of these dogs had previously been treated with a fluoroquinolone), ticarcillin

(36%), ciprofloxacin (25%), and gentamicin or amikacin and norfloxacin (5%). Interestingly, all isolates were susceptible to marbofloxacin, a questionable finding based on likely crossresistance among fluoroquinolones. Doses of drugs used to treat the infection ranged from 6 to 13 mg/kg for enrofloxacin qd, or 5 to 12 mg/kg bid; norfloxacin at 18 to 23 mg/kg qd, marbofloxacin at 3 to 5 mg/kg qd, and cephalexin 20 to 25 mg/kg bid. All but two dogs responded after treatment for 3 to 12 weeks (mean 4.8 weeks). However, a potentially important observation that some dogs responded to cephalexin was interpreted to potentially imply that *Pseudomonas* was only a secondary pathogen in some of the dogs.

Considerations in Drug Selection

For most antimicrobials used to treat canine pyoderma, adverse events or side effects become less important to the selection and other considerations can take precedence. Exceptions might occur for erythromycin; up to 50% of animals should be expected to develop gastrointestinal upset when treated with erythromycin.⁵¹ Gastrointestinal side effects in particular are likely to increase if higher doses of antimicrobials are used. Immune-mediated side effects caused by potentiated sulfonamides may limit their long-term use.⁵² Sulfonamides are also able to decrease thyroid hormone synthesis at high doses that might otherwise be indicated to effectively treat pyoderma.

Drug Movement to the Site of Infection

Distribution of antimicrobials applied topically is limited by the presence of the stratum corneum, although distribution of topically applied drugs should be be enhanced in the presence of inflammation. Accumulation of inflammatory debris, however, also impedes drug movement after either topical or systemic administration. Shampooing not only removes inflammatory debris but also softens the stratum corneum, thus facilitating movement of topically applied antimicrobials to deeper tissues. Distribution of systemically administered antimicrobials to the skin is somewhat limited even with normal conditions. Despite the skin being the largest organ of the body, blood flow to the skin represents only 9% of the cardiac output. Drug distribution to the skin takes longer than to tissues with greater blood flow. Although skin is well perfused, blood supply to the epidermis consists of capillaries that lie under the epidermis, and drugs must passively diffuse to the epidermis and, with folliculitis, through the hair follicle. The plexi of arteries and veins that supply the skin include arteriovenous anastomoses that allow blood to bypass capillary beds. Blood supply to the skin can be altered easily in disease, particularly in the extremities and deep dermis.

Many antimicrobials used to treat pyoderma are lipid soluble, although the degree varies with each drug. Drugs that are characterized by a favorable distribution pattern to the skin include the fluoroquinolones, the sulfonamides (including those potentiated), the macrolides (erythromycin), the lincosamides (clindamycin and lincomycin), and chloramphenicol.⁵³ The distribution of water-soluble drugs (beta-lactams, aminoglycosides) to interstitial fluid of skin should be anticipated to be less than that of plasma, particularly in the presence of physical barriers presented by fibrosis. Note that the poorer distribution of beta-lactams coupled with their time dependence indicates that those drugs with longer elimination half-lives are preferred. The presence of marked inflammatory cells may be taken advantage of with use of antimicrobials that accumulate in white blood cells (e.g., fluoroquinolones, clindamycin, macrolides, rifampin); higher intracellular concentrations may also facilitate intracellular killing of microorganisms that may survive phagocytosis.

Antimicrobial Resistance

Antimicrobial resistance may affect antimicrobial therapy of pyoderma or other infections associated with staphyloccocci. Resistance to penicillins by *S. aureus* or *S. intermedius* generally reflects an increase in chromosomally mediated beta-lactamase production.⁴⁹ However, use of beta-lactamase protectors (e.g., beta-lactamase–resistant drugs (e.g., cephalosporins) has led to adaptation by *Staphylocccus* spp. through mutations in the penicillin-binding proteins (PBP-2) encoded by the *mecA* gene, located on the staphylococcal chromosomal cassette (SCC_{mec}). The expression of this gene prevents efficacy of any beta-lactam antibiotic.

S. aureus has developed an increasing pattern of resistance against many antimicrobials (discussed in depth in Chapter 6). Indeed, the proportion of S. aureus susceptible to drugs generally chosen to treat pyodermas is consistently less than that of S. intermedius. In contrast, S. intermedius has not appeared to be as adaptable; antimicrobial resistance in S. intermedius has been slow to emerge, and the impact of previous antimicrobial use on the susceptibility pattern of the microbe to other drugs has been controversial.^{34,35} However, although S. intermedius is a species distinct from S. aureus, transmission between these organisms of plasmids responsible for multiple antimicrobial resistance may be a factor that appears to be contributing to antimicrobial failure in canine pyoderma.^{34,35} In humans antimicrobial resistance is a rapidly emerging concern in dermatology.⁵⁴ In patients with skin wounds, S. aureus (44% methicillin resistant) and P. aeruginosa were the most common bacteria isolated. The incidence of MRSA increased from 26% in 1992 to 75% in 2001. Resistance was not limited to Staphylocccus spp.; P. aeruginosa resistance to quinolones increased in deep wounds from 19% in 1992 to 56% in 2001, and in superficial wounds from 0 to 18% by 2001. Although these statistics have been generated from human medicine, their changing pattern mimics what is occuring in veterinary medicine. Several studies have demonstrated the advent of MRS in veterinary patients (see previous discussion).

The frequency of methicillin resistance in coagulase-positive and -negative *Staphylococcus* spp. in dogs with and without skin disease was previously cited.⁴⁵ As early as 1998, in a retrospective study of 131 *S. intermedius* strains isolated from apparently healthy dogs and another 187 *S. intermedius* strains isolated from dog pyodermas, the proportion of multidrugresistant (three or more drug classes) strains increased from 10.8% in 1986 to 1987 to 28% in 1995 to 1996.⁵⁵ In dogs with pyoderma, 26% of the isolates in one study were associated

with multidrug resistance, including resistance to methicillin, albeit in only 2 of 57 cases. However, although not revealed in the phenotype, close to 50% of the organisms studied carried the gene (mecA) responsible for formation of PBP2a, the penicillin-binding protein that confers resistance to methicillin. S. schleiferi was the second most common Staphylococcus organism cultured; most were resistant to methicillin (coagulase-negative versus positive subspeciation not provided). ⁴⁹ That previous antimicrobial therapy may have been associated with Staphyloccoccus antimicrobial resistance was supported by the more common isolation of S. schleiferi in dogs currently receiving antimicrobials (10 of 12) compared with dogs that were not (5 of 28).⁴⁷ A multiclinic prospective study that compared susceptibility in organisms isolated from samples from first-time and recurrent cases of canine pyoderma (n = 394 Staphylococci) found that resistance to macrolides, lincosamides, fusidic acid, tetracycline, and streptomycin was significantly greater in recurrent cases (45%) compared with the first-time cases (20%). Identification of S. schleiferi was not addressed. Resistance was not detected in penicillinase-stable beta-lactams.43

More recently, Morris¹⁹ retrospectively determined the proportion of Staphyloccoccus isolates expressing methicillin resistance in dogs and cats. Samples were collected from a variety of tissues; the method varied with the clinician; isolates were processed at a veterinary teaching hospital according to Clinical and Laboratory Standards Institute (CLSI) guidelines. Isolates included S. aureus (n = 139; resistant isolates = MRSA), S. intermedius (n = 463; MRSI), and S schleiferi (n = 148; MRSSs vs MRSSc not distinguished). The frequency of resistance for each Staphylococcus spp. was as follows: MRSA 35% (more commonly associated with deep infections), MRSS and MRSSc, together, 40% (more commonly associated with superficial infections), and MRSI, 17%. The higher percentage of resistance in this hospital population probably reflects the referral nature of the patients and the likelihood that patients had previously received antimicrobials. The frequency of MRSA was the same in both dogs and cats, whereas MRSI and MRSS were higher in dogs compared with cats. Of the resistant isolates, 28% of MRSA, 40% of MRSI, and 33% of MRSS were in the skin, and 5% of MRSA, 26% of MRSI, and 47% of MRSS were located in the ear. Among the organisms, MRSS remained most susceptible to all drugs save the fluoroquinolones, but susceptibility to the fluoroquinolones was ≤35% (see Table 8-3). Although chloramphenicol was the most consistently effective drug, its use as the sole agent should be questioned.

A study of healthy cats (n = 50) and cats with ISD (n = 48) found that four healthy cats and one ISD cat harbored a coagulase-positive MRS.⁴⁴ In healthy dogs (n = 50), zero of six *S. aureus* isolates were MRSA, whereas one *S. intermedius* (n = 34) isolate was MRSI. In dogs with ISD (n = 48), one of six *S. aureus* isolates were MRSA, whereas 4 of 52 *S. intermedius* isolates were MRSI.⁴⁵

Note that not all multidrug-resistant *Staphylococcus* organisms are methicillin resistant. Disconcertingly, MRS is expanding to include drug classes other than beta-lactams.⁵⁶ Fluoroquinolone resistance may be associated with MRSA

(ciprofloxacin and levofloxacin) and also has been associated with emergent MRSA,⁵⁷ although it is not clear if the resistant isolates emerge once other microbes are inhibited by drugs, or if fluoroquinolones facilitate infection by increasing adherence of MRSA at the site of infection. On the other hand, multidrug resistance not in association with methicillin resistance (e.g., to clindamycin, chloramphenicol, doxycycline) also has emerged. Finally, resistance to vancomycin occurs with acquisition of the vanA resistance gene, usually from enterococci, which also prevents the drug from binding to the target peptidoglycan. Resistance to linezolid also has been documented.

The prudent clinician will take a proactive approach to prevent the development of antimicrobial resistance among organisms that cause canine pyoderma. Previous antimicrobial use should be considered in the selection of an antimicrobial without the benefit of culture and susceptibility data. Susceptibility data should be considered as a basis for selection of antimicrobials for patients with a history of recent antimicrobial use. Persistent infections imply therapy has failed; recurrent infections may have previously been successfully treated, but underlying disease or other factors that as yet are not identified or cannot be corrected, have facilitated return. Certainly, previously used drugs that failed should be avoided if the infection is considered persistent rather than recurrent, with selection best based on susceptibility testing for both. Perhaps more so than gram-positive isolates, resistance more likely may be encountered in gram-negative organisms associated with deep pyoderma,^{34,35} and culture and susceptibility data become increasingly important for antimicrobial selection with these infections. Resistance is more likely to develop with long-term therapy (as must occur for deep pyoderma) and conditions that are likely to result in subtherapeutic concentrations at the site of infection (e.g., beta-lactam antibiotics, particularly those with short half-lives compared with the dosing interval). Repetitive cultures that yield increasing MICs for the same drug may indicate development of resistance, and alternative drugs or combination antimicrobial therapy should be considered in such cases.53

Antimicrobial Selection

The number of antimicrobials recommended for initial therapy of pyoderma increases with the number of papers published regarding therapy. Clinician preferences vary, appropriately so, with experience. Although clinicians might not agree on their first-choice antimicrobial, there is little disagreement regarding the target organism. Initial therapy should be topical. If a decision is made that systemic drugs are indicated, therapy should begin with an orally bioavailable drug effective against S. intermedius. Ideally, the dosing interval should be 12 hours or longer to facilitate owner compliance; as such, time-dependent drugs with half-lives of less than 4 hours (e.g., amoxicillin, and potentially cephalexin) should be avoided in clients unwilling to dose every 8 hours. Subsequent considerations regarding drug selection vary with the severity of the disease. The more severe the disease, the greater the care that must be taken with antimicrobial selection. Tissue penetration should be increasingly predictable as the infection deepens. Detection and avoidance of resistance become increasingly important as the duration of therapy and the risk of subtherapeutic drug concentrations at the site of infection increase. With few exceptions, adverse effects are not a common cause of therapeutic failure and, as such, may not have a major impact on antimicrobial selection. Cost often has a major impact on selection. Clients may be reminded, however, that they might as well spend their money on an appropriate drug and dosing regimen rather than on prolonged therapy with an inappropriate drug or dosing regimen.

A number of drugs are indicated for initial therapy of pyoderma. Among the most frequent first-choice drugs for first time infections are beta-lactam antibiotics that tend to be resistant to Staphylococcus beta-lactamases. Cephalexin has been the treatment of choice for many clinicians. It and cefadroxil were among the earliest studied.⁵⁸ As time-dependent drugs, based on integration of maximum drug concentrations and MIC₅₀ or MIC₉₀, high doses and frequent intervals may be indicated (Tables 8-6 and 8-7). The approval of cefpodoxime, a third-generation cephalosporin, has been a potentially important addition to the armamentarium of drug therapy for treatment of canine pyoderma. Attributes include an MIC₉₀ for S. intermedius of 0.5 µg/mL and plasma drug concentrations that remain above this MIC for longer than 24 hours, with a dose of 10 mg/kg (but not 5 mg/kg if the 95th percentile of animals is targeted). The large structure of cefpodoxime appears to render it less susceptible to the development of resistance due to production of cephalosporinases. Another recently approved drug that will facilitate compliance is cefovecin. Based on plasma concentrations of unbound drug or interstitial concentrations,59 concentrations will remain above the MIC₉₀ of S. intermedius, as reported on the package insert for at least 13 (plasma) to 18 days (interstitial fluid); the duration, however, will be much less if the 95th percentile is used. The advantages of this drug mandate its judicious use such that emergent methicillin resistance is minimized.

Amoxicillin-clavulanic acid also is chosen as an initial drug for treatment of canine pyoderma. Its efficacy is similar to the first-generation drugs cephalexin and cefadroxil, although cephalexin is probably the most cost effective. Amoxicillinclavulanic acid may be less likely than either first-generation cephalosporin to induce resistant bacteria at subinhibitory concentrations.^{34,35} However, its short half-life and low C_{max} at recommended dose compared with the MIC₅₀ or MIC₉₀ for S. intermedius mandate an unacceptably short dosing interval if the targeted pharmacodynamic indices are to be achieved. The interpretive standards for amoxicillin have recently been updated by CLSI, causing many isolates previously considered susceptible now to be classified as resistant. Alternatively, betalactamase-resistant beta-lactams such as oxacillin and dicloxacillin might be used for initial or long-term therapy, although the cost may preclude their selection until initial therapy fails. Data regarding the current state of susceptibility of Staphylococcus spp. to these drugs is not available. A disadvantage of the beta-lactams is their failure to accumulate in phagocytic white blood cells. Further, distribution into tissues characterized by marked inflammation and fibrosis may be limited.

MIC, Minimum inhibitory concentration; TMPS, trimethoprim-sulfonamide; SC, subcutaneous; NA, not applicable; PI, package insert.

C_{max} = Peak plasma drug concentration when administered at the cited dose. Data collected from literature or package inserts (also see Table 7-1).

MIC = Refers to either the MIC₅₀ or MIC₉₀ (50th or 90th percentile, respectively) reported for *S. intermedius* in the cited reference.

 $C_{max}/MIC = Calculated$ by dividing C_{max} by MIC; for concentration-dependent drugs, a ratio of >12 was chosen to minimize resistance.

T>MIC = Calculated by dividing C_{max} by MIC; for each doubling, plasma drug concentration is above the MIC (T>MIC) for one half-life.

Interval = Based on avoiding resistance; that is, a T>MIC for 75% of the dosing interval. Calculated by multiplying T>MIC by 1.75. A target interval is reached if considered sufficiently convenient to facilitate compliance.

Dose is in mg/kg, half-life is in hours; target C_{max}/MIC_{50} or C_{max}/MIC_{60} (preferred) is \geq 10 and for most drugs, T >MIC is 50% of dosing interval

*Unbound drug

[†]Reference number

*With ciprofloxacin

§See Table 7-1

KEY POINT 8-12 A beta-lactam with a longer half-life should be selected for treatment of pyoderma; doses may need to be increased to adjust for reduced tissue distribution.

Chloramphenicol may also be an effective first-choice antimicrobial, although concerns for human exposure and its bacteriostatic nature to the drug may preclude its use. Decreased use of this drug because of toxicity concerns has probably contributed to its consistent efficacy against *Staphylococcus* spp., including methicillin resistance. If chloramphenicol is chosen, care must be taken to use it at appropriate dosing intervals. MIC₉₀ data for *S. intermedius* was not available, but doses can be designed around MIC (generally 8 µg/mL in our hospital) from the patient's data when available. Its use as sole agent for treatment of methicillin resistance should be avoided if possible because of its bacteriostatic nature. In our hospital, it has proven largely ineffective for treatment of MRS or multidrug resistant organisms. Combination with rifampin might be considered.

For infections that do not respond to initial therapy and become increasingly complicated, a drug that targets both *S. intermedius* and gram-negative organisms might be selected. Because bactericidal concentrations at the site of infection are desirable,³⁷ a drug that is likely to distribute to and through the inflammatory site is desirable. The use of beta-lactams should be de-emphasized for infections associated with marked

inflammatory debris or scarring because these drugs do not penetrate these barriers well.⁵³

Appropriate drugs should be based on susceptibility testing. Lipid-soluble drugs include the fluoroquinolones and potentiated sulfonamides (i.e., trimethoprim- or ormetoprim-sulfonamide combinations), erythromycin, azithromycin, and lincomycin or clindamycin; of these, only the potentiated sulfonamide and fluoroquinolones are classified as bactericidal. Each of these classes, except the potentiated sulfonamides, also accumulate in phagocytic WBC. Increasingly common reports of immune-mediated diseases such as keratitis sicca or impaired thyroid hormone secretion may decrease the use of potentiated sulfonamides, particularly at high doses and for long-term therapy. An advantage might, however, be once- to twice-daily therapy (sulfadimethoxine/ ormetoprim), which has proved effective for some authors.^{34,35} A cautious reminder, however: efficacy based on resolution of clinical signs does not preclude emerging resistance.

The fluoroquinolones, such as enrofloxacin and marbofloxacin, are the drugs of choice for complicated infections. They are characterized by rapid bactericidal activity, and their spectrum includes both *S. intermedius* and gram-negative organisms.^{34,35,37} These drugs distribute very well to the skin.⁶⁰ Inflammatory debris and fibrous tissue should be traversed well with little impact on antimicrobial efficacy.⁶⁰ Efficacy of the fluoroquinolones is maintained despite slow growth of

organisms or low oxygen tension.⁶¹ All fluoroquinolones that have been studied accumulate in white blood cells,^{40,62–66} thus increasing drug at the site of inflammation.⁶⁷ Fluoroquionlones are able to penetrate the lipopolysaccharide covering of gram-negative organisms. Their spectrum includes Pseudomonas spp., although increasing resistance to this organism and to S. aureus is reported. In one study of 383 isolates, the MIC for enrofloxacin against S. intermedius from 1995 to 1999 ranged from 0.063 to 64 mg/mL; the MIC₅₀ and MIC₉₀ were 0.125 and 0.25 mg/mL, respectively. Two resistant strains were found, but only among isolates collected in 1999. However, the authors concluded that the emergence of resistant mutants following 10 in vitro passages suggests that inappropriate use might favor the development of resistant strains in vivo. Like enrofloxacin, the MICs of marbofloxacin for S. intermedius are low, ranging from 0.125 to 2 μ g/mL; MIC₅₀ and MIC₉₀ are both 0.25 µg/mL (according to the package insert). The fluoroquinolones are concentration-dependent drugs; doses should achieve a target C_{max}:MIC of greater than 8 to 10. Both enrofloxacin (with its active metabolite ciprofloxacin) and marbofloxacin achieve nearly 2 µg/mL in plasma at 5 mg/kg, yielding an inhibitory quotient of about 8. Tissue concentrations are likely to be even higher. Following administration of 5 mg/ kg of enrofloxacin daily for 3 days, concentrations reached 1.9 and 4.2 µg/mL in the biopsied skin of animals with superficial and deep pyoderma, respectively, compared with 1.5 µg/mL in plasma and normal skin68; ciprofloxacin was not measured in either tissue. However, these studies are based on homogenate data, and relevancy to clinical response is not clear.

Despite favorable skin distribution of fluoroquinolones, use of high doses are recommended when possible. In one study, based on Staphylococcus organisms isolated from dogs with spontaneous disease (antimicrobial history unknown), a target C_{max} :MIC₉₀ \geq 10 might be achievable based on the highest dose and the MIC₅₀ for four of five fluoroquinolones used clinically in dogs (the exception being difloxacin), with ratios greatest for enrofloxacin and ciprofloxacin. However, no drug was able to achive the target when using the MIC₉₀ (Table 8-6).¹³¹ However, if the isolate is known to be susceptible to fluoroquinolones, the ratio of C_{max}: MIC₉₀ can be achieved for ciprofloxacin, enrofloxacin, or marbofloxacin using the MIC₉₀ at the high dose.¹³¹ These findings were supported by a study that found the MICs of orbifloxacin for S. intermedius isolates to be higher compared with enrofloxacin or marbofloxacin. In a study of 254 isolates (69 skin and 171 ear), the MICs for orbifloxacin ranged from 0.016 to 8 mg/mL; MIC₅₀ and MIC₉₀ were 0.5 and 1 µg/mL, respectively. Peak concentrations at 2.5 mg/kg achieve 2 µg/mL, yielding an inhibitory quotient at 2. Data are not available for 5 and 7.5 mg/kg. However, extrapolating doses for 7.5 mg/kg from 2.5 mg/kg, a ratio of 6 might be anticipated. Orbifloxacin exhibited a concentration-dependent, bactericidal effect against S. aureus reference strain, but a time-dependent bactericidal effect against S. intermedius.69 Tissue concentrations for comparison with MIC data are not available for orbafloxacin.

Newer third-generation fluorquinolones may have the advantage of potentially being effective toward isolates resistant

to second-generation drugs. This susceptibility should not be assumed but should be based on culture data and doses (using known pharmacokinetic data) designed around MIC.

Like the fluoroquinolones, clindamycin and the macrolides (including the azalide azithromycin) accumulate in white blood cells, distribute well to skin, and target Staphyloccoccus spp.; however, neither is characterized by a gram-negative spectrum. Although these drugs are bacteriostatic in action, bactericidal concentrations may be achieved in some tissues, including phagocytic WBC. (see Chapter 7). These may be reasonable choices for treatment of canine pyoderma. Note, however, that azithromycin will not reach steady-state concentrations for 4 to 7 days after therapy is begun; accordingly, a loading dose (twice the maintenance dose) should be given the first 2 days. In an uncontrolled study of superficial pyoderma in dogs (n = 21), clindamycin at 11 mg/kg every 24 hours for 14 to 42 days (depending on response) yielded a clinical score of excellent in 71% of animals within 14 days of initiating therapy. However, the authors noted that clinical response should be evaluated at 14 and 28 days because resistance developed. Cultures should be considered to detect resistance.⁷⁰ Azithromycin (10 mg/kg daily) was effective in 90% of dogs with either superficial or deep bacterial pyoderma in an uncontrolled clinical trial.⁷¹ Interestingly, rifampin as sole therapy may be effective for treatment of S. pseudintermedius (but not S. aureus), although clinical trials supporting this approach are indicated. Accumulation in phagocytic cells may facilitate its efficacy.

The use of aminoglycosides for treatment of complicated pyoderma should be limited to life-threatening conditions associated with sepsis (e.g., cellulitis) or to organisms with known (i.e., based on susceptibility data) resistance to enrofloxacin. The aminoglycosides are generally effective against Staphylococcus spp. (particularly gentamicin) and gramnegative organisms including Pseudomonas (particularly amikacin). However, aminoglycosides generally should not be used as sole agents to treat Staphyloccoccus spp. unless evidence supports such use under the intended conditions. Combination with rifampin should be considered. For gram-negative organisms, resistance is less likely to develop against amikacin than against gentamicin, particularly for Pseudomonas spp. The aminoglycosides do not distribute well through inflammatory debris and fibrous tissue, are not effective against facultative aerobes (i.e., in the presence of reduced oxygen tension), and are not accumulated in white blood cells.⁴⁰ Therefore care must be taken to ensure that an adequate dose is given. Oncedaily administration is encouraged, and combination antimicrobial therapy with a beta-lactam effective against the target organism should be strongly considered.

As sole therapy, rifampin is generally discouraged in part because resistance develops rapidly (indeed, resistance to rifampin is used experimentally to detect mutation frequencies). However, in an open, uncontrolled clinical trial in dogs (n = 20; all but 2 were superficial pyoderma), 40% were *S. pseudintermedius* positive.^{71a} Treatment with rifampin at 5 mg/kg once daily for 10 days was clinically successful in 90% of dogs; the two dogs that failed therapy had deep pyoderma. Recurrence did not occur for at least 1 month in responders.

Designing a Dosing Regimen

Perhaps an often overlooked reason that bacterial pyoderma is difficult to resolve in dogs is use of an inappropriate dosing regimen of an otherwise appropriate drug. Although the importance of culture and susceptibility testing for chronic, recurrent, and deep pyoderma cannot be denied, it is critical to realize that in vitro conditions do not and cannot mimic the microenvironment of the host. They also do not reflect the ability of the drug to reach the site of infection, including inside white blood cells, nor do they take into account active metabolites. The effects of underlying skin disease including changes in the patient's immune status (local or systemic) also cannot be taken into account by the in vitro system. Thus it is critical that both the dose and interval of a dosing regimen be designed such that drug concentrations are maximized at the site of infection.

In general, the dose of an antimicrobial should be as great as possible when treating complicated pyoderma to ensure effective concentrations at the site of infection. Twice the recommended dose has been suggested by some authors, and this is a reasonable starting point, but it is likely to be insufficient for some drugs in some patients, particularly if the drug is time dependent and characterized by a short half-life.^{34,35} Doses up to fourfold higher than recommended may be necessary for organisms whose MIC for the drug is close to breakpoint or in the presence of factors that will decrease the movement or efficacy of antimicrobial at the site of infection. Higher doses are critical for concentration-dependent drugs (see Table 8-6). The greater the inflammatory response at the site (and particularly fibrosis) and the deeper the infection, the more important the need for increasing the dose. If necessary, selection of an antimicrobial might be made with an emphasis on safety so that doses can be increased with minimal risk of side effects. High tissue concentrations in relation to the MIC of the infecting organism are particularly important to the antimicrobial efficacy of selected drugs, most notably the aminoglycosides and the fluoroquinolones. For concentration-dependent drugs (aminoglycosides and fluoroquinolones), antimicrobial efficacy is enhanced in the presence of a high Cmax:MIC ratio in part because of an enhanced postantibiotic effect. In addition, both aminoglycoside efficacy and safety are facilitated by a moderately long drugfree period during a dosing interval. Thus for aminoglycosides once-daily administration of the total daily recommended dose should be considered for pyoderma. With the fluoroquinolones, the dose should likewise be modified to maximize plasma (and thus tissue) drug concentration; this is particularly important

For time-dependent antimicrobials, the interval of drug administration must be considered. These include the betalactams and bacteriostatic antimicrobials. For these drugs the duration that the drug concentration at the site is above the MIC is more important to antimicrobial efficacy. Thus for betalactams, antimicrobial efficacy is likely to be facilitated more by a shorter dosing interval than by increasing the dose. For example, to improve the efficacy of amoxicillin-clavulanic acid or cephalexin, the dose should be increased such that 2 to 4 times the MIC is reached and then an 8-hour dosing interval should be used in lieu of 12-hour intervals when treating cases at risk for development of resistance. Unfortunately, owner compliance is less likely with this regimen and may be a reason for considering an alternative class of drugs for treatment of complicated pyodermas. The long half-life of cefpodoxime supports its use at 10 mg/kg at 24-hour dosing intervals for many susceptible organisms. Cefovecin is particularly appealing; it should be effective with a single dose, particularly if the underlying cause of the disease can be identified and corrected. If healing is critical to resolution of infection (to be differentiated from resolution of clinical signs), a second dose may be indicated.

Duration of Therapy

An insufficient duration of therapy is another common cause of therapeutic failure in the treatment of pyoderma with an otherwise appropriate antimicrobial. However, clinical trials are indicated to establish if the issue may also be a less-thanideal dose (i.e., a dose that fails to achieve the highest MIC of the infecting colony) that would allow a shorter duration. Recommendations have varied with authors, although the consensus is that the duration of therapy for pyoderma increases with the severity of infection.^{34,35} Historically, therapy has extended 7 to 21 days (depending on the severity of infection) after surface healing has occurred. However, whether this is based on resolution of infection versus resolution of clinical signs has not been established. Superficial infections should resolve within 3 to 4 weeks of antimicrobial therapy if the patient is immunologically normal. Recommendations for deep pyoderma or the presence of immune compromise have suggested at least 4 to 6 weeks of therapy. Treatment for 12 weeks or longer is not unusual. Evaluation by the clinician at 7 days and then at 14-day intervals may be prudent, and reculture might be considered to reconfirm infection and should be implemented to detect resistance. Clinical evaluation should continue for several more weeks after therapy has been discontinued to ensure resolution.

Several authors have suggested alternative dosing regimens for antimicrobials for patients whose disease will not resolve. Examples include dosing once daily, every other day, or pulse dosing. Pulse dosing involves administration of a drug using full dosing regimens either 2 days a week or every other week. With the every-other-week approach, if recurrence is prevented, the duration of the "off" week can be gradually increased. Intervals of greater than 3 weeks are, however, likely to result in recrudescence.^{34,35} Conceivably, the risk of resistance should be increased if infecting microorganisms are exposed to intermittent concentrations of drugs. Clinically, however, this does not appear to happen, although clinical trials that focus on emerging resistance (rather than resolution of infection) are lacking. It is possible that the impact of prolonged antimicrobial therapy on normal skin microflora might be minimized by pulse dosing, particularly if dosing occurs at levels high enough to target those colony-forming units (CFUs) with the highest MIC whose survival otherwise would facilitate emergence of a resistant population. If pulse dosing is to be implemented, a drug with a narrow spectrum (i.e., oxacillin, clindamycin, erythromycin) should be used to minimally affect the normal flora; further, high doses should be used to ensure efficacy against targeted organisms. Compliance may be an issue with pulse dosing, and care must be taken to ensure that drug therapy is maintained. Pulse dosing with cephalexin on the weekend (15 mg/kg every 12 hours) decreased the number of relapses compared with placebo (n = 13) after 1 year of therapy for prevention of relapse of idiopathic superficial or deep pyodermas in dogs (n = 28). The time to relapse also was greater in the treatment group (6.6 months) compared with the placebo group (2.5 months). Dogs were assigned to either group after clinical resolution was acheived following cephalexin at 15 mg/kg twice daily until 2 weeks beyond clinical cure. Dogs did not receive other systemic antibacterial drugs or any antiinflammatory.

Other Clinical Trials

Efficacy for treatment of pyoderma exists for both enrofloxacin^{72,73} and marbofloxacin.⁷⁴ In an open (uncontrolled) study of dogs with superficial pyoderma (n = 66) caused predominantly by *S. intermedius*, marbofloxacin was effective in 86% and improved in another 8% after 21 to 28 days of therapy.⁷⁴ In another study 81% of dogs with recurrent superficial or deep pyoderma (n = 228) associated primarily with *S. intermedius* receiving marbofloxacin (2 mg/kg) for 3 to 16 weeks were classified as having responded at 1 week after cessation of therapy; at 1 month 70% of the dogs were still classified as responders, whereas 11% were classified as having relapsed.⁷⁵

The efficacy of azithromycin for treatment of canine pyoderma (n = 26; 8 superficial and 18 deep) was studied prospectively using open uncontrolled design and was reported as an abstract.⁷¹ Underlying disease was accepted and diagnosis was based on cytologic examination. The duration of azithromycin (10 mg/kg qd) varied with the deepness of the lesions ranging from 5 to 10 days. Eighty-eight percent of dogs recovered, with dogs that had superficial lesions requiring 5 to 7 days and dogs that had deep lesions requiring 7 to 10 days. Side effects occurred in only 24% of dogs, these included intense salivation, anorexia, and vomiting. One dog required antiemetic therapy (metaclopramide).

Stegemann and others⁷⁶ reported the efficacy of cefovecin for treatment of canine pyoderma and skin wounds. Dogs

(n = 354) were from the United Kingdom and were evaluated in three studies, each using a randomized parallel design such that dogs received either amoxicillin-clavulanic acid (12.5 mg/kg bid for 2 weeks; n = 112) as positive control or cefovecin (8 mg/kg, administered subcutaneously; n = 242). The blinding method varied for each study, with a double-dummy design (each dog received placebo) implemented in one of the studies (Study B). Exclusion criteria included antimicrobial use within the past 14 days, short-acting glucocorticoids in the previous 10 days, or long-acting corticosteroids for 30 days. Up to 0.5 mg/kg/day of methylprednisolone or prednisone was allowed to control intense pruritis. Concurrent otitis was treated topically. Parasitic and fungal diseases were ruled out, and bacteria were confirmed by culture (sampling technique not delineated). Animals were evaluated 28 days after the final treatment. The most common organism cultured was S. intermedius (data are included in Table 8-7) (n = 223), with the MIC₅₀ and MIC₉₀ being 0.12 and 0.25 μ g/mL, respectively. The next most common isolate was E. coli (MIC₅₀ and MIC₉₀ of 0.1 and 1 µg/mL, respectively). The number of treatments did not differ between groups and depended on clinical response, with nearly 50% of animals with superficial pyoderma in both groups responding after a single 14-day course of therapy; for animals with deep pyoderma, the numbers approximated 30% for both groups. For animals with deep pyoderma, 89% of animals enrolled in two of the studies had responded by the end of the third course of treatment (42) days, which is consistent with the recommendation to treat deep pyoderma for 4 to 6 weeks. Cefovecin was considered numerically more effective in treatment of superficial pyoderma. Criteria for success varied with the study and ranged from total absence of clinical signs to mild clinical signs. The study targeted a "noninferiority" classification of cefovecin, demonstrating that it was not worse than the positive control. Clinical success with cefovecin averaged 97% (study A & C) and 87% (study B) for all indications, compared with 92.5% and 80%, respectively, for amoxicillin-clavulanic acid. For cefovecin the lowest proportion of responders was for deep pyoderma (n = 13), at 77% for the double-dummy study versus 96% for the other two studies; only one animal with deep pyoderma was treated with amoxicillin-clavulanic acid. The incidence of side effects was similar in both groups, except for vomiting, which occurred more commonly in the group receiving amoxicillin-clavulanic acid.

KEY POINT 8-13 The long half-life of cefovecin will facilitate appropriate dosing. However, the impact of persistent drug concentrations must be monitored, and indiscriminate use of this potentially important drug must be avoided.

The efficacy of pradofloxacin (n = 56, 3 mg/kg by mouth qd) was compared with that of amoxicillin–clavulanic acid (positive control; n = 51, 12.5 mg/kg by mouth bid) for the treatment of deep pyoderma in dogs (n = 56) using a multicenter, randomized blinded controlled clinical trial.⁷⁷ Treatment continued until 2 weeks past remission, for a maxium treatment period of 9 weeks; final assessment took place 2 weeks later. Exclusion criteria included antiinfective or antiinflammtory

drugs in the previous 14 days. Inclusion criteria required a positive culture (swabs; two attempts made before exclusion); positive cultures were found in only 71% (n = 92) of the 130 dogs studied. Bacteria isolated were predominantly *Staphylococcus* spp. (n = 115), with other organisms including but not limited to *Enterococcous* spp. (n = 5), *Pseudomonas* spp. (2), and *E. coli* (2). For the pradofloxacin group, 86% achieved clinical remission and recurrence did not occur during the 2 week posttreatment period. For the amoxicillin–clavulanic acid group, 73% (n = 37) achieved clinical remission; for the remaining dogs, 3 improved, 5 did not respond, and 6 had recurrence of clinical signs within 2 weeks of remission.

Topical Therapy

Topical antimicrobial therapy may be the only method of antimicrobial administration needed to treat selected surface and superficial pyodermas. Antiseptic bathing (e.g., benzoyl peroxide, chlorhexidine, ethyl lactate, iodine, or triclosan) should be considered as initial sole therapy in uncomplicated pyodermas. Topical antimicrobials also might be considered, particularly for localized infections. Mupirocin might be considered for treatment of localized dermatologic problems, including interdigital abcesses, pressure point pyodermas, and secondary pyodermas associated with lick dermatitis. Early use of mupirocin, in particular, may be beneficial in limiting the recurrence of pyodermas. The efficacy of mupirocin 2% ointment (bid for 3 weeks) was reported as good to excellent in an open, uncontrolled design for treatment of chin acne in cats (n = 25). Therapy had to be discontinued in one cat because of a contact allergy.⁷⁸

Topical antimicrobial therapy should also be considered an adjuvant for superficial and deep pyodermas. Shampoos remove debris that might impede drug movement or affect drug efficacy. In addition, the combined effect of a topical and systemic antimicrobial may result in additive or synergistic antibacterial effects in the patient with pyoderma. Although irritating with long-term use, products that contain benzoyl peroxide tend to be the most efficacious in controlling bacterial growth and removing accumulated debris on the skin.⁷⁹ Products containing chlorhexidine, sulfur, triclosan, and ethyl lactate are also acceptable. Shampoos should be used twice weekly.^{34,35}

KEY POINT 8-14 The combined effect of a topical and systemic antimicrobial may result in additive or synergistic antibacterial effects in the patient with pyoderma.

A human clinical trial examined the effect of terbinafine cream (1%) compared with gentamicin (0.1%) using a contralateral design in patients with pyoderma associated with *S. aureus*.⁸⁰ After treatment, *S. aureus* could not be isolated in any patient treated with gentamicin and in only three patients treated with terbinafine; a negative control was not reported. Both groups markedly improved during the treatment period and treatments did not differ significantly. The authors concluded that terbinafine might be beneficial for treatment of *S. aureus*, particularly that associated with fungal infections. Checkerboard MIC studies have demonstrated that the combined effect of benzoyl peroxide and terbinafine is greater than that of either drug alone against *Candida* spp., *S. aureus*, and *Pseudomonas* spp., resulting in additive or synergistic effects against all three isolates.⁸¹

Adjuvant Therapy

The importance of adjuvant therapy should not be overlooked in the treatment of pyoderma.^{34,35} Adjuvant therapy may target the underlying skin disease or support antimicrobial therapy. Antihistamines (see Chapter 29) and 3-omega fatty acids should be considered when appropriate in conjunction with antimicrobial therapy to control the inflammatory response associated with infection or the underlying disease. Antimicrobial efficacy will be complicated by coadministration of drugs that alter the immune response. Most notably, glucocorticoids should not be used in patients with pyoderma. Although these drugs effectively ameliorate the inflammatory response and are useful in cases of pruritus leading to self-trauma, they also may facilitate the spread of bacterial infection.^{34,35} Other adjuvant therapies to consider include immunomodulatory therapy and topical antimicrobial therapy. Although immunomodulatory therapy (levamisole and cimetidine) may prove beneficial, there is often a bimodal effect with these drugs: if the proper dose is not given, immunosuppression rather than enhancement of the immune system may occur.^{34,35}

Adjvant therapy may include immunomodulators. In a pilot study human recombinant interferon alpha-2b (1000 IU/day by mouth) was only minimally effective compared with placebo in dogs with idiopathic recurrent superficial pyoderma.⁸² Analgesic therapy also should be considered, particularly in animals that are experiencing pain. To prevent immunosuppression, nonsteroidal antiinflammatories should be considered. Indeed, meloxicam proved better than a placebo in control of pain associated with pyotraumatic dermatitis or folliculitis.⁸³ Tepoxalin might be worthwhile because it targets both prostaglandins and leukotrienes, the latter implicated in perpetuation of chronic inflammatory allergic diseases such as atopy (see Chapter 31). It is reasonable to consider the use of nonsteroidals, and tepoxalin in particular for treatment of pruritis associated with pyoderma. In a report from the Czech Republic, dogs (n = 18) with recurrent pyoderma received either cephalexin or cephalexin and an immunomodulator (characterized by natural killer cell activity, lymphocyte proliferation, and enhanced macrophage activity). The study did not appear to be randomized or blinded; further, dogs had previously received glucocorticoids. The authors reported that dogs receiving the immunomodulator had a better cure rate and a shorter time to cure.84

Juvenile Cellulitis (Puppy Strangles)

Juvenile cellulitis is probably more appropriately addressed as an immune-mediated disease, but its potential microbial-based pathophysiology as well as its presentation warrant inclusion under bacterial infections. Juvenile cellulitis is an unusual but often painful nonpruritic inflammatory condition afflicting puppies generally from 4 weeks to 4 months of age.^{85,86} Clinical signs of inflammation generally involve the face or head. Its presentation may begin as a mild inflammation (e.g., redness and edema at tips of ears) but may rapidly become severe. Lymphadenopathly of nodes draining the inflamed areas (e.g., submandibular) has led to the misnomer "puppy strangles"; prescapular and other lymph nodes may become involved. Lesions range from (granulomatous) inflammation to pustules, ulcers, or erosions; fistulae may develop. Pustular otitis externa may be present. Less commonly, other areas of the body may be involved, including the abdomen, thorax, feet, vulva, prepuce, or anus. The extent of lesions may result in systemic illness; leukocytosis caused by neutrophilia and anemia typical of chronic disease may be present. Occasionally, other body systems will be involved (e.g., sterile suppurative arthritis)87. Cytologic examination reveals sterile pyogranulomatous inflammation; cultures generally are negative. Histopathology generally reveals granulomas and pyogranulomas consisting of clusters of large epithelioid macrophages. The cause of juvenile cellulitis is unknown, but the syndrome responds well to immunosuppressive doses (prednisolone at 2 mg/kg/day for up to 3 weeks), indicating a potential immune dysfunction. Hypersensitivity to (previously eradicated) microorganisms has been proposed. Therapy should be early and aggressive to prevent scarring. Antimicrobials are indicated only if supported by diagnostics. Although an etiologic agent has not been identified, a streptococcal-based reaction is suspected. Ideally, a lipid-soluble drug effective against Streptococcus spp. would be indicated to penetrate inflamed tissues. Fluoroquinolones are not recommended, not only because of questionable efficacy toward Streptococcus spp. but also because of age-related effects on cartilage as well as the potential induction of bacteriophage toxolysins carried by Streptococcus spp. (see Chapter 7). Assuming that there is a need for antimicrobial therapy targeting Streptococcus spp. high doses and frequent intervals of penicillin beta-lactams (amoxicillin-clavulinic acid) are indicated. Supportive therapy (e.g., cleaning of wounds, use of astringents) are indicated as needed. Analgesic therapy should be considered.

Wounds

The use of systemic antimicrobials for treatment of wounds is controversial, particularly in human medicine, for which diabetic and decubitus ulcers present a profound problem. Although the pathophysiology of these wounds may differ from that of the most common wounds treated in veterinary medicine, the principal approach should be similar. Disruption of skin or other tissue exposes the wound to infection, dehydration associated with fluid loss occurs, immunity is compromised, and scarring occurs. In contrast to the noninfected surgical wound that heals by primary intention, all open skin wounds, including those healing by secondary intention,⁸⁸ will be colonized with microbial organisms. This does not, however, indicate infection or the need for antimicrobial therapy. Host factors largely will determine if growth of the microbial population will be limited to colonization, with healing proceeding normally. Chronic wounds in particular are predisposed to infection because extensive synthesis of new, primarily granulation, tissue must occur. Scar tissue, which contains no epidermal appendages, is more extensive. As such, multiple aspects of the skin immune system are absent. Chronic wounds are further complicated by the presence of fibronectin, an adhesive glycoprotein that, while intended to serve as a matrix adhesive, also binds bacteria. Neutrophil and macrophage influx is critical to keeping bacteria in check.

KEY POINT 8-15 All open skin wounds, including those healing by secondary intention, will be colonized with microbial organisms. This does not, however, indicate infection or the need for antimicrobial therapy.

Colonizing microbes generally do not penetrate to deeper tissues, whereas infecting microbes will; accordingly, swabs are undesirable culture methods. Whether colonization progresses to infection depends on the number of organisms per gram of tissue (thus tissue samples rather than swabs are critically important to proper culture) and the ability of the patient to mount an effective immune reponse. Infection generally requires greater than 100,000 CFU/g tissues in a wound. An exception occurs for beta-hemolytic Streptococcus, which is particularly virulent in humans. Successful wound healing depends on an organism load below 100,000 CFU/gm. Studies generally demonstrate that in contrast to acute wounds, systemically administered drugs generally do not reach deeper tissues where infection occurs. This reflects not only the changes associated with healing but also the formation of biofilm (see Chapter 6). The impact of biofilm on healing of chronic wounds can be profound. Infections involving biofilm are resistant to host immune responses and more resistant to antimicrobials and topical antibacterials. The moist environment generally associated with chronic wounds facilitates biofilm, as does fibroinnectin.

KEY POINT 8-16 The impact of biofilm on healing of chronic wounds can be profound, leading to resistance to host immune responses and resistance to both systemic and topical antimicrobials.

In human medicine the consensus is that wound care should be optimal. Wound care should prevent microbial growth, which will inevitably occur on the surface of the wound, from progressing from colonization to infection. Accordingly, cleansing, débridement, nutritional support, and actions that enhance oxygenation, including increased perfusion, are paramount to success. A variety of wound-assessment tools have been developed in human medicine.88 Wound care should be thoroughly reviewed before implementing systemic antimicrobial therapy. Topical antimicrobials are considered the key to successful management of wounds and are indicated if there is a risk that colonization will progress to infection. In humans wound contamination is treated simply with irrigation and cleansing with sterile water or saline. Likewise, wound colonization is treated with irrigation and cleansing of wounds, removal of necrotic tissue and foreign bodies, and nanocrystalline silver dressings. Critical colonization may require systemic

antimicrobials but should be accompanied by medicated bandages and the topical application of slow-release antimicrobials (e.g., topical silver and cadexomer iodines). *Wound infection* is an indication that systemic antimicrobials should be added to topical therapy. Both systemic and topical medications are particularly critical in the face of poor wound perfusion.

KEY POINT 8-17 Topical antimicrobials are considered the key to the successful management of wounds and are indicated if there is a risk that colonization will progress to infection.

The most common topical antimcirobials used for wound management in humans are mupirocin, neomycin, bacitracin, polymyxin, erythromyicn, gentamicin, and silver sulfadiazine. Other topical antimicrobials to consider include fusidic acid and metronidazole. Their use for wound management was reviewed by Spann et al.⁸⁹ In addition to these traditional drugs, newer antimicrobials are under development. These include protegrin-1, an antimicrobial peptide that occurs naturally in a number of mammalian tissues, including neutrophils. These are particularly effective against gram-positive organism, including MRSA and vancomycin-resistant *Enterococcus* spp. Other topically applied antimicrobials are under investigation (see Box 8-1).

The use of antiseptics on wounds is controversial, in part because of their impact on wound healing. This impact appears to be concentration dependent.⁹⁰ Topical antiseptics include sodium chloride, (preferred) chlorhexidine, and povidone-iodine. The Food and Drug Administration has approved povidone-iodine for short-term treatment of superficial and acute wounds, indicating that its impact on wound healing is neither positive nor negative. A potential reason for using antiseptics, rather than antimicrobials, on wounds, is to prevent antimicrobial resistance. However, care should be taken not to use antiseptics and disinfectants indiscriminately. Resistance has developed toward most antiseptics or disinfectants for many microbes, with the mechanisms similar to those for which antimicrobial resistance has emerged. For example, a number of organisms, including Pseudomonas spp., have become resistant to quarternary ammonium compounds, Klebsiella and E. coli have expressed resistance to chlorine, and peroxides are among the compounds toward which the most resistance has emerged.91

KEY POINT 8-18 Resistance that has developed toward most antiseptics or disinfectants by many microbes occurs by way of mechanisms similar to those that result in antimicrobial drug resistance.

Occlusive or vapor-permeable dressings may reduce the risk of bacterial contamination. Note that for all levels of infection, appropriate cleansing, including débridement, is key to the success of antimicrobial therapy, whether topical or systemic.

Dog or cat bite wounds may be deep, penetrating wounds. As such, the risk for infection may be greater compared with more superficial skin wounds. However, particularly with cat bite wounds that are open and in which the risk of cellulitis is minimal, antimicrobial therapy may not be indicated (Figure 8-4). Hot-packing is an important component of therapy.

The microbiology of canine bite wounds was recently reviewed prospectively.92 Wounds were clipped and cleansed with 70% alcohol. Culture samples were collected before cytologic samples, using swabs, which may limit accuracy and preclude colony counts. Swabs were inserted deep within puncture wounds or deep pockets. Both aerobic and anaerobic cultures were collected from dogs (n = 50) in which wounds were inflicted within the previous 72 hours. A total of 104 wounds were studied, with 21 assessed cytologically as infected and 83 noninfected. However, based on growth, 75% were positive. Sixty-six of the 83 noninfected (cytologically) wounds yielded positive growth, for a total of 213 isolates. Aerobic isolates were equally represented by gram-negative and gram-positive organisms (see Table 8-1). Anaerobic organisms were cultured in 17 of 50 wounds; 17 yielded anaerobic organisms. The most common anaerobic organisms (obligate) were Prevotella melaninogenica (59%) followed by Clostridium and Peptostreptococcus spp.

Cat bite wounds have also been studied (Australia).⁹³ *P. multocida* historically is recognized to be a causative agent on the basis of wounds in humans. However, as in the dog, a range of aerobic and anaerobic organisms are associated with feline bite wounds. In humans the sequelae of cat bites

Figure 8-4 Feline abscesses are an example of an infection that may not require treatment with antimicrobials, particularly if the abscess is open and draining well. Treatment is indicated if associated with a risk of cellulitis.

result in infection with a variety of aerobes, including *Staphylococcus* spp., *Streptococcus* spp., including alpha-hemolytic; *Moraxella* spp., Enterobacteriaceae spp., *Weeksella zoohelcum*; and *Capnocytophaga*. Anaerobic organisms include a number of *Fusobacterium* spp., *Bacteroides* spp., *Porphyromonas* spp., *Prevotella* spp., *Peptostreptococcus* spp., and *Propionobacterium* spp. Bite wounds as they develop in cats include *Pasteurella* spp. (the most common facultative anaerobe), *Bacteroides* spp. (19%), *Peptostreptococcus* spp. (13%), and *Actinomyces* spp. Closed abscesses in cats contain an average of three isolates, although as many as eight have been identified. Isolates have been confirmed to be of oral origin. Accordingly, the role of *Porphyromonas*, and particularly *Porphyromonas* gingivalis, is increasingly recognized for its importance.

Miscellaneous Infections

Dapsone is an antimicrobial that inhibits para-aminobenzoic acid metabolism to folic acid. Selected mycobacterial strains, most notably Mycobacteria leprae or Mycobacteria lepraemurium, are exquisitively sensitive to its effects. In addition, the drug appears to be capable of some form of immunomodulation and may prove beneficial in deep skin infections associated with a pyogranulomatous response for which no organism has been identified. Because of difficulty associated with identifying infectious organisms such as Nocardia spp. and atypical mycobacterial organisms, however, use of dapsone should be reserved until a susceptible organism has been identified or other causes of inflammatory skin disease have been ruled out. The drug has not been studied in animals, and in humans, it is characterized by marked differences in disposition. Hemolytic episodes have been reported in humans; however, generally these individuals are suffering from metabolic defects of red blood cells. Dapsone also is used to treat bites caused by brown recluse spiders in humans. When Dapsone is administered within 48 hours of the bite, tissue necrosis is markedly decreased and wound healing is subsequently faster.

INFECTIONS OF THE MUSCULOSKELETAL SYSTEM

Osteomyelitis

Because bacterial myositis is rare unless it accompanies infection of the surrounding soft tissues, this discussion is limited to bacterial infections affecting the skeletal structures.

Pathophysiology

Similar to models described in humans,⁹⁴ infections of the bone occur by a hematogenous route, secondary to a contiguous focus or direct inoculation through surgery or trauma.⁹⁵ The metaphyses of long bones are the most common sites of hematogenous infection.⁹⁴ Blood flow becomes slow and turbulent in this region, and capillaries lack phagocytic cells. Acute infection causes local cellulitis resulting in leukocyte accumulation, increased bone pressure, decreased pH, and reduced oxygen tension. Contiguous infections generally result from direct inoculation of the bone because of trauma, extension from surrounding soft tissues, or contamination associated with surgery. Vertebral osteomyelitis most commonly reflects a hematogenous source of infection, usually from an artery. Because each artery supplies two adjacent vertebrae, the infection usually involves two vertebrae. Secondary osteomyelitis is further classified on the basis of the presence or absence of vascular insufficiency.

Both hematogenous and secondary osteomyelitis can be classified as acute or chronic. Acute osteomyelitis is a suppurative infection accompanied by edema, vascular congestion, and small vessel thrombosis. Vascular supply to the site of infection becomes compromised as the infection extends into the soft tissue. Both medullary and periosteal blood supplies can become compromised, resulting in necrotic, ischemic, and ultimately dead bone forming a sequestrum. Bacteria located in this tissue become isolated, with acute osteomyelitis progressing to chronic osteomyelitis. Chronic osteomyelitis is characterized by local bone loss, a nidus of infected dead bone or scar tissue, an area of ischemic soft tissue, persistent drainage, and sinus tracts. The clinical course can be refractory. The risk of infection continues even in apparently cured osteomyelitis because of this nidus of infection. Indeed, the term arrested is often used instead of the term cured when referring to successful therapy in human patients. The presence of foreign bodies facilitates sustained infection through formation of biofilm (see Chapter 6), promotion of virulence factors (e.g., adherence receptors), and their negative impact on local immune function.95 Successful treatment of osteomyelitis is less likely in the presence of necrotic surrounding soft tissue, foreign bodies, bone instability, nonunion, or septic joints. Consequently, surgical removal of the nidus of infection and foreign bodies often must accompany antimicrobial therapy.

KEY POINT 8-19 Successful treatment of osteomyelitis is less likely in the presence of necrotic soft tissue, foreign bodies, bone instability, nonunion, or septic joints.

In addition to the classes of osteomyelitis based on route of infection, a more clinically relevant classification system (Ciemy–Mader) developed in humans⁹⁴ yields 12 distinct stages based on patient status, anatomic considerations, cause of infection, treatment factors, and prognosis. The advantages of this approach is that stages delineate factors that complicate therapy. Four stages are described on the basis of anatomic considerations, with each stage characterized by additional complications.

Stage 1 (medullary) occurs early; the primary site of infection is endosteal or may include infected intramedullary pins. Therapy may simply include antimicrobials but may also include surgical débridement or removal of the surgical foreign body. Stage 2 (superficial) osteomyelitis occurs as a result of extension of infection from soft tissue. As such, a secondary contiguous focus exists; this focus requires surgical débridement in conjunction with antimicrobial therapy. Stage 3 (localized) osteomyelitis is characterized by full-thickness infection of the cortices with sequestration that requires surgical removal. Stage 4 (diffuse) osteomyelitis involves the full diameter of the infected bone and may cross a joint. Bone instability occurs as a result of either infection or surgical treatment. Therapy includes débridement, management of dead space, and stabilization. Each of these four stages can be further categorized on the basis of the status of the host: A (normal), B (local or systemic compromise), or C (treatment of the infection is more life threatening than the osteomyelitis). Local compromise includes chronic lymphedema, venous stasis, compromise of major vessels, arteritis, and extensive scarring fibrosis. Systemic compromise includes malnutrition, evidence of metabolic disease (e.g., renal or liver disease, diabetes mellitus), malignancy, age extremes, or immunosuppression. These stages are dynamic, being affected by therapy, progression of disease, and host status.

Microbial Targets

Hematogenous osteomyelitis is usually caused by a single pathogenic organism, with Staphylococcus spp. (50% to 70%) predominating and S. intermedius most common. Vertebral osteomyleitis also is most commonly caused by Staphylococcus spp. Common sites of infection in humans that lead to vertebral osteomyelitis are the genitourinary tract, skin and soft tissue, respiratory tract, mouth, endocardium, and intravenous lines.⁹⁴ Multiple pathogenic organisms are usually involved with contiguous infections, and as in hematogenous infections, Staphylococcus spp. is one of the most common organisms isolated. Gram-negative and anaerobic organisms are also commonly involved.94 The most common gram-negative are E. coli, Klebsiella, Pasteurella, Serratia, and Proteus spp. The most common anaerobes are Bacteroides, Fusobacterium, (including F. necrophorum), Clostridium spp., and others. The risks of therapeutic failure associated with osteomyelitis outweigh the risks associated with culture and susceptibility testing; accordingly, drug selection and the design of the dosing regimen should be culture based. Care must be taken with sample collection to ensure that proper techniques are followed.

Antimicrobial Therapy

Clinical trials have provided only limited direction in the successful treatment of osteomyelitis, being handicapped by variations in duration (acute versus chronic), organisms studied, the model of osteomyelitis used, mode of infection (in nonspontaneous models), presence of foreign material, previous surgical procedures, and previous antimicrobial therapy. Among the critical host factors of concern when treating osteomyelitis is drug distribution to the site. Distribution may be limited because of changes in blood flow, presence of inflammation, and poor local immunity. Note that some drugs distribute to the bone only to bind to calcium or other cations (e.g., tetracyclines, potentially fluoroquinolones) (Table 8-8). As with other sites of infection, drug penetration in osteomyelitis is determined by the molecular weight and the lipid solubility of the drug. Protein-bound drugs do not distribute to the site of infection. The mechanisms of capillary transport in osteomyelitic bone are similar to those in normal bone,

		C	IS (μg/m)		
Drug	Dose	Serum	Bone	Serum Ratio	Breakpoint MIC
Beta-lactams					
Nafcillin	40 mg/kg	21.9	2.1	0.095	≤ 2 to ≥ 4
Moxalactam	40 mg/kg	65.2	6.2	0.095	≤8 to ≥64
	5 mg/kg	45.6	3.2	0.07	≤ 8 to ≥ 32
Cefazolin	15 mg/kg	67.2	2.6	0.04	≤8 to ≥32
Cephalothin	40 mg/kg	34.8	1.3	0.04	≤8 to ≥32
Aminoglycosides

MIC, Minimum inhibitory concentration.

*Monitoring recommended.

Adapted from Mader JT, Calhoun J: Osteomyelitis. In Mandell G, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases*, ed 4, New York, 1995, Churchill Livingstone, pp. 1039-1050.

although permeability ratios to the site of the drugs differ. A blood-bone barrier does not appear to exist. However, the impact of the intramedullary infection on blood distribution may limit drug delivery. The impact of biofilm on successful therapy also may be profound, particularly in the presence of foreign bodies.

Determining the extent of drug distribution to potential sites of infection in bone is difficult. Distribution studies often are based on cannulation of nutrient artery and the ipsilateral femoral vein. Detection of drug in bone is limited by recovery of the drug, which tends to be low because tissue is lost during the extraction procedure. Volume of distribution studies generally have shown that concentrations of biologically active drug in the interstitial fluid space of normal cortical bone are equivalent to that in the serum, regardless of the lipophilicity of the drug. The characteristics of cefazolin have resulted in its use for surgical prophylaxis in patients undergoing orthopedic surgical procedures.96 Cefazolin readily traverses capillaries of both normal and osteomyelitic bone, and the pathophysiology of osteomyelitis enhances penetration. Although the volume of spaces (plasma and interstitial) increases in osteomyelitis by 330% and 941%, respectively, the distribution of cefazolin increases proportionately. Cefazolin is not as highly protein bound in dogs as it is in humans (35% versus 80%); accordingly, effective concentrations of pharmacologically active drug should be expected in normal bone tissues of dogs.⁹⁶ However, other drugs appear to penetrate infected bone better than cefazolin. The prophylactic use of antimicrobials increasingly is not considered necessary (see Chapter 6). Although the long half-life of cefovecin might support its indication for treatment of osteomylitis caused by susceptible bacteria, it is not indicated for prophylaxis. Not only will maximum concentrations take up to 8 to 24 hours to achieve (with efficacy depending on the MIC₉₀ of the target microbe), but therapy cannot

be discontinued after surgery (the elimination half-life causes drug to persist for 1 to 2 weeks), as is indicated for prophylaxis.

In experimental rabbit models of osteomyelitis caused by *S. aureus*, drugs characterized by the best bone-to-serum ratio were, in order, clindamycin, vancomycin, moxalactam (a beta-lactam antibiotic), tobramycin, cefazolin, and cephalothin (see Table 8-8).⁹⁴

Because of the potential difficulty in achieving high concentrations at the osteomyelitic site, a number of methods of local drug delivery might be considered, particularly for infections associated with multidrug-resistant organisms. Advantages include high local concentrations for a longer period of time and avoidance of systemic exposure to antimicrobials that might otherwise be toxic. Among those methods most considered are antimicrobial-impregnated beads. Two forms of beads have been used. Beads made of polymethyl methacrylate (PMMA) are nonbiodegradable; their use in horses has been reviewed, and much of the information is applicable to dogs and cats.97 A number of commercially available PMMA cements are available; additionally, compounding pharmacies are beginning to offer antimicrobial-impregnated beads. Mixing drug in PMMA results in an exothermic reaction, causing tissue damage and the potential release of toxins; bone-healing and phagocytic function may be impaired. Antimicrobials are added in powder form but must be heat stable. More recently, calcium-based (e.g., sulfate, plaster of paris) antimicrobialimpregnated beads have been studied. In contrast to the PMMA, these beads are biodegradable and their formation is not exothermic. However, beads should be sterilized using non-heat-based methods. The advantages of calcium sulfate includes osteoconductivity, potentially facilitating bone healing; the biodegradable nature often precludes the need for retrieval surgery. Even more recently, biodegradable matrices are being studied.

KEY POINT 8-20 Local drug delivery may be a viable adjuvant for treatment of problematic osteomyelitis, particularly if infection involves a multidrug-resistant organism.

Regardless of the matrix type, antimicrobial release or elution tends to be bimodal, with an initial rapid release (12 to 48 hours) followed by a slower release over weeks or months. For PMMA, elution rates (based on in vitro studies) vary with antimicrobial concentration, pore and bead size, and permeability of the cement (which, in turn, can be affected by the amount and type of antimicrobial). The form (e.g., liquid versus powder form) of the antimicrobial will also influence elution. Host factors influencing elution rates include surface area available for bead exposure, blood flow, and fluid content. In general, concentrations in the first stage of elution surrounding the area can be anticipated to exceed the MIC₉₀ of most susceptible organisms by more than a hundredfold, increasing the likelihood of a quick kill. Concentrations during the second phase of elution will be much lower but may still surpass the MIC₉₀ of infecting microbes by several to a hundredfold. Sayegh97 indicates that encapsulation of the beads during healing results in therapeutic concentrations being achieved up to 2 to 3 mm surrounding the beads.

Atilla and others⁹⁸ have demonstrated that the combination of drugs in beads alters their elution rate, causing it to be more rapid. Atlhough concentrations are initially higher, the duration of effective concentration may be shorter. The authors also demonstrated that, interestingly, the elution rate may change even if drugs are not mixed in the same bead but are in different beads. Antimicrobial-impregnated beads can be used to treat bone, synovial structures, and other soft tissues; use of PMMA in joints is discouraged, however, because it tends to be irritating. Indications include refractory infections, particularly osteomyelitis, and prophylaxis after surgery of contaminated wounds.

A disadvantage of beads, particulary PMMA-based beads, is the foreign nature. Further, the PMMA can inhibit phagocytic function. Heat-damaged tissue may facilitate infection. Host response to the cement may also facilitate infection by *S. aureus*, and microorganisms can secrete materials that protect against host defense mechanisms. As such, they may be associated with risk of infection, as has been described in a series of human patients (n = 20). Cultures of gentamicin-loaded beads removed 2 weeks after implantation from prosthesis-related infections revealed 90% to be infected. Of the 28 isolates, nearly 70% were gentamicin-resistant.⁹⁹ Interestingly, 12 of the 18 infected patients were considered infection free before removal of the infected beads. Most common isolates were *P. aeruginosa* and *S. aureus*. In contrast, the prosthetic devices in the area of the beads tended to not be infected.

The use of tobramycin antimicrobial-impregnated calcium sulfate beads in a series of dogs (n = 6) was recently reported.¹⁰⁰ The beads are commercially available, approved for use as bone filler. Sites included forelimb and hindlimbs. Infecting organisms included *S. intermedius*, *S. aureus*, and *P. aeruginosa*. The number of beads implanted ranged from four to nine; one dog

that received a total hip replacement received 24 beads. Beads generally lost their radio-opacity by 4 weeks and were no longer visible radiographically by 6 to 8 weeks. Clinical signs associated with infection resolved in all but one dog.

A case report described the successful use of a commercially available gentamicin-impregnated collagen sponge (CollaRx) in the treatment of septic arthtritis associated with MRSA in a dog.¹² Other matrices are under investigation, with a focus on those that slow release or are biodegradable. However, a commonality of most of the studies addressing drug elution from foreign matrices is of questionable applicability to the patient. This includes studies that expose representative pathogens (e.g., *Staphylococcus* spp.) to eluent containing the antimicrobial. The accuracy of concenterations measured *in vitro* from eluent representing matrices incubated in buffer as predictors of interstial concentrations in a surgical patient receiving these drug delivery devices is debatable. As such, studies are needed based on concentrations measured *in vivo* using ultrafiltration probes that collect interstitial fluid.

Medical management of chronic osteomyelitis in humans has not been well supported by well-designed controlled clinical trials; the knowledge base in veterinary medicine is even more limited. Variability in risk factors, pathophysiology of infection, and etiologic agents and failure to identify the organism preclude the generation of consensus regarding recommendations in humans. Further, outcome measures of therapeutic success are not always identified or clear. A large trial using expensive therapies for extended periods of time is prohibitively expensive and is complicated by the ability of pathogens to cause low-grade symptoms or lie dormant for many years, requiring long-term follow-up.95 It is not surprising, therefore, that recommendations have been based on historical observations, experimental models, and nonrandomized trials.95 Retrospective studies have been helpful but generally are more representative of complicated cases.101

Although drug distribution to healthy bone is adequate, the detrimental effects of osteomyelitis minimize drug distribution to the site of infection. As such, culture-based drug selection and dosing regimen design is likely to be paramount to therapeutic success. Parenteral antimicrobial therapy should begin with drugs targeting the most likely organisms; drug therapy can be changed if indicated on the basis of susceptibility data. Duration of therapy for osteomyelitis is generally recommended for 4 to 6 weeks, in part because tissue revascularization after débridement requires at least 3 to 4 weeks.⁹⁵ However, as with other therapies, the evidence for duration of therapy is limited by the lack of clinical trials. The need for longer term therapy might be anticipated for chronic osteomyelitis.

The first 2 weeks of therapy should be by parenteral administration (data from the start of therapy or after surgical débridement). For acute hematogenous osteomyelitis, the causative agent must be properly identified. Mismanagement with inappropriate antimicrobial can lead to extension of the infection, necrosis, and the formation of sequestra, as well as emergence of resistance. If the patient has not responded to specific antimicrobial therapy (i.e., based on culture) within 48 hours, surgical intervention is indicated for human patients. Bone biopsy specimens are necessary for culture for human patients94 unless the patient also has positive blood cultures. Because of its excellent distribution characteristics, oral quinolone therapy may be an acceptable alternative for gram-negative and Staphylococcus spp. infections. Note, however, that the activity of the second-generation fluoroquinolones against anaerobes and other gram-positive organisms (e.g., Streptococcus spp., some Corynebacterium spp.) is less predictable, whereas third-generation fluoroquinolones have a broader spectrum. In addition, although bone concentrations of difloxacin are high (see package insert), concentrations do not decline over time, suggesting that the drug is bound and thus inactive. Whether this is true for other fluoroquinolones is not clear. Clindamycin, metronidazole, or amoxicillin-clavulanic acid can be used in combination with the quinolones to provide gram-positive and anaerobic coverage. Intravenous therapy generally is recommended, in part because antimicrobials most commonly associated with clinical success (e.g., cefazolin and vancomycin) are characterized by poor oral bioavailability. However, because of the potential risks and inconvenience, alternative therapies, such as oral antimicrobial therapy, have been considered. The potential efficacy of oral therapy is more reasonable with the availability of several drugs that are safe and highly bioavailable after oral administration. Several oral antimicrobial agents have undergone evaluation for the treatment of acute and chronic osteomyelitis in human medicine. Oral antimicrobials are considered for treatment of acute osteomylitis in children and chronic infection caused by atypical gram-positive and selected gram-negative organisms. Choices include the fluoroquinolones, clindamycin, and linezolid, the latter being reserved for MRS or potentially enterococci.95 Retained foreign material or prosthetic devices complicate oral management of osteomyelitis, and therapy is more likely to fail with oral rather than intravenous therapy.⁹⁵ Despite these drawbacks, a number of studies have supported oral therapy for chronic osteomyelitis. In general, oral therapy with ciprofloxacin as sole agent compares favorably to parenteral therapy with single or combination antimicrobials. However, resistance in gram-positive organisms appears to develop rapidly. Rifampin used in combination with other antimicrobials appears to be effective for treatment of staphylococcal orthopedic implant-related infections. Thus whereas intravenous antimicrobials for 2 weeks followed by long-term oral (ciprofloxacin) therapy appears to be effective, longerterm therapy (3 to 6 months or more) with a combination of ciprofloxacin and rifampin was associated with a 100% cure rate compared with a 58% cure rate for ciprofloxacin only.95 A meta-analysis study of 22 trials involving 927 human patients with orthopedic devices associated with S. aureus-induced osteomyelitis offers some insight into antimicrobial therapy. Disconcertingly, most of the studies were characterized as poor in quality, impaired by inappropriate methods and statistical analysis. However, a trend of improvement was detected for the combination of rifampicin-ciprofloxacin compared with ciprofloxacin alone. Use of ticarcillin for bone infections associated with Pseudomonas spp. was described as favorable.

Therapeutic success with oral fluoroquinolones did not differ from success with intravenous beta-lactams. Comparison of locally placed PMMA gentamicin bead chains compared with parenteral antimicrobials could not be evaluated well because all patients received systemic therapy.¹⁰²

Chronic contiguous osteomyelitis may be particularly difficult to resolve. Assessment of vascular integrity by cutaneous oxygen tension can be useful for determining the extent of damaged tissue to be removed.⁹⁴ Hyperbaric oxygen therapy may facilitate healing in tissues characterized by low oxygen tension. Dead space can be managed short term with antimicrobial-impregnated acrylic beads; the beads are generally replaced with a cancellous bone graft after 2 to 4 weeks. Hyperbaric oxygen is an important adjunct therapy for human patients with osteomyelitis. It serves to restore intramedullary oxygen tension and thus facilitates phagocytic killing. Furthermore, it supports collagen production, angiogenesis, and wound healing.⁹⁴

Infections associated with prosthetic devices involving cement are particularly problematic to resolve. Infections generally occur at the bone-cement interface. Infectious pathogens are numerous and, in humans, often include microorganisms considered to be contaminants of cultures (e.g., corynebacteria, propionibacteria, and Bacillus spp.). PMMA cement may predispose the site to infection, as previously discussed. Infection can be treated with removal of the prosthetic device and 6 weeks of antimicrobial therapy followed by reimplantation or surgical removal and débridement with immediate reimplantation accompanied by polymethyl methacrylate cement inpregnated with an antimicrobial (an aminoglycoside). When the prosthesis cannot be removed, lifelong antimicrobial therapy has been implemented for human patients, assuming that the microorganism is sufficiently susceptible to oral antimicrobial therapy and the patient can tolerate the therapy.

Septic Arthritis

Pathophysiology

Septic arthritis most commonly reflects hematogenous inoculation. Patients with osteoarthritis or immune-mediated arthritis, trauma, or intraarticular inflammation are predisposed to infections in the inflamed joint. Trauma may predispose to infection because of a loss of vascular integrity. Synovial tissue is very vascular, and the lack of a basement membrane facilitates bacterial penetration. Bacteria can contribute to the process of inflammation through production of tissue-damaging mediators such as proteases. S. aureus is among the organisms most commonly causing infection in humans, in part because of its ability to bind to bone sialoprotein, a glycoprotein of joints.¹⁰³ It is able to contribute to destruction of cartilage because of the production of chondrocyte proteases. Infection often affects a single joint and usually is limited to the joint. Exceptions are made in the presence of predisposing factors that affect multiple joints (e.g., immunemediated arthritis). Drug distribution into inflamed synovium occurs more rapidly and results in higher concentrations than in uninflamed joints.

Clinical signs associated with septic arthritis include fever, limited joint motion, and swelling of peripheral joints associated with joint tenderness. Synovial fluid analysis discriminates between septic and nonseptic causes of arthritis. In general, septic arthritis more commonly is associated with increased polymorphonuclear leukocytes. The presence of immunomodulating drugs (e.g., glucocorticoids) may blunt leukocyte infiltration. In human patients the presence of bacteria can be detected in approximately 33% of cases by cytologic examination of a smear of synovial fluid. Cytologic examination should include Gram stains. Synovial fluid should be cultured; for human patients blood culturing also is recommended.¹⁰³ False-negative cultures may not, however, rule out bacterial arthritis; in human patients with documented infection, synovial fluid cultures were negative 10% of the time. Radiographic examination may help rule in arthritis.

Microbial Targets

The most common causes of septic arthritis reported in animals are bacterial in origin. The potential for viral causes should not be ignored. In human patients two syndromes of arthritis are described: acute and chronic, nonarticular. The syndromes are caused by different types of organisms, with mycobacterial or fungal infections of the joint largely responsible for the chronic form. According to surgical texts, organisms most commonly associated with septic joints include *Staphylococcus* spp., *Streptococcus* spp., *E. coli*, and *Pasteurella* spp.

Antimicrobial Therapy

In human patients septic arthritis is treated aggressively. Empirical therapy is begun after culture collection using an intravenously administered antimicrobial effective against S. aureus. Examples include cefuroxime, cefotaxime, and ceftriaxone; the role of extended-spectrum beta-lactamases and therapeutic success has not been addressed, and the prudent clinician might consider combining therapy with a drug that is not vulnerable to these destructive enzymes. The use of fluoroquinolones for treatment of infections associated with joints or ligaments should be done cautiously. Their impact on healing cartilage may be similar to that of cartilage in growing animals, and evidence has emerged that demonstrates their negative impact on ligaments. Use of chondroprotective disease-modifying agents (including both glucosamine and chondroitin sulfates) should be considered in any patient with joint disease receiving any fluorinated quinolone. Note that fluoroquinolones have been associated with impaired healing in tendons^{103a}; the impact on other skeletal tissues is not clear. The use of an antimicrobialimpregnated collagen sponge was addressed previously.

KEY POINT 8-21 The use of a fluoroquinolone for treatment of infections associated with joints or ligaments requires caution.

Duration of therapy for treatment of septic arthritis in humans generally is at least 3 weeks, although these recommendations are based on older retrospective studies.¹⁰¹ Shorter treatment periods are being promoted, particularly in children. Similarly, a recent trend is oral treatment after a brief period of intravenous therapy. Response to antimicrobial therapy is based, in humans, on repetitive analysis of synovial fluid collected by joint aspiration. Persistence of infusion beyond 7 days is interpreted as the need for surgical drainage. Use of appropriate antimicrobials early in the course of arthritis will minimize damage to the joint.¹⁰³

Adjuvant Therapy

Because septic arthritis can be accompanied by the loss of collagen and erosion of articular surfaces, therapy with diseasemodifying agents should strongly be considered. Injectable products such as polysulfated glycosaminoglycans (Adequan), pentosan polysulfate, and hyaluronic acid (the latter perhaps in combination with either of the former) are more apt to act more rapidly than oral products. Oral disease-modifying agents such as chondroitin sulfates, keratan sulfates, and glucosamines (e.g., Cosequin) also should be strongly considered until the joint is healed.

URINARY TRACT INFECTIONS (UTIs)

UTIs include but are not limited to pyelonephritis, ureteritis, cystitis, urethritis, and prostatitis. Infection occasionally is restricted to urine (bacteriuria).¹⁰⁴ Identification of the site of a UTI may be difficult, as might be discrimination of the infection as primary or secondary. However, because infection in any region of the urinary tract can be accompanied by or result in infection throughout the tract, terminology inclusive of all sites (i.e., UTI) often is preferred to terms limited to a single site of infection (e.g., upper or lower UTI). However, the site of infection has implications because of potential differences in ease of treatment, including drug distribution. The incidence of UTIs in dogs is higher (estimated at 14%) than that in cats (1% to 3%).¹⁰⁴ However, it is not clear whether this takes into account occult infections (see later discussion).

Microbial Targets

Because the urinary tract is a site for which bacterial contamination is common, the size of the inoculum should be considered when identifying target pathogens and the need for treatment. This need increases in the face of emerging antimicrobial resistance. Generally, the urinary tract is sterile above the urethra. Bacteriuria simply refers to the presence of bacteria in the urine. Infection of the urinary tract begins with bacterial adherence to uroepithelial cells of the urinary mucosal surface. The number of CFUs indicative of infection is higher than that for tissues for which contamination is unlikely and is influenced by both the method of sample collection and the gender. In his retrospective evaluating risk factors associated with UTI in dogs (n = 8354) from 1969 to 1995, Ling et al.¹⁰⁵ defined clinically important bacteriuria when samples were collected by catheterization as ≥100,000 CFUs/mL in female dogs and ≥10,000 CFUs/mL in males, whereas ≥100,000 CFUs were considered significant in either gender if collected midstream. In an uncontaminated cystocentesis, any growth was considered significant. Other investigators (e.g., Seguin¹⁰⁶)

 Table 8-9
 Pharmacokinetic and Pharmacodynamic Indices for Treatment of Canine and Feline

 Escherichia coli
 Associated with Urinary Tract Infections

BP, Breakpoint, *MIC*, minimum inhibitory concentration; *NA*, not applicable; *SC*, subcutaneous; *IM*, intramuscular; *TMPS*, trimethoprim–sulfadoxine; *CHPC*, chloramphenicol. *475 isolates are from the urinary tract. Personal data of author (in press).

[†]Data based on MIC₅₀, but MIC₉₀ preferred. However, this data includes dogs previously exposed to antimicrobials. MIC₉₀ is likely to be lower if only antimicrobial-naïve dogs are considered (see Table 8-11). The MIC₉₀ of susceptible isolates is likely to be lower (see Table 8-11).

*This dose is approximately twofold higher than recommended.

[§]Doses are those delineated in Table 7-1.

 C_{max} /MIC (target ≥10) and T >MIC (target generally 50% of dosing interval) are likely to be higher and longer, respectively, for renally excreted drugs if infection is limited to the bladder, biofilm is minimal, and renal concentration is normal.

have considered growth significant in cystocentesis samples only if CFUs are greater than 1000. This seems to be a reasonable basis for criteria when considering treatment of UTI, as long as the criteria are considered in the context of the circumstances surrounding the infection, including the presence of clinical signs. The presence of three or more different organisms was considered by Ling et al.¹⁰⁵ as indicative of contamination regardless of the method of collection and indicated the need to resample and reculture.

Historically, *E. coli* has been recognized as the predominant cause of UTIs in both dogs and cats (Table 8-9).^{107,108} *Staphylococcus* spp. and other gram-positive organisms historically have accounted for 25% of UTIs in dogs. Other cited causative agents in the dog include *Proteus, Klebsiella, Enterobacter*, and *Pseudomonas* spp.¹¹⁰ *Proteus* and *Staphylococcus* spp. cause urinary alkalinization and as such often are associated with struvite formation in dogs. In the cat, organisms other than *E. coli* that cause UTIs have included *Proteus, Klebsiella, Pasteurella, Enterobacter, Pseudomonas*, and *Corynebacterium* spp.¹⁰⁸ *Mycoplasma* spp. also should be considered as a less common cause of UTIs.¹¹¹

KEY POINT 8-22 The need to treat a urinary tract infection should be carefully critiqued. Resolution of the cause of the infection is critical to therapeutic success, including avoidance of resistance.

Enterococcus spp. increasingly is competing with E. coli as the predominant organism associated with UTI. Ling and coworkers¹⁰⁵ found that most UTIs were caused by a single agent, with E. coli the organism most commonly isolated (45%; see Table 8-1). The number of animals exhibiting signs associated with UTI was not indicated in the study nor was identification of the UTI as a first occurrence or a recurrence. Although UTIs occurred more frequently in female dogs, the frequency of specific organisms causing UTIs was generally similar between genders, with the exception of Proteus and Enterococcus spp., which were cultured more frequently from females (10.5% and 9.6%, respectively) compared with males (5% and 5% to 6%, respectively). Multiple organism infections were more likely to be found in females than in males. Age did not appear to be an important predictive factor of the most likely pathogen. The majority of infections were associated with ≥100,000 CFUs/mL, whereas approximately 20% of infections, regardless of the number of infecting organisms or the gender of the dog, were characterized by ≤1000 CFUs/mL.

A retrospective study of UTI in dogs admitted to a veterinary teaching hospital and subsequently diagnosed with UTI (n = 240)¹¹² found that *E. coli* was the causative organism in 50% of the cases. Although the majority of the remaining organisms were gram-negative coliforms (e.g., *Proteus, Klebsiella* spp.) selected gram-positive organisms (*Staphylococcus* and *Enterococcus* spp. being the majority) also were cultured.

The causative agents associated with recurrent UTI (defined later) appears to be similar in that E. coli is most common. However, the causative agents in the remainder may differ. Seguin¹⁰⁶ retrospectively examined recurrent UTIs in dogs (n = 441 isolates from 373 positive cultures). E. coli (47%) was the most commonly isolated, followed by Enterococcus spp. (21%). Other organisms included Proteus (7.7%), Klebsiella (5.9%), Staphyloccoccus (5.2%), and Pseudomonas spp. (4.1%). Mixed infections occurred in 17% of the cultures. In a prospective study of dogs receiving glucocorticoids (n = 127), the most common organism isolated was E. coli followed by *Enterococcus* spp. A retrospective study in cats (n = 141) with diabetes mellitus¹¹³ also identified E. coli as the most common organism. However, a study of 123 specimens collected from asymptomatic cats found Enterococcus faecalis to be the most commonly isolated organism (43%), with E. coli the second most common (32%).¹¹⁴ There does not appear to be any information regarding the causative agent associated with infection in different regions of the urinary tract.

Limited information is available regarding the susceptibility of organisms causing UTI. Attention to this issue in clinical studies generally addresses patterns of susceptibility but not the level; however, the latter becomes important to the detection of emerging resistance in those isolates considered susceptible based on CLSI criteria. Boothe and coworkers¹¹⁵ (see Table 7-3) have described the proportion of E. coli isolates susceptible to traditional first-choice antimicrobials, with regional differences apparent. Decreasing susceptibility is likely to limit empirical predictability of those drugs that remain effective. These data underscore the importance of susceptibility methods that allow discernment of different levels of susceptibility. The data also underscore the importance of designing dosing regimens that maximize doses or (for timedependent drugs) intervals such that resistance might be minimized (see Chapter 6).

In a retrospective study of UTI in dogs receiving glucocorticoids,¹¹⁶ organism susceptibility was recorded (n = 32): trimethorpim–sulfonamide (97%), amoxicillin–clavulanic acid (76%), tetracycline (70%), ampicillin (61%), and cephalexin (52%). Interestingly, only 7% were susceptible to enrofloxacin, but only 6 dogs were receiving enrofloxacin.

Pathophysiology

The clinical signs of UTI vary with the site of infection. As with other body systems, the inflammatory response largely is responsible for the clinical signs of UTI. Bacteriuria can be asymptomatic, detected on urinalysis but causing no clinical signs.¹⁰⁹ Acute cystitis can cause dysuria but rarely causes signs of systemic inflammation. Acute pyelonephritis, however, is often associated with signs of systemic inflammation, including fever. As in any body system, evidence of inflammation is not necessarily evidence of infection and the need for antimicrobial therapy. Likewise, absence of inflammation does not rule out bacterial infection.

Possible sources of UTI include ascension from the urethra and hematogenous and lymphatic factors. Ascending infection is by far the most common route of infection, although the kidney is predisposed to develop infection associated with blood-borne organisms. In both humans and dogs the origin of bacteria infecting the urinary tract is generally fecal, with the frequency of infection by a particular strain depending on the virulence of the organism. Pathogens generally travel along the urethra to the bladder. Anatomic deformity and turbulent urine flow may facilitate antegrade movement of organisms toward the bladder. Female patients are more predisposed to ascending infection because of the shorter length of the tract and increased risk of contamination. Once in the bladder, infection can continue to ascend the ureter to the kidney, particularly if vesicoureteral reflux is present.

Because E. coli is consistently the most common organism associated with UTI, a focus on its pathophysiology is warranted. E. coli can be identified based on the presence of selected antigens that serve as a basis for serotyping: O, or somatic (more than 140 serotypes); K, or capsular (which may be associated with more virulence factors); and H, or flagella (necessary for ascending infection and renal invasion). E. coli is also represented by a number of pathogenic strains based on the presence of specific virulence factors that facilitate infection. Strains are broadly categorized as intestinal or extraintestinal; the latter group generally is recognized to originate from intestinal strains that subsequently acquire virulence factors that facilitate extra-intestinal survival. Among the extraintestinal strains are uropathogenic E. coli (UPEC) represented by many different serotypes.¹⁰⁹ Initial infection by UPEC depends on adherence to uroepithelial cells (e.g., pili or fimbriae). Type 1 pili are among the most important virulence factors facilitating invasion, adherence, and persistence of E. coli infections; similar factors are associated with infection by Proteus spp. and Klebsiella spp.^{117b} Toxins are released; examples include hemolysin, causing uroepithelial cell death (thus providing nutrients for UPEC) and cytotoxic necrotizing factor, which stimulates apotosis and inflammatory cell chemotaxis. Other virulence factors act to scavenge environmental iron necessary for extra-intestinal survival of the bacteria (e.g., enterobactin, which itself is inactivated by lipocalin 2, a bacteriostatic factor secreted by host leukocytes); others impair the hosts' defensive ability to scavenge iron. Factors also facilitate uroepithelial cell penetration by E. coli; rapid intra-epithelial proliferation of microbes is accompanied by biofilm formation. Exfoliation of surface uroepithelial cells that occurs with urination is an important host protective mechanism but may facilitate recurrence as infected uroepithelial cells are exposed from the deeper layers. Inflammatory cells respond to cell destruction.

Much of the understanding associated with UPEC pathogenesis comes from contrasting it to a UPEC strain that is associated with much less pathogenicity, causing asymptomatic bacturia (ASB; strain 83792). This strain has been used prophylactically to infect the bladder of humans afflicted with UTI associated with more pathogenic UPEC; this unique approach to treatment is currently undergoing clinical trials.^{117c}

Understanding the role of virulence factors in UTI is a prelude to identifying therapies and alternative antimicrobials. Among the factors targeted are adherence factors, in part because of their critically important role in initial infection. E. coli contains adhesins that bind to the glycolipid receptors. Mannose-containing receptors are present on most Enterobacteriaceae. On entry into the lower urinary tract E. coli organisms associated with canine UTI appear to adhere primarily through these mannose-sensitive adhesins, initiating colonization. In contrast, mannose-resistant fimbriae and other adhesins appear to be critical for colonization of the renal structures. Binding between receptor and adhesin changes the receptor-bearing cell. The severity of a UTI may be correlated with the degree of adherence to uroepithelial cells. Organisms causing acute pyelonephritis in human patients are characterized by higher adherence compared with organisms causing asymptomatic bacteria.¹¹⁷ The interaction between microbe and receptors may offer a target for treatment. Treatment with mannose or similar molecules has been proposed to block the receptors, thus reducing adherence.¹¹⁷ However, while this may decrease infection in the bladder, some of the most pathogenic E. coli do not recognize mannose (e.g, UPEC associated with renal infection). Further, interaction between the pathogen and the mannose receptor may be important in the initiation of host defense. Cranberry juice extract contains proanthocyanidins that appear to block uroepithelial cell adherance (Type pili) receptors, presumably precluding bacterial adherence. Several antimicrobials interfere with bacterial expression of fimbrial adhesins and thus may prevent bacterial attachment and colonization. Examples include penicillin, ampicillin, amoxicillin, and streptomycin. Once-daily administration of antimicrobials at reduced (one half to as little as one eighth) doses also may be able to prevent UTIs because of interference with fimbrial expression or formation.¹¹⁹ The role of fosfomycin for this indication requires further development. Among the adherence factors, biofilm has a profound influence on UTI, particularly persistent or recurrent UTI caused by E. coli.117a,b Although bioifilm clearly contributes to infections associated with urinary catheters, its role in chronic UTI is less appreciated. Biofilm physically and functionally contributes to antimicrobial resistance. A crystalline-based biofilm produced in association with urease production (and urinary alkalinization) appears to contribute to, and indeed, be necessary for the formation of struvite crystals. Use of compounds such as iodoacetamide (IDA) and N -ethyl maleimide (NEM) that inhibit enzymes necessary for the formation of the biofilm matrix of these crystials is an area of investigation.

Predisposing Factors

A number of microbial factors increase the risk of UTI.¹⁰⁴ Siqueira and coworkers¹¹⁸ have described virulence factors associated with *E. coli* isolated from dogs with UTI (n = 51) and pyometra (n = 52) and feces of healthy dogs (n = 55). These include but are not limited to other microbial antigens, production of toxins such as hemolysin or urease, and the mucoid polysaccharide capsules (e.g., *Pseudomona* spp.). Urease producers (*Staphylococcus, Proteus*, or *Mycoplasma* spp.) increase the risk of struvite urolithiasis, predominantly in dogs.

Other host factors increase the risk of UTI. Anatomic predispositions to infection include perineal urethrostomy

(particularly in cats). Bacterial infection is rarely the initial cause of disease of the lower urinary tract in cats, but development of infection is a common sequela.¹⁰⁸ The role of viruses in feline lower urinary tract disease has been reviewed.¹²⁰ Viruses that have been isolated from the urinary tract of cats with spontaneous disease include feline calicivirus, bovine herpesvirus 4, and feline syncytium-forming virus.¹²¹ Other potential uropathogens include mycoplasmas and ureaplasmas.^{111,121} Risk factors have been described in cats with diabetes mellitus, with infection present in 18 of 141 cats.¹¹³ Hyperthyroidism also is a risk factor. Immunosuppressive therapy is a risk factor, as has been demonstrated prospectively in dogs, (n = 127) receiving glucocorticoids (prednisolone or methylprednisolone): 18% were positive (compared with a matched control set of dogs not receiving glucocorticoids) on at least one culture.116

Recurrent UTIs reflect either persistence or relapse of the infection or reinfections.^{106,109} Persistent or relapsing infections reflect therapeutic failure, whereas reinfection reflects a new bacterial species or strain following a period of urine sterility (i.e., negative urine culture). Superinfection refers to infection with a different organism that emerges during treatment of the original organism. Discriminating among persistence, relapse, or reinfection is difficult. Drazenovich and coworkers¹²² used pulsed-field gel electrophoresis (PGFE) to pulsotype E. coli isolates associated with persistent UTI in dogs in an attempt to discriminate between recurrence and reinfection. Interestingly, of the *E. coli* in their study (n = 12)dogs, 47 isolates), only two dogs had the same PFGE genetic pattern (pulsotype); further, few virulence factors were identified among infecting isolates. Frietag and coworkers¹²³ studied whether antimicrobial susceptibility profiles could predict a recurrent infection as persistent or relapsing, versus reinfection, with pulsotypes as the determining factor. Susceptibility was effective only 58% of the time in predicting the pattern of recurrence. However, the study group included only five cats (17 isolates); the interval between diagnosis ranged from 6 weeks to 2.5 years. Of the 17 isolates, 9 unique isolates were identified, with no more than 2 from each cat, but susceptibility patterns differed within and between clones. Because PGFE is based largely on chromosomal DNA (i.e., does not include plasmid DNA) and detects the presence of the gene but not its expression, pulsotypes may not be the most appropriate standard on which to base recurrence patterns.

Causes of recurrent UTI (defined as 2 or more in a 6-month period) were retrospectively studied in dogs (n = 100).¹⁰⁶ The median age was 7.7 years. Persistence (defined as same organism and same susceptibility pattern; 42%) and reinfection (different isolate; 50%) were equally responsible for recurrence. Superinfections were identified in 2% of dogs; it is not clear how many animals were cultured while on antimicrobial therapy; the proportion may be higher if superinfections are prospectively sought. Dogs younger than 3 years of age were at greater risk, whereas dogs older than 10 years were associated with a decreased risk of recurrence. This may reflect, in younger dogs, anatomic or other underlying causes being more important to recurrence. Females were at greater risk

than males, and sporting dogs, nonsporting dogs, and hounds were at risk compared with other breeds. E. coli (56%) and Enterococcus spp. (21%) were the most common organisms. Multiple isolates were present in 18% of infections. An underlying cause (or causes) was found in 71 of the dogs; correction occurred in approximately 25 of these. Disorders include abnormal micturition, anatomic defects, altered urothelium (i.e., tumors or uroliths), altered urine composition (hypoadrenocorticism or diabetes mellitus), and impaired immunity (e.g., chemotherapy, hyperadrenocorticism). Dogs treated without removing the underlying cause of disease were more likely to be considered poorly controlled (74.5%), with duration of a disease-free period being less than 8 weeks. Correction of underlying disease or therapy intended to prevent reinfection (i.e., low-dose, long-term antimicrobials) was associated with better control. Over 29% of the infections were associated with multidrug resistant microbes, with abnormal micturition more commonly associated with resistant organisms. Interestingly, 87% of the dogs in which relapse occurred were initially presented for a problem other than UTI, and 50% of the dogs studied were asymptomatic for UTI. Sediments in 15% of the dogs were not indicative of infection, and these isolates in particular tended to be resistant. The authors concluded that culture and susceptibility testing may be indicated in the presence of a predisposing disorder.

The need for preemptively culturing urine in animals predisposed to infection was supported by the prospective findings of Torres and others¹¹⁶ and Bailiff and others¹¹³ Torres and others¹¹⁶ studied UTI in dogs (n = 127) receiving glucocorticoids; 18% were positive (compared with a matched control set of dogs not receiving glucocorticoids) on at least one culture, although no dog had clinical signs of UTI. However, pyuria or bacturia predicted positive culture 90% and 95% of the time, respectively. The most common organism isolated was E. coli, followed by Enterococcus spp. Superinfection was present in 6 of 52 dogs whose urine was cultured while receiving glucocorticoids; each dog was receiving cephalexin (22 mg/kg bid by mouth), and the cultured isolate was resistant to cephlexin. Bailiff et al.¹¹³ retrospectively studied 141 cats with diabetes mellitus. Of these, 13% also had UTI, with E. coli the most common organism. Risk factors were female and low body weight; no treatment-related risk factors were identified, including level of diabetic control, or glucosuria.

KEY POINT 8-23 Culture and susceptibility testing should be strongly considered as the basis of therapy in any urinary tract infection that is not occurring for the first time.

Occult UTIs are not limited only to animals with underlying disease; it is possible that "asymptomatic bacteria" is a more appropriate term. Occult UTI appears to occur more commonly than previously thought in cats.¹¹⁴ In a study of 123 specimens collected from asymptomatic cats, 38% were positive. Positive cultures were more prevalent in older female cats. In contrast to most studies, *E. faecalis* was the most commonly isolated organism (43%), with *E. coli* the second most common (32%).

Other factors may contribute to recurrence or reinfection. Urinary tract catheterization contributes to an increased risk of UTI in an experimental model of male feline cystitis.¹²⁴ Catheterization is a common cause of ascension of bacteria from the urethra to the bladder. In human patients one catheterization results in infection in 1% of patients, and infection develops in most, if not all, patients within 3 to 4 days of placement of an indwelling, open-drainage catheter system.¹⁰⁹ A study of infection in cats after perineal urethrostomy found that while the surgical procedure does not predispose the cat to recurrent bacterial UTI, surgical alteration of the urethral surface coupled with underlying uropathy may increase the risk and thus prevalence of ascending infection.¹²⁵ Catheters should be used only in cats for which obstruction is likely if catheterization is not performed.¹²⁶ Urinary calculi will contribute to canine and feline lower UTIs. One study reports growth of bacteria in urine or calculi of 41% of cats with urinary calculi.¹²⁷ Staphylococcus spp. were responsible for most (45%) of these infections. Pyometra may serve as a source of reinfecting organisms,¹²⁸ as might tumors (e.g., transmissible venereal tumors).129

Resistant Urinary Tract Infection

Resistant microbes, and particularly E. coli, are increasingly common causes of UTI (Figure 8-5; see also Table 7-3). In a prospective study of E. coli isolates, the majority of which were associated with UTI in dogs (n = 240) at a teaching hospital, Boothe and coworkers¹¹⁵ found the rate of resistance of E. coli to common first-choice antimicrobials limited empirical selection of an appropriate antimicrobial at that hospital (Figure 8-5). The percentage of organisms resistant to first-choice drugs exceeded 50% for ampicillin (e.g., amoxicillin) and was 40% or more for drugs considered relatively invulnerable resistant to beta-lactam resistance (i.e., amoxicillin-clavulanic acid and cephalothin). Moreover, 40% of the E. coli organisms also were resistant to trimethoprim-sulfamethoxazole. Disconcertingly, 40% of organisms were resistant to fluoroquinolones, the first choice for complicated infections, and 50% were resistant to extended-spectrum penicillins (carbenicillin, piperacillin, and ticarcillin). Indeed, the only drugs to which E. coli was predictably susceptible were nitrofurantoin and the aminoglycosides, particularly amikacin. Third-generation cephalosporins ceftiofur and particularly ceftazidime also exhibited susceptibility, although extended-spectrum beta-lactamases (see Chapter 7) were not tested. Several factors were associated with UTI resistance in these organisms, with antimicrobial therapy within the past 5 days and duration of hospital stay being the most important. The incidence of resistance in this retrospective study is in contrast to earlier reports of UTI resistance. For example, in a 2001 study, E. coli isolates (the majority being UTI) cultured from dogs were susceptible to norfloxacin (90%), enrofloxacin (87.5%), gentamicin (90.7%), and amikacin (85.9%).¹³⁰ The proportion of E. coli classified as resistant to amoxicillin or amoxicillin-clavulanic acid is likely to increase in the next few years because CLSI has lowered the breakpoints for these two drugs (along with cephalexin). Other investigators have reported E. coli resistance, particularly to fluoroquinolone.

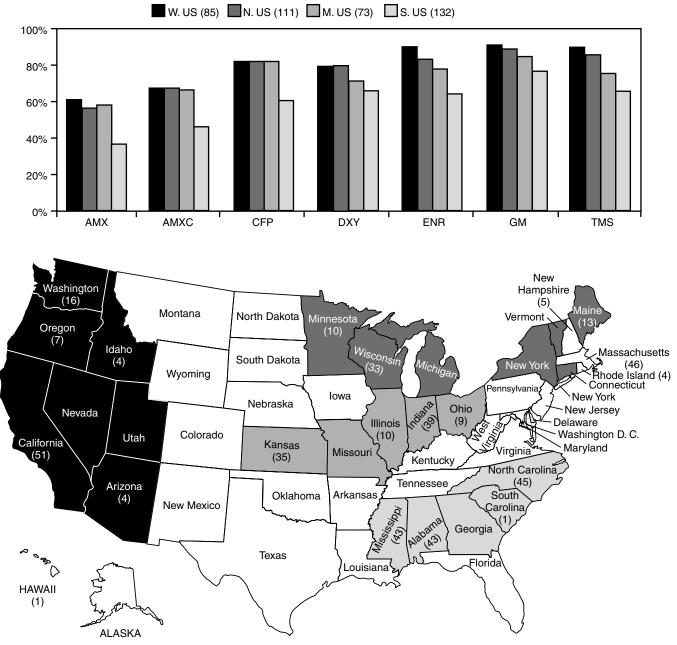

Figure 8-5 Percentage of canine and feline pathogenic *Escherichia coli* (n = 401) collected during May through September 2005 susceptible to selected antimicrobials. Resistance differed by regions (regions delineated in map), with the south characterized by the lowest level of susceptibility for each drug. *AMX*, Amoxicillin; *AMXC*, amoxicillin–clavulanic acid; *CFP*, cefpodoxime; *DXY*, doxycy-cline; *ENR*, enrofloxacin; *GM*, gentamicin; *TMS*, trimethoprim sulfonamide.

In a study by the author of *E. coli* organisms (n = 50)—most of which were isolated from the urine—the MIC₉₀ for the fluroquinolones was greater than 64 µg/mL, suggesting highlevel multistep resistance.¹³¹ Multidrug-resistant *E. coli* has emerged as a cause of nosocomial infections in dogs¹³² and UTI in canine critical care patients.^{106,133} Data generated by the author suggest that resistance to fluoroquinolones is multidrug in nature, reflecting not only mutations in topoisomerases but also induction of efflux pumps.¹³⁴ *E. coli* is not the only organism associated with UTI to which resistance has emerged in clinical cases. *Enterococcus* resistance in particular has emerged, probably reflecting its presence as the major gram-positive aerobe in the gastrointestinal tract, although its role as a uropathogen is not clear.

Although in vitro resistance may not necessarily predict in vivo failure, evidence in human medicine suggests otherwise. As in dogs, *E. coli*, is the most prevalent uropathogen in humans. However, antimicrobial resistance to first-choice drugs, trimethoprim–sulfonamethoxazole (TMP-SMX) and ampicillin, often exceeds 30% in humans. In women with UTI caused by *E. coli* characterized by in vitro resistance to TMP-SMX and subsequently treated with the combination drug, approximately 50% were bacteriologic failures and another 40% clinical failures.¹³⁵ Previous antimicrobial therapy profoundly affected the likelihood of resistance, with the risk greater if the antimicrobial of interest has been used. Again, in women the most important independent risk factors for TMP-SMX resistance in nonhospitalized cases was use of the antimicrobial within the past 3 months. Those who had taken any antimicrobial were more than twice as likely to be infected with a resistant isolate; use of TMP-SMX within the past 2 weeks was associated with a sixteenfold greater risk of infection with a resistant isolate.¹³⁵ Interestingly, trimethoprim by itself results in cure rates that are similar to combination with sulfamethoxazole; because it is associated with fewer side effects, it is the preferred drug for treatment of uncomplicated UTI by some.¹³⁵

Urinary catheterization is not only a recognized risk factor for UTI but also for antimicrobial resistance. Catheterization has resulted in bacteriuria in previous bacteria-free urine and has been associated with changes in urine microflora, as well as increased resistance.¹³⁶ Although aseptic techniques will reduce the risk of infection, infection is not prevented. The risk of persistent UTI in cats with experimentally induced cystitis was increased with catheter placement, despite the use of a closed system of urine drainage.¹¹⁰ The risk of infection can be correlated with duration of catheter placement, with the risk being reduced in patients catheterized for less than 3 days.¹³⁷ Previous antimicrobial therapy is likely to contribute to the risk: resistance in dogs catheterized more than 5 days was strongly associated with the advent of resistant microrganisms.¹¹⁵ Catheter type influences the risk of infection, probably because of its impact on biofilm formation (see Chapter 6) and bacterial swarming.¹³⁸ However, isolation of organisms within microcosms associated with biofilm and subsequently isolated from urine collected from the catheter—or from the catheter tip itself-does not necessarily indicate infection¹³⁷; The incidence of resistance in E. coli collected from catheters tips is greater than that collected by cystocentesis¹¹² If infection is present, the causative organism should be identified based on cystocentesis, or urine collected from the passage of a fresh, sterile catheter. However, catheterization should be kept to a minimum. Intermittent catheterization in spinal patients offers unique challenges. In humans, risk of resistance was related to frequency of catheterization (three times was associated with a greater risk than six times per day) and bladder overfilling (overfilling increased risk); previous indwelling catheterization also increased the risk. Trauma to the urethera during catheterization in itself did not increase the risk of infection, but the development of "false passages" or strictures resulting from repeat trauma did. Hydrophilic catheters appeared to reduce the risk of infection. Antimicrobials should be used judiciously in spinal patients. Whereas symptomatic infections are treated, asymptomatic bacteriuria is not necessarily treated; not surprisingly, long-term prophylactic antimicrobial therapy is associated with an increased risk of infection. As such, antimicrobials therapy tends to be limited to treatment of symptomatic infections or prophylaxis during initial (shortterm) catheterization.¹³⁹ The efficacy of antimicrobial infusion at the end of catheterization is not clear, with studies generating conflicting results. However, in contrast to multiple systemic dosing, single local infusion of high concentrations of drug is less likely to lead to resistance and potentially might do less harm than systemic therapy. Local intravesicular infusion of an antimicrobial might be considered of inducing minimal risk to resistance.

Difficulties encountered in the successful treatment of UTI, and particularly multidrug-resistant UTI, mandate that approaches be taken to prevent resistance, which includes preventing infection. Because previous use of antimicrobials consistently is a major predictor of emerging resistance, the question of the need to treat should be the first consideration for all infections. If reasonable alternatives exist to antimicrobial drug therapy, they might be considered first or in addition to antimicrobial therapy.

Prevention of Urinary Tract Infection

A number of host factors prevent or limit bacterial infection in the bladder.¹⁰⁹ Among the host factors important in preventing infection are normal micturition, normal anatomic barriers, systemic immunocompetence, mucosal defense barriers, and the inherent antibacterial properties of urine. Recurring infections are most likely to reflect failed host defenses, whether originating spontaneously or iatrogenically (e.g., immunosuppressive drugs).¹⁰⁶ Support of factors can be targeted with adjuvant therapies instead of antimicrobial treatment, when possible, or to facilitate antimicrobial therapy, particularly in the patient at risk for recurrent infections.

The decision to treat or not treat an infection might take into account the size of the inoculum (i.e., CFU/mL of urine) but should also take into account host factors (e.g., clinical signs, history, ability to control underlying cause, contributing factors, previous response to therapy). The location of infection may play a major role in determining the need for therapy. Whereas asymptomatic bacteriuria will often resolve or become self-limiting if left untreated, bacterial pyelonephritis is likely to progress.^{104,117} Virulence testing or serotyping eventually may be helpful in the decision to treat or not treat. The normal flora of the vulva and prepuce may be an important host defense mechanism against infecting microorganisms of the urinary tract. Normal flora may prevent colonization by pathogenic organisms or disrupt metabolism of pathogens. Secretory antibodies may coat infecting organisms, preventing adherence, and reduced antibody production may promote infection. Mucus may have other antibacterial effects. In the bladder, mucosal secretion of surface mucopolysaccharides is important to host defense by preventing attachment of bacteria. Destruction of this layer facilitates infection. Treatment with sulfonated glycosaminoglycans intraluminally may coat the uroepithelium and thus provide a barrier to bacterial adherence. Administration of carbenoxolone (a licorice derivative) stimulates secretion of mucosal polysaccharide and (in rabbits and humans) increases the clearance of E. coli infection. In the bladder, the composition of urine can affect bacterial growth. Urine concentration (unless extreme) is not likely to affect bacteria (bacteria are generally hypertonic compared with their environment), but high concentrations of urea or other compounds or low pH may impair bacterial growth. The addition of prostatic fluid inhibits bacterial growth. Exceptions include selected *Staphylococcus* and *Proteus* spp., which are relatively resistant to the antibacterial effects of urea.¹⁰⁹ Tamm–Horsfall protein secreted by the cells of the ascending loop of Henle binds to *E. coli* by way of mannose-containing side chains and, as such, probably acts as a urinary bacterial defense mechanism. Other factors that help prevent or reduce bacterial infection include frequent urination, a small residual urine volume in the bladder, and rapid urination.

KEY POINT 8-24 The use of adjuvant therapies, particularly in the prevention of urinary tract infections, should be considered carefully, particularly with regard to clinical evidence of efficacy.

Therapy

The Need for Drug Therapy

The presence of bacteriuria is not necessarily an indication of the need for antimicrobial therapy (Figure 8-6). Antimicrobial therapy should be used only when reasonable evidence of infection exists. Bacterial UTI occurs much less frequently in cats than in dogs, and even the presence of clinical signs indicative of cystitis should not be interpreted as a need for antimicrobial drug therapy.

In humans, to prevent resistance, treatment generally is not indicated in asymptomatic bacteriuria except under certain conditions in which the patient is at risk, such as during pregnancy or invasive surgical procedures.¹⁴⁰ Likewise, for veterinary patients the risk of emerging resistance must be weighed against the risk of failing to treat. If the patient is one for which aminoglycoside therapy is inadvisable, the need for treatment should be even more closely examined. With *Enterococcus* bacteriuria, treatment should not be implemented unless the need is clear. Clearly, if the decision is made to treat a UTI, therapy must be aggressive, designed to kill invading pathogens as well as emerging mutants as rapidly as possible. Nonantimicrobial alternatives should be considered in lieu of or in addition to antimicrobial therapy.

The Sequelae of Drug Therapy

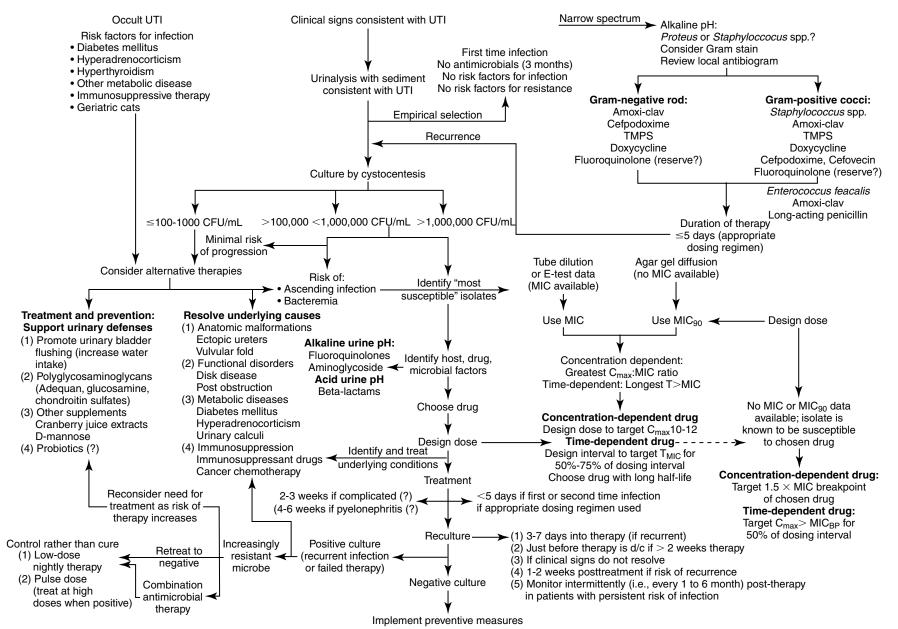

The traditional goal of drug therapy for UTI is to eliminate bacteriuria in animals exhibiting clinical signs and urinalyses consistent with UTI. However, four sequelae of antimicrobial therapy may occur.^{104,109} *Cure* can be defined as negative urine cultures during and after (usually 1 to 2 weeks) antimicrobial therapy. Quantitative bacterial counts should decrease within 48 hours after initiation of an appropriate antimicrobial. Cure does not rule out the possibility of reinfection. UTIs may reflect first-time or recurrent infections. *Chronic UTI* is often used to refer to persistence of infection. The previously defined terms *recurrence, persistence,* and *relapse* often are used interchangeably when referring to UTIs. *Persistence,* or recurrence, can refer to presence of significant or low numbers of bacteria after 48 hours of therapy. If the numbers are

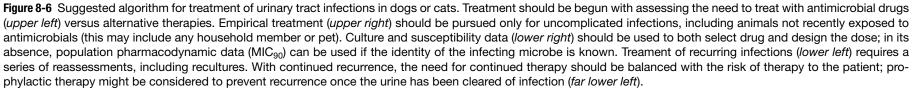

significant, antimicrobial resistance or insufficient drug concentrations (e.g., improper dose, poor oral absorption, poor renal elimination) should be suspected. If numbers are very low, a continuous source of bacteria in the urinary tract (e.g., urinary calculi, prostate, kidney) or contamination from the lower urinary tract might be suspected.¹⁰⁹ In such cases, cultures can identify persistent organisms after therapy has been discontinued. An appropriate approach would be classification of recurrent or persistent infections into three categories. Relapse occurs when the same organism causes infection 1 to 2 weeks after therapy has been discontinued. Relapse generally occurs within 1 to 2 weeks of cessation of therapy and may reflect either a very deep-seated infection or an abnormality of the urinary tract (e.g., structural, renal, or prostatic infection). The presence of a different organism is considered *reinfection* (i.e., a new infection). A new infection also can occur by the same organism located outside of the urinary tract. Generally, reinfection occurs more than 1 to 2 weeks after cessation of therapy. Superinfection may also occur and reflects infection with an additional organism during the course of antimicrobial treatment.¹⁰⁴ Evidence of persistent or relapsing infection or superinfection should lead to more aggressive therapy and to the use of bactericidal rather than static drugs. Among the common causes of complications associated with UTI, antimicrobial resistance, unidentified underlying disease, and inappropriate dosing regimen should be considered.

Identification of the Target

In all but simple UTI, culture is indicated. Culture is recommended in patients whose history includes exposure to antimicrobial therapy within the last 3 months; exposure may include any household member, including other pets. The more complicated the infection or the greater the patient is at risk for resistance to emerge, the more important it is to base therapy on susceptibility data. In human patients diagnosis of UTI in asymptomatic patients is. based on at least two cleancatch midstream urine collections. The same organism should be present in significant (see previous discussion) amounts in both cultures. A single culture is sufficient in the presence of symptoms. Urinary cultures should be the basis of antimicrobial selection in complicated infections (e.g., reinfection or relapse, history of antimicrobial use in the past 4 to 6 weeks)¹⁰⁴ or if the infection represents a risk to the patient's health. Infection after recent urinary catheterization also should lead to culture collection. Increasingly, culturing at the outset, even in simple, first-time infections, may become prudent.

Quantitative urine culture (i.e., colony counts) should be implemented to facilitate discrimination of harmless bacterial contaminations (e.g., from the urethra) from pathogenic organisms (see previous discussion). Bacterial counts of more than 10⁵ CFU are clearly indicative of infection regardless of the method of collection, whereas counts between 10³ and 10⁵ organisms are considered suspect if not collected by cystocentesis or if collected from female dogs. Counts of less than 1000 CFU should lead to a second culture and, in the absence of clinical signs or mitigating circumstances, consideration of alternative therapies. Methods have been described for

culture procedures performed in practice.¹⁰⁴ In addition to the method of collection, consideration must be given to sample handling. Samples should be kept refrigerated if the time from collection to processing by the lab is anticipated to exceed 12 hours, unless an appropriate amount of preservative is added. A viable alternative for submission of urine samples that will be in transit longer than 12 hours is collection and subsequent submission using a "paddle" apparatus (e.g., UriCult®).

Antimicrobial Selection

Presumably, a drug that is renally excreted should be selected for treatment of UTIs. Urinary concentrations of such drugs often surpass serum concentrations (up to 300-fold), which is particularly helpful for concentration-dependent drugs (Table 8-10). Susceptibility data do not take these higher concentrations into account, but this may be appropriate. Several caveats must be recognized when basing antimicrobial selection on renal elimination and anticipation of high urine drug concentrations:

KEY POINT 8-25 The design of the dosing regimen for treatment of a urinary tract infection should be based on plasma, not urine, drug concentrations.

- 1. Drug is not likely to be concentrated in some situations. Examples include but are not limited to fluid therapy, diuretic use, renal disease, and other diseases (e.g., hyperadrenocorticism).
- 2. Drugs characterized by a short elimination half-life may be limited in efficacy if they are time dependent in action. However, plasma elimination half-life may not accurately reflect contact time of drug in the urine if the drug is excreted renally. Contact can be enhanced by drug administration immediately after micturition or before an anticipated micturition-free period (e.g., at night).
- 3. Intraepithelial growth and biofilm may preclude drug efficacy even if concentrations are high in urine.
- 4. If the UTI is associated with infection in the blood (or in the presence of bacteremia), kidney, or prostate, then antimicrobial selection should be based on anticipated plasma (or tissue) drug concentrations and serum breakpoint MICs. A similar approach should be taken for recurrent infections or complicated infections.

A prudent approach for treatment of UTI is choice of a renally excreted drug but dosing based on drug concentrations achieved in plasma. Data from a few prospective studies, including animal model studies and human patient–based clinical trials, generally demonstrate that breakpoints based on plasma drug concentrations rather than urine appear to moderately predict outcomes associated with treatment of UTI.⁴⁵ For example, maximum efficacy of aminopenicillins in treating UTI in human clinical trials is achieved when plasma drug concentrations are maintained above the MIC for 30 hours or more.²⁷¹ Accordingly, CLSI interpretive criteria for infections in other tissues are relevant to UTI. Drugs that are not eliminated in urine might be characterized by lower concentrations in urine compared with tissues but still can be beneficial for

Table 8-10	Mean Urine Concentrations for Antimicrobials Used to Treat Urinary Tract Infections in Dogs			
Drug	Dose	Route	Freq*	Mean Urine Drug Concentration (μg/mL)
Penicillins				
Penicillin G	37,000 U/kg	РО	8	295 ± 210

Modified from Barsanti¹⁰⁷

UTI if dosing regimens are appropriate. Some drugs used to treat UTIs (e.g., indanyl-carbenicillin, nitrofurantoin) are recognized not to achieve effective concentrations in other tissues, and therefore use in areas other than the urinary bladder should be done cautiously.

As resistance to *E. coli* and other uropathogens increases, empirical therapy for UTI increasingly will be limited (Table 8-9). Caution is recommended because of the recent recognition of the growing incidence of antimicrobial resistance. Among the organisms frequently causing UTIs in dogs and cats, *E. coli*, *Proteus* spp., *P. aeruginosa*, and *Enterobacter* spp. are among the organisms that vary widely in their susceptibility pattern and for which empirical therapy is more risky (Table 8-11; see also Tables 7-3 and 7-9). Empirical therapy, if it is to be pursued, is indicated only for *uncomplicated infection*—that is, those patients in which no underlying structural, neurologic, or functional abnormality can be identified.¹⁰⁴ The absence of previous antimicrobial therapy should also be interpreted as uncomplicated. Once relapse occurs (see later discussion), an infection should no longer be considered uncomplicated.

Attention should be paid to the pH of the urine compared with the pK_a of the chosen drug. In the presence of an alkaline pH, weakly basic antimicrobials might be considered (aminoglycosides, and fluoroquinolones, with the latter being amphoteric but more effective in an alkaline urine). Because urease producers may alkalinize the urine, drugs targeting such organisms (e.g., *Proteus, Staphyloccocus*, and some *Klebsiella* spp.) should be selected. In the presence of an acidic urinary pH (perhaps caused by *E. coli*), weakly acid drugs (e.g., penicillins, cephalosporins, potentiated sulfonamides) might be better empirical selections. However, if the drug is highly concentrated in the urine, even a predominantly ionized drug (e.g., a weak base in an acidic environment), may be sufficiently un-ionized to ensure effective concentrations.

Infections uncomplicated by previous antimicrobial therapy or in regions for which resistance has minimally emerged may respond to empiric therapy. E. coli or Enterobacter spp. traditionally have been considered responsive to trimethoprim-sulfadiazine, third-generation cephalosporins (cefpodoxime, cefovecin), or amoxicillin-clavulanic acid combinations. Among these, penicillins may be preferred because of their effects of fimbriae. Approximately 60% of E. coli are resistant to cephalexin. Klebsiella, Proteus, and Staphylococcus spp. are likely to respond to a first- or third-generation cephalosporin or to amoxicillin-clavulanic acid. Amoxicillin or ampicillin (preferably combined with a beta-lactamase protector) should be effective if a decision is made to treat Enterococcus spp. (see Tables 7-9, 8-3, and 8-6). However, for Enterobacteriaceae in particular, integration of pharmacokinetics and pharmacodynamics raise concerns regarding efficacy for drugs with short elimination half-lives, particularly if infection involves tissue other than the urinary bladder. In the absence of an MIC, the more stringent MIC_{90} (see Tables 8-9 and 8-11) and C_{max} from package inserts or the literature (see Table 7-1) can be used to design dosing regimens. The highest end of the dosing regimen is indicated, particulary for at-risk patients. For selected concentrationdependent drugs, C_{max}:MIC should exceed 10 to 12, and for time-dependent drugs, T>MIC should be at least 50% if not more of the dosing interval (generally, initial target concentrations should exceed the MIC by at least two to four fold (see Table 8-9). For time-dependent drugs, those with longer half-lives might be preferred (e.g., cefovecin and cefpodoxime). Although the package insert for cefovecin indicates that MIC_{90} concentrations for *E. coli* (1 µg/mL) are not achieved after a recommended dose of 8 mg/kg subcutaneously, predicted unbound plasma drug concentrations will be maintained at or above this concentration for 3 days. Cefovecin is approved for treatment of canine E. coli UTI in Canada at 8 mg/kg. Note that neither cefovecin nor cefpodoxime are effective against Enterococcus spp., indicating that the Gramstaining characteristics of the infecting organism might facilitate proper antimicrobial choice for empirical treatment of a UTI in dogs or cats. Because resistance in E. coli toward fluoroquinolones with rare exception is associated with MDR, their use for treatment of UTI should be considered second tier and ideally, be based on culture and susceptibility testing. Care should be taken using the fluoroquinolones for Enterococcus spp., for which efficacy can be variable. Boothe et al demonsrated that for E. coli, when using the MIC₉₀ for fluoroquinolones, the C_{max} :MIC₉₀ failed to reach ≥ 10 —as is suggested for concentration-dependent drugs-even with the highest dose for each drug. (see Tables 7-12 and 8-9 for additional MIC data).¹³¹ However, for isolates that are known to be susceptible to ciprofloxacin, enrofloxacin, and marbofloxacin reached the target C_{max}:MIC₉₀ at the high (but not low) dose. Even with susceptibility data that provide MIC, because the tested concentrations are close to the breakpoint MICs, isolates considered susceptible to fluoroquinolones may have already developed low-level resistance, increasing the risk of emergent resistance in at-risk patients.¹⁴² Certainly an "I" to any one fluoroquinolone should be interpreted as emerging resistance to others. Isolates with MIC approaching the breakpoint should be treated with alternative drugs, combination drugs, or "added doses" (e.g., high dose, twice daily). Marbofloxacin is preferred for cats at risk for retinal adversities, particularly if dosing twice daily. Although ciprofloxacin is more potent against gram-negative isolates, dosing should be increased to compensate for differences in oral bioavailability and oral dosing should not be used in cats. Fluoroquinolones are also effective against Mycoplasma and Ureaplasma spp.

A summary of treatment of UTI in humans might offer some guidance for empirical therapy in dogs or cats. In women with risk factors for infection with resistant bacteria, or in the setting of a high prevalence of TMP/SMX resistance, a fluoroquinolone or nitrofurantoin is recommended for empirical treatment. The goal of treatment is eradication of infection using shorter courses of therapy (i.e., 3 days) with once-daily dosing of a selected drug or a single dose of a particularly efficacious antimicrobial.¹⁴¹ The role of nitrofurantoin is increasing for treatment of UTI in women, particularly in the presence of increasing antimicrobial resistance to other urinary antimicrobials. Resistance among uropathogens to nitrofurantoin generally is consistently at a low level despite its use for 5 decades. An advantage to nitrofurantoin is its minimal effect on the normal gut flora. Consequently, selection pressure for antimicrobial resistance is reduced compared with other antimicrobials.¹³⁵ Further, nitrofurantoin does not share cross-resistance with more commonly prescribed antimicrobials, and its use is justified from a public health perspective as a fluoroquinolone-sparing agent. [†]Based on cephalothin.

example, single-dose ciprofloxacin prophylaxis increased the prevalence of ciprofloxacin-resistant fecal *E. coli* from 3% to 12%.¹³⁵ After treatment with ciprofloxacin for prostatitis, 50% resulted in post-treatment fecal colonization with quinolone-resistant *E. coli* genetically distinct from the prostatic infection. Indeed, in humans, although flouroquinolones are effective as short-course therapy for acute cystitis, widespread empirical use is discouraged because of potential promotion of resistance.¹⁴⁰ An exception is made for acute (nonobstructive) pyelonephritis but only if culture results direct continuing therapy.

Beta-lactams and fosfomycin are also considered secondline (to TMP-SMX) agents for empirical treatment of cystitis in humans. Fosfomycin may be a reasonable first choice for treatment of UTI in dogs if data support its use for treatment of canine UTI. Advantages to fosfomycin tromethamine justify consideration of its use in dogs. Despite many years of use in humans, it is characterized by an extremely low incidence of resistance. Indeed, canine and feline isolates expressing MDR maintain susceptibility to fosfomycin.^{135a} Further, pharmacokinetics in dogs support its use for treatment of UTI. Its role for treatment of UTI in dogs is emerging; a prudent approach might be as a second- or third-tier drug because of its importance in human medicine. In general, drugs metabolized by the liver (chloramphenicol) or excreted in the bile (macrolides, clindamycin) do not achieve high concentrations in the urine and should generally be avoided for treatment of UTI. Doxycycline might be appropriate if susceptibility data is available, although concentrations achieved in urine might be bacteriostatic.

Duration of Therapy

The "test for cure"¹⁰⁴ (or perhaps, more appropriately, "response") can be based on a second culture 3 to 5 days into therapy. Cure should be anticipated only if the organism count is less than 100 per mL of urine. Urine culture a second time just before discontinuation of therapy has been recommended,¹⁰⁴ particularly if antimicrobial prophylaxis is to be implemented. The duration for successful treatment of uncomplicated lower UTIs might be as short as 3 to 5 days, particularly if doses are designed to target all infecting isolates, including those with the highest MICs.¹⁰⁴ Such an approach is more likely to be successful if high doses and appropriate intervals are chosen. Treatment may need to be extended, however, if infection occurs anywhere other than the uroepithelium. Traditionally, a 10- to 14-day therapeutic regimen has been recommended for the first episode of therapy; the evidence for this recommendation is limited and clinical trials demonstrating appropriate duration of therapy are needed. Shorterterm antimicrobial therapy (a single high dose) has proved effective for female human patients with a lower UTI. Drugs that have been used successfully in humans for short-term dosing include trimethoprim-sulfonamide combinations, aminoglycosides, selected cephalosporins, and fluoroquinolones. Both single-dose and 3-day antimicrobial treatment regimens have been studied with dogs receiving amikacin and a trimethoprim-sulfonamide combination. Therapy was not uniformly successful, suggesting that caution should be used with this treatment regimen.¹⁴³ However, these studies were implemented before understanding the importance of reaching targeted PDI (i.e., C_{max}:MIC > 10-12 and T>MIC for more than 50% of the dosing interval). Factors that should preclude single-dose antimicrobial therapy for a lower UTI include recurrence, historical poor response to single-dose therapy, underlying predisposing factors to a UTI (including structural abnormalities or metabolic disorders, such as diabetes mellitus, and hyperadrenocorticism), and either pyelonephritis or symptoms of a UTI that have occurred for more than 7 days.

For infections that reflect a relapse, the duration of therapy should be at least 2 weeks; however, for human patients suffering from a relapse, a higher cure rate occurred with a 6-week course of therapy. For animals a duration of 4 to 6 weeks is recommended.¹⁰⁴ The duration also might be based on the cause of the relapse and whether the underlying cause is curable and treated. Because relapse is likely to occur shortly after antimicrobial therapy is discontinued, cultures should be collected again 7 to 10 days after cessation of therapy to detect the recurrence. In general, regardless of the sequence of UTI, doses should always maximize efficacy and avoidance of resistance. A new antimicrobial should be selected if infection occurs more than 10 days after cessation of therapy;¹⁰⁴ as more time elapses between cessation of therapy and the presence of bacteriuria, the more likely it is that reinfection is the cause of recurrence.

In the event of relapse after 6 weeks of therapy, 6 months of therapy or more may be necessary. A 3- to 6-month duration of therapy may be indicated for animals. However, clinical trials are lacking to document these recommendations as well. Greater care must be taken, in the selection of antimicrobials for longer-term therapy, with special consideration to toxicity. Drugs that are used for long-term therapy in human patients include amoxicillin, cephalexin, trimethoprim-sulfonamide combination, or a fluorinated quinolone. Cultures should be repeated monthly, and as long as significant bacteria are not present, the drug need not be changed. Should relapse occur after a drug is discontinued, the same drug or a new drug should be administered for a longer course of therapy. Long-term therapy may be particularly important for animals in which renal parenchymal damage is a risk. As with first-time infection, and perhaps more so, the need for treatment must be balanced with the disadvantages of treatment (or the risks of not treating should be balanced with the benefits of treating).

Clinical Trials

Despite the frequency of UTI in dogs and cats, the number of clinical trials examining therapy are limited. Pradofloxacin (n = 27 dogs; 5 mg/kg) has been compared with doxycycline (n = 23; 5 mg/kg load, followed by 2.5 mg/kg bid for 2 doses, then 2.5 mg qd) and amoxicillin–clavulanic acid (n = 28; 62.5 mg/kg bid for 10 days) in cats with clinical signs of UTI.¹⁴⁴ Cats were not randomly assigned; assignment to treatment group was based on susceptibility; if more than one drug was designated susceptible, animals were assigned to keep groups balanced. All cats receiving pradofloxacin responded, with 13% and 10%, respectively, of the doxycycline and amoxicillin–clavulanic acid groups remaining infected after treatment. However, the proportion of responders was not different among treatment groups, probably reflecting small sample size.

Efficacy of cefovecin (8 mg/kg, administered subcutaneously) was compared with that of cephalexin for treatment of canine (n = 129) UTI.¹⁴⁵ Efficacy was based on elimination of the pretreatment uropathogen. Exclusion criteria included local or systemic antimicrobials within the previous 14 days, or short- (7 days) or long-acting (30 days) glucocorticoids. The study was implemented as a multicenter, blinded, randomized study, with cephalexin (15 mg/kg, administered orally bid) serving as the positive control. Animals were treated for 14 days. The most common uropathogen was E. coli (60%), followed by P. mirabilis (12%) and S. intermedius (12%). As would be expected on the basis of the cephalexin MIC_{90} of *E. coli*, the overall cure rate for animals infected with E. coli was 79% in the cefovecin group compared with 36% for cephalexin. Bacteria were eliminated in 59% of cefovecintreated dogs compared with 35% of cephalexin-treated dogs. Of the infecting isolates, 90.5% of E. coli infections were eradicated compared with 53% of E. coli infections for cephalexin. Of infections caused by S. intermedius, 6 of 6 were eliminated by cefovecin, compared with 7 of 10 for cephalexin; for Proteus mirabilius, 9 of 9 were eliminated by cefovecin, compared with 5 of 7 for cephalexin. Interestingly, although 319 dogs with clinical signs of UTI were evaluated for inclusion, only 137 (43%) actually were bacteriuric.

Prophylaxis

Long-term prophylaxis can be implemented for patients at risk for recurrence. Prophylaxis (by definition) can occur only after the infection has been eradicated. The use of low doses of antimicrobials in the presence of bacteriuria is likely to lead to the generation of resistant organisms and is contraindicated. Thus prophylactic antimicrobial therapy of UTIs is indicated for reinfection but not relapse (the latter suggests that the organism was never completely eradicated). The antimicrobial chosen for long-term prophylaxis should be both safe and inexpensive. Trimethoprim-sulfonamide combinations (monitor for immune-mediated reactions), nitrofurantoin, and fluoroquinolones are examples. However, neurologic side effects with nitrofurantoin may preclude its use, particularly long term. Fosfomycin might also fill this role. The dose for prophylaxis is generally reduced to 30% to 50% of the full dose.¹⁰⁴ Subtherapeutic concentrations of drugs often are

sufficiently inhibitory to prevent infection of the uroepithelium. The drug should be administered at night to maximize contact of the drug with the urinary tract. Intermittent urine cultures (monthly) are indicated to detect breakthrough infections in animals receiving long-term antimicrobial prophylaxis. Negative cultures for 6 to 9 months or more may indicate that prophylaxis is no longer necessary.

Adjuvant Therapy

Diuresis has been advocated in the treatment of UTIs in humans. Advantages include rapid dilution of bacteria, removal of infected urine, and subsequent rapid reduction of bacterial counts. In patients with pyelonephritis, an added advantage may be enhanced host defenses: medullary hypertonicity inhibits leukocyte migration, and high ammonia concentration inactivates complement. In the presence of vesicoureteral reflux, however, diuresis may increase the risk of acute urinary retention.

Use of drugs to modify urinary pH may facilitate the antibacterial effects of urine. The presence of ionizable organic acids (hippuric and gamma-hydroxybutyric acid) in an acidic pH may enhance the antibacterial activity of the urine. Antibacterial activity may be increased by ingestion of cranberry juice (if urinary pH is acidic), which contains precursors of hippuric acid. Cranberry juice extract also should be considered because of its potential ability to block adherence receptors. Methenamine, available as a hippuric acid or mandelate salt, releases formaldehyde at a urinary pH of 5.5 or less, which also can increase antibacterial activity of urine.

Local urinary analgesics, such as phenazopyridine, rarely are indicated for the management of UTIs. Dysuria is most likely to respond to appropriate antimicrobial therapy. These drugs cause methemoglobinemia and are contraindicated in cats.

Drugs or nutraceutical products that enhance polysulfated glycosaminoglycan synthesis (e.g., Adequan, pentosan polysulfate, glucosamine, chondroitin sulfate) might be considered for patients with complicated UTI. Such products may cover or help repair the uroepithelium, thus decreasing bacterial adherence. Gunn-Moore and Shenoy¹⁴⁶ prospectively studied the effects of 60 days oral n-acetyl glucosamine in cats (n = 40) with feline idiopathic cystitis using a randomized, double-blinded, placebo controlled study. Response was based on owner assessment. Both groups improved significantly, with 26 of 40 cats suffering recurrences. Although the power of the study was large, the size of the placebo response limited the ability to detect a significant difference between treatment groups. Improvement in both groups was potentially attributed to owners, most of whom changed the cats to moist rather than dry diets. The quality of the glucosamine was not addressed. Wallius and Tidholm¹⁴⁷ studied the effects of polysulfated glycosaminoglycans (PGAGs) in cats (n = 19) with clinical signs indicative of cystitis but culture negative. Cats were randomly assigned to receive either saline placebo or 3 mg/kg PGAGs on days 1, 2, 5, and 10. Assessment was based on owner perceptions of improvement. A treatment effect could not be detected because clinical signs resolved in essentially all cats (save one from each group). As with the previous study, the authors of this study could not conclude that PGAGs were not beneficial for treatment of inflammation, including that associated with UTI. Treatment with mannose or similar molecules may block mannose receptors, thus reducing adherence.¹¹⁹

The use of probiotics in the treatment of UTIs in human patients was reviewed by Lenoir-Wijnkoop.¹⁴⁸ In general, *Lactobacillus* spp. are most commonly recommended for treatment of UTI. However, selected species are likely to emerge as more effective than others and microbiota may need to originate from the target species. The use of probiotics in the treatment of renal oxalate stones in human patients was also reviewed by Lenoir-Wijnkoop and coworkers.¹⁴⁸ The absence of *Oxalobacter formigenes* from fecal microbiota increases the risk of kidney stones. Although no study has demonstrated an association between probiotic therapy and decreased renal stones, both animal and human studies have documented that *O. formigenes* can become established in the gastro-intestinal tract, and establishment reduces urinary oxalate concentrations.

Pyelonephritis

Treatment of pyelonephritis may require hospitalization with intravenous fluid administration. Oral antimicrobial therapy is acceptable for mild to moderate cases as long as oral therapy is tolerated well. Because renal dysfunction can be life threatening, antimicrobial selection should ultimately be based on culture and susceptibility data. Therapy can be initiated empirically; however, resistance among E. coli organisms should lead to selections with known susceptibility. Combination therapy should be considered. Urine is not likely to be concentrated, thus added attention must be paid to ensure that effective concentrations reach the target tissue. Pyelonephritis can be associated with bacteremia, particularly gram-negative bacteremia. Clinical signs indicative of severe, life-threatening infection should lead to parenteral antimicrobial therapy with predictably effective drugs (e.g., aminoglycosides, fluoroquinolones, extended-spectrum beta-lactams, and third-generation cephalosporins known to not be extended-spectrum beta-lactam producers). Combination therapy also should be strongly considered. The high concentration of antimicrobial that facilitates treatment of the lower urinary tract (bladder and lower) may not occur in pyelonephritis; thus close attention must be paid to using sufficiently high doses and frequent dosing. Drugs whose efficacy is dependent on a hypotonic environment (compared with the target organism), such as beta-lactams, fosfomycin, or vancomycin, may be less effective in the face of medullary hypertonicity, although this may be less than normal in the face of pyelonephritis. Nonetheless, if drug combinations are used, at least one of the two drugs should not target cell walls. As with infection lower in the tract, bacterial numbers should decrease dramatically within the first 48 hours of treatment. For uncomplicated pyelonephritis, 14 days of therapy may be sufficient of treatment. Cultures should be repeated as previously indicated during and within 1 to 2 weeks of discontinuation of therapy. Complications such as abscessation may require surgical intervention and longer-term therapy.

321

KEY POINT 8-26 *E. coli* resistance to fluoroquinolones, when it does emerge, is generally characterized by multidrug resistance.

KEY POINT 8-27 Treatment of pyelonephritis should be approached as a potentially life-threatening disease requiring aggressive but appropriate antimicrobial therapy.

Prostatitis

Pathophysiology

Bacterial prostatitis can present as either an acute or chronic infection. One does not necessarily precede or follow the other. Among the causes of prostatic infection, ascending infection and urine reflux appear to be most likely. Acute prostatitis often is accompanied by fever, pain, and symptoms typical of a UTI. Palpation of the prostate reveals tenderness, swelling, and (potentially) a fluctuant surface (Figure 8-7). Care should be taken when palpating the prostate so that the risk of bacteremia is minimized. Chronic bacterial prostatitis most commonly is caused by gram-negative coliforms, with *E. coli* being most common, followed by *Klebsiella* spp., *Enterobacter* spp., *P. mirabilis*, and *S. aureus*.

Antimicrobial Selection and Use

Antimicrobial penetration into the noninflamed canine prostate is limited. Drugs that are basic and lipid soluble appear to diffuse through tissues best, including macrolides (e.g., erythromycin and presumably azithromycin and clarithromycin), fluoroquinolones, and trimethoprim–sulfonamide combinations. The intense inflammatory response that accompanies acute prostatitis facilitates antimicrobial movement into the prostate,¹⁰⁹ although high doses should be used to ensure adequate concentrations at the site of infection. Parenteral antimicrobials based on culture (prostatic fluid or urine) should be used in the presence of life-threatening infection; otherwise, oral therapy is acceptable. Duration of therapy should be at

Figure 8-7 Aspiration of a prostatic abscess. Most prostatic abscesses require surgical removal. Abscessation carries the risk of peritonitis and bacteremia. Fluid should be submitted for culture and susceptibility testing. (Photo courtesy Harry W. Boothe, DVM, MS, DACVS, Auburn, AL.)

least 4 weeks to minimize the risk of progression to chronic prostatitis. Prostatic abscessation generally requires surgical intervention. Chronic prostatitis in human patients is difficult to cure unless infected tissue is surgically excised. Chronic prostatitis generally results in relapse. Therapy, when successful, generally requires 1 to 2 months of therapy. Antimicrobials that penetrate the noninflamed prostate (e.g., fluoroquinolones, trimethoprim–sulfonamide combinations, or macrolides) should be selected.¹⁰⁹

Adjuvant therapy for the treatment of prostatitis includes stool softeners and, if indicated, analgesics. Neutering should be considered.

INFECTIONS OF THE UTERUS

Endometritis

Endometritis is associated with sanguineous or purulent vaginal discharge in either the pregnant bitch (if the cervix is open) or nonpregnant bitch.¹⁴⁹ As with many organ systems, organisms causing uterine infections tend to be members of the normal flora of the reproductive tract. Organisms most commonly associated with uterine infections include Streptococcus spp., E. coli, Salmonella, Campylobacter, Mycoplasma, and Chlamydia spp.149 Bacterial infections of the uterus resulting in endometritis can be responsible for infertility, abortion, stillbirths, and fetal death. Treatment of endometritis differs in the presence of pregnancy (live fetuses) in part because of potential injury to developing fetuses. Regardless of the antimicrobial, any type of placentation is sufficiently intimate to allow movement of drug administered to the dam or queen to cross the placenta and enter the fetus. In general, however, the fetus can excrete water-soluble drugs more easily than lipidsoluble drugs because water-soluble drugs can be eliminated in the allantoic fluid. In contrast, drug-metabolizing enzymes of the fetal liver are immature and essentially nonfunctional. Although metabolizing activity increases as the term of pregnancy ends, activity remains sufficiently weak that drug elimination is probably ineffectual. Thus lipid-soluble drugs tend to remain in the fetus. When possible, drugs that are water soluble should be selected for treatment of infections in the pregnant bitch.

The beta-lactams are preferred with amoxicillin combined with clavulanic acid or a cephalosporin as first choice, assuming the target organism is included in the spectrum. Care should be taken to avoid cephalexin if an E. coli is suspected. Culture and susceptibility data should be the basis for antimicrobial selection for treatment of endometritis, even if antimicrobials are begun before results are received. Should susceptibility data indicate beta-lactams as resistant, aminoglycosides can be used. Pediatric (and presumably fetal) canine kidneys are protected from aminoglycoside damage because the cortical regions do not fully develop until several weeks postpartum. Fluoroquinolones also appear to be safe for the developing fetus (e.g, enrofloxacin at 15 mg/kg), although the risk of cartilage damage even in the developing fetus might lead to an alternative class of drugs. Response to antimicrobial therapy is indicated by resolution of vaginal discharge, which

should occur within several days of beginning therapy. Therapy should continue for 2 to 3 weeks.¹⁴⁹ In the case of fetal death, prostaglandin therapy may be indicated to evacuate the uterus. Evidence of septicemia indicates more dramatic and aggressive therapy (see the section on bacteremia).

Pyometra

Although bacterial infection is secondary to the cystic changes associated with pyometra, the infection is the primary cause of illness and death. Organisms most commonly associated with pyometra include E. coli (the majority of infections), hemolytic Streptococcus, Staphylococcus, Klebsiella, Pasteurella, Pseudomonas, Proteus, and Moraxella spp.¹⁵⁰ Wadas and coworkers128 demonstrated that E. coli associated with pyometra in dogs was derived from fecal flora and was also identical to those simultaneously cultured from the urine. Hagman and Kühn¹⁵¹ confirmed that E. coli was from the normal flora and was the same as that cultured from the urinary bladder. Host and microbial factors (see Chapter 6) play a large role in the pathogenesis of pyometra and response to drug therapy. In addition to the obvious impact of inflammatory and other debris on antimicrobial efficacy, the local immune response of the uterus is impaired.¹⁵⁰ Complications such as bacterial peritonitis and endotoxin contribute to mortality. Endotoxin concentrations generally are increased before implementation of drug therapy, further complicating antimicrobial selection.¹⁵⁰

Surgical removal of the infected uterus is the treatment of choice; however, antimicrobial therapy should be implemented regardless of whether ovariohysterectomy is performed. Prostaglandin therapy may be implemented in selected cases (see Chapter 23).

Culture and susceptibility data should be collected before empirical therapy with a bactericidal drug that includes E. coli in its spectrum is begun. Although a beta-lactam antibiotic is generally an excellent first choice, concern with rapid cell death and release of lethal quantities of endotoxin should lead to (1) selection of a carbapenem (meropenem or imipenem), the beta-lactam associated with the least endotoxin release; (2) combination therapy with a non-beta-lactam antimicrobial (e.g., an aminoglycoside or fluorinated quinolone) that is administered before (1 to 2 hours) the beta-lactam; or (3) slow administration of the beta-lactam, perhaps over the course of 1 hour. Therapy for pyometra should include supportive measures such as fluid rehydration and, if indicated, therapy for endotoxic shock. Glucocorticoid therapy is discouraged unless the patient is characterized as adrenocortico-deficient (see Chapter 30).

RESPIRATORY TRACT INFECTIONS

Principles of Antimicrobial Treatment

A major barrier to passive drug movement from the blood to the site of infection in the respiratory tract is the bronchialalveolar-blood barrier.^{152,153} Whereas drugs of a molecular weight up to 1000 can move easily through the open junctions of the capillaries, drugs must passively diffuse through the tight junctions of the alveolar epithelial cells.¹⁵² Movement of drugs into bronchial secretions occurs primarily by passive diffusion and is more likely to occur for drugs with favorable physiochemical characteristics such as high lipophilicity and low molecular weight (<450). Few drugs achieve concentrations in respiratory tissues equal to concentrations in the plasma.¹⁵⁴ Thus achieving simply the MIC in the plasma against an organism infecting the respiratory tract is likely to result in therapeutic failure.¹⁵⁴⁻¹⁵⁶ Rather, the targeted plasma drug concentration must be sufficiently great to ensure that the MIC will be reached at the site of infection. The relationship between plasma and bronchial drug concentrations can be described by the partition ratio, 152, 153 which is the area under the plasma drug concentration versus time curve in plasma divided by the same in bronchial secretions. Such a relationship would compare not only peak concentrations but also the time that drug stays in tissues, which generally is longer than in plasma. Collection of sequential bronchial secretion samples necessary for kinetic analysis is, however, difficult, and such information currently is not available for many drugs. A more practical relationship is the ratio of bronchial drug concentration to plasma drug concentration. This ratio has been established for a number of antimicrobial drugs and is often available in package inserts and textbooks. The ratio can serve as a basis for antimicrobial selection and dose manipulation.^{152,153} Ratios can be further manipulated to take into account phagocytic accumulation of antimicrobials.154

Among the antimicrobial classes, the penicillin antibiotics are characterized by one of the lowest plasma to bronchial tissue drug concentrations (mean of 9%), although variation exists among the individual drugs (see Table 7-5). For example, amoxicillin reaches four to five times higher concentrations in bronchial secretions than ampicillin when given at the same dose, although this is probably due to higher plasma concentrations.^{152,153} As little as 1% of some beta-lactams and no more than 23% of plasma amoxicillin, however, reaches bronchial secretions. An exception can be made for meropenem, which appears to reach approximately 50% of plasma concentrations (see Table 7-5). The cephalosporins may be distributed slightly, albeit probably not clinically, better than the penicillins (mean of 15%), again with variation among the individual members. For example, cephalexin achieves only 15% of plasma concentrations, whereas cefoxitin and cefotaxime reach 25% of plasma concentrations. Selected third-generation cephalosporins may reach even higher concentrations.^{152,153}

KEY POINT 8-28 Among the antimicrobial classes, the penicillin antibiotics are characterized by one of the lowest (often less than 10%) plasma to bronchial tissue drug concentrations.

Of the aminoglycosides, amikacin distributes into bronchial secretions somewhat better than most beta-lactams, generally reaching 20% to 30% of plasma concentrations. Clindamycin achieves 61% of plasma concentrations. Tetracyclines, and particularly doxycycline (38%) and minocycline, can reach 30% to 60% of plasma concentrations after a single dose. Macrolides such as erythromycin generally distribute well into bronchial secretions (41% to 43%), although newer drugs such as azithromycin (which can accumulate up to 200-fold in pulmonary tissues) distribute much better than erythromycin.^{152,153} The fluoroquinolones reach 70% or more of plasma concentrations; they also accumulate over fiftyfold to a 100-fold in alveolar macrophages. The potentiated sulfonamides have variable distribution. Whereas trimethoprim reaches 100% of serum concentrations in bronchial fluid, the sulfonamide component may achieve much lower concentrations. For example, sulfamethoxazole achieves only 18% of serum concentrations. Metronidazole, useful for anaerobic infections, achieves 100% of plasma concentrations in respiratory secretions.^{152,153} For drugs with a long elimination half-life (e.g., doxycycline, the azalides), the ratios of bronchial concentrations to plasma concentration may increase with repetitive dosing as drugs accumulate.152,153

Inflammation generally increases concentrations of selected antibacterials (e.g., beta-lactams and aminoglycosides) in bronchial secretions because of local vasodilation and vascular permeability. Excessive inflammation can, however, preclude antimicrobial distribution (Figure 8-8).^{152,153} In such instances, a drug that accumulates in white blood cells should be considered. Mucus produced in response to a bacterial infection in the respiratory tract can also interfere with antimicrobial therapy.^{152,153} Aminoglycoside efficacy may be decreased by chelation with magnesium and calcium in the mucus. Antimicrobials may bind to glycoproteins, and mucus may present a barrier to passive diffusion. In addition, some antimicrobials may alter function of the mucociliary apparatus, either by increasing mucous viscosity or decreasing ciliary activity (e.g., tetracyclines). Because of these negative effects, drugs that decrease mucous viscosity (e.g., expectorants or bromhexine, a drug available outside of the United States) or are mucolytic (e.g., acetylcysteine) may facilitate antimicrobial therapy.^{152,153} Cysteine-containing drugs may facilitate penetration of antimicrobials.¹⁵⁷ N-acetylcysteine may be given by any route and reach effective concentrations in the lung. In addition to its mucolytic effects, the drug imparts some antiinflammatory effects (oxygen radical scavenging) and appears to help bacterial penetration of the mucopolysaccharide capsule of gram-negative bacteria. The use of N-acetylcysteine is addressed in Chapter 20.

Increasingly, the nonantimicrobial benefits of selected antimicrobial drugs are being realized. The effects of long-term azithromycin use on lung function and progression of cystic fibrosis is discussed later in this chapter. The azolides have demonstrated synergistic effects against *P. aeruginosa* with a number of antimicrobials (see the discussion of bacterial rhinitis and sinusitis).

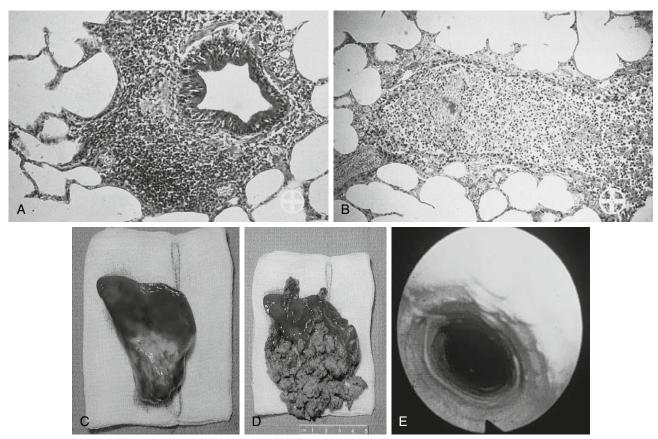

Figure 8-8 The accumulation of inflammatory debris in the peribronchiolar region (A), the alveolus (B), lung lobe (C and D), or trachea (E) is likely to impair drug distribution to the site of infection and may hinder the activity of the drug that is able to penetrate the debris. (Courtesy Bayer Animal Health.)

Bacterial Rhinitis and Sinusitis in Cats

Pathophysiology

The pathophysiology of bacterial rhinitis and sinusitis has not been confirmed in cats, but the role of viral disease in chronic infection increasingly is evident (see the section on microbial targets). Acute manifestations of rhinitis are likely to reflect viral infections; causative agents include FHV-1 (generally identified as the causative agent in the majority of cases), FCV, and *Chlamydia* spp.

Viruses can cause profound local changes in the respiratory epithelium of upper airways. In humans rhinoviral adherence to the epithelium upregulates production of biogenic amines, tumor necrosis factor (TNF), and other cytokines, as well as leukotrienes.¹⁵⁸ At the same time, viruses suppress local immune response. The negative impact of viral infections on local (and potentially systemic) immune mechanisms, particularly if coupled with lysis of nasal turbinates, as can occur in cats, likely predisposes the nares and sinuses to secondary bacterial infection. As the syndrome progresses, the role of viral organisms is likely to become less important. The loss or reduction of mucociliary tract function probably has a profound impact on the pathophysiology of respiratory tract infections in dogs and cats (see Chapter 20). Impaired removal of inflammatory and bacterial debris or bacterial biofilm allows accumulation and retention of material that not only is responsible for clinical signs (e.g., sneezing) but also contributes to infection by promoting an environment conducive to microbial growth. Successful therapy is confounded by (presumed) limited drug distribution to the nares and sinuses, particularly in the face of chronic inflammatory debris. Bacterial adherence to epithelial cells might also profoundly affect therapeutic success. Initial clinical response may be followed by recrudescence of clinical signs and failed response to repeated antimicrobial therapy.

KEY POINT 8-29 Although the initial role of viruses in the pathophysiology of upper respiratory disease is clear, the role of bacteria in perpetuating the syndrome is not clear despite multiple studies that have demonstrated a microbial presence.

Complicating the treatment of chronic sinusitis is the inability to discriminate commensal organisms from pathogens (see Chapter 6). Culture of nasal flushes may be a better means to assess infection than rhinoscopy-guided biopsy.¹⁵⁹ Cytology may be important in distinguishing a bacterial infection from sinusitis that is primarily chronic allergic inflammatory in origin and more likely to respond to immunomodulatory therapy (see Chapter 20). Properly identifying an infectious cause helps prevent the indiscriminate use of antimicrobials, which may contribute to the emergence of resistant bacterial infection.

Microbial Targets

Several studies have addressed the microbes associated with upper respiratory disease in cats, with varied results. Variability reflects, in part, variation in study methods and often

failure to discriminate commensals from infection. A common void is lack of data in control animals. Johnson and coworkers¹⁶⁰ have studied the organisms associated with rhinosinusitis in affected (10) cats, comparing the flora to normal cats (7). Aerobic bacteria were present in 5 of 7 normal and 9 of 10 affected cats; Mycoplasma spp. was present in only 2 of 10 diseased cats. Potential pathogens were cultured more frequently from diseased cats, but it was not clear if their growth reflected infection as opposed to colonization of previously diseased tissue. FHV-1 was detected using polymerase chain reaction (PCR) in 4 of 7 normal cats and 3 of 10 diseased cats. Bordetella bronchiseptica was cultured in 1 cat with disease that had been vaccinated with the same strain. In the review Johnson and coworkers¹⁶⁰ also indicated that a previous study (by the same investigators) found that swab culture of 15 of 21 cats with rhinitis yielded Pseudomonas spp. (53%) and E. coli (40%). Both Pasteurella (4 of 11) and Pseudomonas spp. (7 of 11) also have been cultured from the frontal sinuses of affected cats.

Bannasch and Foley¹⁶¹ evaluated pathogens in animal shelter cats that were either normal (n = 259) or afflicted with clinically mild to severe upper respiratory infection (n = 314). The proportion of all isolates identified for all cats were FCV (54.7%), FHV-1 (28%), Mycoplasma spp. (14.4%), B. bronchiseptica (9.5%), and C. felis (2.8%). Unfortunately, the incidence of pathogens in controlled versus affected cats was not described, limiting interpretation of the role of pathogens in disease. More recently, Spindel and coworkers¹⁶² cultured cats with feline rhinitis before a clinical trial. Organisms most frequently cultured or detected based on PCR from nasal swabs included FHV-1 (75%), Mycoplasma spp. (75%), and Bordetella spp. (47.5%). Additionally, Staphyoloccoccus and Streptococcus were recovered in 12.5% and 10% of cases, respectively. Hartmann and colleagues¹⁶³ prospectively studied cats (n = 39) presented to a veterinary teaching hospital with clinical signs of upper respiratory disease or conjunctivitis. Cats were tested for FCV, FHV-1, C. felis, and Mycoplasma spp.; 37 of 39 cats had at least one organism present. Both C. felis and Mycoplasma spp. were each present in approximately 50% of cats, with both present in 28% of cats and neither in approximately 5%. The role of other microorganisms was not addressed. Finally, Veir and coworkers¹⁶⁴ described bacterial and viral pathogens isolated from nasal and pharyngeal swabs in affected (acute rhinitis) cats (n = 52). However, the impact of the findings on the relevance to clinical signs was limited by the lack of studies in control cats. Cultures in affected cats included an anterior nares swab (using a urethral swab after mucus was removed) and pharyngeal swabs from the oropharyngeal area. Infectious organisms were also detected using PCR for FHV-1, FCV, Mycoplasma, and Chlamydia spp. Eleven different organisms were cultured from nasal swabs, with the most common being Mycoplasma (48%) and Pasteurella spp. (32%). Thirteen different organisms were cultured from the pharyngeal swab, with the most common being Pasteurella (73%), Mycoplasma (52%), and Moraxella spp. (21%); Flavobacterium spp. was cultured from 17% of animals. Pharyngeal and nasal swabs matched in only 12% of the animals. Bordetella sp. was present only in nasal swabs (n = 3; 5%). FHV-1 was detected in 69% of the nasal swabs despite being PCR positive in 82% of cases. The authors considered B. bronchiseptica, C. felis, FCV, and FHV-1 as the primary pathogens, although detection of FHV-1 did not always indicate infection. Nine afflicted cats were negative for primary organisms in nasal culture but positive in pharyngeal culture. Agreement between nasal and pharyngeal data was considered moderate for FHV-1 and Mycoplasma PCR; substantial for FHV-1 isolation, Mycoplasma culture, and FCV; and perfect for C. felis. Collection of nasal swab data was described as difficult, time consuming, and uncomfortable for the subjects. The authors concluded that information yielded from aerobic culture of either nasal discharge or pharynx of cats is not sufficiently useful to justify collection; accordingly, empirical therapy was suggested by the authors. Previous studies had revealed that 80% of aerobic (non-Mycoplasma spp.) isolates were susceptibile to amoxicillin-clavulanic acid, cephalosporins, chloramphenicol, enrofloxacin, and tetracylines.

Based on these studies, although consensus has not been reached, the most likely initiating pathogens associated with rhinitis are FHV-1 and FCV. If bacteria are involved in the initiation, *Mycoplasma* spp., *B. bronchiseptica*, and *C. felis* are the primary bacterial causes.¹⁶² Previous antimicrobial history might be important for discerning the role of gram-negative organisms, particularly in sinusitis.

Antimicrobial Drugs and Treatment

Care must be taken to ensure proper antimicrobial selection and dosing regimen in to minimize the advent of resistance in upper respiratory tract infections. Indiscriminate therapy must be avoided. As infection becomes chronic, persistent antimicrobial therapy is likely to encourage development of resistant organisms through antimicrobial selection pressure. Although the normal lung may be well perfused, marked inflammatory debris will affect the ability of the drug to reach the site in effective concentrations (see Figure 8-8). Drug distribution to normal bronchial or sinus secretions is limited; inflammatory debris may pose an even greater risk of poor delivery. Even drug concentrations that achieve the MIC of the infecting organisms may contribute to antimicrobial failure. As weaker organisms die (e.g., P. multocida), persistent environmental changes coupled with the continued presence of antimicrobials will select the more hardy organisms (e.g., B. bronchiseptica). Eventually, organisms largely resistant to most clinically relevant bacteria (e.g., P. aeruginosa) emerge. In part because of the concern of emerging resistance and the desire to avoid the indiscriminate use of antimicrobials, fever in humans with acute rhinitis is not to be interpreted as secondary bacterial infection, nor is a change in the color of the discharge. Secondary bacterial infection is considered in cases for which acute clinical signs persist for 10 days or more or worsens after 5 to 7 days. Treatment is implemented for 10 to 14 days.158

Curing chronic rhinitis or sinusitis in cats may be an unreasonable expectation, particularly if damage to nasal turbinates precludes adequate mucociliary tract function or other local immune protections. Control of clinical signs, particularly

during flare-ups, may be a more reasonable expectation. Little information exists regarding the role of bacteria in persistence of infection, but human patients with cystic fibrosis are frequently infected with P. aeruginosa, so much so that its appearance is generally associated with a downward spiral in clinical response. Consequently, much research has focused on infection by this organism, some of which may apply to cats with chonic sinusitis or rhinitis. The propensity of infection of cystic fibrosis patients with P. aeruginosa may reflect, in part, adherence of the organism to epithelial cells as well as generation of biofilm.¹⁶⁵ Isolates causing infection appear to be different from isolates infecting other tissues. Biofilm may be induced by the presence of hypoxia and appears to be associated with resistant organisms; low oxygen tension also may cause emergence of the more resistant, nonmucoid pseudomonad organisms. Hypermutability of the organism has been associated with antimicrobial-induced selection pressure.¹⁶⁵ "Late" infection with Burkholderia sp. and aspergillosis has been recognized.

Although chronic sinusitis or rhinitis is generally not life threatening in cats, a therapeutic approach similar to that for cystic fibrosis might be reasonable. Thus focusing on removal of organized bacterial debris is an important component of therapy.¹⁶⁶ Two rules of antimicrobial therapy recommended in patients with cystic fibrosis may apply to chronic sinusitis or rhinitis: (1) Antimicrobial selection should be based on periodic isolation and identification of pathogens and their susceptibility, and (2) indiscriminate use should be avoided. Rather, a rational, clinical endpoint should be considered in the context of duration of therapy.¹⁶⁵ Even with appropriate culture techniques, identifying the infecting organism may be difficult. For example, nonmucoid Pseudomonas spp., which tends to cause early infections in humans with cystic fibrosis, is slow growing and harder to culture, making MIC determination more difficult.

KEY POINT 8-30 Effective therapy of URI in cats may depend more on adjuvant therapy that alters the environment rather than repetitive antimicrobial therapy. Antimicrobial therapy might be approached with the goal of control, rather than cure, with dosing regimens designed to ensure eradication of infection with each therapeutic interlude.

When the decision to use antimicrobials is made, their use should be aggressive, designed to achieve effective concentrations—sufficient to kill even the potential mutants. Lipid-soluble drugs and drugs that concentrate in phagocytic cells should be considered; as infection progresses, combination (double to triple) therapy should be implemented. Pulse dosing at intervals sufficiently long to allow the microflora to normalize as much as possible is a reasonable approach. Early antipseudomonadal therapy designed to eradicate infection is recommended in humans with cystic fibrosis to prevent infection by resistant pseudomonads. Long-term azithromycin appears to improve lung function and slow the progression of the disease in humans with cystic fibrosis and increasingly is included in

the therapeutic regimen.^{167,168} The effects of azithromycin may be immunomodulatory insofar as they occur at concentrations below the MIC of the infecting organisms. Proposed mechanisms have included, among others, a reduction in inteleukins (IL)-1β, IL-8, and neutrophils in bronchoalveolar lavage fluid; reduction in immune complexes directed toward the biofilm produced by mucoid P. aeruginosa; and impaired adherence of P. aeruginosa to the epithelium.¹⁶⁹ Azithromycin and clarithromycin also have exhibited in vitro synergistic effects against both mucoid and nonmucoid P. aeruginosa. The most active combinations demonstrating synergy in patients with cystic fibrosis were azithromycin-sulfadiazine-trimethoprim and azithromycin-doxycycline. Azithromycin occasionally demonstrated synergism when combined with extended-spectrum beta-lactam antibiotics (meropenem, imipenem, and others), ciprofloxacin, chloramphenicol, and tobramycin.¹⁷⁰ Azithromycin has a long half-life in lung tissues of cats (see Chapter 7) and is a reasonable choice for combination, but not sole, therapy of cats with sinusitis infected with Pseudomonas spp. Care should be taken in using antistaphylococcal drugs (unless specifically indicated on the basis of culture and susceptibility data) because of the potential advent of MRS.¹⁶⁵ When used, doses should be modified to ensure concentrations that well exceed the MIC of the infecting organisms for most of the dosing interval.

Several clinical trials have examined the efficacy of selected antimicrobials. The efficacy of amoxicillin (22 mg/kg by mouth bid, tablet form) was compared with that of azithromycin (15 mg/kg by mouth; n = 10) in shelter cats (n = 31) suspected to have bacterial rhinitis (on the basis of nasal discharge). Treatments were randomized, but blinding was not addressed; negative controls were not included.¹⁷¹ Animals had been cultured before initiation of antimicrobial therapy.¹⁶⁴ Response was based on clinical signs assessed before and every 3 days until infection resolved. Failures in one group were subsequently crossed over to the alternative drug for an additional 9 days. For azithromycin, 3 of 10 cats (30%) initially responded, whereas 6 were switched to amoxicillin. For amoxicillin 8 of 21 (38%) responded, whereas 13 were switched to azithromycin. In the second treatment period, 5 of 10 (50%) responded to amoxicillin, and 3 of 6 (50%) responded to azithromycin. No differences were detected in clinical outcome or scores at cross-over; the limitation may be sample size. At the time of the report, the cost of amoxicillin treatment (drug alone) was approximately 35% of that for azithromycin, but the inconvenience of twicedaily dosing was not included in the cost assessment. However, some limitations of this study complicate interpretation. No loading dose was given for azithromycin; therefore azithromycin was not quite at steady state at the 9-day crossover time, and treatment did not occur while drug concentrations were at steady state. For the same reason, because a washout was not implemented to accommodate for the long half-life of azithromycin, those cats switched from azithromycin to amoxicillin were likely to have significant azithromycin concentrations during at least 6 days of the second treatment period.

Pradofloxacin (5 mg/kg [n = 13] or 10 mg/kg [n = 12] qd) also has been compared with amoxicillin (22 mg/kg every 12 hr; n = 15) for treatment of feline rhinitis in shelter cats

(n = 40) using a randomized design (blinding not addressed; no control included); cats that failed the first therapy (7 days' duration) were treated with the alternative therapy.¹⁶² Organisms most frequently cultured or detected based on PCR from nasal swabs included FHV-1 (75%), *Mycoplasma* (75%), and *Bordetella* spp. (47.5%). Additionally, *Staphyloccoccus* and *Streptococcus* were recovered in 12.5% and 10% of cases, respectively. Response rates were 67% for amoxicillin and 85% and 92%, respectively, for 5 and 10 mg/kg pradofloxacin. Differences were not statistically significant, but this may reflect the small number of animals: All except one cat that failed initial therapy responded to the second therapy. Because cats that were infected with *Mycoplasma* spp. responded after treatment with amoxicillin (n = 3), *Mycoplasma* spp. may not have been associated with infection.

Although the contribution of Chlamydia spp. to upper respiratory infection (URI) is less clear, several studies have examined reponse to therapy. Experimentally induced C. felis was not eradicated, but clinical signs resolved in cats receiving 10 to 15 mg/kg azithromycin for 3 days, followed by twice-weekly for 3 weeks. In contrast to azithromycin, infection was eradicated at 5 to 10 mg/kg doxycycline for 3 to 4 weeks.¹⁶ Differences in the pathogenicity among strains may complicate application of the experimental infections to spontaneous disease; however, studies suggest that azithromycin may not offer sufficient advantages to doxycycline for treatment of chlamydiosis in cats.¹⁶ Hartmann and coworkers¹⁶³ prospectively studied cats (n = 39) presented to a veterinary teaching hospital with clinical signs of upper respiratory disease or conjunctivitis. Cats were tested for FCV, FHV-1, C. felis and Mycoplasma; 37 of 39 cats had at least one organism present with the breakdown as follows: FCV (72%), C. felis (59%), Mycoplasma spp. (46 to 64%), FHV (28%) and the combination of C. felis and Mycoplasma spp. (28%) or FHV-FCV (13%); 10% had all four organisms present. The study was placebo controlled and double blinded; all cats were randomly assigned to receive either doxycycline (5 mg/kg bid by mouth) or pradofloxacin (5 mg/kg qd) for 42 days. Cats in both groups responded within 1 week of therapy, including those cats with viral, but not microbial, infection. Mycoplasma spp. was eliminated in all cats; C. felis was eliminated in all doxycycline-treated cats (n = 22) but remained in 4 of the 17 pradofloxacin-treated cats.

Inhalant therapy coupled with systemic therapy prolongs duration of eradication (mean of 8 months extended to 12 months) of *Pseudomonas* spp. infections in human patients with cystic fibrosis. However, the depth of penetration of sinuses in cats with inhaled therapy is questionable. Nevertheless, inhalant therapy should be helpful if coupled with appropriate systemic therapy. The ability to achieve high aminoglycoside concentrations in the presence of mucoid material is important because of the negative effects such debris has on aminoglycoside therapy; inhalation of aminoglycosides (28 days on, 28 days off) has been successful as sole therapy in humans with cystic fibrosis. The use of topical (e.g., ophthalmic solution) aminoglycoside therapy often implemented by clinicians dealing with chronic sinusitis in cats might provide therapeutic benefits similar to inhalant therapy; however, inhalant therapy also should be considered. Aerosolization of polypeptides such as polymyxin–colistin whose systemic use is precluded by systemic toxicity also has been used in human patients to treat *Pseudomonas* infections. Aerosolized doses of 500,000 to 1 million IU of colistin twice daily (potency of 30,000 IU/mL) have been used for several months.¹⁶⁵ Aerosolization of beta-lactams might also be considered.

Facilitating removal of bacterial and host debris, although important, may be difficult. Use of drugs intended to "dry" secretions (i.e., decongestants, antihistamines) generally are not prudent unless serous secretions (e.g., those associated with acute viral infection) are prolific. Methods of assisted mechanical clearance used in human patients are not likely to be effective in the upper airway disease of cats. Recombinant human DNase digests polymeric extracellular DNA and reduces the viscosity of pulmonary secretions; as such, it has become the cornerstone of mucolytic therapy in patients with cystic fibrosis. The drug is delivered by inhalation and is generally used as maintenance rather than limited to acute exacerbations. Cost may preclude its use in cats. Inhaled hypertonic saline has also increased fluidity of secretions; pretreatment with adrenergic agonists may be prudent to minimize the risk of irritant bronchoconstriction. The use of N-acetylcysteine as a mucolytic is described in Chapter 20.

The efficacy of once daily L-lysine (250 mg if less than 5 months or 500 mg if greater than 5 months of age) was studied for its impact on emergent URI in animal shelter cats (n = 144 treated and 147 nontreated cats). No difference was found in the subsequent incidence of URI that emerged between the two treatment groups.¹⁷²

Bacterial Tracheobronchitis

Pathophysiology

Infectious tracheobronchitis is a contagious disease in dogs. Although it is generally mild and self-limiting, it can become serious, particularly if multiple bacteria become involved. Likelihood of infection reflects, in part, variability among strains. Host ciliated epithelial cell receptors are recognized by fimbrial and nonfimbrial filamentous (hemagglutinin and pertactin) adhesions. Upon colonization, exotoxins (adenylate cyclase-hemolysin, dermonecrotic toxin, and tracheal cytotoxin) and endotoxin impair the host response (e.g., phagocytosis, humoral and cell-mediated response) and cause local damage. Recent evidence suggests the organism may not be limited to an extracellular location but may survive intracellularly under some conditions.¹⁷³ The mucosal defense generally is able to clear most organisms within 3 days of infection. Bordetella spp. will, however, persist for up to 14 weeks after infection.174,175 Active attachment to cilia and ciliostasis induced by Bordetella spp. appear to be important reasons for bacterial persistence. Whereas the disease generally is self-limiting to 7 to 10 days' duration, systemic signs indicative of pneumonia dictate the need for antimicrobial therapy.

KEY POINT 8-31 Canine tracheobronchitis generally is a selflimiting disease, with antimicrobial therapy generally not indicated unless infection persists beyond 7 to 10 days.

Microbial Targets

B. bronchiseptica remains the primary bacterial pathogen associated with infectious tracheobronchitis in dogs and appears to be the only agent that has induced classic kennel cough either experimentally or spontaneously. However, other viral organisms (e.g., canine parainfluenza virus and canine adenovirus type-2) may initiate or complicate the syndrome and Mycoplasma spp. may worsen it.¹⁷³ Chalker and colleagues¹⁷⁶ reviewed the role of pathogens and specifically mycoplasmas in canine respiratory disease. Dogs were from two groups: a rehoming kennel with a history of endemic canine infectious respiratory disease (n = 210; samples collected from nonvaccinated dogs with variable clinical signs during 1999 to 2002) and a training center (n = 153; dogs vaccinated regularly, with only sporadic outbreaks). At least 12 different Mycoplasma spp. were cultured from both groups of animals, with isolates obtained from tonsillar, tracheal, and bronchial lavage samples. Isolates were speciated on the basis of PCR. Differences in the two groups were limited to the lower respiratory tract (Mycoplasma cynos); its presence was associated with an increased severity of disease. Previous studies by the same group in the same rehoming facility based on bronchial alveolar lavage (n = 209) indicated that canine respiratory coronavirus predominated in dogs with mild disease, B. bronchiseptica in dogs with moderate disease, and Streptococcus equi subsp. zooepidemicus in dogs with severe disease, with the bacterial load being greater in dogs with more severe disease.¹⁷⁷ Pasteurella spp. may also be involved (as reviewed by Chalker et al.¹⁷⁷)

Therapy should be based on culture and susceptibility data because organisms other than Bordetella spp. frequently complicate infection. It is likely that Mycoplasma spp. also play a role in infectious tracheobronchitis in dogs, and drug selection should include this organism. Despite the presence of other organisms, once the need for antimicrobial therapy is identified, therapy should include a drug with known efficacy against B. bronchiseptica (see later discussion). Culture of B. bronchiseptica does not necessarily indicate infection; the significance of growth depends on the number of colonies and sample location. Whereas isolation from the trachea is significant, isolation from the nares or pharynx is likely to be significant only if growth is moderate to heavy.¹⁷⁸ First-choice antimicrobials generally include the tetracyclines, chloramphenicol, and the macrolides (including erythromycin, clarithromycin, and azithromycin). Fluoroquinolones should be based on culture and susceptibility support. Glucocorticoids should not be used in the presence of bacteriostatic drugs; alternative mechanisms to control cough (e.g., narcotic antitussives) should be considered. Prophylaxis might be considered in animals exposed to B. bronchispetica; treatment, however, is not always indicated because the disease tends to be self-limiting.

Because of the location of the organism and the difficulty of drug penetration into bronchial secretions, aerosolization of selected antimicrobials (aminoglycosides, polymyxin B) should be considered as an adjunct to systemic antimicrobial therapy for kennel cough. Systemic therapy should include a drug that penetrates bronchial secretions well. Drugs with known in vitro efficacy against both *B. bronchiseptica* and *Mycoplasma* spp. include the fluoroquinolones, doxycycline or minocycline, chloramphenicol, and the macrolides. Among these, only the fluoroquinolones typically are associated with bactericidal concentrations. Accumulation of the macrolides in lung tissue may, however, result in bactericidal concentrations of these otherwise bacteriostatic drugs. Vaccination should be used to immunize dogs against the primary pathogens of infectious tracheobronchitis.

Bacterial Pneumonia

Bacterial pneumonia is much more common in dogs than in cats.

Microbial Targets

Although B. bronchiseptica and S. zooepidemicus are among the bacterial organisms commonly associated with pneumonia, many other organisms can cause infection, including E. coli, Pasteurella, Klebsiella, Staphylococcus, and Pseudomonas spp.¹⁷⁵ The potential for Mycoplasma spp. and anaerobic organisms (particularly in the presence of abscessation) as a cause of infection should not be ignored. Generally, the respiratory tract is sterile below the larynx. Mycoplasma spp. were associated with pneumonia in cats on the basis of isolation in large numbers and pure growth. Clinical signs resolved on treatment with doxycycline or ciprofloxacin, potentially supporting their role.¹⁷⁹ Foster and coworkers¹⁸⁰ also retrospectively reviewed the microbiology associated with lower respiratory tract infection in cats (n = 21; Australia); isolates were collected by bronchoalveolar lavage between 1995 and 2000. Organisms were identified as pathogens on the basis of purity of growth, absence of oral contaminants, and a review of supportive clinical signs and diagnostic indicators (e.g., radiographs). Mycoplasma spp. was the sole pathogen in 11 of 19. Other infecting organisms included a combination of Mycoplasma spp. with P. multocida, or B. bronchiseptica. Pasteurella spp. was a cause of infection with other microbes in two other animals. Other infectious organisms include toxoplasmosis, cryptococcosis, mycobacterium, and miscellaneous bacteria. Other studies reporting on the bacteria associated with airways of healthy cats have identified Pasteurella spp., Pseudomonas spp., Staphylococcus spp., Streptococcus spp., E. coli, and Micrococcus spp. Those organisms most commonly reported as the causes of pneumonia in cats included P. multocida, E. coli, K. pneumoniae, B. bronchiseptica, Streptococcus canis, Mycobacterium spp., and Eugonic Fermenter-4.

Antimicrobial and Adjuvant Therapy

Cytology and culture collected by tracheal wash, bronchoscopy, bronchoalveolar lavage, or lung aspiration should serve as the basis for treatment. Cultures of the pharyngeal area should not be the basis of antimicrobial selection for infections of the respiratory tract. The more severe the infection, the more important lipid solubility becomes to drug selection and the greater the need to choose a drug that accumulates in inflammatory cells. Doses should be sufficiently high to establish bactericidal concentrations of drug at the site of infection. Among the antimicrobials, fluoroquinolones such as enrofloxacin should be considered because of their spectrum and lipid solubility. In addition, accumulation by alveolar macrophages might enhance drug distribution at the site of inflammation.^{63,65-67} Accumulation has been documented for enrofloxacin, marbofloxacin, and pradofloxacin. Combination therapy should be considered to not only broaden the spectrum of antimicrobials but also to enhance efficacy. Aerosolization should be considered in addition to (never instead of) systemic antimicrobial therapy, particularly in severe cases. Aerosolization may be particularly important for infections associated with *B. bronchiseptica*.

Mobilization of respiratory secretions may be important to resolution of infection. In addition to physical techniques such as coupage, mucolytic and mucokinetic agents should be administered. Bronchodilators may also facilitate movement of respiratory secretions as well as facilitate airway movement. Their use is controversial, with some authors suggesting that their antiinflammatory effects may be detrimental. As such, control of inflammation in a nonimmunosuppressive manner may be of benefit. Therefore theophylline should be considered because of its antiinflammatory effects. Theophyllilne can cause ventilation perfusion mismatching, and oxygen therapy should be available to patients when this drug is administered in moderate to severe cases. Alternatively, β_2 -selective bronchodilators such as terbutaline may be indicated; they may also facilitate ciliary activity by decreasing viscosity of airway secretions. Combination therapies also should be considered (e.g., theophylline, terbutaline) to facilitate bronchodilation. N-acetylcysteine (200 to 500 mg orally or intravenously bid) should be considered for adjuvant therapy in infections associated with marked inflammatory debris. Intravenous administration (e.g., Mucomyst®) is preferred in patients whose clinical signs are indicative of serious or life-threatening inflammation. The drug will facilitate antimicrobial penetration through mucoid debris present at the site of infection but also through the lipopolysaccharide membrane of gram-negative organisms. Treatment might continue until resolution of radiographic signs indicative of pneumonia, which may require up to 6 weeks. The use of non-immune-suppressing antiinflammatories should be considered in the presence of fulminating inflammation. Among the bronchodilators that might be used, theophylline is the most effective antiinflammatory. Pentoxyfylline also might be considered (see Chapter 20). Drugs that decrease bronchial secretions, including diuretics, should be avoided. Further, dehydrated patients should be rehydrated to facilitate the functions of the mucociliary tract.

Pyothorax

Pathophysiology

Pyothorax, otherwise known as *empyema*, refers to the accumulation of white blood cells in the pleural space.¹⁸¹ Organisms reach the pleural space by direct introduction (most commonly by way of a foreign body), hematogenous or lymphatic spread, or extension from an adjacent structure.^{182,183} In cats, parapneumonic spread currently appears to be the most common route of infection. The physiologic forces that keep the pleural space essentially free of fluid are overcome

Figure 8-9 Intraoperative view of pyothorax in a dog. The inflammatory response can be profound, requiring analgesic therapy. Intrathoracic lavage with fluids containing heparin may increase the chance of long-term survival. (Photo courtesy of Harry W. Boothe, DVM, MS, DACVS, Auburn, AL.)

by inflammation, resulting in an increase in regional blood flow, capillary hypertension, increased capillary permeability, and increased oncotic draw (by inflammatory proteins) of fluid into the pleural space (Figure 8-9). Lymphatic drainage becomes progressively more important as oncotic draw into capillaries is lost, but accumulation of inflammatory debris and fibrosis ultimately preclude lymphatic drainage of the pleural space. Gram stain of fluids collected by thoracentesis can be a rapid method of diagnosing the bacterial cause of infection. The incidence of anaerobic organisms as either sole agents (particularly in cats) or in combination with other bacteria is high. Thus samples submitted for culture should include both aerobic and appropriately collected anaerobic specimens. The presence of a foul smell (reflecting the production of organic matter by-products) is supportive of infection by anaerobic organisms.

Microbial Targets

In cats anaerobes predominate as the causative organisms of pyothorax. Organisms include Bacteroideaceae (Bacteroides, Porphyromonas, and Prevotella spp.), Fusobacterium, Actinomyces, Nocardia, Peptostreptococcus, Clostridium, Propionibacterium, Pasteurella, and Mycoplasma spp. Barrs and Betty¹⁸² recently reviewed feline pyothorax and observed that infecting flora is similar to oropharyngeal flora. Aspiration of oral flora was suggested as the most likely mechanism of infection in 15 of 18 cats in one study.¹⁸³ Causative organisms in the dog include but are not necessarily limited to Fusobacterium, Actinomyces, Nocardia, Corynebacterium, Streptococcus, Bacteroides, Pasteurella, E. coli, Klebsiella, and Peptostreptococcus.¹⁸¹ The most common aerobic organisms isolated in dogs in a retrospective study were P. multocida (37%), followed by E. coli (26%); anaerobic organisms included Fusobacterium (13%) and Bacteroides spp. (10%). Actinomyces organisms were collected in 26% of the patients.¹⁸⁴ In a more recent retrospective

study of pyothorax in dogs Boothe and coworkers¹⁸⁵ found *E. coli* to be the most common infecting organism.

Both cytology and culture and susceptibility data should be an important component of antimicrobial selection for treatment of pyothorax. A retrospective study¹⁸⁵ revealed that empirical therapy resulted in inappropriate antimicrobial selection in 35% of the patients. Further, some dogs with cytologic evidence of infection yielded no growth on culture, whereas other dogs had no cytologic evidence of bacteria despite growth on culture. Multiple organisms should be suspected in all cases of pyothorax even if only a single culture is identified; infections were mixed in 46% of patients, with 65% of the organisms being gram negative, 17% gram positive, and 17% to 43% anaerobic.¹⁸⁵ Because such a high percentage of infections may involve anaerobic organisms, antimicrobial selection might most appropriately include drugs effective against anaerobes.

KEY POINT 8-32 Both cytology and culture and susceptibility data should be an an important component of antimicrobial selection for treatment of pyothorax.

Fungal organisms also should be considered as a cause of pyothorax.

Antimicrobial and Adjuvant Therapy

For both dogs and cats, nonsurvivors usually die or are euthanized within the first several days of hospitalization.^{182,183,185} Removal of inflammatory debris is a critical component of effective antimicrobial therapy for the patient with pyothorax. Drainage by thoracentesis alone is not likely to be effective; indeed, up to an 80% mortality rate can be expected with this approach. Progression to a chronic stage can be expected in many patients in whom drainage has been inadequate, increasing both mortality and cost compared with patients in whom drainage was adequate. Thus therapy should include chest tube drainage (potentially by continuous water seal suction at 20 cm).

Adequate hydration will be important to offset the risk of hypotension induced by continuous removal of pleural effusion. Effective removal of debris not only will remove mediators associated with morbidity but also will facilitate antimicrobial distribution. Response to antimicrobial therapy should be based on repeated cytology and Gram stains. Clinical signs and cytologic findings should improve once chest tube drainage is in place. Bacteria generally are undetectable 2 to 3 days after therapy is begun; however, serial cultures should be used to confirm the absence of growth. Antimicrobial selection should be based on culture and susceptibility data. Unfortunately, growth often does not occur despite cytologic evidence of bacteria. An anaerobic environment should be assumed even if aerobes are cultured because many of these organisms are able to survive and grow in an anaerobic environment.

Bilateral chest tube placement may be necessary in some patients, whereas surgical intervention may be critical to many. In a retrospective study of pyothorax in dogs, medical

management was successful (based on absence of disease for 1 year) in only 25% of dogs, as opposed to 78% that were surgically managed.¹⁸⁴ Boothe and coworkers¹⁸⁵ retrospectively compared drainage, chest tube-based drainage and lavage, and surgical intervention followed with chest tube placement in dogs (n = 46) with pyothorax. There was no difference in either short-term or long-term survival. In cats antimicrobial therapy coupled with needle thoracentesis is associated with a 50% to 80% mortality rate, indicating that chest tube placement with intermittent thoracic lavage is preferred.¹⁸³ Lavage not only facilitates exudate drainage but also dilutes inflammatory debris and the inoculum, which should facilitate antimicrobial penetration. Lavage may also cause débridement of pleura and breakdown of adhesions. Recommended lavage fluids include warmed 0.9% NaCl or lactated Ringers solution at a rate of 10 to 30 mL/kg with each lavage. Up to 25% of lavage fluid may not be recovered. Hypokalemia is a potential complication; it may be necessary to add potassium to lavage fluid. Use of intrapleural fibrinolytics in an attempt to reduce adhesions is generally discouraged. However, Boothe and colleagues¹⁸⁵ demonstrated that lavage with physiologic saline containing heparin (10 IU/mL) was positively associated with long-term survival in dogs with pyothorax. The addition of antimicrobial therapy to lavage fluid probably offers no added benefit and may be a detriment if it irritates the pleura.

Antimicrobials initially should be administered intravenously to ensure that the highest concentration reaches the site of infection. Once response is achieved, oral therapy can be implemented. Combination antimicrobial therapy should be considered for the treatment of pyothorax, in part because of the frequent mixed nature of infection. In particular, antimicrobials that are not effective in an anaerobic environment (e.g., aminoglycosides) should not be used as sole agents in the treatment of pyothorax. A penicillin should be considered with initial therapy because the spectrum includes anaerobic organisms and synergistic interactions that occur with a number of antimicrobials. However, limited susceptibility to aminopenicillins (ampicillin, amoxicillin) may indicate the need for extended-spectrum beta-lactams.¹¹⁵ Because many of the organisms (including anaerobes) associated with pyothorax produce beta-lactamases, protected drugs or drugs inherently resistant to beta-lactamases should be selected, although increasingly these drugs are also limited in susceptiblity. The use of cephalosporins for the treatment of pyothorax is generally not recommended because their efficacy against anaerobes is less than that of penicillins unless the anaerobic spectrum of the drug is confirmed (e.g., cefoxitin) or combination therapy is implemented. The aminoglycosides (particularly amikacin) are among the drugs to which Nocardia spp. is very susceptible and should be considered in combination with a beta-lactam for treatment of this organism. The advantages of fluoroquinolones include lipid solubility, general potency, and accumulation in phagocytic white blood cells, which will not only facilitate intracellular killing but also increase movement of drug to sites of inflammation. The newer-generation fluoroquinolones, including the cyanofluoroquninolone pradofloxacin, have an enhanced spectrum against anaerobic organisms compared with their earlier counterparts.

For initial therapy, particularly in serious cases, the author prefers a combination of parenteral (intravenous) meropenem, particularly in serious cases, and amikacin. If ampicillin is used, it should be protected with sulbactam and should be given at a high dose at least every 4 hours. The most appropriate dose and interval should be based on the MIC of the infecting organism when possible. Amikacin should be given once daily. Therapy should be continued for 3 to 5 days or until improvement is evident (e.g., 7 to 10 days). At that time, assuming improvement is evident, oral therapy can be implemented. The author prefers high doses of amoxicillin-clavulanic acid (25 to 30 mg/kg every 8 hours) and a sulfadiazine/ trimethoprim combination (30 to 45 mg/kg twice daily) based on both drugs. Alternatively, metronidazole or clindamycin and a second or third-generation fluoroquinolone as sole therapy may be reasonable choices. Synergistic actions against Nocardia spp. have been documented (in vitro) with a number of antimicrobial combinations, including amikacin and sulfadiazine-trimethoprim.¹⁸⁶ Other drugs that have shown efficacy against Nocardia or Actinomyces spp. and are characterized by adequate distribution to the pleural space include clindamycin, minocycline, and doxycycline.¹⁸⁶ Precaution is advised, however, when using these bacteriostatic drugs in combination with a bactericidal drug.

Involvement of anaerobic organisms and presence of devitalized tissues is likely to mandate an extended period of antimicrobial therapy, with 4 to 6 weeks being a reasonable target.

INFECTIONS OF THE GASTROINTESTINAL TRACT

Oral Cavity

Pathophysiology

Dental diseases are associated with both the accumulation of dental plaque and the emergence of pathogenic organisms. The type of microbe appears to be more important in the initiation of disease, where the microbial load is more important for persistence (i.e., chronicity) of disease¹⁸⁷ The impact of periodontal disease on general health warrants a proactive approach to management. Effective prevention can be realized with effective control of the microbes located in subgingival or supragingival plaque. Mechanical débridement is important to treatment, with antimicrobial therapy indicated with probing depths that exceed 5 mm.¹⁸⁷ Therapy should target those microorganisms capable of destroying periodontal connective tissues. Specifically, therapy should target the eradication of organisms such as *Porphyromonas gingivalis* and *Prevotella intermedia*: their absence is a predictor of resolution of disease.

Microbial Targets

The aerobic and anaerobic flora from gingival pockets of 49 dogs with severe gingivitis and periodontitis were cultured. The susceptibility of each isolate to four antimicrobial agents currently approved for veterinary use in the United States (amoxicillin–clavulanic acid; clindamycin; cefadroxil; and

enrofloxacin) was determined. In a study of organisms cultured from canine gingivitis and periodontitis, the combination of amoxicillin–clavulanic acid had the highest susceptibility against aerobes (94%) and anaerobes (100%) compared with clindamycin, cefadroxil, and enrofloxacin. Enrofloxacin had the highest in vitro susceptibility activity against aerobic gram negatives.¹⁸⁸ Similar findings were reported in cats (n = 40): susceptibility against all isolates was greatest with amoxicillin– clavulanic acid (92%). Anaerobes were equally (99%) susceptible to amoxicillin–clavulanic acid and clindamycin, whereas susceptibility to aerobes was greatest to enrofloxacin (90%).¹⁸⁹

Antimicrobial and Alternative Treatments

Use of culture and susceptibility data as a basis for antimicrobial selection in the mouth is complicated by normal polymicrobial anaerobic growth. Culture of a relatively pure growth may indicate the organism as the cause of infection. Representative cultures should be obtained from infections in deeper, isolated tissues (e.g., abscessation or osteomyelitis). Care should be taken in collection of the anaerobes; these organisms can be exquisitely sensitive to oxygen. Because infections are likely to involve anaerobic organisms, drugs that target anaerobes and distribute well to the mucosa and (if indicated) bone should be selected. Examples include clindamycin; the aminopenicillins, including amoxicillin-clavulanic acid combinations; and metronidazole. Among these drugs, clindamycin has proved the most effective in penetrating the glycocalyx and other material serving as a barrier to antimicrobial penetration in the presence of plaque. Metronidazolefluoroquinolone combinations (e.g., ciprofloxacin [humans] or enrofloxacin) have been shown to act synergistically in the treatment of periodontitis. Pradofloxacin was demonstrated to be effective against subgingival bacteria associated with periodontal disease in dogs.¹⁸⁷ Anaerobic organisms, including Bacteroides species, produce beta-lactamases, and therefore, clavulanic acid combinations should be considered for more complicated or serious infections. The role of gram-negative organisms in causing infections should not be ignored even in the presence of abscessation.

Prophylactic antimicrobial use has been commonplace for dental procedures but not warranted for healthy animals. Decreasing the microbial load is probably a more appropriate goal than is proplyaxis. The duration of antimicrobial therapy before the procedure depends on the intent of prophylaxis. Protection of the patient predisposed to endocarditis during the procedure is particularly important. A single dose of antimicrobials timed such that peak plasma concentrations occur as the dental procedure is begun may be sufficient for most animals. For an orally administered drug, the time of administration should approximate the time to peak tissue concentrations, which is generally 1 to 2 hours after administration. For intravenously administered drugs, drug concentrations will not be highest at the tissue site until distribution has occurred, generally 30 to 60 minutes after administration. If the intent of prophylactic therapy is to decrease the bacterial load of the oral cavity before the procedure, then the drug should be administered several days before the procedure. Because the oral cavity contains a large population of normal organisms, prophylaxis for surgical procedures involving the oral cavity often has been extended to 1 week or longer before or after the procedure. A novel drug delivery system has recently been designed for treatment of periodontal disease in dogs. Doxycycline, characterized by a broad antimicrobial spectrum, is prepared in a vehicle that is injected into the periodontal pocket after dentistry. The moist environment causes the vehicle to gel, resulting in a slow-release drug delivery system. In clinical trials associated with Food and Drug Administration approval, animals receiving the drug after dental work improved more rapidly than animals treated with a placebo. The cleaning procedure itself, however, appeared to be the more important means of improving the health of the local environment.

Antiseptic agents can prove beneficial in home care dentistry.¹⁹⁰ Chlorhexidine is considered one of the most efficacious products and is indicated for patients with periodontal disease. It is available in several 12% preparations: an oral acetate rinse (Nolvadent, Fort Dodge); a more palatable gluconate solution (CHX Oral Cleansing Solution, VR_x Products), or a gluconate gel. In addition to having an immediate bactericidal effect, chlorhexidine adsorbs to the tooth pellicle, which serves as a reservoir, allowing continuous release of chlorhexidine. Chlorhexidine has caused toxicity when applied as a disinfectant in catteries after grooming by the cats. Although there are no reports of chlorhexidine toxicity when used for periodontal disease in cats, research focused primarily on Beagles suggests that caution should be exercised when this product is used for cats. Fluoride-containing products also should be used cautiously because dogs appear to be more susceptible than other species to acute toxicosis.

Esophagus and Stomach

Primary infections of the upper gastrointestinal tract are unusual. Thus treatment of infections generally includes resolution of the underlying cause.¹⁹¹

Megaesophagus

Regardless of the cause of megaesophagus, aspiration pneumonia is a serious, potentially life-threatening complication. The continuous use of antimicrobials for prevention of pneumonia in cases of unresolvable megaesophagus is controversial and probably not indicated unless continuous bacterial infection has been documented. The inflammatory response of aspiration pneumonia is likely to be induced by chemicals (including hydrochloric acid) or foreign bodies. Accordingly, drugs that control the inflammatory response with minimal immune suppression should be used in a timely fashion (see Chapter 20). The treatment of pneumonia was discussed earlier.

KEY POINT 8-33 The continuous use of antimicrobials for prevention of pneumonia in cases of unresolvable megaesophagus is controversial and probably not indicated unless continuous bacterial infection has been documented.

Stomach

Vomiting originates from many central and peripheral causes, including acute gastritis. Acute gastritis, in turn, has many causes and is most likely to respond when the underlying cause is resolved, which generally occurs in 1 to 5 days. Bacteria are an unlikely cause of vomiting, and antimicrobial therapy rarely is indicated. Therapy is supportive, including fluids and appropriate additives (e.g., potassium if vomiting is profuse) and antiemetics.

The normal flora of the stomach of dogs consists of large spiral bacteria, including Helicobacter species.¹⁹² Spiral bacterial and a nonpathogenic chlamydial organism occur in the feline stomach. The role of spiral organisms (most notably Helicobacter spp.) in gastrointestinal diseases in dogs and cats is currently being investigated, but it is likely that these organisms will become the target of drug therapy in the medical management of several diseases. Numbers of bacteria in the gastrointestinal tract gradually increase distally to the ileocecal valve.¹⁹³ Numbers of bacteria abnormally increase when normal bowel defenses are impaired. Several mechanisms exist to protect the normal gastrointestinal tract from infection. Among the most important are gastric and bile acids, which limit the concentration of bacteria. In humans more than 99.9% of ingested coliform bacteria are killed at a pH of less than 4 within 30 minutes. In contrast, no reduction of bacteria occurs in the stomach in the presence of achlorhydria.¹⁹⁴ Among the reasons that Helicobacter pylori has been recognized for its pathogenicity in the cause of human gastrointestinal disorders is its ability to alter the gastrointestinal pH and thus increase host susceptibility to other infections.¹⁹⁴ Treatment for *Helicobacter* is discussed in Chapter 18.

Drugs that contribute to bacterial overgrowth include antisecretory drugs and antacids. Mucus and mucosal tissue integrity provide physical barriers and help clear bacteria from the upper and small intestine.¹⁹⁴

Small and Large Intestines

Normal Control Mechanisms

Intestinal motility. Intestinal motility has several roles in the prevention of gastrointestinal bacterial infection. Gastrointestinal motility and diarrhea help remove offending pathogens from the gastrointestinal tract, not unlike the cough reflex does in the respiratory tract. Bowel stasis increases the risk of bacterial overgrowth in the small intestine and contributes to the risk of inflammatory bowel disease. Antimotility drugs (e.g., opioids) increase the risk of overgrowth;¹⁹⁴ in contrast, the use of prokinetic drugs may be beneficial if decreased motility is a factor in the development of diarrhea. Obstruction or stasis of intestinal or bile flow and decreased mucosal blood flow contribute to bacterial infections in the intestinal tract.¹⁹³

Normal microflora. Microflora is established at 2 to 3 weeks of life. The population remains stable under normal conditions but does vary among species. The high-meat diet of carnivores supports a predominant population of streptococci and *Clostridium perfringens* and suppresses *Lactobacillus*.¹⁹³ Anaerobes comprise the majority of intestinal microflora, outnumbering aerobic organisms by tenfold to 1000-fold;¹⁹³

in humans 99.9% of enteric microbes are anaerobic. Aerobic gram-negative coliforms in humans include E. coli, Klebsiella, Proteus, and enterococci.¹⁹⁴ The normal microflora is important to the control of infecting microorganisms in the gastrointestinal tract. Normal floral bacteria compete for available nutrients, maintain redox potentials, and produce antibacterial compounds that prevent colonization by infecting organisms. Normal flora also have a number of physiologic functions. Microflora produce volatile fatty acids and vitamins as well as metabolize bile acids and some drugs. Indigenous (anaerobic) microbes attach to the intestinal epithelial surface and act synergistically with host immune mechanisms to interfere with experimental Salmonella infections.¹⁹⁴ Gram-negative aerobes such as Proteus spp., Enterobacter spp., and E. coli act in concert with host immune mechanisms to prevent infection with Vibrio species. Gram stains of fecal smears might be used to help identify a loss of balance in the normal microflora of dogs or cats. In meat eaters, normally 75% of the flora is represented by gram-negative organisms and 25% gram-positive. A loss of gram-positive or an increase (that might include *Clostridium*) may be supportive of an imbalance.

In the presence of diarrhea, anaerobic numbers decline because the organisms require stasis and a low oxygen potential. In the presence of antimicrobials, the loss of normal microflora in humans can shift the balance of bacteria to gram-negative aerobes and replacement of anaerobes with organisms such as Pseudomonas spp., Klebsiella spp., anaerobes such as Clostridium spp., and yeast (Candida).¹⁹⁴ Diarrhea associated with antimicrobial use has long been associated with disruption in the balance of normal microflora, in part because of the loss of toxic products produced by normal microflora. The number of organisms (e.g., Salmonella) needed to cause infection is markedly reduced after administration of a single dose of selected antimicrobials (e.g., for Salmonella spp., streptomycin). Resistance to infection can be restored with a return of the normal enteric flora (in humans, especially Bacteroides spp.). Outbreaks of gastrointestinal infections in humans, particularly with Sal*monella* spp., can be associated with antimicrobial exposure.¹⁹⁴

Host immunity. Host intestinal immunity plays an important role in the prevention of gastrointestinal infection. The intestine is normally in a state of physiologic inflammation because of the presence of neutrophils, macrophages, plasma cells, and lymphocytes. The loss of neutrophils and their phagocytic capability results in an increased susceptibility to gram-negative (rod) infections originating in the gastrointestinal tract.¹⁹⁴ Secretory IgA is resistant to intraluminal degradation and as such provides an important source of local immune protection. The intestinal antibodies are directed toward a variety of bacterial antigens, including endotoxin, capsular material, and exotoxins. In addition, they may have bactericidal, opsonic, or neutralizing effects on bacteria.¹⁹⁴ In the nursing animal, several compounds produced by the mother are important. In humans breast milk contains lactoferrin, lysosome, phagocytic activity, oligosaccharide fractions, and other materials that afford protection to the newborn.

Factors facilitating infection. A number of microbial factors facilitate gastrointestinal infection. Factors that determine

bacterial virulence and pathogenicity are well represented by E. coli and include production of enterotoxins, the capacity to invade, induction of hemorrhagic colitis, and expression of adherence and enteroaggregation.¹⁹⁴ Production of enterotoxins (defined as having a direct effect on intestinal mucosa such that fluid secretion increases) by organisms such as Staphylococcus spp., C. perfringens, Bacteroides spp., and *E. coli*) can result in disruption of fluid fluxes across the intestinal mucosa. The organisms producing enterotoxins generally are part of the normal microflora but, in the presence of predisposing factors (e.g., garbage enteritis, bacterial stasis, bacterial overgrowth), proliferate in the small intestine. Noninvasive organisms can induce diarrhea by actions of exotoxins that stimulate adenyl cyclase and subsequently sodium, chloride, and water secretion into the intestinal lumen. Cytotoxins produced by several pathogens cause mucosal destruction and a subsequent inflammatory response.^{193,194} Some organisms (Salmonella, particularly in the ileum, and Shigella spp.) are capable of causing mucosal invasion, resulting in hemorrhagic feces. Enterohemorrhagic E. coli produces cytotoxins, and the enterotoxin produced by C. perfringens also causes cytotoxicity. The pathogenesis of Campylobacter jejuni and H. pylori infections also has been attributed to cytotoxins.194

Adherence factors contribute to the ability of organisms to colonize the intestinal epithelium and cause infection. Adherence antigens generally are fimbrial in nature but are distinct from those responsible for urinary adherence. A number of distinctly different adhesions have been described for enteric microorganisms. Invasiveness, as represented by Shigella spp. and selected strains of E. coli, results in the destruction of epithelial cells and superficial inflammation. The degree of invasiveness depends on the protein to which the organism is bound and may also depend on the production of cytotoxic exotoxins.194 Newer antimicrobial agents may target the adherence of toxins, acting to prevent their synthesis or antagonizing their effects and thus blocking the ability of the microbe to infect. Drugs also may minimize the actions of enterotoxins. Other virulence factors that facilitate infection in the gastrointestinal tract include motility, chemotaxis, and production of mucinase.194 The ability of H. pylori to alter gastric acidity has already been mentioned.

Treatment of bacterial diarrhea. The role of bacteria in causing diarrhea and the treatment of these causative organisms are also discussed in Chapter 19. The role of translocation of bacteria is addressed in Chapter 26. Several diarrheal syndromes have been described in small animals.¹⁹³ Neonatal colibacillosis occurs in dogs and cats. Puppies are generally only 1 week old, but diarrhea can persist in older puppies. Factors contributing to infection with E. coli include immunologic incompetency (including failure of passive transfer), immaturity of intestinal epithelial cells (nonselectively permeable) for the first 2 to 3 days of life, and exposure to E. coli in colostrum. The syndrome of bacterial overgrowth is a cause of chronic or recurrent diarrhea; German Shepherd Dogs appear to be predisposed. Increased numbers (more than 10⁵/mL) of E. coli and enterococci (considered normal flora) and selected anaerobes (e.g., Clostridium

spp.) are found in duodenal secretions of affected dogs. Underlying factors are not well described but include motility disorders, hypochlorhydria, and deficiency of secretory antibody (IgA). Animals generally respond to antimicrobial therapy.

Adjuvant therapy. The importance of fluid therapy for patients with diarrhea induced by bacterial infections should not be overlooked. The composition of electrolyte losses in severe diarrhea is similar to that of serum, and both intravenous and oral rehydration therapy should reflect this composition. Absorption of oral solutions depends on the intact intestinal mucosa. Sodium and glucose should be present in equimolar concentrations; amino acids (e.g., glycine) might be added in veterinary preparations to facilitate electrolyte absorption.¹⁹³ In humans an oral recipe is recommended to contain 3.5 g NaCl, 2.5 g NaHCO₃, 1.5 g KCl, and 20 g glucose (dextrose) per liter of boiled water.¹⁹⁴

INFECTIONS ASSOCIATED WITH BACTEREMIA

Bacteremia is defined as the presence of live bacteria in the bloodstream. Bacteremia does not necessarily lead to sepsis (the systemic inflammatory response to infection) unless microbial growth overwhelms host defenses.

Infective Bacterial Endocarditis

Causative organisms of infectious endocarditis (IE) are not limited to bacteria but include *Chlamydia* spp., *Mycoplasma* spp., fungi, and viruses. Because more is known about bacteremia caused by bacteria, it serves as the basis of discussion here. Regardless of the type of infecting organisms, the events that allow development of IE are probably the same. IE includes infection and colonization of the endocardial and adjacent surfaces of the cardiac valves, their supportive structures, and the wall of the heart. The incidence in dogs and cats appears to be low (0.06% to 6.6% based on necropsy findings).¹⁹⁵

The incubation period of IE, that is, the time that elapses between the bacteremic event and the onset of clinical symptoms, may be up to 2 weeks. Historically, IE has been classified in humans on the basis of the progression of untreated disease. Acute disease is characterized by a fulminant course of events, characterized by high fever, evidence of systemic involvement, leukocytosis, and death generally within a couple of days (taking as long as several weeks). Subacute (death in 6 to 12 weeks) and chronic (duration longer than 12 weeks) IE are characterized by a slower course with low-grade fever and vague clinical signs.¹⁹⁵

Pathophysiology

Microbial factors. Several independent events lead to the development of IE.¹⁹⁶ The endothelial surface of the valve first must be altered (e.g., by blood turbulence induced by valvular insufficiency) such that bacteria can adhere to and colonize it. Initially, the damaged surface induces the deposition of platelets and fibrin, forming a nonbacterial thrombotic endocarditis. Organisms with the ability to adhere to platelets or fibrin have the advantage of inducing disease with smaller

inoculums. Bacterial adhesion to the thrombus forming on the damaged valvular surface is critical to the initial stages of IE. The thrombus provides a protective environment for bacterial growth in that phagocytic and other host defenses are impaired below the surface.¹⁹⁶ This thrombus provides a surface for bacterial adherence and colonization. Organisms particularly capable of adherence include S. aureus, S. epidermidis, and P. aeruginosa. Colonization is followed rapidly by the formation of a protective sheath of fibrin and platelets, which facilitates bacterial multiplication and vegetative growth. Transient bacteremia such as might occur during dental, gastrointestinal, or urogenital procedures can lead to colonization of a thrombus that has formed on a previously damaged valve. Infecting organisms tend to be nonpathogenic organisms associated with the mucosal surface (e.g., P. acnes, Actinomyces spp., S. epidermidis) or organisms that are resistant to complement-mediated bactericidal activity (e.g., E. coli, P. aeruginosa, Serratia marcescens). Within genera of bacteria, differences in the ability of strains to cause infection also might be related to their lack of encapsulation (thus allowing adherence). Dextran, a complex polysaccharide produced by some organisms (e.g., Streptococcus) spp., is an example of an extracellular molecule that may facilitate bacterial adhesion to the valvular surface. Some organisms are able to directly bind to endothelial surfaces; indeed, endothelial cells may ingest some organisms (e.g., S. auerus) as the initial event. Some organisms are potent stimulators of platelet aggregation (e.g., Staphylococcus and Streptococcus species), thus facilitating growth of the vegetative lesion as well as formation of thrombi in systemic circulation.196

Host factors. Host defenses can both impair and facilitate the formation of the vegetative lesion. Although humoral antibodies should decrease the number of circulating bacteria, they also may facilitate bacterial invasion by stimulating agglutination. Constant antigenic challenge results in the formation of circulating antibodies. Rheumatoid factors (anti-IgG IgM antibodies) develop in 50% of human patients within 6 weeks of developing IE. Antinuclear antibodies also are formed. Circulating immune complexes are more likely with long illnesses. Although antibodies may provide some protection, they also may contribute to the development of glomerulonephritis, musculoskeletal abnormalities, and low-grade fever. Interestingly, platelets provide the host with some defenses during the course of IE. Low-molecular-weight cationic proteins (thrombodefensins, or platelet microbicidal protein [PMP]) are released after exposure of the platelet to thrombin. These appear to damage the bacterial cell membrane or wall and may act synergistically with select antimicrobials to cause bactericidal effects. Organisms resistant to PMP may be more likely to contribute to the pathophysiology of IE.¹⁹⁶

Complications of infectious endocarditis. Complications of IE that may require medical management develop in several organs. In humans myocardial abscesses are found in 20% of cases autopsied, generally as a result of acute staphylococcal endocarditis. Embolism is common, most commonly occurring in the splenic, renal, coronary, or cerebral circulation. The kidney is often afflicted in patients with IE because of septic embolization (with or without abscessation), infarction, or

glomerulonephritis. Cerebral emboli occur in 33% of human cases of IE, leading to arteritis, abscessation, and infarction. Splenic abscesses, although potentially common, may not be clinically evident. Petechiae may indicate arteritis of the vascular supply of the skin or immune complex deposition.¹⁹⁶

Antimicrobial therapy. Despite the low incidence of therapeutic success, venous blood culture is probably the most important diagnostic tool for IE. Multiple blood cultures (at least three are recommended in the first 24 hours for human patients) are more likely to yield a positive result. Bacterial counts in blood are generally low, and growth can be slow. Cultures should be held 3 weeks. Newer technologies may include methods that detect bacterial cell constituents.

Empirical therapy should begin after cultures have been collected. In human patients Staphylococcus and Streptococcus spp. are among the most common causes of IE. In dogs, S. aureus, E. coli, and beta-hemolytic streptococci are the most commonly isolated.¹⁹⁵ Antimicrobial selection should be broadly based, however, targeting gram-negative as well as gram-positive organisms. Anaerobic organisms also should be included in the spectrum. The same approach is indicated for culture-negative IE. Drug distribution is less of a concern for IE, thus minimizing the need for lipid-soluble drugs. An exception must be made if bacterial embolization of organs (e.g., spleen, brain, or kidneys) has occurred or if the original source of infection remains a potential source of continuing infection. Antimicrobials should be based on efficacy in the presence of potential immune suppression. Bactericidal concentrations should be achieved in blood or tissues, indicating intravenous therapy. Consideration should be given to release of endotoxin. Combination therapy should be considered not only to enhance the spectrum of a single antimicrobial but also to enhance efficacy. Beta-lactams should be considered because of their broad spectrum as well as their ability to increase antimicrobial delivery into bacteria. Imipenem or meropenem stand out among the beta-lactams for their minimal release of endotoxin. Likewise, the fluoroquinolones and the aminoglycosides cause minimal release of endotoxin.

KEY POINT 8-34 Empirical antimicrobial selection for infective endocarditis should be broadly based, but properly collected cultures should be attempted first.

Peritonitis and Other Intraabdominal Infections *Pathophysiology*

Infection of the abdomen includes infections of the peritoneal space, retroperitoneal space, and the viscera, including the liver, pancreas, spleen, and kidney.¹⁹⁷ In veterinary medicine peritonitis is most commonly secondary to an intraabdominal infection. Bacteremia is a common finding in infections associated with aerobic organisms but less common if infection involves anaerobes. Bacteria can gain access to the peritoneal cavity directly by way of transmural migration, through the (damaged) intestinal wall, or through other intraabdominal abscesses. In patients with liver disease, organisms that might otherwise be removed from portal circulation can gain access to the peritoneum through lymph or blood. Fever, abdominal pain, nausea, vomiting, and diarrhea are common clinical signs associated with peritonitis. Analysis of peritoneal fluid collected by paracentesis should provide the basis of diagnosis and the need for surgical intervention. Surgical correction is indicated for both diagnostic and therapeutic intervention. Peritoneal fluid can also provide a basis for initial antimicrobial therapy as well as culture and susceptibility data.

The causative organisms of peritonitis are likely to vary with the source; each organ is characterized by its own natural flora. Gastric flora is variable, depending on the state of hydrochloric acid secretion, but can include flora from the oral cavity. The flora of the small intestine is also variable, but in the presence of disease (including achlorhydria), the number of organisms also increases. Large bowel organisms can be present in small bowel obstructions, stasis, and so forth. *E. coli*, enterococci, and anaerobes (e.g., *Bacteroides, Fusobacterium, Peptostreptococcus* spp.) are among the likely causative organisms. The primary flora of the large bowel are anaerobic.

Penetration of organisms into the peritoneal cavity generally is insufficient for the development of peritonitis. Chemical damage such as that associated with bile peritonitis may cause necrosis that increases the severity of peritonitis. The presence of free hemoglobin in the peritoneal cavity contributes to peritoneal infection, perhaps by providing iron required for bacterial metabolism. Intraperitoneal fluid and fibrin increase the inflammatory response to microbial organisms. Fibrin may serve to trap organisms, yet allow abscess formation. In addition, it causes abdominal organisms to adhere to one another. Bacteria produce a number of substances that contribute to the pathophysiology of peritonitis. Endotoxin concentrations increase rapidly in the presence of peritonitis; aerobic organisms possess more endotoxin with greater biologic activity than anaerobic organisms. Anaerobic organisms, however, produce collagenases and proteolytic and other enzymes. In addition, anaerobes may be more resistant to granulocyte killing mechanisms.197

The mixture of organisms may contribute to the pathophysiology of infection and may increase (synergistically) the pathogenicity of infection. On the other hand, facultative organisms may facilitate the growth of anaerobic organisms by reducing the oxygen tension of the environment. Each bacterial component may contribute differently to the peritoneal infection. Early peritonitis may be characterized predominantly by infection with gram-negative aerobes; later peritonitis reflects abscessation by obligate anaerobes. Either stage can be lethal.

Antimicrobial and Adjuvant Therapy

Antimicrobials should be used to control or prevent bacteremia, to limit infection locally, and to prevent an inflammatory response to infection. The presence of inflammation indicates a need for surgical intervention, including drainage of the abdomen. Therapy should begin immediately after cultures are collected, but antimicrobials should be modified on the basis of data received after therapy has begun.

Infections are generally polymicrobial. Data generated from human patients are likely to be applicable to small animals.¹⁹⁷ Antimicrobial therapy should target a mixed infection, with organisms most likely derived from the gastrointestinal tract. E. coli, Klebsiella, Enterobacter, and Proteus, spp. are among the more common aerobic (but facultative anaerobic) organisms. In human patients infection that develops during hospitalization most commonly involves highly resistant strains of aerobic gram-negative organisms: Acinetobacter spp., Serratia spp., and P. aeruginosa.¹⁹⁷ Bacteroides, Clostridium, Fusobacterium, Peptococcus, and Peptostreptococcus spp. are among the most common obligate anaerobic organisms. Antimicrobial therapy should include anaerobic organisms because they often are involved even when not present on culture. Several factors impair culture of anaerobic organisms. Cultures require longer time for growth and susceptibility testing. In addition, susceptibility data often have not been standardized for anaerobic organisms.

Data from human patients indicate that survival of subjects with peritonitis is decreased if initial therapy is inappropriate, even if "adequate" therapy is ultimately implemented.¹⁹⁷ Thus initial antimicrobial therapy is very important. Combinations of two or more antimicrobials are generally selected for treatment of peritonitis; however, care must be taken to avoid antagonistic combinations (see Chapter 6). Attention should be given to the potential release of endotoxin. Antimicrobials need not be effective against all organisms. Eradication of the most virulent organisms may remove the synergistic effect of multiple organisms, thus allowing host defenses to destroy organisms not affected by antibiotics. Clindamycin is particularly appealing because of its efficacy against approximately 95% of anaerobic organisms and has been effective as the sole agent in infections caused by mixed infections with anaerobic Enterobacteriaceae. In addition, it is effective against Staphylococcus spp. Metronidazole is also a good choice because of its efficacy against anaerobes. In addition, it may have efficacy against E. coli in mixed aerobic-anaerobic infections. Beta-lactams, and particularly penicillins, remain excellent choices for treatment of abdominal infections. The penicillins are preferred because of their efficacy against anaerobes compared with cephalosporins. Beta-lactamase protectors provide enhanced efficacy against both aerobes and selected anaerobes. The carbapenems have among the broadest efficacy of the antimicrobials currently available; that of ticarcillin is also broad, especially when combined with clavulanic acid. Aminoglycosides are indicated for resistant aerobic gram-negative and selected positive organisms and provide synergistic activity when combined with beta-lactams. They are not, however, efficacious against anaerobic organisms and have limited efficacy against facultative anaerobes when in an anaerobic environment. Likewise, care must be taken in the selection of a first-generation cephalosporin. Cefoxitin, a second-generation drug, includes many gram-negative organisms and Bacteroides fragilis in its spectrum. The synergism expressed between fluoroquinolones and metronidazole in treatment of peridontitis may reasonably be expressed in treatment of peritonitis as well, which suggests that this combination is appealing.

KEY POINT 8-35 Survival of peritonitis is decreased by inappropriate initial antimicrobial use, even in patients in which appropriate therapy ultimately is implemented.

Intravenous administration is recommended to maximize drug delivery to the gastrointestinal tract, which may be poorly perfused. Once gastrointestinal function is normal, oral administration can be reinstituted. Irrigation of the peritoneal area and the peritoneum is recommended. Although bactericidal activities of the host (specifically opsonins) may be diluted by irrigation, dilution of microbes and fibrin is of greater advantage. Addition of heparin will further reduce fibrin deposition and the risk of adhesions or pockets of microbial growth. Although povidone-iodine can decrease the incidence of intraabdominal infection when used as an irrigant, it also may impair host defenses. More important, cytotoxicity and proinflammatory effects can worsen inflammation associated with peritonitis, hence it is to be avoided. Intraperitoneal administration of antimicrobials does not appear to offer distinct advantages over intravenous administration. An exception is made with peritoneal dialysis as adjuvant therapy; antimicrobials should be added to the peritoneal lavage to maintain antibiotic concentrations in the peritoneal fluid.

Prophylactic therapy includes use of preoperative cleansing with diet, as well as cathartics and enemas to reduce the total fecal and bacterial mass. Oral antimicrobials should be used to cleanse the gastrointestinal tract. Gastrointestinal flora are susceptible to oral neomycin (aerobic gram-negative organisms) and metronidazole (anaerobes). Intravenous antimicrobials should also be used preoperatively for patients for which the surgical procedure is accompanied by a high risk of contamination.

Peritoneal dialysis as a method of treating peritonitis should be accompanied by antimicrobial use. Contamination from organisms inhabiting the skin (e.g., *Staphylococcus* spp.) is the most common source of infection in patients receiving peritoneal dialysis as a means of controlling renal failure.

Sepsis and Septic Shock Syndrome

Definitions

Sepsis is defined by clinical evidence of a systemic response to an infection (e.g., tachycardia, fever, or hypothermia), with severe sepsis associated with hypotension or organ failure.^{198,199} Sepsis syndrome is characterized by altered perfusion of organs (e.g., respiratory or renal dysfunction), whereas septic shock is sepsis syndrome accompanied by hypotension that is not responsive to fluid therapy but is responsive to pharmacologic intervention. Refractory shock, on the other hand, is septic shock that (in humans) lasts longer than 1 hour and does not respond to conventional pharmacologic therapy. The systemic inflammatory response syndrome can result from sepsis but may also indicate a response to any number of systemic mediators of inflammation. Multiorgan response and potential failure is involved. Note that none of these definitions is based on the presence of bacterial (or other microbial) infection; rather, each

is based on clinical signs. Presumably, at some time during the course of infection, bacteremia (positive blood cultures) and endotoxemia (presence of endotoxin in the blood) have been evident if a diagnosis is made. Regardless, because the syndrome can be a progressive, fatal clinical situation, management is intensive and meticulous (see Box 8-2).

Shortfalls of human studies regarding treatment of sepsis include inappropriate models and limited outcome measures, particularly mortality, which precludes identification of benefits of therapies. Although information can be drawn from the human literature, the relevance of findings to dogs or cats is often not clear. In a review of the state of sepsis in veterinary patients, Otto²⁰⁰ calls for the refinement of consensus guidelines for staging and treatment of sepsis in veterinary patients, as has been promulgated in humans¹⁹⁹ (Box 8-2). In her editorial, she reports that respondents to a survey (approximately 100 small animal practices) reported an incidence of sepsis in 1% to 5% of feline patients, with a 10% to 25% survival rate, and 6% to 10% of dogs, with a 25% to 50% survival rate. A 50% survival rate has been cited for dogs (as reviewed by Hopper and Bateman²⁰¹). Survival differs with the cause of sepsis, being 97% for pyometra compared with 40% for peritonitis. Although this section will attempt to address therapy of sepsis, such a review should not be substituted for a comprehensive review of the current state of sepsis management in veterinary patients, which is likely to be a dynamic approach evolving over the next decade.

Although ultimately, novel therapies may target specific mediators of disease (e.g., biomarkers), currently treatment is limited to supportive care.²⁰⁰ Application of human treatments to dogs or cats will require validation through studies, particularly for polypeptide therapies, which may be antigenic in animals.²⁰⁰

Pathophysiology

Systemic disease caused by gram-negative bacteria is the most common cause of the sepsis syndrome. Bacterial translocation of indigenous bacteria from the gastrointestinal tract to extraintestinal sites is the most likely source of the bacteria. The lipid moiety of the lipopolysaccharide (LPS) covering of gram-negative organisms is the most common virulence factor. It is LPS that triggers the host response to bacterial invasion, including both humoral and cellular aspects. Although the host response may be successful in killing the microbes, the negative sequelae increase host mortality. Cytokines and, in particular, TNF and interleukin-1 (IL-1; the classic endogenous pyrogen) are produced by macrophages and monocytes within minutes of contact with LPS (Figure 8-10). Each is capable of inducing fever and inflammation. TNF in particular has been implicated as the most potent mediator of the pathophysiology of sepsis. TNF alone, however, probably is not sufficient to be lethal; yet, when present with other released mediators and, in particular, interferon-y, the effects of TNF become more lethal. The majority of lethal effects caused by TNF can be attributed to its effects on tissue metabolism, cardiac function, and vascular tone. Nitric oxide (endothelialderived relaxing factor) is being delineated as an important

Box 8-2

Management of Severe Sepsis¹⁹⁹

- 1. Early (first 6 hours) goal-directed resuscitation for septicinduced shock is based on fluid therapy: goals for successful therapy are based on central venous pressure, mean arterial pressure, urine output, and central venous or mixed venous-oxygen saturation. Insufficient response indicates the need for treatment with packed cells or dobutamine infusion (or both).
- 2. Diagnosis should be based on cultures collected before initation of antimicrobial therapy if collection does not significantly delay treatment.
 - a. Cultures include two blood cultures (one percutaneously and the other through any catheter in place 48 hours or longer) and a quantitative culture from other obviously or potentially infected sites. If cultures in the vascular device and blood yield the same organism, the catheter might be considered the source of infection.
 - b. Imaging diagnostic tools should be used in an attempt to identify the source of infection.
- 3. Intravenous antimicrobial therapy with a sufficiently broadspectrum drug should be empirically initiated within 1 hour of diagnosis of sepsis.
 - a. Decisions to cure infections should take precedence over decisions that minimize superinfection.
 - b. Empirical selection should include one or more drugs that target all likely pathogens and adequately penetrate the presumed infected tissue.
 - c. Recently used antimicrobials should be avoided.
 - d. Antimicrobial therapy should take into account local resistance patterns (e.g., the possibility of methicillin-resistant Staphylococcus infections).
 - e. Restriction of antimicrobials as a strategy to reduce the development of antimicrobial resistance or to reduce cost is not an appropriate initial strategy in this patient population.
 - f. Monitoring can be helpful if information is provided in a timely fashion.
 - g. Experienced clinicians (pharmacists and pharmacologists) should be consulted to ensure that doses maximize efficacy and minimize toxicity.
 - h. The antimicrobial regimen should be assessed daily to maximize efficacy, prevent resistance, reduce toxicity, and minimize cost.
 - i. Combination therapy is recommended for certain infections (e.g., Pseudomonas spp.) or neutropenic patients with severe sepsis.
 - j. De-escalation of antimicrobial therapy should be implemented as soon as possible, based on susceptibility data, including limitation of combination therapy to 3 to 5 days.
 - k. Anatomic infections requiring control at the source must be identified early and treated appropriately, using the least invasive but most effective intervention.

- 4. Fluid therapy: natural/artificial colloids and/or crystalloids: a. Evidence does not support one over the other.

 - b. Fluid challenges should be implemented to assess patient response to fluids, which should be based on CVP and should be continued as long as hemodynamic improvement continues.
 - c. Fluid rates should be substantially decreased if indicators of cardiac filling increase without evidence of hemodynamic improvement.
- 5. Vasporessors (e.g., norepinephrine):
 - a. Perfusion should be maintained in the face of life-threatening hypotension even if hypotension has not been resolved.
 - b. Response is based on mean arterial pressure as measured by an arterial catheter.
 - c. Norepinephrine or dopamine are preferred initial choices with epinephrine indicated in norepinephrine non-responders.
- 6. Inotropic support:
 - a. Dobutamine should be administered in the face of myocardial dysfunction, as based on increased cardiac filling pressures and low cardiac output.
 - b. Combined vasopressor/inotrope (norepinephrine, dopamine) is indicated if cardiac output is not measured.
- 7. Glucocorticoids:
 - a. Intravenous hydrocortisone (targeting relative adrenal insufficiency) is given if blood pressure responds poorly to fluid resuscitation of vasopressor therapy.
 - b. Dexamethasone should be avoided because of the potential for suppression of the hypothalamic-pituitary-adrenal axis.
 - c. An ACTH stimulation test is not used to identify those patients for which glucocorticoid therapy is indicated.
 - d. Oral fludrocortisone is administered if the steroid used has no mineralocorticoid activity.
 - e. Steroid therapy is discontinued when vasopressor therapy is no longer needed.
- 8. (Recombinant Human Activated Protein C) is indicated in patients assessed at high risk for death, if no contraindication exists. This therapy is not currently recommended in animals because of the risk of allergic response).
- 9. Blood products:
 - a. Red blood cells are recommended after hypoperfusion has resolved to maintain hemoglobins above 6 g/dL.
 - b. Platelets are recommended when counts are below 5000 mm³ and can be considered when counts are between 5000 and 30,000 mm³.
 - c. Erythropoeitin is not indicated unless for reasons other than sepsis.
 - d. Fresh frozen plasma should not be used to correct clotting abnormalities, and antithrombin should not be administered for treatment of severe sepsis or shock.

mediator of the lethal effects of TNF. The inducible nitric oxide synthase is the likely cause of hypotension associated with septic shock.198

Humoral mediators contribute to the systemic response to LPS. The coagulation pathway can be directly initiated by either LPS or TNF and other cytokines (most commonly through

the extrinsic pathway). The fibrinolytic pathway also can be activated. Disseminated intravascular coagulopathy is not an uncommon sequela of septic shock. Complement activation and platelet-activating factor contribute to the response. The relationship between the mediators of septic shock is intricate and yet to be defined. These relationships, however, lead to the

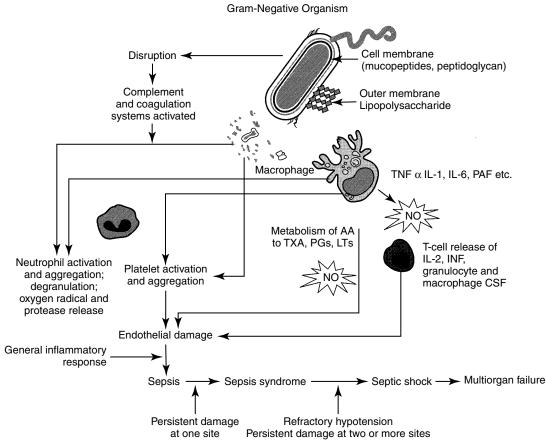

Figure 8-10 The sequelae of endotoxemia. Selected antimicrobials are more likely to cause endotoxin release, most notably the beta-lactams (with imipenem being an exception). The aminoglycosides cause little endotoxin release. *AA*, Amino acids; *CSF*, colony stimulating factor; *IL*, interleukin; *INF*, interferon; *LT*s, leukotrienes; *PAFs*, platelet-activating factor; *PGs*, peptidoglycans; *TNF*- α , tumor necrosis factor- α ; *TXA*, thromboxane synthase A.

progressive nature of the syndrome, as well as the difficulty in pharmacologically manipulating response.

Splanchnic ischemia and specifically intestinal mucosal ischemia may play a major role in bacterial translocation. Selected drugs may increase the risk owing to detrimental effects on the mucosa, including glucocorticoids, nonsteroidal antiinflammatories, and vasopressors. Drugs that target anaerobic bacteria may facilitate the growth of gram-negative organisms; their growth might be supported by antisecretory drugs that alter gastric pH and enteral nutrition. However, adequate nutrition is important to maintenance of the mucosal barrier. The most important means to prevent bacterial translocation is to protect the gastrointestinal barrier through maintenance of gastrointestinal perfusion, avoidance of increased gastric pH, and selective bacterial decontamination.

Studies that document the microbes associated with sepsis in animals are limited. Greiner and coworkers²⁰² (in Germany) retrospectively described the microbes associated with sepsis in cats (n = 292) during the period of 1994 to 2005. Only 23% of the cats had positive cultures. Of the microbes cultured, the distribution of gram-positive and -negative organisms was equal. For gram-negative (43%), 31% of the total isolates were Enterobacteriaceae (16% *E. coli*, 8% *Enterobacter* spp., and 4% *Salmonella* spp.). The breakdown for gram-positive isolates (45% of total) was as follows: *Staphylocccous* coagulase negative (11%), *Streptococcus* spp. (11%), and miscellaneous grampositive (14%). Obligate anaerobes represented another 12%. Overall susceptibility for all aerobic or facultative anaerobic organisms was highest for enrofloxacin (76%), followed by chloramphenicol (69%), gentamicin (67%), and cephalexin or amoxicillin–clavulanic acid (64%). For the remaining drugs, less than 50% of isolates were susceptible (doxycycline, trimethoprim sulfonamide, ampicillin).

Antibacterial Therapy

Successful antimicrobial therapy of sepsis will be enhanced by anticipation (i.e., looking for clinical signs), early diagnosis, aggressive yet appropriate antimicrobial therapy, and intensive supportive therapy. Identifying and correcting the cause of sepsis (e.g., loss of gastrointestinal mucosal integrity, granulocytopenia, foreign bodies) is an underlying focus of management. Although antimicrobial therapy is the cornerstone of therapy, it can also contribute to the pathophysiology.

In human critical care environments, an apparent increase in the incidence of sepsis is attributed to an increase in the severity of illnesses, the complicated nature of care, including invasive procedures and immunosuppressive drugs, as well as the longer survival of patients with chronic illnesses. The high morality rate of sepsis (35% to 50%) reflects, in part, unacceptable delays in appropriate treatment. This partially reflects the difficulty in identifying sepsis. One of the most important predictors of outome in human patients with severe sepsis is prompt and appropriate antimicrobial therapy. Appropriate therapy includes use of drugs that target the infecting microbe within 1 hour of the recognition of sepsis. A major risk factor for mortality is failure to initiate antimicrobial therapy with a drug to which the causative agent is susceptible within 24 hours of receipt of susceptibility results. Disconcertingly, even subsequent correction of previously inappropriate therapy may not reduce the risk of death. Septic patients are predisposed to infection with resistant microbes (Box 8-3). Initial antimicrobial selection must cover a wide range of organisms, including resistant isolates, which makes adequate coverage difficult to achieve. Yet initial adequate antimicrobial therapy is the most important determinant of outcome. A meta-analysis²⁰³ in humans focused on mortality as an outcome indicator of appropriate versus inappropriate therapy in patients with severe sepsis (septic patients). Appropriate was defined as treatment with at least one antimicrobial to which all causative microorganisms (based on blood cultures) were susceptible within 24 hours of identification of the organism; *inappropri*ate was defined as administration of an antimicrobial agent to which at least one of the infecting microorganisms was resistant or the lack of an antimicrobial to which the organisms were considered susceptible within 24 hours of microbial isolation. Of the 904 patients studied, 23% received inappropriate therapy. After adjusting for confounding factors, the overall 28-day mortality was greater in the inappropriate group (28%) compared with the appropriate group (39%).

In addition to the most appropriate drugs, adequate coverage also includes proper modification of dosing regimens for the critical septic patient. Increased volume of distribution, decreased protein, and altered blood flow to organs of clearance complicate design of dosing regimens.¹⁵⁸ The highest doses of antimicrobials are recommended in human critical care patients; intervals of time-dependent drugs should be designed to avoid resistance.²⁰⁴ Decreased doses or longer intervals should not necessarily be implemented in critical patients with altered renal function unless the risk of toxicity is imminent. Monitoring should be considered.

The approach to antimicrobial therapy in the critical care patient should be to "hit early, hit hard, and get out fast."²⁰⁴

Box 8-3

Risk Factors for Colonization with Resistant Microbes

- Hospital stay longer than 5 days
- Previous hospital stay longer than 2 days within past 90 days
- Antimicrobials, especially broad-spectrum, within the past 90 days
- Antimicrobial resistance in the environment
- · Poor underlying condition
- Immunocompromised (including use of immunosuppressive drugs) or neutropenic patient
- Invasive procedures/hardware

Accordingly, therapy should be initiated early with a broadspectrum antimicrobial that targets all potential pathogens, including resistant organisms, at doses designed to kill. Therapy should then be de-escalated to a narrow spectrum as soon as possible, generally on the basis of culture and susceptibility testing. Because human critical care patients often succumb to illnesses that do not necessarily occur in veterinary patients (i.e., pneumonia, particularly that associated with ventilatory support caused by Streptococcus pneumoniae), initial treatment should not necessarily reflect empirical therapy in humans. However, resistance patterns are potentially similar. A number of risk factors have been identified for colonization with resistant organisms (see Box 8-3). Patients that fall into these categories warrant consideration as candidates for second- or third-tier choices. The initial therapy in these patients should be based on resistance data promulgated for dogs or cats in the treatment facility. Accordingly, surveillance programs that monitor patterns of resistance must be promoted in the interest of increased patient survivial and judicious antimicrobial use. Concerns in humans are the same for veterinary patients. These concerns include MRS and, increasingly, resistant gram-negative infections. Up to 40% of E. coli infections in humans are resistant to ampicillin; a similar pattern has been reported in veterinary medicine. The advent of extended-spectrum beta-lactamases is decreasing efficacy of third-generation cephalosporins. Increasing resistance to fluoroquinolones (10% in human medicine, more in veterinary medicine) is limiting their use as well. Accordingly, carbapenems are considered more often.

KEY POINT 8-36 The approach to antimicrobial therapy in the critical care patient should be to "hit early, hit hard, and get out fast." Initial therapy should target any potential infecting organism (including nosocomials) with de-escalation to less potent drugs as therapy progresses.

Allthough evidence is lacking that confirms combination antimicrobial therapy improves the chances of a favorable outcome in human medicine, the consensus is that combination therapy is reasonable, and is indicated for treatment of selected organisms (e.g., Pseudomonas spp.). Combination therapy may be the reason that patient response to antimicrobials has improved (in human medicine) during the last several decades. Combination therapy should be considered not only to increase efficacy (particularly if the antimicrobials act synergistically) but also to reduce the advent of resistance. For bacteremia, antimicrobial combinations should be chosen that provide a broad spectrum, enhance (synergistic) efficacy against gram-negative organisms, and minimize resistance. In the presence of sepsis, selected drugs should also minimize endotoxin release. Organisms particularly adept at developing resistance include Pseudomonas, Serratia, and Enterobacter spp. Combination therapy is particularly important in neutropenic patients. Monotherapy, generally with a carbapenem, a fluoroquinolone (e.g., enrofloxacin), or a third-generation cephalosporin (e.g., ceftazidime), may be effective if the cause is a highly susceptible gram-negative organism. However, the

prudent clinician will use a combination of drugs likely to be effective against the suspected organism. Combination therapy (discussed in Chapter 6) may be important to decrease the risk of resistance as well as enhance efficacy against the infecting microbe. For example, aminoglycosides should never be used alone because of their poor penetrability. The combination of an animoglycoside with a beta-lactam with either cefazolin or ampicillin-sulbactam might be indicated for treatment of bacterial translocation associated with parvovirus; because puppies are likely to be drug naïve, E. coli resistance is likely to be minimal for these drugs. In contrast, the combination of aminoglycosides with carbapenems may be indicated in the patient with a previous history of antimicrobial therapy. Treatment regimens should be changed if indicated by culture and susceptibility data. Design of dosing regimens is discussed in Chapter 6; monitoring as a tool to ensure adequate drug concentrations is particularly important for the septic patient.

Antimicrobial de-escalation, which is important to minimize the advent of resistance, is a two-pronged approach. Narrowing the spectrum as soon as possible is important in minimizing selection pressure.²⁰⁴ Further, decreasing the duration of therapy increasingly is being associated with an improved outcome in human medicine.²⁰⁴ Using hospitalacquired pneumonia as an example, studies in humans have demonstrated a reduced proportion of relapses in shorterduration (5 to 8 days) treatment groups, with response to therapy as an indicator of the need for therapy. In contrast, infections associated with S. aureus bacteremia may require longer durations of therapy because of the potential to cause septic emboli. Catheter-related bacteremia in immunocompromised animals is an example of a condition for which duration of therapy might be 14 days. Therapy for neutropenic patients might continue as long as neutropenia persists. Therapy for infections of areas with poor blood supply may need to be longer; examples include valvular disease (4 to 6 weeks) or necrotic tissue (e.g., osteomyelitis; up to 8 weeks).

Adjuvant Therapy

Drugs that target inflammatory mediators associated with sepsis are also discussed in Chapters 31 and 32. Cardiovascular support can be provided in the form of volume replacement and positive inotropes/pressors. Fluid therapy should be intensive, with the goal of reestablishing normal perfusion. A number of colloids and some crystalloids are available. Drugs intended to maintain or increase blood pressure should be used cautiously. Certainly, adrenergic agents such as dopamine, dobutamine, norepinephrine, and isoproterenol should be administered only in the presence of adequate volume replacement and in conjunction with intensive monitoring of central venous pressure and, ideally, pulmonary wedge pressure. Fluid therapy likely will need to be more intensive in the presence of pressor agents, dobutamine in particular. Vasoconstrictive drugs should be avoided. Thus, although dopamine at low doses (5 µg/kg per minute) may be preferred in the presence of impaired renal perfusion, dobutamine may be preferred otherwise. Of the two, dobutamine (5 to 10 µg/kg) is more likely to increase oxygen delivery and consumption in tissues.²⁰⁵

Hopper and Bateman²⁰¹ reviewed the hemostatic dysfunctions associated with sepsis, with a focus on the integration of hemostatic and inflammatory signals. The inflammatory mediators associated with multiple organ dysfunction syndrome systemically activate coagulation, causing intravascular fibrin formation typical of disseminated intravascular coagulation. The primary means by which inflammation associated with sepsis mediates coagulation is through mediator-induced expression of the procoagulant tissue factor (Factor III). Example mediators include endotoxin, TNF-a lipoprotein, and growth factor. Increased coagulation, in turn, contributes to inflammation, which can increase patient morbidity or mortality associated with sepsis. Endogenous tissue factor pathway inhibitor (TFPI) blockade may decrease mortality. Heparin, including low-molecular-weight heparin, increases the release of TFPIs from endothelial cells, platelets, and that stored with lipoproteins. Despite its role in the pathophysiology, clinical trials in humans receiving recombinant TFPIs have failed to demonstrate a difference in 28-day mortality rates. Antithrombin (AT, previously antithrombin III) binds to and inhibits thrombin and Factor Xa, as well as a number of other factors. High- (but not low-) molecular-weight (LMW) heparin and other glycosaminoglycans of sufficient length bind to and sterically hinder AT, potentiating its anticoagulant activity. Thus, while both unfractionated and low-molecular-weight heparin inactivate Factor Xa, only low-molecular-weight heparin (LMH) targets AT. The latter's longer half-life allows its intermittent subcutaneous use in place of constant-rate infusions of unfractionated heparins. However, in addition to its anticoagulant effects, AT has substantial antiinflammatory effects; these effects require AT binding to endothelial cells, an action that is prevented by binding to heparin. Its antiinflammatory effect has led to studies examining potential efficacy of AT therapy for patients with sepsis. Despite its potential antiinflammatory effects, evidence demonstrating the beneficial effects of AT with clinical trials of humans with sepsis is lacking. The Surviving Sepsis Campaign Guidelines currently do not support treatment with AT. Protein C (PC) is a vitamin K-dependent protein that directly inactivates or enhances the inactivation of a number of coagulation factors, including Factors Va and VIII. It also has direct antiinflammatory actions. Activation of PC is accomplished by thrombomodulin (TM) located in endothelial cells; activation is enhanced 1000-fold if thrombomodulin is bound to thrombin. Therefore thrombin, which is one of the most procoagulant substances in the body, contributes to the primary anticoagulant pathway. Receptors on the surface of the cell bind to PC such that it concentrates at sites of TM-thrombin complexes. Clinical trials have demonstrated that human septic patients are deficient in PC (possibly because of increased destruction, increased consumption, decreased formation possibly related to vitamin K deficiency), and this deficiency affects survival. Although the same has been demonstrated in dogs, an impact on outcome was not demonstrated. Administration of recombinant PC has been associated with improved positive outcomes in human patients. However, species specificity necessitates a fifteenfold to twentyfold higher dose of the human recombinant product when administered to dogs. Further, it is rapidly eliminated. However, antigenicity precludes readministration.

Correction or prevention of impaired tissue perfusion (i.e., with fluid replacement or pressor agents) helps prevent decreased microcirculation. Additional preventive measures might be implemented in the presence of normal platelet counts and coagulation times. Synthetic colloids (which themselves can prolong bleeding times), or the combination of crystalloids and low-dose heparin, are indicated to maintain microcirculatory flow. Evidence of disseminated intravascular coagulation (prolonged coagulation times and low platelet counts) indicates the need for replacement of coagulation factors. Heparin therapy should be implemented with caution in the presence of disseminated intravascular coagulation to minimize the risk of bleeding. Certainly, heparin therapy is indicated in the presence of pulmonary thromboembolism.

The advent of oliguria or anuria indicates the need for diuretic therapy. Opiate antagonists have been shown to reverse the course of septic shock in selected studies. Because patients with prolonged hypotension were particularly responsive, it is likely that the drugs (e.g., naloxone) provide a transient vasopressor effect. Naloxone, however, appears to have no clinically relevant effect in patients in septic shock.

The intravenous administration of polyclonal immunoglobulin increasingly is emerging as a therapy associated with an increase in survival. The use of IgM, in particular is associated with decreased morality.^{206,207}

The role of drugs intended to ameliorate the signs of sepsis syndrome is controversial. Glucocorticoids, nonsteroidal antiinflammatories, and lazeroids (an investigational category of drugs; see Chapters 29 and 30) are variably effective to noneffective, depending on the study. The most important variabilities that appear to affect response to these drugs are dose and timing of administration. For glucocorticoids, most studies in human patients afflicted with sepsis have failed to show a significant benefit to survival; some patients dosed with glucocorticoids were more likely to develop suprainfections. Yet experimental studies have shown that, when provided sufficiently early (within 4 hours of sepsis), "shock" doses of glucocorticoids may ameliorate release of the more important mediators of septic shock. Similarly, nonsteroidals (and, in particular, flunixin meglumine) may decrease the release of or response to a number of mediators of septic shock.²⁰⁸ Again, however, timing of administration is critical: Benefits are most likely to be realized when administration occurs within several hours of the onset of sepsis. Unfortunately for veterinary patients, clinical signs of sepsis are usually not identified until the critical period of antiinflammatory administration has passed.

Among the indications for glucocorticoids in septic patients is replacement therapy in the face of relative adrenocorticotrophic deficiency (see Chapter 30). A recent clinical trial in humans explored the impact of hydrocortisone therapy on 28-day survival rates and found no difference between groups. Although responders responded more rapidly if treated with hydrocortisone, the incidence of superinfection and subsequent recurrence of septic shock increased.²⁰⁹ Nonetheless, the current criteria for use of glucocorticoids, as delineated in the Surviving Sepsis Campaign Guidelines, are based on hypotension responsiveness to fluid and vasopressor therapy.

The advent of recombinant technologies has led to the development of granulocyte colony-stimulating factors. These drugs are likely to prove useful for selected patients (most notably granulocytopenic patients). Treatment protocols have not, however, been well established. Therapy with antiserum has enjoyed a resurgence of interest in human medicine. Administration of serum from patients that have recovered from shock induced by Pseudomonas spp. or patients "immunized" with mutant strains of E. coli has increased the survival of patients suffering from profound shock. Monoclonal antibodies that bind endotoxin, TNF, and other mediators of shock have been or are being studied. Pentoxifylline is a methylxanthine derivative that is accompanied by properties not present in other methylxanthines. Among those potentially beneficial in sepsis is the ability to scavenge oxygen radicals and alter the rheologic properties of blood, thus facilitating microcirculation.²⁷⁰

A number of adjuvant therapies have been studied for their ability to ameliorate clinical signs associated with sepsis. The use of low doses of an antimicrobial that binds endotoxin (e.g., polymyxin B; PMB) yet is otherwise nephrotoxic has not been well studied in either dogs and cats. A very early study reported that lipopolysacharides (LPS) modified with PMB was less lethal in dogs compared to PMB alone.²⁷² A placebo-controlled clinical trial in naturally occurring parvovirus-associated endotoxic dogs (n = 30) compared PMB and ampicillin to ampicillin alone.²⁷³ Treatment with PMB (12,500 IU/kg, IM, every 12 hr for 5 days) administered with ampicillin (10 mg/kg IM, every 12 hr) was associated with greater hemodynamic improvement and lower serum TNFa concentrations compared with dogs receiving ampicillin alone (other supportive therapy in both groups included fluid therapy, colloidal solutions, metoclopramide, ranitidine and sucralfate). Serum urea nitrogen and creatinine actually were higher numerically in the control group. In cats, the effect of PMB was studied both ex vivo and in vivo, the latter using a randomized, blinded, placebo-controlled experimental model of low dose endotoxin infusion in cats (n = 12).²⁷⁴ Ex vivo, TNF α release was less in whole blood cultures. In vitro, response to endotoxin was significantly less in cats receiving PMB (1 mg/kg over 30 minutes, 30 minutes after LPS administration) compared with cats receiving only LPS. The authors interpreted this response as supportive for clinical trials addressing the clinical use of PMB in cats with sepsis.

A polyvalent equine origin antiserum against LPS endotoxin has been used in small animals (SEPTI-serum, Immvac, Inc., Columbia MO 75201); 4.4 mL/kg diluted 1:1 with intravenous crystalloid fluids was administered slowly over 30 to 60 minutes.²⁷⁵ The product should be administered before treatment with antimicrobials that might cause the release of endotoxin. Retreatment, if necessary, is recommended 5 to 7 days after the first treatment. The equine origin may result in anaphylaxis; patients should be monitored closely.

Use of sucralfate rather than antisecretory drugs is indicated if the patient is at risk for gastrointestinal ulceration in the face of possible bacterial translocation. Prevention of reperfusion injury is likely to be important, although pharmacologic interventions have not yet been well defined. Selective (e.g., gram-negative [polymyxin B, neomycin] and fungal organisms [amphotericin B]) decontamination of the gastrointestinal flora coupled with endotoxin binders (e.g., kaolin pectate, activated charcoal) might be considered. Use of dilute chlorhexidine or betadine enemas has been anectodally helpful in puppies with parvovirus.

Prophylaxis remains an important tool for the prevention of sepsis. Among the more important tools in the critical care environment is meticulous adherence to cleanliness policies in the environment to minimize nosocomial infections.²¹⁰ Prophylactic antimicrobials are discussed later.

ANAEROBIC INFECTIONS

Anaerobes differ from other bacteria in that they do not require the presence of molecular oxygen for metabolic activity and growth but instead depend on fermentative processes. Strict anaerobes cannot tolerate the presence of oxygen, and few are clinically significant. Growth of obligate anaerobes depends on an environment characterized by reduced oxygen tension and low oxidation-reduction (redox) potential. Most clinically significant anaerobic organisms are obligate and include the genera Fusobacterium, Bacteroides, Clostridium, (selected species), Peptostreptococcus (enteric Streptococcus), and Peptococcus spp. Although oxygen-tolerant anaerobes cannot utilize oxygen, they can grow in its presence. Oxygen-tolerant organisms include Clostridium perfringens and Propionibacterium spp. Finally, facultative anaerobes are characterized by flexible oxygen requirements and can grow in the presence or absence of oxygen. Facultative anaerobes, which are clinically important in small animals, include Staphylococcus spp. and the enteric gram-negative bacilli such as E. coli and Klebsiella and Pasteurella spp.^{211,212} Like aerobic organisms, anaerobic organisms are also classified by their gram-staining characteristics. Gram-positive cocci include Peptococcus and Peptostreptococcus. Gram-positive rods include those that form spores (Clostridium spp.) and those that do not (Actinomyces and Propionibacterium spp.). Gram-negative anaerobic rods include Bacteroides and Fusobacterium spp.

Results of studies investigating the incidence of anaerobic organisms as causative agents of infections in veterinary medicine have been relatively consistent. The most frequently isolated organisms in one study²¹³ were *Bacteroides, Peptostreptococcus, Fusobacterium,* and *Porphyromonas* spp. These organisms represented 70% of the isolates. Other previously reported clinically significant isolates include *Clostridium, Propionibacterium, Actinomyces,* and *Peptococcus* spp.²¹² Some older studies suggest that *Clostridium* spp. are more commonly isolated, but this finding may reflect inappropriate culturing techniques or regional differences in prevalence of selected genera.

Pathogenesis

Anaerobic infections are endogenous in origin because the causative organisms are most commonly members of the normal bacterial flora that occur in surrounding uninfected tissues. The normal bacterial flora of the body are predominantly anaerobic. Anaerobic organisms are particularly prevalent on mucous membrane surfaces, as exemplified by an anaerobic to aerobic ratio of 1000:1 in the large intestine (colon) and 10:1 in the oral cavity.¹⁹³ Anaerobic organisms, and particularly Bacteroides spp., are also prevalent in the female reproductive tract (vagina). Infections by anaerobic organisms usually require a break in the normal skin or mucosal defense barriers, thus allowing penetration and contamination, or a break in the host's immune defenses. Thus certain areas of the body are more predisposed to the development of anaerobic infections. The most common sites of anaerobic infections reported in small animals are the oropharynx, skin (including bite wounds), respiratory tract, abdomen, reproductive tract, musculoskeletal system, and CNS. Anaerobic organisms are also causes of bacteremia.

Anaerobic bacteria, particularly gram-negative rods, are often considered serious pathogens because they are capable of producing toxins and enzymes, which enhance their pathogenicity. Both *Bacteroides* (especially *B. fragilis*) and *Fusobacterium* spp. produce potent toxins that not only cause tissue necrosis but also enhance the spread of infection. *Bacteroides* spp. may also produce collagenase. Clostridial organisms also produce a variety of toxic compounds that, in addition to tissue necrosis, may cause hemolysis, disseminated intravascular coagulation, and renal failure.²¹¹ Several organisms produce compounds that destroy leukocytes, thus debilitating a component of the host's immune system.²¹¹

Diagnosis of anaerobic infections is often difficult. *Bacteroides* and *Fusobacterium* spp. are often difficult to visualize in Gram stains when in the presence of exudates and tissue debris. Gram-positive organisms may appear as gram-negative, or they may assume usual morphology in older exudates or after antibacterial therapy.²¹¹ Improper culturing techniques are probably the most common cause for failure to isolate all infective organisms.^{211,214}

Anaerobic infections should be suspected when an infection is characterized by one or more of the following: close proximity to a mucous membrane; a putrid, foul-smelling exudate; necrotic or gangrenous tissue; gas; a blackish discoloration of tissues (which may fluoresce under ultraviolet light if caused by Bacteroides melaninogenicus); sulfur granules (indicating infection caused by a variety of different organisms, including Actinomyces spp.)185 a subacute onset of inflammation; and leukocytosis associated with a high fever.^{211,215} Anaerobic infections also should be suspected when cultures are negative despite observation of organisms with a Gram stain and in cases of endocarditis associated with negative blood cultures. Closed-space infections such as pyothorax; pyometra; and brain, lung, or intraabdominal abscesses are frequently caused by anaerobic infections. Other infections commonly caused by anaerobes include aspiration pneumonia, peritonitis associated with bowel contamination, chronic osteomyelitis associated with open fractures, bite wounds, penetrating foreign bodies, and solid tumors with a necrotic center.

Factors Affecting Selection of Antimicrobials

Factors that contribute to therapeutic (antimicrobial) failure for anaerobic infections include improper culturing techniques, mixed infections, and inactivation of the antimicrobial. Culture information important for the proper management of anaerobic infections. Failure to isolate anaerobic organisms caused by improper culturing techniques should be suspected whenever routine aerobic cultures of purulent exudate yield no growth.

Most clinically significant anaerobes are obligate and thus cannot survive exposure to oxygen for more than a few seconds. In addition, facultative bacteria generally grow faster than anaerobic organisms and thus may overgrow and mask anaerobic organisms, particularly if specimen culturing is delayed.²¹¹ The best specimens for anaerobic culture are aspirates or tissue biopsy specimens (1 cm²) rather than swabs.^{216,217} Suitable aspirates include those of infected body fluids (i.e., peritoneal, pericardial, pleural), aspirates of pus (from abscesses, deep wounds, or pyometra), tracheal or percutaneous lung aspirates, surgical tissue specimens (including samples from deep infections, bone biopsy material, and sequestra), and blood.^{216,217} All air or gas bubbles should be removed from both the needle and syringe immediately after sample collection.²¹⁵ Urine; swabs for the oropharynx, upper airway, external airway, and external reproductive tract; sputum or nasal exudates; and bronchoscopy brushings or aspirates (unless obtained with a double-lumen sleeve) are generally considered inappropriate. Culture samples should be placed in culture vials.²¹⁵ Specialized transport receptacles should be devoid of oxygen and contain anaerobic media that will also allow isolation of aerobic organisms. Specimens collected in plastic syringes should also be placed in transport tubes because oxygen can slowly permeate through the syringe. Specimens generally should be kept at room temperature until transported.

Many anaerobic infections are caused by more than one organism. Both anaerobic-anaerobic and anaerobic-aerobic mixed infections have been reported in small animals. A mean of 1.7 to 1.9 anaerobic organisms were isolated per specimen in several studies. Samples usually also contained facultative anaerobes.^{214,218} According to one study, 80% of infections with obligate anaerobes simultaneously contained facultative anaerobic or aerobic organisms, with members of the family Enterobacteriaceae being the most common organisms isolated.²¹³ These include E. coli, followed by Pasteurella spp. and S. intermedius. Mixed bacterial infections are often more virulent than infections caused by single organisms.²¹¹ Because synergistic mechanisms develop between facultative and anaerobic organisms, infection by multiple organisms may promote the overgrowth of commensal anaerobes such as Actinomyces spp.^{208,212,219} Bacteroides spp. can inhibit phagocytic activity of surrounding white blood cells when present in mixed infections. Commensal bacteria may act as symbiotes by producing growth factors required by pathogenic anaerobic organisms. Facultative organisms may also provide a more favorable environment for anaerobes by removing oxygen and

adding reducing substances.²¹² The number of microorganisms located within an abscess may also have an effect on drug efficacy because antimicrobial inactivation is more likely.

The environmental conditions surrounding an anaerobic infection can be detrimental to the activity of antimicrobial drugs. These effects, discussed in Chapter 6, are very likely to be marked in some anaerobic infections. The inflammatory exudate that usually accompanies anaerobic infections can have profound effects on drug efficacy. Cellular membranes, breakdown products of phagocytic cells, and inflamed tissues are all capable of binding to and reducing the effective concentration of pharmacologically active antimicrobial drugs.¹⁵⁵

The anaerobic environment that characterizes anaerobic infections can also profoundly alter the efficacy of antimicrobials. The oxidation-reduction potential (referred to as EH), which measures the anaerobiosis associated with an abscess, is estimated to be approximately -400 mV in human abscesses, which is indicative of an environment free of oxygen. The lack of oxygen has profound effects on two activities important to the success of antimicrobial therapy. The first is its effect on white blood cells. To kill selective organisms, white blood cells must be able to initiate oxidative bursts, an activity that is very difficult to accomplish in the anaerobic environment.^{220,221} In addition, white blood cell chemotaxis in response to bacterial factors is reduced in anaerobic environments.²¹⁵ The second detrimental effect of an anaerobic environment relates to the mechanism of transport or action of the drugs. The efficacy of aminoglycosides and the combination of trimethoprimsulfamethoxazole are particularly affected. Aminoglycosides require active transport into cells by mechanisms dependent on oxygen. In addition, the mechanism of action of these antimicrobials depends, in part, on cellular respiration processes that utilize oxygen. The lack of oxygen renders these antimicrobials ineffective; all anaerobic organisms are thus resistant to aminoglycosides. The aerobic component of a mixed infection may also be resistant to aminoglycoside therapy because the oxidative transport systems of such organisms (e.g., E. coli) may shut down in an anaerobic environment.

The development of resistance by anaerobic organisms to selected antimicrobials is an important cause of therapeutic failure. As with other bacteria, plasmid-mediated, transferable drug resistance and the inability of drugs to penetrate bacterial cells are important mechanisms by which anaerobic organisms develop resistance to antimicrobials.²¹⁵ Several studies have concentrated on the development of resistance to betalactam antibiotics. Anaerobic organisms, and particularly B. fragilis, develop resistance to these drugs primarily by blocking all penetration by the drug or by producing beta-lactamase enzymes that inactivate the drug. B. fragilis is particularly adept at developing resistance because of the production of betalactamases (penicillinases or cephalosporinases), enzymes that cleave the beta-lactam ring, thus effectively destroying antimicrobial activity. Most strains of B. fragilis produce a chromosomally mediated beta-lactamase, which inactivates many cephalosporins, particularly first-generation drugs. In

addition to this cephalosporinase, many strains of B. fragilis can acquire novel beta-lactamases that are characterized by greater impact on the penicillins than the cephalosporins. One study found that some strains of B. fragilis could produce beta-lactamases that are capable of inactivating cefoxitin and imipenem, two drugs that historically have been effective for the treatment of anaerobic infections.²²¹ Several of these strains are, however, capable of producing massive quantities of the cephalosporinase. Although this enzyme does not have much specific activity against cefoxitin, the drug is inactivated because of the vast quantities produced. Cefoxitin resistance of this nature can be transferred to other strains of Bacteroides spp. A study that investigated the emerging resistance patterns of B. fragilis to various antimicrobial agents over a 3-year period found that resistance to cefoxitin, originally the most active drug against this species, doubled in 2 years.²²¹

Bacteroides spp. also possess a sophisticated system of resistance. In the aforementioned 3-year study, resistance to clindamycin did not increase, and no organisms were resistant to metronidazole or chloramphenicol. Although tetracyclines were the drug of choice for infections caused by B. fragilis in the early 1950s, almost 66% of the organisms were resistant to the drug. Variation in anaerobic (e.g., B. fragilis) resistance patterns have been described for different geographic regions. In addition, various patterns have been described according to the site of tissue or sample collection. One study found that organisms isolated from the blood were more resistant to piperacillin, cefoxitin, and clindamycin than were the same isolates obtained from the abdominal cavity. Experimental studies have shown that resistance genes can be naturally transferred from B. fragilis to E. coli. This finding may have profound implications for the treatment of mixed anaerobicaerobic infections, particularly those originating from colonic bacteria. One study²¹³ has documented a 29% incidence of resistance of Bacteroides spp. to ampicillin; in contrast, 100% were susceptible to amoxicillin, clavulanic acid, and chloramphenicol, and most were susceptible to metronidazole. Only 83% were susceptible to clindamycin.

Clostridium difficile has been associated with hospital outbreaks of illness in hospital environments (based on the author's personal experience).²²² Its ability to form spores to minimize exposure to oxygen renders it resistant to most environmental disinfectants, with the exception of chlorine bleach. Animals receiving anticancer or antibacterial chemotherapeutic agents are at a risk of developing infection when exposed to environmental clostridial spores. Treatment in such situations generally is accomplished with metronidazole until clinical signs resolved; feces should be negative for enzyme-linked immunosorbent assay (ELISA) toxin (1 to 15 days).

Antimicrobial Drugs

The successful treatment of an anaerobic infection depends on altering the local environment in a manner designed to reduce bacterial proliferation and checking the spread of infection into adjacent tissues. The first goal is achieved by surgical débridement of dead tissue. At the time of surgery, pockets of pus should be drained, trapped gas released, and any obstructions to drainage eliminated. Surgery should also improve circulation to the site of infection, which will improve oxygenation of tissues. Local spread of infection is managed by administration of an antimicrobial. Although the number of antimicrobials that can be used to treat anaerobic infections is limited, there are several that are effective and safe. Resistance does not yet seem to have impaired empirical selection of anaerobes (Table 8-12), although caution is still indicated in patients that previously received antimicrobials or those at risk for therapeutic failure for other reasons.

Beta-Lactam Antibiotics

Penicillin G, a natural antibiotic, is the prototype penicillin. The anaerobic susceptibility of the semisynthetic aminopenicillins ampicillin and amoxicillin is similar to that of penicillin G. In contrast to penicillin G, they are effective after oral administration. Penicillins are the drug of choice for clostridial infections and for Peptostreptococcus spp. They are generally effective against Fusobacterium and Actinomyces spp. Although the penicillins are effective against many Bacteroides spp., several species, including B. melaninogenicus and B. fragilis, both of which are clinically important, are uniformly resistant to most penicillins,²¹¹ with the exception of piperacillin.²²⁰ A 33% rate of resistance by Bacteroides spp. to penicillin G has been reported in veterinary patients. A large percentage of these strains was also resistant to ampicillin and cephalothin.²¹⁴ Jang and colleagues²¹³reported that 29% of Bacteroides isolates in veterinary medicine are resistant to ampicillin. The efficacy of penicillin (and cephalosporin) antibiotics against B. fragilis can be improved by combining the antibiotic with clavulanic acid or sulbactam. Indeed, Jang and colleagues²¹³ reported all Bacteroides isolates to be susceptible to amoxicillin-clavulanic acid. Both of these drugs have a greater affinity for beta-lactamases than do the betalactam antibiotics and preferentially bind to and inactivate the bacterial enzyme. The efficacy of amoxicillin against B. fragilis is greatly enhanced when combined with clavulanic acid.²²³ The addition of clavulanic acid also enhances the efficacy of amoxicillin against several gram-negative enteric organisms, which may be important factors in the pathogenesis of mixed infections. Jang and coworkers²¹³ found 100% of clostridial organisms to be susceptible to ampicillin, compared with 80% of isolates that were susceptible to clindamycin.

The cephalosporins are very similar to the penicillins in pharmacokinetic characteristics but as a class are less efficacious against anaerobes. First-generation cephalosporins (e.g., cephalothin, cefazolin, and cefadroxil) may be effective against many anaerobic organisms, with the exception of *B. fragilis*; use should be based on susceptibility testing. The second-generation cephalosporin cefoxitin is, however, one of the most effective antibiotics against anaerobic infections, including *B. fragilis*, although resistance is increasing, as was previously noted. As a second-generation cephalosporin, cefoxitin is also effective against many gram-negative enteric organisms, which enhances its utility for the treatment of mixed infections. Many *Clostridium* spp. are resistant to most

cephalosporins; thus alternative antimicrobials should be considered for infections caused by these organisms. Currently, piperacillin and cefoxitin remain the most active beta-lactam antibiotics for the treatment of human anaerobic infections. Because of the variable nature of susceptibility patterns and the unique mechanisms and characteristics of beta-lactams exhibited by anaerobic bacteria, however, culture and susceptibility monitoring of these pathogens in crucial. The carbapenems are the newest class of beta-lactam antibiotics and are among the the most effective beta-lactam antibiotics against anaerobic infections.

Other Antimicrobials

Chloramphenicol is one of the most effective antimicrobial drugs against all strains of anaerobic bacteria, including penicillin-resistant B. fragilis.213 Its utility, however, is decreased by its bacteriostatic nature as well as by its tendency to cause adverse reactions, particularly in the cat, and concerns regarding human exposure. Clindamycin is a lincosamide antimicrobial whose mechanism of action is similar to that of chloramphenicol. Like chloramphenicol, it is bacteriostatic against anaerobic organisms. Clindamycin is more efficacious for the treatment of anaerobic infections than its parent drug, lincomycin. Clindamycin is also concentrated in white blood cells at the site of infection, which is considered to be an important factor in the efficacy of this drug. This is an active energy process, however, which may not occur in the oxygen-deficient environments that characterize anaerobic infections. The spectrum of activity of clindamycin includes anaerobic organisms. It is generally very effective against most strains (83% cited by Jang et al.²¹³) of B. fragilis, including those resistant to penicillin, and is very effective against veterinary isolates of Clostridium. Clindamycin is not, however, effective against C. difficile, and its use may be associated with pseudomembranitis or other gastrointestinal disorders related to microbial overgrowth. Although fluoroquinolones are generally not considered sufficiently broad in spectrum to include anaerobes, newer-third generation drugs may be very effective. An example is pradofloxacin, whose efficacy includes anaerobes associated with gingival disease in dogs and cats.267

SELECTED ANAEROBIC INFECTIONS

Clostridum difficile

C. difficile is reaching epidemic proportions in human patients. Antimicrobial exposure results in suppression of normal flora and is a major risk factor with clindamycin, penicillins, and cephalosporins. A more recent study in humans found fluoroquinolones to be the primary risk factors for the emergence of a clonal-based outbreak in a hospital.²²⁴ Transmission is fecal to oral through contaminated environment and hands of health care personnel in human patients (as with MRSA), and a new strain with increased virulence has emerged. Outbreaks have increased in the hospital setting, although community-acquired infections are increasing in Europe.²²⁵ Outbreaks have been reported in veterinary hospitals as well.²²² Clinical signs

range from mild diarrhea to pseudomembranous colitis and toxic (and potentially fatal) megacolon. Toxin binds to intestinal cells and disrupts tight junctions, leading to inflammation and watery diarrhea, the hallmark of infection. Toxins are downregulated by the *tcdC* gene; deletions of this gene leads to clinical signs. A binary toxin also has been described, although its role in human disease is not well defined. A seasonal pattern has been described for selected human hospitals.²²⁶ Epidemiologic description in humans is complicated by diagnosis based on the presence of toxin rather than organism culture. Resistance to newer 8-methoxy fluoroquinolones used to treat the organism (e.g., gatifloxacin and moxifloxicin) has already emerged.²²⁷

C. difficile may massively increase its exotoxin production in the gastrointestinal tract in the presence of subinhibitory plasma clindamycin concentrations because of increased bacterial synthesis of exotoxin.²²⁸ The use of metronidazole, a popular antigiardial drug, for the treatment of anaerobic infections in dogs and cats has markedly increased. The drug is consistently effective against most anaerobes, including *B. fragilis* as well as most other strains of *Bacteroides*. Metronidazole is also effective for treatment of human cases of *C. difficile*. It is generally not effective against *Actinomyces* or *Propionibacterium*. Its mode of action probably results from disruption of bacterial DNA after bacterial metabolism to toxic metabolites. The low oxidation-reduction potential of the anaerobic environment is conducive to bacterial formation of toxic metabolites.

Vancomycin is the drug of choice for humans for the treatment of antibiotic-associated colitis caused by *C. difficile*. Its mechanism of action results from inhibition of bacterial cell wall synthesis. Thus its actions are primarily bactericidal. Its spectrum includes *Clostridium*, gram-positive bacilli (*Bacillus*, *Actinomyces*), and *Propionibacterium*.

The sulfonamides can be effective against many anaerobic organisms. Caution should be taken, however, because of the patterns of resistance that have been noted for veterinary anaerobic isolates. For serious or difficult anaerobic infections, sulfonamide use should be based on susceptibility data.

Clostridum tetani

Tetanus is caused by the neurotoxin tetanospasmin produced by vegetative Clostridum tetani, a motile, gram-positive sporeforming anaerobe.²²⁹ Spores contaminating an anaerobic site (e.g., in the presence of a foreign body or tissue necrosis) vegetate. The toxin, tetanospasmin, enters axons of local motor neurons, and by retrograde movement reaches the axonal body in the spinal cord. Eventually the toxin reaches the brain, where it acts to cleave the protein responsible for fusion of the gamma-aminobutyric acid-containing synaptic vesicle with the neuronal cell membrane.²³⁰ As such, it inhibits the release of inhibitory neurotransmitters gamma-aminobutyric acid as well as glycine, resulting in presynaptic blockade for selected synapses of the spinal cord (predominant site) and brain. Dogs and cats are considered fairly resistant to tetanus and therefore are not generally vaccinated; indeed, vaccination is not protective in humans, necessitating revaccination with exposure.²³¹ Clinical signs generally occur within 5 to 10 days of wound acquisition, although delays of up to 3 weeks have been reported.²³¹ Wounds closer to the head are associated with more rapid onset of generalized tetanus. Relative resistance of carnivores to the toxin may result in signs localized to the wound area, manifested as stiffness that usually spreads to the opposite limb or beyond. Generalized tetanus is associated with a guarded prognosis and is characterized as extreme muscle rigidity, manifested as a stiff gait, difficulty in standing or lying down, and hyperthermia. Intracranial signs accompany localized tetanus, resulting in hypertonic facial muscles (e.g., trismus or lockjaw) and reflex muscle spasms. Animals have difficulty with prehension or swallowing solid food. Dysuria, urine retention, constipation, and gas distention are not unusual. Autonomic clinical signs may not appear until several days after rigidity has occurred. Signs include ptyalism, tachycardia, tachypnea, and hypertension.²³¹ Death, when it occurs, usually results from respiratory compromise.²²⁹ Untreated cases can prove fatal, although natural resistance often limits the disease to localized or mild cases.

Treatment focuses on antimicrobial therapy in an attempt to decrease formation of neurotoxin and neutralization with antitoxin of any toxin not yet bound to nerve tissue. The intravenous route is preferred to the intramuscular or subcutaneous routes (the latter may require 48 to 72 hours for therapeutic concentrations to be reached). Antitoxin (100 to 1000 U/kg, <20,000 U total) should be administered every 5 to 10 minutes; the dose should be decreased for larger dogs. Pretreatment of anaphylaxis is appropriate; administration of a test dose (0.1 to 0.2 mL) subcutaneously or intradermally may help identify those at risk (formation of a wheal at the site). Localized injection at the wound site (1000 U) may be helpful; likewise, intrathecal (I-10 U) injection has been shown experimentally to reduce morbidity and mortality rates in dogs, probably because of better access to neurotoxin bound to nervous tissue. In humans 500 U is injected proximal to the wound. Recovery is slow and progressive, even when antitoxin is administered. Recovery at sites were tetanospasmin is bound requires formation of new receptors, which takes approximately 3 weeks.²³¹

Local and systemic antibiotic therapy should be used to eradicate vegetative clostridial organisms, thus reducing the amount of toxin released. Metronidazole is superior to penicillin G and tetracyclines. Penicillins inhibit type A gammaaminobutyric receptors, which is the target of tetanus toxin. Studies comparing the time to recovery and mortality of penicillin with those of metronidazole for treatment of tetanus in humans are controversial, with studies ranging from improved outcome for metronidazole to no differences between treatments.²³⁰ The studies are complicated by differences in the form of penicillin studied, limiting conclusions. However, because of the possible impact of penicillin, metronidazole might be preferred; at the very least, procaine penicillin probably should be avoided because it may exacerbate CNS symptoms.²³⁰

Animals should be removed from stimulating environments. Supportive therapy for tetanus includes control of autonomic signs, reflex spasms, or convulsions. Anticholinergics may be indicated to treat bradyarrhythmias. Phenothiazines

(chlorpromazine preferred) combined with barbiturates (pentobarbital or phenobarbital) have been recommended as the preferred treatment.²²⁹ Caution with the use of phenothiazines is recommended for patients with seizures; phenothiazines lower seizure threshold and can worsen seizures associated with other disorders. However, use for treatment of muscle rigidity may preclude concerns regarding seizures. Further, a retrospective study of acepromazine use in dogs experiencing seizures found no increase in seizure activity associated with acepromazine. However, acepromazine may be sufficiently different from other phenothiazines to warrant caution in extrapolating information to phenothiazines as a class.²³² Phenobarbital should be administered as a loading dose (12 mg/kg to achieve the lower end of the recommended range for epilepsy). Glycopyrrolate should be administered to control bradycardia that may occur with the combined use of these drugs. Benzodiazepines (e.g., diazepam) may be useful for controlling spasms and hyperexcitability; methocarbamol is a less effective centrally acting skeletal muscle relaxant. Methocarbamol, dantrolene (a peripherally acting skeletal muscle relaxant), or gamma-aminobutyric acid antagonist may be useful, including in combination, for the control of spasticity. Tetanus-induced respiratory compromise requires intubation and respiratory support, which may require sedation, paralytic agents, or both. Linnenbrink²³¹ discussed the limited use of supraphysiologic concentrations (2 to 4 mmol/L) of magnesium for control of autonomic dysfunction in human patients. Magnesium decreased rigidity and imparted a dose-sparing effect on sedatives. Hypocalcemia occured but generally did not need correcting. The loss of tendon reflexes was monitored as an indication of toxicity. Successful management of tetanus in two dogs has been reported.233 Therapy included a combination of general anesthestics (pentobarbital, propofol), anticonvulsants (diazepam, including by constant-rate infusion, phenobarbital), and muscle relaxants (diazepam, methocarbamol), including phenothiazine sedatives (for muscle rigidity). Supportive therapy was intensive and crucial to therapeutic success, with full recovery requiring several weeks.

Clostridium botulinum

Botulism in dogs is almost exclusively caused by type C Clostridium botulinum organisms that release the neurotoxin in a vegetative state.¹¹⁰ Although released in the inert form, cleavage by tissue or bacterial proteinases generates the dichain metalloproteinase neurotoxin, which is similar to tetanus toxin. Generally, clinical signs result from ingestion of the preformed toxin, in part because adult animals generally are resistant to colonization by the organism, although antimicrobial therapy can facilitate colonization. The toxin is absorbed by intestinal lymphatics as with nutrient proteins; toxin complexed with other proteins appears to protect the toxin from intestinal degradation. At the nerve terminal, the toxin prevents the presynaptic release of acetylcholine by irreversibly binding. The toxin is characterized by a very high affinity for the presynaptic membrane receptors, making it one of the most potent toxins. At this point the toxin is susceptible to inactivation by antitoxin. However, once receptor-mediated endocytosis has moved the toxin into the cell, antitoxin activation can no longer occur. Of the two chains, the L chain is more likely to inhibit acetylcholine release. Clinical sequelae, evident within hours but delayed for up to 6 days, include paralysis and degeneration of the affected synapse with subsequent lower motor neuron and parasympathetic dysfunction. Death generally does not occur unless paralysis extends to the respiratory tract. Recovery follows formation of new terminal axons and neuromuscular junctions with cranial nerve, neck, and forelimb functions generally returning to normal first.

Therapy focuses on supportive care; spontaneous recovery generally will occur in all animals if respiratory function is not affected. Antitoxin is ineffective if nerve endings have been penetrated, which generally occurs rapidly; however, treatment may be beneficial if oral absorption of the toxin is ongoing. Type C antitoxin (10,000 to 15,000 U, intravenously or intramuscularly) should be administered twice, with each dose 4 hours apart. The antitoxin remains in the system for 40 days, mitigating the need for follow-up therapy. Penicillin or metronidazole can be administered to reduce the intestinal growth of *C. botulinim*, although the efficacy of this practice is questionable and may be contraindicated if organism death is thought to increase toxin release. Neuromuscular potentiators (aminopyridine, diaminopyridine, guanidine hydrochloride) have not proved effective.

Clostridium perfringens

C. perfringens capable of producing an enterotoxin can cause severe diarrhea.²³⁴ Binding of the toxin to intestinal epithelial cells increases permeability, causing fluid and ion secretion, cell death, and sloughing of the intestinal mucosa. Sporulation leading to enterointoxication can occur after antimicrobial therapy, increased intestinal pH, dietary alteration, and immunosuppression; it also is associated with viral enteritis. Enterotoxemia can cause rapid death. Very occasionally, clinical signs may occur after ingestion of contaminated meat or as a result of nosocomial infections. Therapy includes antimicrobials and intensive fluid therapy. Antimicrobials that are variably effective include metronidazole, ampicillin, amoxicillin–clavulanic acid, tylosin, clindamycin, and tetracyclines.

MISCELLANEOUS INFECTIONS

L-Form Bacterial Infection

L-form bacteria either have a deficient cell wall or lack one altogether. Their role in causing infections in animals is not well understood. A number of organisms are capable of becoming cell wall deficient, including *Staphylococcus* and *Streptococcus* species. Information regarding the causes of an organism assuming this structural state are not clear, nor is the role of L-forms in the cause of disease. Presumably, the infection starts in the skin and progresses as multiple abscesses form and then dehisce. Bacteremia can lead to polyarthritis. Because of their cell wall–deficient state, microorganisms are difficult to detect by light microscopy but can be visualized inside phagocytes by electron microscopy. Drugs whose antibacterial effects do not target the cell wall are indicated. Tetracyclines have been the drug of choice.²³⁵

Hemobartonellosis (Hemotropic Mycoplasmosis)

The causative agent of feline infectious anemia was recently reclassified as *Mycoplasma* on the basis of RNA sequence analysis, leading to a change in terminology to hemotrophic mycoplasmosis. Mycoplasma are gram-negative organisms that lack a cell wall. At least two variants have been identified in the cat, with the large form, Ohio strain (*Mycoplasma haemofelis*) being more pathogenic compared with the small form, California strain (*Candidatus Mycoplasma haemominutum*); the latter apparently has not been associated with disease.²³⁶ *Mycoplasma haemocanis* has been associated with anemia in splenectomized dogs, although the distinction between *M. haemofelis* and *M. haemocanis* is not clear.

Experimentally, inoculation is followed by a period of 2 to 34 days before clinical signs and anemia associated with parasitemia appear; this second period persists from 18 to 30 days. Mortality rates are highest during this phase, with hematocrit levels returning to near normal in surviving cats. Recovered cats remain carriers for years and may experience recrudescence of clinical signs. Anemia reflects predominantly extravasular rather than intravascular hemolysis. Inclusions and other changes in the surface of the red blood cell result in osmotic fragility, reduced deformability, and subsequent removal from the bloodstream by the spleen. Afflicted animals may have lowered resistance to concurrent infections; an association with feline leukemia virus (but apparently not feline immunodeficiency virus) may worsen the pathopyhysiology of either syndrome.²³⁶

Doxycycline is the treatment of choice (5 mg/kg orally every 24 hours for 21 days) but will not necessarily eradicate the infection. Care should be taken to either administer a liquid preparation or follow capsules with a liquid wash to prevent esophageal damage. Experimentally, azithromycin was ineffective at 15 mg/kg orally twice daily for 7 days for treating large-form mycoplasma in cats.²³⁷ Cats remained PCR positive and anemic after treatment. In contrast to azithromycin, fluoroquinolones may be effective for treatment. Dowers²³⁸ prospectively compared 2 weeks of treatment with enrofloxacin at a low (5 mg/kg po qd) and high dose (10 mg/kg po qd) to doxycycline (5 mg/kg po bid) in cats (n = 16, 4 per group, including a no treatment group) experimentally infected with large form H. felis. All treatment cats responded. The high dose enrofloxacin group had fewer days of anemia compared to the other groups; 1 doxycycline and 2 high-dose enrofloxacin cats cleared of organisms based on PCR and remained disease free for at least 6 months. Ishak et al.²⁶⁸ studied the efficacy of marbofloxacin (2.75 mg/kg daily for 2 weeks beginning 16 days after infection) for treatment of experimentally induced *M. haemofelis* infection in cats (n = 12; including 6)untreated control). Marbofloxacin was associated with more rapid hematologic response. However, PCR-based detection of organisms (viral numbers not quantified) did not differ from that of the nontreated group, indicating that infection was not consistently eradicated. Nonetheless, the authors concluded that marbofloxacin was a reasonable treatment option. Tasker et al.²⁶⁹ also studied the efficacy of marbofloxacin (2 mg/kg orally daily for 4 weeks) for treatment of *M. haemofelis* in experimentally infected cats with or without chronic feline immunodeficiency virus (n = 6/group, 3 cats from each group treated). Organism counts were reduced and animals improved, but animals were not cleared.

Dowers et al.²³⁹ also compared the efficacy of pradofloxacin at a low (5 mg/kg orally qd) and high dose (10 mg/kg orally qd) to doxycycline (5 mg/kg orally bid) in cats (n = 23) experimentally infected with M. haemofelis. Therapy was initiated when cats became positive on PCR and continued for 6 weeks. However, cats that became PCR negative by day 42 (the last day of treatment) were also treated with methylprednisolone sodium acetate (20 mg/kg intramuscularly) in an attempt to cause recrudescence after immunosuppresion. The number of days of anemia did not differ among treatment groups; all were less than the control group. Organism copy numbers were significantly lower in the low-dose group compared with the doxycycline group for 4 of the 5 posttreatment weeks. Four of 6 cats in the highdose and 2 of 6 cats in the low-dose pradofloxacin group tested negative (cPCR) on day 42 of treatment and were immunosuppressed. None of the doxycycline cats yielded negative PCR results. Immunosuppression yielded transiently positive results in 5 of the cats; 1 cat became persistently negative. By day 28 of glucocorticoid therapy, however, 4 of the 6 transiently positive cats (3 low doses and 1 high dose) became negative. These studies consistently indicated that, under experimental conditions, fluoroquinolones may play a role in the treatment and possible clearing of *M. haemofelis* and are reasonable alternatives when doxycycline fails or cannot be used. Lappin²⁴⁰ prospectively evaluated the efficacy of imidocarb (5 mg/kg intramuscularly; repeated in 2 weeks) for treatment of experimentally induced (11 cats) chronic haemobartonellosis. Both the large form (M. haemofelis; n = 4; 3 treated, 1 control), and small form (*M. hemominutum*; n = 3, 2 treated, 1 control) were studied. Three cats were infected with both organisms. Side effects were limited to irritation at the injection site. Both control cats remained PCR positive throughout the study. One cat inoculated with both forms and one cat inoculated with *M. haemofe*lis became persistently negative at weeks 4 and 6 after treatment (the remaining cats became negative at week 2 but positive at weeks 4 and 6) and were subsequently treated with methylprednioslone. One cat died as a result of undetermined causes, and the second became PCR positive. Imidocarb does not appear to be a reasonable alternative for clearing chronically infected cats.

KEY POINT 8-37 Doxycycline remains the drug of choice for treatment and eradication of feline mycoplasma, with high-dose fluoroquinolones a potential treatment alternative.

The concurrent use of immunosuppressive doses of glucocorticoids is controversial. Glucocorticoids may increase the number of microogranisms in the blood and may exacerbate accompanying concurrent infections.²³⁶

Bartonellosis and Coxiella

Bartonella is an aerobic, gram-negative, intracellular organism, probably transmitted by ticks. It targets cells of the immune system, living in endothelial and red cells. The organism is associated with a reduction in CD8+ cells and the expression of adhesion molecules. The association with *Bartonella* and IE has been described.²⁴¹ All seropositive dogs were also seropositive for *Anaplasma phagocytophilum*. Its association with valvular disease in people results in a poor prognosis. Treatment should be at least 2 weeks in duration. Potentially effective drugs include doxycycline.

Brucellosis

Pathogenesis

An infectious disease, brucellosis draws attention because of its insidious nature, difficulty to treat, and zoonotic potential. Brucella canis, the causative agent of brucellosis in dogs, is a small gram-negative coccobacillus. Among Brucella, B. canis stands out in morphology, biochemistry, and immunology. Among its differences compared with other organisms is its zoonotic potential: The disease can be transmitted only between members of Canidae. Cats are only transiently infected after experimental infection. Dogs are susceptible to infection with Brucella abortus but do not appear to be important to the spread of infection. Infection by Brucella involves penetration of mucous membranes after contact with contaminated fluids from an infected urogenital tract or an aborted fetus. Phagocytized organisms are transported to lymphatic and genital tissues, where multiplication occurs. Leukocyteassociated bacteremia can persist for years. Organisms can be intermittently shed from infected animals (during estrus, breeding, or abortion).²⁴²

Although antibodies are generated against Brucella species, as with most intracellular organisms, cell-mediated immunity is the primary mechanism of host defense. Cell-mediated immunity can provide protection against reinfection, although persistent infection may be necessary to provide persistent protection. Immune response to inflamed infected tissues (e.g., spermatozoa) contributes to infertility. Immunosuppressive drugs appear to increase the risk of infection but may not alter the course of the disease in dogs already infected. Spontaneous recovery can occur but may take up to 5 years. During this period infection might be associated with bacteremia. As with other blood-borne organisms, Brucella may localize in tissues other than the urogenital tract. Discospondylitis; anterior uveitis; and, less commonly, glomerulopathy or meningoencephalitis may result. Diagnosis is based on agglutination tests, agar-gel immunodiffusion, or ELISA.²⁴² Therapy with antibiotics does alter the progression of the disease.

Antimicrobial and Adjuvant Therapy

A number of antimicrobial drugs are effective in vitro against *Brucella* but may not be able to eradicate infection. Antimicrobial therapy can relieve symptoms, shorten the duration of illness, and reduce the likelihood of complications yet not eradicate the organism.²⁴³ Success will be enhanced by

a combination of effective drugs at high doses for at least 4 weeks. Drugs should be able to penetrate cell membranes; accumulation in phagocytic cells should further facilitate success. Among effective antimicrobials, lipid-soluble tetracyclines (minocycline and doxycycline) are particularly efficacious when used at a high dose and in combination with an aminoglycoside. The World Health Organization has also recommended doxycycline in combination with rifampin, although doxycycline with streptomycin was found to be more effective in the treatment of discospondylitis.²⁴³ Fluoroquinolones should also be effective when combined with aminoglycosides,²⁴³ although clinical trials documenting efficacy in dogs have not been reported. An added advantage of these drugs is intracellular accumulation. Fluoroquinolones may not, however, be effective as sole agents against brucellosis. Human patients intolerant of tetracyclines also responded well to combinations of trimethoprim-sulfonamides and aminoglycosides. Antimicrobial therapy should not be discontinued too early; sequential titers can be used to assess response to therapy.

Infected dogs should be neutered as soon as possible. Glucocorticoids or other immunosuppressive therapy may be indicated for treatment of infections associated with lifethreatening or organ-threatening inflammation (e.g., CNS). Currently, prevention is best implemented through good hygiene practices, neutering of infected animals, and vaccination of cattle.

Leptospirosis

The genus *Leptospira* belongs to the family Treponemataceae, which contains all spirochetes, including *Borrelia* species. Leptospirosis is primarily a disease of wild and domestic animals; humans are infected only occasionally.²⁴⁴ However, it is a reemerging disease for reasons that are not yet known.²⁴⁵

Pathogenesis

Leptospirosis generally causes an acute generalized infection or interstitial nephritis. Leptospires are motile spirochetes; *Leptospira interrogans* tends to be the pathogenic organism in animals. At least three antigenically distinct serovars cause disease in dogs; infection in cats is rare.²³⁴ Infection occurs through the mucosa or abraded skin and can occur between animals or in animals that come in contact with the contaminated environment. Once the mucosa is penetrated, the organism multiplies rapidly in the bloodstream. Inflammation causes parenchymal damage, particularly in the liver and kidney. Persistence in renal tubular cells leads to colonization of the kidney.²⁴⁴ Chronic active hepatitis can be a sequela of infection in dogs.

Leptospirosis can present as a peracute infection manifested by shock and death. Less acute presentation involves fever, anorexia, vomiting, and dehydration. Clinical laboratory tests may reveal thrombocytopenia, electrolyte alterations, and liver damage. Diagnosis is based on serologic testing (paired serum titers). Leptospires are very difficult to recover, with urine analysis by dark field microscopy providing the best chance of discovery.

Antimicrobial Therapy

Treatment focuses on eradication of the causative organism and supportive therapy. Acute renal failure may require intensive management. Antibiotics should inhibit the multiplication of the organism as well as eradicate it. Response manifested as a decrease in fever should be apparent within several hours of administration.²³⁴ Drugs shown to be effective in vitro include most penicillins, third-generation cephalosporins, and tetracyclines but not first- and second-generation cephalosporins. Not all penicillins appear to be able to eradicate the organisms, but high doses of penicillin G, ampicillin, and amoxicillin are among the more effective choices in clearing the urine.^{244,245} Procaine penicillin G (40,000 units/kg intramuscularly or subcutaneously every 24 hours or a divided dose given every 12 hours) is the antibiotic of choice for leptospiremia. It may be necessary to decrease the dose if the animal is in renal failure (e.g., dividing the dose by the serum creatinine), although the real risk of side effects in the presence of renal disease is not clear. Penicillin clears infection with leptospirosis if continued for a sufficient period of time. An injectable form of penicillin should be used for 14 days or until azotemia resolves; an oral form (amoxicillin [22 mg/kg every 8 hours]) can then be initiated. Intravenous ampicillin or amoxicillin (22 mg/kg every 6 to 8 hours) have also been used successfully during initial therapy. Doxycycline can also be used for initial therapy and to clear leptospiremia.^{234,245} Initial penicillin therapy of 2 weeks' duration can also be followed by doxycycline (5 mg/kg twice daily) for 6 to 8 weeks to achieve elimination of the carrier state.

KEY POINT 8-38 Procaine penicillin is the antibiotic of choice for leptospiremia and may clear the infection if administered for a sufficient length of time.

In human patients doxycycline appears to be beneficial for the prevention of infection even after exposure, whereas the penicillins do not appear to prevent infection after exposure (despite their ability to eradicate infection).²⁴⁴ Clearing tissues may be more difficult than clearing urine; doxycycline for 2 weeks appears to be the most frequently recommended for clearing the carrier state in dogs.²⁴⁵ Fluoroquinolones (ciprofloxacin and enrofloxacin) also appear to be effective against leptospires, although clinical studies supporting their use are lacking. Hamsters experimentally infected with L. interrogans responded to ciprofloxacin.²⁴⁶ In vitro studies of five serovars of Leptospira indicated efficacy on the basis of MICs (0.05 to 0.20 µg/mL), although the effect was bacteriostatic; bactericidal concentrations were tenfold to a hundredfold higher.²⁴⁷ Orbifloxacin has proved ineffective.²³⁴ Experimentally, the macrolides also appear effective.²³⁴ Protection is best implemented by prevention of exposure and elimination of reservoirs.

Most dogs presenting with leptospirosis have developed renal disease.²⁴⁵ Thus supportive therapy should focus on treatment of acute renal failure and its associated signs (i.e., uremic gastritis, hypertension). Leptospirosis may be the most widespread zoonotic disease in the world, and vaccination is important to prevention. Gloves should be worn when handling carrier animals. Like *Leptospira* species, *Borrelia* species belong to the family Treponemataceae. *Borrelia* are motile spirochetes that have an outer slimelike layer. They are rapidly killed by desiccation and ultraviolet lights. *Borrelia* infect both humans and animals; up to 15 *Borrelia* species cause disease. The Centers for Disease Control and Prevention has designated Lyme disease as the most common vector-borne infection in the United States. However, the disease may be overdiagnosed in humans.²⁴⁸

Ixodes species are the primary insect vectors of the spirochete Borrelia burgdorferi. Lyme borreliosis afflicts primarily humans and dogs, although cats can be infected experimentally. Organisms are able to adhere to many different types of mammalian cells as well as avoid elimination by phagocytic cells.²⁴⁸ The immune response appears to be initially suppressed during infection, apparently allowing the organisms to spread. The disease is multisystemic, with nonspecific clinical signs such as relapsing fever (during which borreliae are present in blood), anorexia, lethargy, and lymphadenopathy. Polyarthritis might result in episodic lameness; clinical signs often do not develop until several months after infection.^{248,249} Heart block, which occurs in humans,²⁴⁸ has been reported in one infected dog. Clinical laboratory changes are also variable, depending on the site of localization of the infection. Diagnosis is facilitated by serum titers, although interpretation is complicated by interlaboratory variability and overlap between titers indicative of clinical versus subclinical infection. Resolution of natural disease in humans appears to be dependent on class II major histocompatibility complex genes.

According to the 16th Consensus Conference on Antiinfective Therapy,²⁵⁰ the goal for treatment of borreliosis is eradication of infection (not negative serology) such that progression to chronic disease might be prevented. Treatment should be implemented for 14 to 21 days. Based on in vitro testing, antimicrobials effective against B. burgdorferi include, in order of most to least effective, ceftriaxone, erythromycin, amoxicillin, cefuroxime, doxycycline, tetracycline, and penicillin G.²⁴⁹ In human medicine the first line of oral therapy for the primary phase of illness is amoxicillin or doxycycline, with cefuroxime-axetil implemented as second line. Azithromycin is indicated if first or second line cannot be administered. Treatment for the subsequent phases include ceftriaxone (intravenous or intramuscular) or penicillin (intravenous), doxycycline, and amoxicillin (orally) for 21 to 28 days. Antimicrobial therapy based on clinical response includes, in order of preference, tetracyclines (doxycycline is the drug of choice), high doses of ampicillin or amoxicillin, and erythromycin and its derivatives.²⁴⁸ Third-generation cephalosporins (e.g., ceftriaxone) are also generally effective. One study in humans found similar clinical cure rates for ceftriaxone (85%) compared with doxycycline (88%).²⁵¹ No information appears to be available regarding the efficacy of cefpodoxime; however, initial studies by the manufacturer may have indicated a lack of in vitro susceptibility.^{251a} Accordingly, the use of either cefpodoxime or cefovecin should be based on susceptibility data. The organisms appear to be resistant to ciprofloxacin (and

presumably enrofloxacin and other veterinary fluoroquinolones) and to the aminoglycosides. Oral therapy is sufficient except in cases of neurologic signs; intravenous therapy should be instituted in such cases. B. burgdorferi is a potent inducer (in vitro) of TNF-alpha and interleukin-1ß. Antimicrobial therapy in humans is occasionally characterized by a Jarisch-Herxheimer reaction, which may reflect release of spirochetal endotoxin and subsequent septic shock syndrome.²⁴⁸ Supportive therapy includes nonsteroidal antiinflammatories as needed for joint lameness. Disease-modifying chondroprotective agents should be strongly considered. Care should be taken when combining nonsteroidals with doxycycline or minocycline because of the competition for protein-binding sites and the potential for adverse reactions to the nonsteroidal drug. Glucocorticoids should be limited to treatment of acute spirochetemia; recrudescence of spirochetemia will be facilitated with their use. Prevention focuses on eradication of the vector.

Higher Bacteria: Nocardiosis and Actinomycosis *Pathogenesis*

Nocardiosis is generally presented as a localized infection. The organism is an acid-fast, aerobic, soil-borne actinomycete, usually introduced through the respiratory tract. Traumatic penetration may result in a localized skin infection.^{252,253} *Actinomyces* are commensal anaerobic organisms found in the oral cavities of animals. Infection commonly follows penetrating wounds, such as inhalation of grass awns. *Actinomyces* are distinctive in their configuration, presenting as filamentous growth with true branching.

The taxonomy of Nocardia is currently evolving, but Nocardia asteroides is among the more commonly identified pathogens. Culture is made difficult sometimes by the slow growth that characterizes this organism when present in mixed cultures from clinical material. Rapidly growing bacteria often obscure the smaller Nocardia colonies. Colony characteristics may take up to 2 to 4 weeks to be noticed. Gram staining may help identify the organisms earlier, although smears may also be negative. Nocardia, but not Actinomyces, stains acid fast, although acid-fast staining in Nocardia is also variable. Nocardia appears as beaded, branching filaments when Gram stained but will not stain with hematoxylin and eosin preparations or in periodic acid-Schiff stains for fungi (see Figure 6-14)).²⁵² In human patients, positive cultures and smears occur in only one third of the cases. Pus from a fistula or abscess will facilitate identification. Nocardia and Actinomyces also stain gram positive, but again staining is irregular.²⁵⁴

Nocardiosis is an opportunistic infection. In humans a number of underlying diseases, most of which are accompanied by an altered immune system, predispose the patient to nocardiosis. Infections occur because the organism is able to evade bacterial protective mechanisms of the host. Immune T cells and neutrophils are important to eradication of *Nocardia*. *Nocardia* may be resistant to oxidative bursts of neutrophils. Filamentous log-phase cells of *Nocardia* are more virulent and toxic to macrophages than are the coccoid stationary-phase organisms, which can be easily phagocytized.

Nocardia produces suppurative necrosis and abscess formation. In humans Nocardia in skin seldom causes a marked fibrotic response; rather, granulation tissue will be loose, with bands of fibrous tissue surrounding the lesions. Confluent abscesses form with little to no encapsulation. Extension to the pleura or chest wall may result in empyema, subcutaneous abscesses, or sinus tracts. Occasionally, bony involvement may occur. Calcium-containing "sulfur granules" present a barrier to bacterial penetration and may indicate reversion of the organism (*Actinomyces*) to an L-form.

Antimicrobial and Adjuvant Therapy

A number of antimicrobials are effective against both Actinomyces and Nocardia. An anaerobic environment and hence infection with Actinomyces should be assumed unless proved otherwise, thus leading to more conservative antimicrobial selection. Penicillins (penicillin G, amoxicillin) are generally preferred, although resistance and L-form organisms can preclude their efficacy.²⁵⁴ Clavulanic acid can reduce the risk of resistance. The formation of protective calcium granules by certain strains of Actinomyces limits antibiotic penetration into the organisms. The formation of these granules is stimulated by the presence of penicillin antibiotics. Trimethoprimsulfonamide combinations are also very effective, although high doses are recommended. Combinations of penicillins with trimethoprim-sulfonamide result in synergistic actions against Nocardia and Actinomyces186 (high doses and frequent intervals). Clindamycin and erythromycin are also effective, particularly against L-forms.²⁵⁴ The aminoglycosides are highly effective against Nocardia and Actinomyces, and synergistic activity has been documented against this organism with combinations. Minocycline (and presumably doxycycline) also is effective, although use of this bacteriostatic drug may preclude combinations with other antimicrobials.

Treatment for both Nocardia and Actinomyces should occur for at least 6 weeks, with high doses at frequent intervals (see the discussion of respiratory tract infections in this chapter). Treatment should continue beyond resolution of clinical signs. Adjuvant therapy should include drainage and lavage of empyema and, when indicated, chest tube drainage or surgical débridement. Lavage should continue for several days until cytologic examination of aspirated fluid indicates resolution of infection and fluid accumulation decreases (5 to 10 days; see previous discussion of empyema). The author has often recommended initial hospitalization and intravenous therapy with amikacin and amoxicillin-clavulanic acid or, for serious, lifethreatening infections, a carbapenem followed 10 to 14 days later with very high (45 to 60 mg/kg twice daily; note the risk of thyroid gland suppression at this dose) oral sulfadiazine, with trimethoprim replacing the aminoglycoside and high, frequent doses of amoxicillin-clavulanic acid replacing the carbapenem. The amoxicillin-clavulanic acid combination should be continued with the sulfonamide for 4 to 6 weeks or more. The beta-lactam should be administered at 6- to 8-hour intervals.

Mycobacteria

Mycobacteria are composed of a number of aerobic, acid-fast bacteria. They vary markedly in host affinity and ability to cause disease. Disease is frequently accompanied by granulomatous inflammation because of their ability to survive phagocytosis. The acid-fast nature of these microorganisms reflects the large amount of lipid material in the cell wall. Constituents of the cell wall stimulate the granulomatous response. The organisms are more resistant than most organisms to environmental changes (e.g., pH, heat) and are more resistant to disinfection. Some organisms (most notably Mycobacterium avium) can survive in the environment for several years. They are, however, very susceptible to 5% phenol or 5% household bleach. Generally, organisms causing disease are characterized by one of three forms.²³⁵ Tuberculosis generally is internal in location. Infecting organisms include Mycobacterium tuberculosis (more common in dogs) and Mycobacterium bovis (more common in cats). Leprosy is characterized by localized cutaneous nodules; Mycobacterium lepraemurium is probably the most common infecting organism (in cats). Atypical mycobacteria generally presents as a spreading subcutaneous inflammatory disease (Figure 8-11); among the several organisms causing this complex is M. avium. Dogs and cats are most commonly infected by owners with disease or exposure to infected farm animals.

Tuberculosis

Dogs and cats are more susceptible to infection by tuberculous mycobacteria than by atypical mycobacteria. Infection generally occurs through the respiratory or alimentary tract. Local multiplication at the site of infection results in a granulomatous response at the primary complex (site of deposition) and local lymph nodes. Particularly in cats, however, a granulomatous response may develop only in surrounding lymph nodes. For tuberculosis respiratory infections are more common in dogs; intestinal infections are more common in cats. Infection can be followed by elimination of the organisms in animals with a sufficient immune response. The more common sequelae are location within phagocytic cells, intracellular multiplication, and granuloma formation as the body attempts to eradicate the organism. Organisms that outpace the host immune system can cause disseminated disease. Immunity is incurred by the cell-mediated response, but factors that facilitate an adequate response in the host are not known. Diagnosis can be facilitated with intradermal skin testing in dogs with the highest concentration of antigen used in humans. Cats do not react strongly to intradermal testing. Diagnosis can be facilitated by the presence of acid-fast organisms in tissue biopsy material.

Antimicrobial therapy is complicated by the fastidious nature of the organism. Drug penetration into the organism is likely to be more difficult than for other organisms; intracellular survival further complicates efficacy of drugs reaching the site of infection. Treatment should generally include combination therapy for at least 6 to 9 months. A combination of isoniazid (10 to 20 mg/kg orally once daily) plus rifampin (10 to 20 mg/kg orally every 12 to 24 hours) plus ethambutol (15 mg/kg orally every 24 hours) is the most effective therapy (in humans), although isoniazid-resistant organisms have become increasingly difficult to treat. More rapid remission is likely with intravenous administration. The isoniazid can also be administered prophylactically (6 to 12 months) in cases of exposure. The fluoroquinolones are also effective against

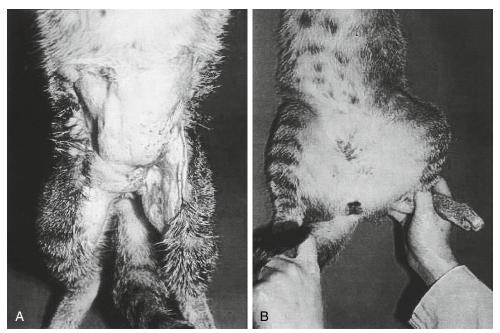

Figure 8-11 Atypical mycobacterium in a cat before (*A*) and 3 months after (*B*) treatment with a combination of enrofloxacin and sulfadiazine–tribrissen. Note the granulomatous tissue and multiple fistulous tracts. (Photographs courtesy Katrina Mealey, DVM, PhD, DACVIM, DACVCP, Washington State University, Pullman, WA.)

selected species of mycobacteria. *M. avium* (see later discussion of atypical mycobacteria) is an exception, although it does also respond to other drugs used to treat atypical mycobacteria. Infected animals remain a health hazard because they serve as temporary sources of dissemination in the environment.

Leprosy

Feline leprosy is caused by *M. lepraemurium*, also the causative organism of rat leprosy. The infection causes rapidly growing, soft, fleshy nodules in the skin and subcutaneous tissues, usually on the head or extremities. Infected cats are generally healthy, and the lesions are not painful. Feline leprosy may comprise two different clinical syndromes, one tending to occur in young cats and caused typically by *M. lepraemurium* and another in old cats caused by a single novel mycobacterial species.

Diagnosis is generally based on the presence of granulomatous inflammation and acid-fast organisms in biopsy specimens or impression smears; PCR may also be available. Treatment includes surgical removal and antimicrobial therapy. Drugs include dapsone (1 mg/kg [dogs] orally every 8 hours or 50 mg [cats] orally every 12 hours) for 2 weeks or clofazimine (8 mg/kg orally every 24 hours for 6 weeks and then twice weekly thereafter). Rifampin may also be useful. Cats with feline leprosy caused by a slow-growing mycobacterium responded well to a combination of two or three antibiotics:²⁵⁵ rifampicin (10 to 15 mg/kg once a day), clofazimine (25 to 50 mg once daily or 50 mg every other day) or clarithromycin (62.5 mg per cat every 12 hours).

Atypical Mycobacteria

Both slow-growing organisms (*M. avium*) and rapid-growing organisms (e.g., *Mycobacterium fortuitum*, *Mycobacterium chelonei*) cause disease in dogs and cats, although the rapid-growing organisms are more common. These organisms are ubiquitous in natural environments (especially wet soils) and generally are not pathogenic. Infection is generally acquired after trauma to the skin; the location of entrance into the body determines the presentation of the disease. Penetration into subcutaneous tissue appears to promote pathogenicity. Generally, infection presents as a localized but spreading infection characterized by granulomatous inflammation and acid-fast organisms. Multiple fistulous draining tracts are evident, usually in the caudal abdominal, inguinal, or lumbar subcutaneous tissues (see Figure 8-11). Cats are usually clinically healthy even if cutaneous involvement is extensive. Less commonly, fever, anorexia, and weight loss occur. Hypercalcemia as a result of the release of parathormone-like hormone from macrophages associated with the inflammatory response may occur,²⁷⁵ and has, in the author's experience, occurred in a cat infected with atypical mycobacteria. Diagnosis of atypical mycobacterium is difficult in part because organisms are not abundant. Tissue biopsy specimens should be taken from the subcutaneous tissues because organisms are more likely to be located in the panniculus. Nocardiosis should be considered as a differential. Bacterial culture provides the definitive diagnosis.

Therapy focuses on antimicrobial drugs. Antitubercular drugs are generally ineffective against atypical mycobacterial species. Quinolones, aminoglycosides (particularly amikacin), and doxycycline (or minocycline) are effective and can be used in combination if more aggressive therapy is desired. Other combinations include clofazimine, rifampin and the azolides, azithromycin, or clarithromycin. Other drugs that might be beneficial include trimethoprim–sulfonamide combinations and clofazimine. High doses are recommended to maximize drug delivery into the granulomatous tissue. Surgical debulking may be indicated for large granulomatous masses. Care should be taken not to discontinue drugs too early. At least 4 to 6 weeks of therapy should be anticipated.

Horne and Kunkel²⁵⁶ retrospectively reported on 10 cases of rapidly growing mycobacterium in cats (n = 10); 6 of 10 yielded M. fortuitum on culture, 2 of 10 Mycobacterium abcessus, and 1 of 10 Mycobacterium goodii. Five of the cases resolved. Susceptibility patterns for the drugs were as follows ("I" considered resistant): amiikacin (9 of 10), kanamycin (3 of 10), gentamicin (7 of 10), cefoxitin (6 of 10), imipenem (8 of 10), doxycycline (4 of 10), minocycline (7 of 10), ciprofloxacin (7 of 10), moxifloxacin (7 of 8), clarithromycin (5 of 10), azithromycin (5 of 10), trimethoprim sulfamethoxazole (6 of 8), linezolid (2 of 8), and amoxicillin-clavulanic acid (3 of 10). Organisms were resistant to ceftriaxone, cefepime, cefotaxin, and erythromycin. The drugs used to treat all cases varied but included marbofloxacin, clarithromycin, minocycline or doxycycline, cefodroxil, and a potentiated sulfonamide. The drug most commonly associated with resolution appeared to be clarithromycin. The duration of treatment ranged from 3 to 21 months (median 7 months).

Melioidosis and Tularemia

Melioidosis is caused by *Burkholderia (Pseudomonas) pseudomallei*, a bipolar, aerobic, gram-negative motile bacillus occurring predominantly in Southeast Asia, northern Australia, and the South Pacific. It is characterized by fever, myalgia, dermal abscesses, and epididymitis.²⁵⁷ Effective antimicrobials include tetracyclines, chloramphenicol, trimethoprimsulfonamide combinations, amoxicillin–clavulanic acid, and novobiocin–tetracycline. High doses of parenteral ceftazidime for 2 weeks has proved most effective; imipenem–cilastin may also be effective.

Tularemia, caused by *Francisella tularensis*, is a ticktransmitted disease of both dogs and cats.²⁵⁸ Infection begins with localized lymphadenopathy followed by bacteremia and multiple organ involvement. Clinical signs vary and include fever, mucopurulent nasal or ocular discharge, abscess at the site of inoculation (or associated with lymphadenopathy), myalgia, shivering, and signs indicative of septicemia. Preferred antimicrobial therapy in human patients includes the aminoglycosides. Chloramphenicol or tetracyclines may be associated with relapses. The fluoroquinolones also may be effective.

RICKETTSIAL AND ANAPLASMID DISEASES

Rickettsial and *anaplasmid* organisms are fastidious, obligate intracellular parasites that appear as pleomorphic coccobacilli. They multiply by binary fission, contain both DNA and RNA, and are capable of synthetic and energy-producing reactions. Their life cycle involves insect reservoirs (primarily ticks) and mammals.²⁵⁹ The rickettsial organisms have undergone reclassification such that two families exist: *Anaplasmataceae* and *Rickettsiaceae*. *Ehrlichia* has recently been reclassified from the family Rickettsiaceae to the family Anaplasmataceae; other animal pathogens in this family include *Anaplasma* and *Neorickettsia*. Reclassification has resulted in renaming *Ehrlichia* *platys* as *Anaplasma platys*, *Ehrlichia risticii* as *Neorickettsia risticii*, and *Cowdria* sp. as *Ehrlichia* sp. The family Rickettsiaceae is limited to Rickettsia. *Coxiella burnetii*, the causative agent of Q fever, is not included in either group and stands out additionally because of its robust nature outside of host cells and presentation of disease.²⁵⁹

Although advances in recent years have increased our knowledge regarding the physiology of these organisms and the pathophysiology of the disease, much information is still missing. The pathogenesis of the other rickettsial organisms reflects vasculitis caused by proliferation of the organisms in endothelial cells. Diagnosis is generally based on serologic testing. Serologic evidence of disease generally does not, however, occur until several weeks after clinical signs have developed.

Ehrlichiosis

Pathophysiology

Diseases caused by Ehrlichia can be varied in presentation and often mimic other diseases, making diagnosis difficult.²³⁶ Disease can present in an acute, clinical, or subclinical phase. The acute phase lasts 2 to 4 weeks, during which the organisms replicate in the mononuclear phagocytic cells of the liver, spleen, and lymph nodes. Infected cells travel to the lung, kidney, and meninges, where endothelial inflammation can occur. Nonspecific clinical signs during this phase include fever, anorexia, weight loss, ocular and nasal discharge, and edema. Additional clinical signs depend on the severity of infection in each organ and include dyspnea, neurologic abnormalities, and lymphadenopathy. Platelet consumption, sequestration, and destruction contribute to thrombocytopenia, which often characterizes this phase. Leukopenia and anemia become more likely as the disease progresses. The subclinical phase occurs at 6 to 9 weeks and is characterized by pancytopenia. An adequate immune response should eradicate the disease, but immunoincompetence leads to chronic infection. Clinical signs in chronic disease vary with the severity of infection and can range from asymptomatic to severe. Bleeding tendencies, anemia, chronic weight loss, and debilitation are nonspecific clinical signs. Abdominal tenderness, ophthalmic complications (anterior uveitis, retinal detachment), and neurologic abnormalities may be present. Secondary infections (bacterial and, less commonly, fungal) may reflect immune suppression. Diagnosis is based on clinical laboratory changes and serologic diagnosis using indirect fluorescent antibody. Treatment is oriented toward eradication of the infecting organism and supportive therapy based on clinical signs. Therapy in chronic stages may also require targeting opportunistic infections in the immunosuppressed animal.

Causative Organisms

Disease caused by canine ehrlichiosis generally targets bloodforming units. Ehrlichiosis is caused by *E. canis*, the brown dog tick, and *Rhipicephalus sanguineus* serves as the primary insect vector. Other infections carried by this vector (*Babesia canis* and *Hepatozoon canis*) can simultaneously infect the host. *E. canis* is a pleomorphic organism that circulates in peripheral monocytes. Infection is transmitted through the saliva of the tick into the bloodstream of the host. Transmission has also occurred between hosts (patients) through blood transfusions. Although the dog is the primary target of *E. canis*, infections in cats is suspected but has not yet been documented.²⁶⁰ Other *Ehrlichia* organisms infecting animals include *Ehrlichia chaffeensis* in dogs (mononuclear cells), *Ehrlichia ewingii* (granulocytes, dogs), *Anaplasma phagocyophila* (formerly *Ehrlichia equi*, probably responsible for a significant number of granulocytic ehrlichiosis in dogs in northeastern and upper Midwestern states and California²⁶⁰), *Anaplasma platys* (previously *Ehrlichia platys*; platelets in dogs) and *N. risticcia* (formerly *Ehrlichia risticcia*), which can cause infection in monocytic and granulocytic cells of dogs or cats (or horses).

Antimicrobial and Supportive Therapy

Doxycycline or minocycline are the treatment of choice (10 mg/kg orally every 24 hours for 4 weeks) for ehrlichiosis.²⁶⁰ Although fluoroquinolones (e.g., enrofloxacin) appear to be effective for the treatment of Rickettsia rickettsii at a dose of 3 mg/kg orally twice daily, based on experimental infection, they do not appear to be effective at 10 mg/kg orally twice daily for the treatment of ehrlichiosis.²⁶¹ The effects of combination therapy with doxycycline and enrofloxacin on antimicrobial efficacy against ehrlichiosis have not been established, but the combination might be considered for patients that do not respond to doxycycline. Chloramphenicol is also effective against ehrlichiosis but is less ideal clinically than tetracyclines and enrofloxacin; its use might be limited to puppies if tetracyclines are not acceptable because of brown discoloration of teeth. However, doxycycline is less likely to cause discoloration (see Chapter 7). Imidocarb diproprionate is as effective as doxycycline (5 mg/kg intramuscularly followed by a second injection 2 weeks later), but care must be taken to minimize the side effects of this drug. It recently has been approved in the United States. It should be used to treat patients that have not responded to doxycycline or enrofloxacin. Because chloramphenicol targets a different ribosomal target site than doxycycline, combination therapy with the two drugs might be considered but should be based on clinical trials,

Imidocarb (6.6 mg/kg intramuscularly, two injections, 2 weeks apart) was ineffective in clearing *Ehrlichia* in dogs (n = 10 treated and n = 5 untreated controls) experimentally infected.²⁶² However, twice-daily administration of doxycycline at 5 mg/kg orally bid for 4 weeks cleared five of the imidocarb-treated dogs; two control dogs spontaneously cleared as well.²⁶³

Supportive therapy for ehrlichiosis includes fluid and electrolyte therapy; blood or blood component transfusions; hematinics (vitamins, iron if bleeding has been extensive); and, less commonly, drugs that stimulate erythropoiesis. Anabolic steroids should be used cautiously in the presence of liver involvement. Short-term gluocorticoids may be indicated in severe cases to minimize immune-mediated destruction of platelets or immune-mediated arthropathies, vasculitis, or meningitis. Serologic titers generated by ehrlichiosis are not protective, and reinfection may occur. Platelet counts may decrease despite rapid clinical improvement in response to doxycycline. Serum antibodies may not be useful because they remain elevated for months after therapy. Monitoring PCR may be the best method of evaluating therapeutic success; because it cannot differentiate dead from live organisms, a strong positive the week after completing doxycycline suggests persistent infection.²⁶⁰

Long-term prophylaxis might be considered in endemic areas or kennels and consists of tetracycline (3 to 6 mg/kg once daily orally) or reposital tetracycline (200 mg intramuscularly twice weekly). Davoust and coworkers²⁶⁴ reported a prophylactic program based on French military dogs (614; average weight 29 kg) returning after 4 months of stay in an area highly endemic for ehrlichiosis. The study was coupled with detection of plasma doxycycline concentrations (n = 124dogs) and its association with chemoprevention. Dogs were treated with doxycycline (100 mg [approximately 3 mg/kg] by mouth qd). In 10 of these dogs, the time course of doxycycline was determined. Peak doxycycline (approximately 5 hours) in these dogs ranged from about 1 to 1.7 µg/mL; half-life approximated 9 hours. The drug was assayed by high-performance liquid chromatography; the peak concentrations were based on total drug. At 24 hours, concentrations ranged from 0.26 to 0.4 µg/mL. Spot checks on 114 dogs in the field yielded concentrations that were above 2 µg/mL. Of the 614 dogs, 4% (n = 24) were seropositive; concentrations were not determined in these dogs. They were asymptomatic. Based on a previous report that demonstrated an MIC of equal to or less than 0.03 µg/mL for ehrlichia and doxycycline, the authors concluded that the chemoprevention program was appropriate.

Rocky Mountain Spotted Fever

Causative Organism

The causative agent of Rocky Mountain spotted fever is *R. rick-ettsii.* It is transmitted primarily by *Dermacentor* species, with the American dog tick being the principal vector in the eastern United States and the wood tick the principal vector in the western United States. Transmission of disease requires tick attachment to the host for at least 5 hours and up to 20 hours; thus the disease might be prevented by routine checks of the animal's body.²⁶⁵ The incidence of infection in dogs caused by this organism only now is being appreciated. Unrecognized and untreated illness can lead to death, although the severity of clinical signs depends, in part, on the degree and location of the initial vascular damage induced by the organisms. Diagnosis is complicated by cross-reactivity to several nonpathogenic members of *Rickett-sia* and should be based on both acute and convalescent serum titers or direct immunofluorescence in skin biopsy material.²⁶⁵

Pathophysiology

Organisms are transmitted through the saliva of the tick into the bloodstream, where they replicate in endothelial cells of small blood vessels and capillaries. Damaged endothelial cells become inflamed. Vessels become permeable, causing extravasation of fluid into perivascular spaces. Depending on the severity of infection, clinical signs may indicate edema, hemorrhage, hypotension, or shock. Infection in vessels of the CNS may lead to neurologic signs and a more rapid deterioration of clinical signs.

Other clinical signs vary and may require medical management, depending on which organs are infected: Cardiac abnormalities may include conduction abnormalities or other life-threatening arrhythmias; the respiratory system may be characterized by clinical signs reflecting pulmonary edema, which is minimally responsive to diuretic therapy; ocular abnormalities range from subconjunctival inflammation to retinal detachment; and, in severe cases, acute renal failure occurs as a result of decreased renal perfusion. Severe inflammation causing vascular obstruction can lead to gangrene of peripheral limbs, ears, lips, scrotum, or mammary glands. Other less specific clinical abnormalities include fever, anorexia, depression, muscle pain, polyarthritis, and weight loss.²⁶⁵ In addition to increases in liver enzymes and serum bilirubin, clinical laboratory tests may reveal the need to treat thrombocytopenia; severe acute infection may also cause leukopenia and anemia. Hypoproteinemia, azotemia, hyponatremia, and hypocalcemia may also be present. Treatment is focused on both eradication of the organisms and supportive therapy of derangements in the infected body system.

Antimicrobial and Supportive Therapy

Tetracyclines remain the treatment of choice for rickettsial infections. Although tetracycline may be sufficient, drugs characterized by better lipophilicity (e.g., doxycycline, minocycline) may be more advantageous. Chloramphenicol is also effective, but less so than tetracyclines. Fluoroquinolones are also effective experimentally,265 although clinical efficacy has not been established. Combinations of both doxycycline and enrofloxacin may be additive to synergistic, but the effects of this antimicrobial combination on rickettsial organisms has not been established. Clinical response should be rapid except in cases with severe vascular sequelae (i.e., neurologic or renal damage). Supportive therapy should target abnormalities previously described. These include electrolyte abnormalities and replacement of colloid (protein). Vascular permeability, however, will complicate volume replacement (with either crystalloids or colloids) and, if too intensive, may contribute to peripheral (including pulmonary) edema.

Breitschwerdt et al.²⁶⁶ reported the efficacy of azithromycin (3 mg/kg by mouth qd) and trovofloxacin (5 mg/kg by mouth bid) compared with doxycycline (5 mg/kg by mouth bid) in dogs (n = 16; 4- to 5-month-old beagles; four per group, including untreated control) experimentally infected with R. rickettsii. Treatment duration was for 7 days (starting day 5 post infection), except for azithromycin, which was used for only 3 days. Drug concentrations were measured after the last treatment, with peak concentrations ($\mu g/mL$) evident at 1 hour: 0.15 (azithromycin), 3.5 (doxycycline), and 1 (trovafloxacin). Whereas all three antimicrobials caused rapid improvement in a number of outcome measures, ocular lesions were rare with doxycycline or trovafloxacin but present in all azithromycin-treated dogs. Based on PCR, DNA was present though day 21 after infection, although organisms were not isolated. The authors concluded that fluoroquinolones might be a reasonable alternative to doxycycline. Although azithromycin was discouraged as a first-line treatment by the authors, the half-life of the drug was not known at the time of the study, leading to the shorter duration of therapy. As such, azithromycin (which has a 29-hour half-life in dogs) would not have yet reached steady state at the time that it was discontinued. Further, a dose used was lower than that currently recommended; as such, azithromycin might be reconsidered through controlled studies.

Other Rickettsial-Like Diseases

Canine cyclic thrombocytopenia is caused by E. platys, an organism that replicates in platelets. Cyclic thrombocytopenia occurs at 10- to 14-day intervals. Both platelet numbers (as low as 20,000) and aggregation are impaired. Treatment should be with tetracyclines as described for E. canis. Neorickettsia helminthoeca is one of the causative agents of salmon poisoning disease, which is transmitted after ingestion of fish containing the trematode vector. Like other rickettsial diseases, it is treated with tetracyclines. Hemobartonellosis is caused by a hemotrophic organism that causes acute or chronic anemia in dogs or cats. Damaged red blood cells are removed by the host's immune system. The host is not able to resolve infection without treatment. Tetracyclines are the drug of choice. Supportive therapy may include glucocorticoids at immunosuppressive doses. Metronidazole (40 mg/kg orally once daily for 3 weeks) has been used to treat resistant infections.²⁶⁵

Treatment of Fungal Infections

Dawn Merton Boothe

Chapter Outline

FUNGAL PHYSIOLOGY PATHOPHYSIOLOGY OF INFECTION ANTIFUNGAL DRUGS POLYENE MACROLIDE ANTIBIOTICS: AMPHOTERICIN B Structure-Activity Relationship Mechanism of Action Spectrum of Activity and Pharmacodynamics Resistance Preparations Pharmacokinetics Toxicities and Side Effects Drug Interactions Therapeutic Use Other Polyenes **AZOLE DERIVATIVES** Structure-Activity Relationship Mechanism of Action Spectrum of Activity and Pharmacodynamics Resistance Pharmacokinetics Preparations **Drug Interactions** Therapeutic Use BENZIMIDAZOLES

ECHINOCANDINS FLUCYTOSINE Structure-Activity Relationship Mechanism of Action Spectrum of Activity Pharmacokinetics Preparations Side Effects GRISEOFULVIN Structure-Activity Relationship Mechanism of Action Spectrum of Activity Pharmacokinetics Preparations Side Effects and Drug Interactions ALLYLAMINES AND THIOCARBAMATES **IODIDES LUFENURON** COMBINATION THERAPY THERAPEUTIC USE OF ANTIFUNGAL AGENTS Dermatologic Fungal Infections: Dermatophytosis Yeast or Yeastlike Infections Systemic Fungal Diseases Subcutaneous Mycoses

Currently, only nine antifungal drugs, representing five classes, are approved for use in the United States.

FUNGAL PHYSIOLOGY

The pathogenic fungi affecting humans and animals are eukaryotes, generally existing as either filamentous molds (hyphal forms) or intracellular yeasts (Table 9-1).¹ Dimorphic fungi grow in the host as a yeastlike form but as molds in vitro at room temperature. Some fungi (e.g., *Coccidioides immitis, Histoplasma,* and *Rhinosporidium* species) grow inside host cells, dividing into spores until released from the cell as it ruptures. The fungal cell wall is a target for several of the antifungal drugs (Figure 9-1). It is rigid and contains chitin, a structural component, and polysaccharides. These generally preclude Gram staining and serve as a barrier to drug penetration. The cell membrane is complex and, unlike bacteria

but as with higher eukaryotes, contains sterols.² Ergosterol is the primary sterol component of fungal cell membranes, regulating both permeability and membrane-bound enzymes. Because it also is a major component of organelle membranes, it also influences mitochondrial respiration and oxidative phosphorylation.³ The rate of chitin synthesis is influenced by ergosterol content, being inhibited at high concentrations and stimulated at low concentrations. Fungal content of ergosterol influences drug efficacy and the potential risk of resistance for some drugs. Microtubular structures found in all eukaryotic cells support the cellular cytoskeleton and mitotic spindle; they support not only cell division but also cellular integrity. Organelle position and movement are supported by microtubules. The tubules in turn are comprised of tubulin, a heterodimer containing α and β subunits. Because microtubules are constantly being assembled and dissembled, impaired microtubular synthesis alters integral cellular function.

Table 9-1 Classification of Selected Fungi of Medical Importance

Level	Name	Disease or Infecting Organism	Level	Name	Disease or Infecting Organism
Kingdom	Fungi		Order	Ophiostomatales	
Subkingdom	Amastigomycotera		Family	Ophiostomataceae	
Phylum	Zygomycota		Genus	Ophiostoma	Sporothrix schenckii*
Class	Zygomycetes		Order	Hypocreales	1
Order	Mucorales		Family	Many	Fusarium
Family	Mucoraceae		Order	Clavicipitales	
Genus	Absidia	Absidia (Zygomycosis,	Family	Clavicipitaceae	
Genus	1051010	mucormycosis)	Genus	Ergot alkaloids	St. Anthony's fire
	Mucor	Mucor (Zygomycosis,	Phylum	Basidiomycota	7
		mucormycosis)	Subphylum	Holobasidiomycont	
	Rhizopus	Rhizopus (Zygomycosis,	1 7	Basidiomycot	
	-	mucormycosis)	Class	Phragmobasi-	
Family	Several others			diomycetes/	
Order	Entomophthorales			Tremellomycetes	
Family	Basidiobolaceae		Order	Trichosporonales	Trichosporon asahii*
Genus	Basidiobolus	Basidiobolus sp.	Order	Filobasidiales	
Subkingdom	Eumycotera		Family	Filobasidiaceae	
Phylum	Ascomyta		Genus	Filobasidiella	Cryptococcus neoformans
Subphylum	Saccharomycotina		Phylum	Fungi Imperfecti/	
Order	Saccharomycetales			Deuteromycota	
Family	Saccharomycetaceae	Budding yeasts	Form-Class	Blastomycetes	
Genus	Saccharomyces	Budding yeasts	Form-Order	Cryptococcales	
Genus	Debaryomyces	Candida*	Form-Family	Cryptococcaceae	
	Khyveromyces	Candida*	Genus	Candida	Candida
	Lodderomyces	Candida*	Genus	Cryptococcus	Cryptococcus
	Pichia	Candida*	Genus	Malassezia	Malassezia
Subphylum	Pneumocystio-	Gunuuu	Genus	Pityrosporum	Pityrosporum
Subpliyiulli	diomycetes		Genus	Rhodotorula	Rhodotorula
Order	Pneumocystidiales		Genus	Trichosporon	Trichosporon
Family	Pneumocystideaceae		Form-Class	Hyphomycetes	
Genus	Pneumocystis jirovecii	Pneumocystis pneumonia	Form-Order	Moniliales	
Subphylum	Euascomycotina		Form-Family	Moniliaceae	
Order	Eurotiales		Genus	Aspergillus	Aspergillus
Family	Eurotiaceae		Genus	Blastomyces	Blastomyces
Genus	Eurotium, Emericella	Aspergillus*	Genus	Coccidioides	Coccidioides
Genus		Penicillium*	Genus	Epidermophyton	Epidermophyton
Order	Talaromyces	Penicillum	Genus	Geotrichum	Geotrichum
	Onygenales		Genus	Hostoplasma	Hostoplasma
Family	Gymnoascaceae/ Ajellomycetaceae		Genus	Microsporum	Microsporum
Genus	Ajellomyces	Blastomyces dermatitidis*	Genus	Paracoccidioides	Paracoccidioides

(From Reference Guide to the Classification of Fungi and Fungal-like Protists, with Emphasis on the Genera with Medical Importance (circa 2007), accessed December 17, 2009, at http://www.sbs.utexas.edu/mycology/bio329/pdf_files/sp2007/refguidefungal_sp2007.pdf.)

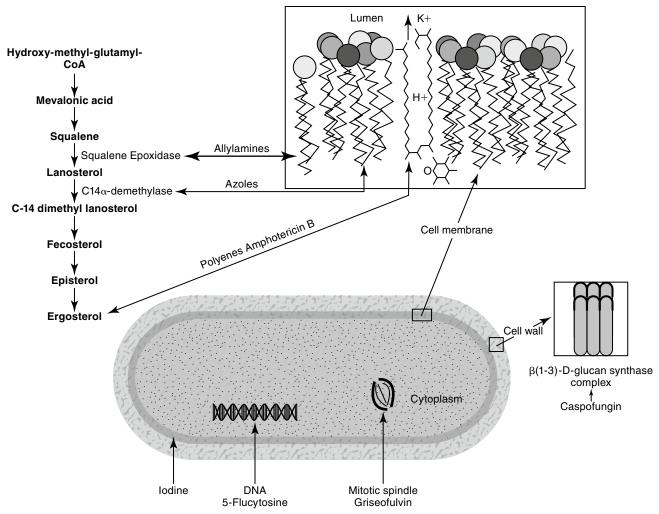

Figure 9-1 Mechanism of action of antifungal drugs. Most clinically relevant antifungals target cell wall ergosterol through different mechanisms. Amphotericin B binds to it, creating channels in the cell membrane. Azoles impair ergosterol synthesis by target-ing C-14 α -demethylase while allylamines (e.g., terbinafine) inhibit squalene epoxidase. Drugs or drug classes that do not target ergosterol include 5-flucytosine, which impairs DNA synthesis upon its intracellular conversion to 5-fluouracil; griseofulvin, which impairs formation of the mitotic spindle; and caspofungin, an echinocandin that targets β -D-glucan synthesis in the fungal cell wall. lodine may precipitate cellular proteins.

PATHOPHYSIOLOGY OF INFECTION

Fungal infections differ from bacterial infections in several respects, and pathogenic fungi have developed several characteristics that complicate antimicrobial therapy.⁴ Some of the differences in the eukaryotic structure of fungal organisms compared with the prokaryotic structures of bacteria were delineated in the preceding section. Other differences exist. For example, Cryptococcus and occasionally Sporothrix schenkii produce an external coating or slime layer that encapsulates the cells and causes them to adhere and clump together.² Whereas many fungal organisms produce exotoxins in vivo, there is no conclusive evidence that fungi produce endotoxins. Fungal organisms are characterized by a low invasiveness and virulence. In fact, most animals will overcome a fungal infection. Factors that predispose the patient to infection include necrotic tissue, a moist environment, and immunosuppression. Innate immunity generally rapidly identifies and destroys

fungal organisms that present pathogen-associated molecular patterns recognized by specific receptors on host cells. Pattern recognition receptors include the lectinlike receptor dectin-1, which binds beta-glucan in the fungal cell wall, and the Toll-like receptors. Binding by neutrophils and macrophages results in a cascade of intracellular events that cause rapid clearance in tissues of exposure. Organisms that are able to penetrate these tissues initiate an immune response. Immunity to fungal organisms appears to be T-cell mediated, with tumor necrosis factor-alpha (TNF- α) being a major signaling cytokine, although all but dermatophytes also stimulate antibody production.⁵ In response, fungal organisms impair an effective immune response through a number of mechanisms. A number of molecules scavenge oxygen radicals generated by inflammatory cells (melanin, mannitol, catalase). The cell wall of *Histoplasma capsulatum* contains β -glucan, which covers and hides α -glucan, preventing recognition by phagocytic cells. Further, it is able to survive intracellular locations in phagocytic cells by a number of mechanisms. Phenotype switching prevents receptor recognition by host cells.⁵ Gliotoxin is an immunosuppressive mycotoxin, produced particularly well by *Aspergillus fumigatus*.⁵

KEY POINT 9-1 The slow-growing nature of fungal infections requires long-term therapy. However, antifungal drugs are inherently more toxic than antibacterial drugs because fungal targets are often similar to mammalian targets.

Although an adequate immune response and recruitment of appropriate inflammatory cells to the site of infection is critical to resolution of fungal infections, progression to uncontrolled, pyogranulomatous inflammation is often deleterious. Proper early cellular recruitment may determine the difference between success and failure. The positive effects of some antifungals may include their immunomodulatory capabilities. These beneficial effects, which are largely based on in vitro studies, with an occasional murine mouse model verification, have been reviewed by Ben-Ami and colleagues.⁵ Amphotericin B, the azoles, and the echinocandins have been studied most. Among the effects is downregulation of inflammatory cytokine genes. The use of antiinflammatories should be considered in critical situation. The use of glucocorticoids is addressed in the section on the treatment of fungal infections, but other antiinflammatories that minimally affect lymphocytic-mediated immunity (e.g., nonsteroidal antiinflammatories, leukotriene receptor antagonists) should be considered as long as attention is paid to potential negative drug interactions involving imidazoles in particular. Manipulation of the immune response in combination with antifungal drugs is a more recent area of focus that is likely to affect treatment of fungal disorders.

Fungal infections can be primarily superficial and irritating (e.g., dermatophytosis) or systemic and life threatening (e.g., dimorphic fungal infections including blastomycosis, cryptococcosis, histoplasmosis, and coccidioidomycosis). Fungal organisms may exhibit an affinity for certain tissues, such as the dermatophytes for keratin and *H. capsulatum* for macrophages. Animals may develop a hypersensitivity to the infecting organism (as is often seen in dermatophyte infections), which can result in a pathologic response to the infection as well as facilitate dissemination. The role of proteolytic enzymes in infections caused by dermatophytes is being investigated. On the other hand, the lack of hypersensitivity may also indicate a poorer prognosis for recovery.²

Information regarding antifungal drug use in animals is limited. Human literature often focuses on candidiasis, an infection that is much less common in dogs and cats; as such, relevance of information must be considered. The risk factors for fungal infection have been recently reviewed.⁷ Using candidiasis as an example, broad-spectrum antimicrobials or immunosuppressive drugs (glucocorticoids, chemotherapy) play a major role. Malnutrition, malignancy, age extremes, and neutropenia also predispose to candidiasis. Similar risk factors occur for aspergillosis, although increased organ transplantation and its accompanying immunosuppression probably has contributed to not only the increased incidence of infection but also the emergence of newer species. Likewise, the increased invasiveness of life-extending procedures coupled with increased survival is contributing to an increased incidence of infection. Improved diagnostic techniques are allowing identification of previously unknown organisms; for example, other filamentous organisms that are emerging in human medicine include the *Zygometes (Mucor, Rhizopus, Rhizomucor, Absidia,* and *Cunninghamella), Fusarium, Paecilomyces,* and *Scedosporium.*

Several factors can lead to therapeutic failure or relapse after antifungal therapy.⁴ Most antifungals are fungistatic in action, with clearance of infection largely dependent on host response.⁶ In humans relapsing infections are not uncommon for selected Trichophyton species and for invasive mycoses in immunocompromised patients. In the latter group, aspergillosis infections are particularly problematic. As with bacteria, the pattern of fungal disease is constantly changing. The advent of acquired immunodeficiency syndrome in human patients has been important in the development of new strains of resistant organisms, and there remains a continuing need for development of new antifungal agents. However, this represents only one of many factors that increase the risk of fungal infection. In some instances, therapeutic failure reflects poor penetration of drug into infected tissues (particularly the central nervous system and bone) or into those organisms that are encapsulated.

Several organisms, particularly the superficial pathogens and systemic opportunistic organisms, have a primary resistance to antifungal drugs, contributing to therapeutic failure. Like antibacterial resistance, antifungal resistance can be intrinsic (primary) or acquired (secondary). A third type of resistance, referred to as *clinical resistance*, involves the progression or relapse that occurs despite laboratory-documented susceptibility to the treatment drug.⁸ Primary resistance occurs with amphotericin B to filamentous fungi and dermatophytes. The risk factors for acquired resistance have not been well identified. Because resistance is an increasingly emerging problem, dosing regimens should maximize antifungal plasma concentrations. However, much more so than antibacterial drugs, antifungal drugs present a risk of toxicity causing the design of dosing regimens to be much more restrictive compared to antibacterial therapy.

Toxicity of antifungals is a common cause of therapeutic failure. Because both the antifungal target organism and the host cells are eukaryotic, the cellular targets of fungal organisms are substantially different from those of bacterial organisms. As a result, antibacterials generally are ineffective against fungal organisms, and, in contrast to most antibacterials, antifungals are often toxic or associated with undesirable side effects in the host. The incidence of side effects has limited the number of effective yet safe antifungal drugs available. Some strategies for reducing toxicity have allowed dose escalation, increasing the likelihood of efficacy and decreasing the risk of resistance. Their use (e.g., liposomal amphotericin B products) are particularly important in the immunosuppressed patient. A potentially important strategy for avoidance of resistance is combination therapy.^{8,9} Combination therapy, if correctly designed, should also enhance efficacy and reduce toxicity

through more rapid response to therapy. Dose reduction may be possible. Finally, a common reason for therapeutic failure is discontinuing therapy after resolution of clinical signs but before eradication of infection. Therefore antifungal therapy should extend well beyond clinical cure.

As with antibacterials, efficacy is influenced by the relationship between plasma or tissue concentrations, minimum inhibitory concentration (MIC) of the infecting microbe and antifungal. Studies for antifungal organisms generally begin with killing curves followed by animal models; however, as with antibacterials, their relevance also must be supported by pharmacokinetic studies that determine drug concentrations at the site of infection coupled with pharmacodynamic studies that determine susceptibility in terms of end points of efficacy.¹⁰

Compared with bacterial testing, antifungal culture and susceptibility testing have not been well developed as a tool for the treatment of fungal infections. As with antibacterial testing, antifungal testing is principally identification of resistant microbes rather than a description of the level of susceptibility.8 In vitro susceptibility testing of antifungal agents is highly dependent on test conditions, and interlaboratory results vary markedly. Interpretation of culture and susceptibility data may be limited by a lack of standardized testing methods for some drugs and organisms. As with bacteria, the MIC for a fungal organism is the concentration of the antifungal drug that inhibits the growth of the fungus under standardized conditions (Table 9-2). The minimum lethal concentration is the concentration that kills the organisms.¹ Correlation between MIC and clinical response is poor, and assessment of antifungal agents appears to be best accomplished through efficacy studies in animal models. Fortunately, the need for fungal culture and susceptibility testing may not be as critical for fungal organisms as it is for bacterial organisms because, with the exception of 5-flucytosine, fungal development of resistance to antimicrobial therapy is not common.¹¹ Resistance is more likely with a rapidly growing organism exposed to high concentrations of an antifungal for a long period of time.1 However, resistance does occur, and as with antibacterials, use of previous antifungal drugs appears to increase the risk of resistance. This has been demonstrated for Candida, the MICs of which tend to be higher in human patients previously treated with antifungals than in drug-naïve patients. Mechanisms of resistance of fungal organisms are similar to those of bacterial organisms (e.g., failure to accumulate in cells, altered target structures, formation of alternative pathways).¹² The advent of newer antifungal agents and resistance among fungal organisms is, however, likely to cause in vitro testing of antifungals to become more important to therapeutic success.

KEY POINT 9-2 Resistance by fungal organisms is not as common as in bacterial organisms, but it is more likely in those that are rapidly growing.

One author notes that never before have so many new antifungals been under development, ranging from entirely new compounds with new targets to modifications of existing drugs (e.g., cyclodextrin–itraconazole and polyethylene glycol–amphotericin B).¹³ Newer concepts being explored include combinations of antifungals with one another or with nonantibiotic compounds. Newer therapies may focus on immunomodulation¹⁴ with a balance between recruitment (cytokines, chemokines, lymphokines, and growth factors) and antiinflammatory effects. The need for new therapies is timely, as the epidemiologic behavior of fungal organisms, at least as they occur in human medicine, increasingly is shifting toward opportunistic organisms for which traditional antifungals often are characterized by limited efficacy.⁷

ANTIFUNGAL DRUGS

The primary agents used to treat fungal infections are the natural antibiotics; the polyene macrolides (amphotericin B as the prototype); the synthetic agents, including the azoles (ketoconazole as the prototype); and the newer allylamine antifungals (Figure 9-2). Flucytosine has a less important role in the treatment of dimorphic fungal diseases, particularly in animals. The natural antibiotic griseofulvin belongs to no group but has an important place in the armamentarium against dermatophytosis. As recently as 1988, the treatment of systemic fungal infections in humans emphasized the use of amphotericin B, ketoconazole, and flucytosine. In the decade that followed, further development of the azole derivatives has led to a new age in the treatment of systemic fungal diseases. Currently, antifungal therapy is most effective when based on an understanding of the therapeutic ratio of the drug in the infection being treated. For amphotericin B, this ratio tends to be small because of its toxicity. The newer azole derivatives have proved to provide much of the efficacy of amphotericin B without its toxicity. Doses for selected antifungal drugs are found in Table 9-3.

POLYENE MACROLIDE ANTIBIOTICS: AMPHOTERICIN B

Structure–Activity Relationship

Examples of polyene (i.e., multiple double-bond; see Figure 9-1) antifungal drugs include amphotericin B, nystatin, and pimaricin. Each antibiotic is produced by a different species of Streptomyces (family Actinomyces). Amphotericin B was developed in the 1960s and was so successful in fulfilling the need for a broad-spectrum antifungal that further advancement of antifungal therapy was largely ignored. These drugs are very large molecules, consisting of a macrolide containing a large lactone ring. The polyene contains three to eight double bonds, which represent the lipophilic portion of the molecule. The number of double bonds categorizes the polyenes into trienes, tetraenes (natamycin [paramycin]), and pentanes; amphotericin B and candicidin are heptanes, whereas nystatin is classified as a pseudo-heptane/tetraene.3 A hydroxylated hydrocarbon backbone represents the hydrophilic portion of the molecule. These compounds are insoluble in water and are unstable, and they will rapidly decompose if exposed to sunlight.

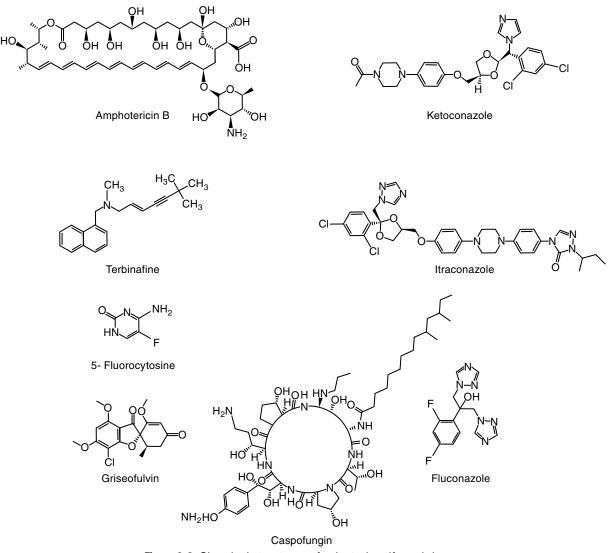

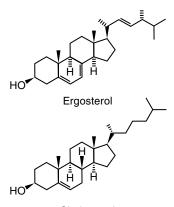

Figure 9-2 Chemical structures of selected antifungal drugs.

Mechanism of Action

Polyene macrolides bind with the sterol portion of the phospholipids that make up the fungal cell membrane. Amphotericin has a much higher affinity for ergosterol, the major sterol component of fungal cell membranes, than for cholesterol, the major sterol in mammalian cell membranes (Figure 9-3).¹ The interaction of the drug and the sterol results in the formation of channels or pores in the cell membrane (Figure 9-4). The result is an increase in cell permeability and disruption in proton gradient flow; loss of membrane fluidity may alter H+-ATPase activity.³ Altered K⁺/H⁺ exchange results in the loss of K⁺ and Mg²⁺ from the cell. Cellular metabolism is disrupted; internal acidification of the fungal cell and the loss of important organic molecules from the cell result in irreversible cell damage. The efficacy of some of the drugs can be related to their ability to bind to ergosterol. However, the polyenes also are associated with the formation of lethal reactive oxygen molecules. Polyenes also are defined according to the concentration of drug necessary to cause erythrocyte hemolysis,

Cholesterol

Figure 9-3 Cholesterol, the major sterol of mammalian cells, is structurally similar to ergosterol, the major sterol of fungal cell walls. Binding of amphotericin B to cholesterol results in complicated pharmacokinetics as well as host toxicity.

Table 9-3 Do	sing Recomr	mendations for	Antifungal Drugs (1)	
Drug		Indication	Dose	Route	Interval (hr)
Amphotericin A (1,2) (Fungizone [AmBD])	Test dose	0.25-0.5 mg/kg	IV	Once
		General mycoses	0.15-1 mg/kg in 30 mL 5% D/W	Rapid IV infusion (over 5 minutes through a butter- fly catheter after flushing catheter with 10 mL 5% dextrose)	48 or 3 × per week to a cumula- tive dose of 4-12 mg/kg (D) or 4-6 mg/kg (C)
			0.15-1 mg/kg in 200- 500 mL 5% D/W via peripheral venous catheter	IV (over 4-6 hrs)	48 or 3 × per week to a cumula- tive dose of 4-12 mg/kg (D) or 4-6 mg/kg (C)
		Blastomycosis	Initial dose: 0.5 mg/kg (D)	IV	48 or 3 × per week to a cum- mulative dose of 4-10 mg with ketaconazole
			Followed by: 0.15- 0.25 mg/kg (D)	IV	1 × per month with ketaconazole
		Cryptococcosis	0.5-0.8 mg/kg	SC	48 or $2-3 \times$ per week. Dilute to
			0.15-0.4 mg/kg (C)	IV	<20 mg/mL in 5% dextrose 48 or 2-3 × per week for 3-4 weeks. Total cumulative dose of 4-6 mg/kg with flucytosine
		Histoplasmosis	Initial dose: 0.5 mg/kg (D)	IV	3 × per week to a cumula- tive dose of 4-6 mg with ketaconazole
			Followed by: 0.15-0.25 mg/kg	IV	1 × per month with ketaconazole
			0.25 mg/kg (C)	IV	48×4 -8 weeks with
			0.15-0.5 mg/kg (C)	IV	ketaconazole 1 × per month with ketaconazole
		Gastroinestinal pythiosis	1-2 mg/kg (D)	IV	48 or 3 × per week to a cumula- tive dose of 12-24 mg/kg
		Resistant filamentous fungi	2-2.5 mg/kg	IV	48 or 3 × per week to a cumula- tive dose of 15-30 mg/kg
		Leishmaniosis	0.5-0.8 mg/kg	IV	48 to a cumulative dose of 8-16 mg/kg
		Pulmonary fungal disease	Systemic dose diluted in 5% D/W	Aerosol (nebulization)	Use the chosen systemic dose, prepared as 5 mg/mL in 5% dextrose
		CNS fungal disease	0.2-0.5 mg	Intrathecal	48 or 2-3 × per week. Dilute in 5 mL cerebrospinal fluid or 10% dextrose
		Fungal cystitis	50 μg/mL prepared in 5% D/W	Urinary bladder infusion	24; repeat once if necessary.
Amphotericin B,	(Amphotec)	Test dose	0.25-0.5 mg/kg	IV	Once
colloidal disper- sion (ABCD) (1,2	(Amphocel)*	General mycoses	1-2.5 mg/kg	IV	48 or 3 × per week to a cumula- tive dose of 15-30 mg/kg
Amphotericin B, lipi complex (ABLC) solution (1,2)		Test dose	0.25-0.5 mg/kg	IV	Once
		General mycoses	1-2.5 mg/kg	IV	48 or 3 × per week to a cumula- tive dose of 12-30 mg/kg
		Blastomycosis, severe	1-2 mg/kg (D)	IV	3 × per week to a cummulative dose of 12-24 mg/kg
		Cryptococcosis	1 mg/kg (C)	IV	48 or 3 × per week to cumulative dose of 12 mg/kg

Drug		Indication	Dose	Route	Interval (hr)
Amphotericin B, liposomal (AmBD) (1,2)	Ambisome (B LamB)	Test dose	0.25-0.5 mg/kg	IV	Once
		General mycoses	1-4 mg/kg (D)	IV	48 or 3 × per week to a cumula- tive dose of 12-30 mg/kg
		Leishmaniosis	3-4 mg/kg (D)	IV	48 or 3 × per week to a cumula- tive dose of 12-30 mg/kg
			250-300 mg/(D)	PO (on food)	24 × 7-12 days
			60-100 mg (C)	РО	24×5 days
			300-400 (C)	PO (on food)	24×5 days
		Coccidiosis prophylaxis	28.8 mg/L water	PO (in water)	24×14 days
		1 1 7	1.25 g of 20% powder	PO (on food)	24×14 days
		Coccidiosis treatment	150 mg/kg	РО	24×14 days with sulfadimethoxine
Captan powder 50%		Dermatomycoses	30 mL/1 L of water (2 tbsp/gal of water)	Topical. Do not rinse	$2-3 \times \text{per week}$
Chlorhexidine diacetate		Fungal skin infection	1 mL of 2% solution to 9 mL water	Topical	PRN
Clotrimazole		Dermatophytosis	Apply to lesions	Topical	12 until culture is negative
		Antifungal	60 mL of 1 g/dL in polyethylene glycol	Topical (intranasal)	Over 1 hr (under general anesthesia); repeat in 3-4 weeks PRN
Enilconazole		Nasal aspergillosis	5% solution	Topical (instill into nasal sinus)	12 × 7-10 days
			10-20 mg/kg (10% solution diluted 50:50 with water)	Topical (instill into nasal sinus)	12 × 10-14 days
		Dermatophytes	Dilute to 0.2% solution	Wash affected area???	$72-96 \times 4$ treatments
Fluconazole (3)		Blastomycosis	5 mg/kg	РО	12
		Cryptococcosis	2.5-10 mg/kg	PO (with food)	12-24
			150-200 mg/C	РО	24 or divide dose and administer q8h
Flucytosine (combination therapy)		Cryptococcus	125-250 mg/C	РО	Divide dose and administer q6-8h. Do not use as sole therapy
			150-175 mg/kg	PO	Divide dose and administer q6-8
			25-50 mg/kg	РО	6
		Urinary candidiasis	50-75 mg/kg Maxi- mum of 100 mg/kg	PO	8. Alkalinize urine to > 7.4
Griseofulvin (microsize) (3)		Dermatophytosis	10-30 mg/kg	PO (with fatty meal)	24 or divide dose and administe q8-12h
			50 mg/kg	PO (with fatty meal)	24 or divide dose and administer q8-12h
			80-130 mg/kg	PO (with fatty meal)	24 or divide dose and administe q8-12h

	Ocular fungal infections	Apply topically as directed	Topical	4-12 times per day
Natamycin	Ocular fungal infections	Several drops	Topical	3-8
Povidone-iodine		Apply light coating	Topical	12-24
Sodium hypochlorite (bleach)	Rinse	1:20 (0.5%) in water	Topical spray	Every 5-7 days

Table 9-3	ble 9-3 Dosing Recommendations for Antifungal Drugs (1)—cont'd								
Drug	Indication	Dose	Route	Interval (hr)					
Terbinafine	Dermatophytosis	30-40 mg/kg (D)	PO	24					
Voriconazole(5)	Aspergillosis, sus- ceptible fungal infections	3-6 mg/kg (D)	РО	12-24; use higher dose once daily. Dose has not been verified					

C, cat; CNS, central nervous system; D, dog; D/W, dextrose in water; IV, Intravenous; PO, by mouth; PRN, as needed; SC, subcutaneous.

1. Minimum of treatment time reflects infectious agent. See text for renal-saving tactics. For nondermatophytes a minimum of 2 months, generally 4 to 6 months, extends to 8 to 10 months for cryptococcosis and beyond for coccidiodomycosis, and always should be 1 to 2 months beyond resolution of clinical signs. Doses collected from *Greene's Infectious Diseases of the Dog and Cat* (2006 and other resources)

2. Precede with 0.1 to 0.25 mg test dose diluted in 10 mL in dextrose. Dilute calculated dose in 10 to 60 mL (rapid) or 250 to 1000 ml (slow infusion) 5% dextrose. See text for rapid versus slow infusion techniques. Administration may be subcutaneous, although concentrations greater than 20 mg/mL are locally irritating. Total cumulative dose varies with target organism from 4 to10 mg/kg in dogs (8-12 mg/kg if coccidioidomycosis) or 4-8 mg/kg in cats. Higher daily and cumulative doses are generally indicated for lipid-complexed amphotericin (see text). See text for more specific guidance for each organism and combination therapy protocols. Use at 30-day intervals for prevention of relapse (scientific basis for this approach is lacking).

3. Duration for dermatophytosis 4-6 weeks; may be longer with long-haired breeds

4. Lower dose is given bid, higher once daily.

5. Induction in dog may result in decreased drug concentrations. Monitoring would be ideal if available.

*Amphocel (Amphocil) is no longer available in the US.

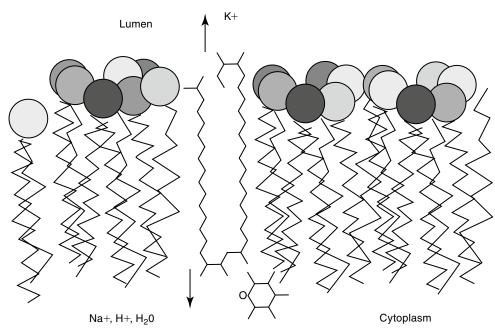

Figure 9-4 The mechanism of antifungal action and nephrotoxicity of amphotericin B reflect binding of the drug to ergosterol, the major sterol in fungal cell walls. Binding results in cell membrane permeability and the loss of critical micronutrients and electrolytes.

presumably because of cholesterol binding. Pimaricin causes lysis at low concentrations, limiting use to topical application, whereas amphotericin B and nystatin cause lysis at much higher concentrations.³

Amphotericin is fungistatic but can be fungicidal at high concentrations. At high concentrations the drug directly disrupts the fungal cell membrane. As with some other select antifungal drugs, amphotericin appears to have some immunomodulating characteristics. Both humoral and cell-mediated immunity may be enhanced, thus increasing the host's ability to overcome infection. Amphotericin B activates macrophages and stimulates TNF- α and interleukin-1 (IL-1), both of which facilitate macrophage killing by way of nitric oxide-dependent pathways.^{5,14}

Spectrum of Activity and Pharmacodynamics

Despite the advent of the azole antifungal drugs, amphotericin B remains the most effective agent against most of the major fungal pathogens. The indications for amphotericin therapy include most systemic fungal diseases, including those caused by the dimorphic fungi (histoplasmosis, blastomycosis, cryptococcosis, and coccidioidomycosis) and disseminated sporotrichosis, phycomycosis, aspergillosis, and candidiasis. Amphotericin B has greater activity against some organisms (e.g., *Candida* and *Aspergillus* species and coccidioidal meningitis) than the newer azoles and particularly fluconazole. Amphotericin B is not effective against dermatophytes. Amphotericin MICs appear to correlate well with efficacy in animal models and human patients.¹⁰ The MICs of

amphotericin B toward selected fungal microbes are listed in Table 9-4.^{15,16} Although these are based on humans, they represent a reasonable target for isolates infecting animals as well. In addition to the MIC, the minimum fungicidal concentration (MFC) has been reported for selected organisms infecting humans (or animals).¹⁵ The MFC₅₀ and MFC₉₀; μ g/mL) are, respectively, Blastomyces dermatitidis (0.125, 0.5); H. capsulatum (0.5, 2), and C. immitis (4, 16). In killing-curve studies, amphotericin B consistently exhibits concentration-dependent killing. However, killing is variable among organisms, being fungicidal toward Candida sp. but not toward many yeasts and other organisms. As a concentration-dependent drug, amphotericin B may exhibit a long post-antifungal effect (PAFE), which, like the postantibiotic effect of concentration antimicrobials, varies in duration with the organism and the relationship of the MIC to the plasma drug concentration (PDC).¹⁰ However, it can prolong the dosing interval of the drug. A PAFE of only 0.5 hours occurs at approximately 2 hours exposure at drug concentrations that reflect 0.5 times the MIC, but this duration is prolonged to approximately 10 hours at 32 times the MIC for Candida and Cryptococcus neoformans; the PAFE for the latter may exceed 12 hours.¹⁰

KEY POINT 9-3 Despite the advent of the azole antifungal drugs, amphotericin B remains the most effective agent against most of the major fungal pathogens.

Sufficient data exist to integrate Ambisome pharmocokinetics and pharmacodynamics toward selected microbes that infect the dog (Table 9-4; see also Table 9-2). Two targets are considered: the MFC and a 12-hour PAFE (targeting PDCs that equal the MIC_{90} of the infecting microbe by 32). Based on the C_{max} of dogs for Ambisome measured at day 1 and day 30 of dosing, the MFC of *B. dermatitidis* and *H. capsulatum* will be achieved on the first day of dosing at 1 mg/kg. Assuming the PAFE as described in animal models would be exhibited by dimorphic fungal organisms infecting dogs, based on MIC₉₀ for B. dermatitidis of 0.05 µg/mL (see Table 9-2), a target of 1.6 μ g/mL (32 times the MIC) is indicated to achieve a 10 to 12-hour PAFE. Again, the target will be reached in dogs on day 1 with a 1 mg/kg dose of Ambisome; the 12-hour PAFE could be added to the time the PDCs are above the MIC (which in turn, is based on half-life). For *H. capsulatum*, the MIC_{90} is

1 µg/mL; accordingly, a target of 32 µg/mL (for at least 2 hours) might be indicated to achieve a 10 to 12-hour PAFE. Assuming linear kinetics, reaching the target on day 1 will require a dose of approximately 4 mg/kg, which is likely not to be tolerated (an exception may occur for lipid-based products). However, the target is likely to be approached with 30 days of dosing at 2.5 mg/kg. C. immitis is less susceptible to the killing effects of amphotericin B; the MFC₉₀ (11 μ g/mL) is likely to be reached on day 1 of dosing at 2.5 mg/kg, but 30 days of dosing will be required to reach the MFC₉₀ or the 12-hour PAFE. These calculations were based on the MIC₉₀ of the respective organisms; if the MIC of the infecting microbe is known, then a lower dose might be reasonable.

Resistance

The incidence of resistance to amphotericin B is low and has been documented primarily for Candida. The development of resistance may be related to changes in the number of sterol components in the fungal cell wall, with low ergosterol content associated with resistance.³ Pythium insidiosum, classified as a pseudofungus, (the cause of what was previously and inappropriate referred to as fungal phycomycosis), as with other oomycetes, is largely devoid of cell membrane sterol. As such, they are inherently resistant to polyenes.¹ However, other mechanisms of resistance also exist, probably reflecting multiple mechanisms. Some organisms are able to resist concentrations that exceed 2 µg/mL. The azole derivatives may contribute to amphotericin B resistance by preventing the formation of ergosterol, the target of amphotericin B.¹

Amphotericin appears to act synergistically with the following: 5-flucytosine against cryptococcosis, tetracyclines against coccidioidomycosis, and imidazoles (discussed later) for a variety of fungal disorders. The use of synergistic combinations may enhance efficacy while reducing the potential of toxicity.

Preparations

Because amphotericin is unstable, it is prepared with desoxycholate as a lyophilized cake form (amphotericin B; previously Fungizone®; AmBD). Supplies were limited at the time of publication,8 perhaps reflecting declining use in human medicine in favor of newer lipid-based formulations.

Desoxycholate-also referred to as deoxycholate, a bile salt-is added to aid solubilization of the lyophilized cake form of the drug, which, when reconstituted, is in a colloidal suspension. Reconstitution should be with sterile water only; the solution will remain stable for 1 week if refrigerated. Storage should include protection from light, although protection during therapy is probably not necessary; potency is unaffected after light exposure of up to 24 hours. Labeled directions indicate that dilution should occur only with 5% dextrose to prevent drug precipitation and inactivation; Trissel's Handbook on Injectable Drugs (http://online.statref.com/ titles/titleinfopage.aspx?titleid=141) indicates that normal saline is incompatible with amphotericin B, leading to a 43% drop in drug concentrations within 2 hours. Although the drug has been mixed by veterinarians with 0.45% NaCl and 2.5% dextrose with no apparent change, the basis for this observation is unclear, and the prudent clinician would avoid the combination and provide sodium loading (see the section on therapeutic use) through a different catheter. In general, amphotericin B should not be mixed with other drugs; although known to be compatible with some, it is incompatible with many others. The drug should be administered only intravenously, with exceptions for localized treatment in selected body tissues or fluids (e.g., aqueous humor, cerebrospinal fluid [CSF]). For small animals, which do not require a complete vial, the reconstituted drug can be divided into smaller aliquots and frozen.

Amphotericin also has been complexed to lipid mixtures in an attempt to reduce nephrotoxicity. Reticuloendothelial cells phagocytize the lipid component, facilitating directed delivery to the site of fungal infection. Drug uptake by the hepatic and splenic macrophages, bone marrow, and inflammatory tissues is thus enhanced. For liposomal products, some studies have shown that amphotericin B is selectively transferred from liposomes to fungal but not host cell membranes. Prolonged antifungal activity (compared with nonliposomal preparations) has been documented for these preparations. Each product is injectable and differs in the lipid makeup as well as the ratio of lipid to amphotericin B. Lipid-based products include a lipid complex (ABLC; Abelcet) suspension that forms a tightly packed ribbonlike structure and is the largest of the lipid-based products (250 nm); a colloidal dispersion of cholesterol sulfate, which forms 122 nm disks (Amphotec or Amphocil [ABCD]); and a single-layered liposomal product, Ambisome (LAmB; see Table 9-4), which is the simplest and smallest (60 to 70 nm) of the molecules.17,18 The differences among these products have recently been reviewed.¹⁹ Amphotericin B also has been administered with a lipid vehicle (intralipid; AMB-IL) rather than 5% dextrose. Although nephrotoxocity appears to be reduced in some patients, it does not appear to be decreased in the patients at most risk for toxicity, and therefore liposomal lipid-based products should be considered.^{18a} Administration of AMB-IL also is not recommended because of mixed product is unstable. The differences among the lipid-based or lipid-containing products and their clinical use in humans have recently been reviewed.19

Amphotericin is also available as a topical preparation (Fungizone), including cream, lotion, and ointment forms.

Pharmacokinetics

Amphotericin is not water soluble and thus is not bioavailable after oral administration. It is more than 90% bound to circulating serum lipoproteins (including cholesterol). Penetration into the pleura, peritoneum, inflamed tissues, CSF, and aqueous humor may result in a drug concentration two thirds of that in the plasma. The metabolism and excretion of amphotericin is not well characterized and is complex, being complicated by binding to cholesterol, which is structurally similar to ergosterol (see Figure 9-3). Biliary elimination may be the primary method of excretion (in humans only 3% of the drug is eliminated in the urine); however, concentrations are detectable in both bile and urine for up to 7 weeks in human patients.

The pharmacokinetics of the various amphotericin B preparations, including those complexed to lipids, vary markedly in humans; interpretation of kinetics is complicated by the lack of discrimination between free amphotericin B and that complexed to the various carriers. Because of its small size, Ambisome is characterized by the slowest uptake, and the highest PDCs. In humans, peak PDCs (µg/mL) vary with the dose (indicated in mg/kg), reflecting differences in volume of distribution that vary on account of tissue uptake: AmBD, 2.9 μg/mL at 1 mg/kg); Albecet (ABLC), 1.7 μg/mL at 5 mg/kg); Amphotec (ABCD), 3.1 µg/mL at 5 mg/kg; and Ambisome (LAmB), 83 µg/mL at 5 mg/kg. For LAmB, concentrations appear to be both dose and time dependent in dogs (Table 9-4). An advantage of the liposomal product is that it accumulates at sites of infection and targets the fungal cell wall, with release of amphotericin into the cell.¹⁹ For ABLC (and LAmB), tissue or fungal phospholipases appear to release amphotericin B at the site of infection. However, the colloidal form of amphotericin B (Amphocil), which is taken up by reticuloendothelial cells, was demonstrated in humans to accumulate in lung tissues to a greater concentration than Ambisome, suggesting that it might be preferable for respiratory infections.²⁰ This finding requires further support by animal model or clinical studies. That LAmB may be preferred for central nervous system (CNS) infections is supported by the study and review of Ibrahim and coworkers,²¹ who address the potential inability of ABLC to penetrate the brain in mice or rabbit models. Comparing dosing ranges, LAmB was effective without nephrotoxicity at 5 to 20 mg/kg in animal models of disease, with highest tolerated doses being 30 to 50 mg/kg (as reviewed by Adler).¹⁹ Although ABLC was efficacious at doses ranging from 5 to 15 mg/kg, nephrotoxicity and decreased efficacy occurred at 15 mg/kg compared to 5 mg/kg. (as reviewed by Adler).19

The pharmacokinetics of Ambisone (LAmB) have been described in Beagles (n = 10 per group) as part of a toxicity study in humans and compared historically to AmBD (see Table 9-4).²² Dogs received 0.25 to 16 mg/kg/day as an intravenous infusion over 5 minutes, with PDCs determined on days 1, 14, and 30. Dogs receiving 8 and 16 mg/kg daily did not finish the treatment period because of severe weight loss (n = 17/20); this same pattern of weight loss was also described

in dogs receiving AmBD at 0.75 mg/kg every other day (as reviewed by Bekersky and coworkers²²). However, dogs tolerated 4 mg/kg Ambisone daily with peak concentrations at this dose were markedly variable, ranging from 18 µg/mL at day 1 to 94 μ g/mL at day 30. Concentrations of Ambisone were a hundredfold higher than other formulations: A dose of 0.6 to 0.75 of AmBD resulted in peak amphotericin concentrations of 1.25 to 4.4 µg/mL after multiple dosing. This compares to a peak concentration of $54 \pm 16 \,\mu\text{g/mL}$ at 4 mg/kg daily. Ambisome kinetics were nonlinear, with clearance and distribution decreasing as dose increased, potentially reflecting saturation of distribution and clearance processes. For example, although dose only increased 64-fold in the study, area under the curve (AUC) on day 1 at 0.25 mg/kg was 2.6 µg*hr/mL (compared) to 2592 μg hr/mL at 16 mg/kg, representing a 2500-fold increase. Multiple dosing also resulted in accumulation at each dose, with 30-day to 1 day AUC ratios being 2.5 and 10 at low (0.25 mg/kg) and intermediate (4 and 8 mg/kg) doses, respectively. (see Table 9-4). Kinetics are likely to be equally complex in other dogs and cats, and lack of predictability may limit use.

Toxicities and Side Effects

Nephrotoxicity is the major side effect associated with the use of amphotericin B. Renal function becomes impaired in more than 80% of patients receiving amphotericin, 4,23,24 with serum creatinine at least doubling in 40% to 60% in human.²³ Although largely reversible, renal toxicity depends on total cumulative dose and duration of therapy. In human patients chronic renal disease occurs in close to 50% of patients receiving more than approximately 60 mg/kg total dose compared with only 17% who receive less than 57 mg/kg. The proportion decreases to 8% in those receiving less than 14 mg/kg total dose.²³ Although renal function usually returns to normal before completion of therapy, some residual damage often persists after discontinuation of the drug. Two mechanisms are important in renal toxicity. Intense arterial vasoconstriction occurs within 15 minutes of administration and lasts 4 to 6 hours. The mechanism is unknown but can lead to acute tubular nephrosis secondary to ischemia. Nerve degeneration, angiotensin II receptor blockage, adrenergic blockade, and potent vasodilators do not prevent renal vasoconstrictive effects. Amphotericin B may activate formation of vasoconstrictive (thromboxane) arachidonic acid metabolites, which suggests that direct vasoconstriction may be responsible. Amphotericin B can increase calcium fluxes. Histologic lesions are most profound in regions vulnerable to hypoxia or areas rich in oxygen.²³

KEY POINT 9-4 Liposomal-based amphotericin is among the safest with regard to nephrotoxicity.

Distal renal tubular toxic effects result from binding of membrane cholesterol in the tubular cell membrane (see Figure 9-4). Altered electrolyte fluxes result in acidification abnormalities (metabolic acidosis), hypokalemia, and concentrating defects (polyuria, polydipsia). Renal tubular acidosis is common, dose related, and generally reversible (although resolution may take several months) and generally precedes significant decreases in glomerular filtration rate (GFR). Potassium and magnesium wasting in humans can lead to substantial deficits.²³ Magnesium deficits appear at 2 weeks and are maximal at 4 weeks. Both potassium and magnesium should be monitored; electrolyte abnormalities may persist for several weeks after therapy is discontinued. Rarely, hyperkalemia has been reported in association with rapid infusion as potassium shifts from the intracellular compartments. The risk is greater in patients with renal failure. Concentration defects occur in essentially all human patients, are not related to azotemia, and may persist for months. Urine specific gravity may not be an effective measure by which to assess renal damage.

Ampohtericin B toxicity has been documented in dogs. Ceylan and colleagues²⁴ described the nephrotoxicity of AmBD in dogs (n = 18; cross-bred) receiving 0.5 mg/kg in 25 mL 5% dextrose in water as a 4- to 5-minute intravenous bolus; 1 mg/ kg in 50 mL as a 4- to 5-minute bolus, or 2 mg/kg in 1000 mL over 4 to 5 hours. Dogs were treated for 12 days. Side effects (vomiting, diarrhea, anorexia, fever, tachycardia, and phlebitis) were evident in all dogs by day 3 but were worse in dogs receiving 1 mg/kg and least in dogs receiving 2 mg/kg. Indicators of renal damage (blood urea nitrogen, creatinine) were increased in all groups by day 5 but were highest in the 1 mg/kg group. Serum calcium was significantly decreased compared with baseline in the 1 mg/kg and 2 mg/kg groups. Hematologic indicators of anemia were evident in the 1 mg/kg group. Among the indicators of nephrotoxicity studied was urine γ -GGT, which was significantly higher than baseline in all groups by day 5 of therapy but did not differ among groups or times during treatment. On the basis of this study, the authors suggested that infusion over a 4- to 5-hour period (or fluid support) decreases the risk of aminoglycoside toxicity. However, no study has determined the long-term effects of any method of administration of amphotericin B on renal failure in dogs or cats.

In their pharmacokinetic study of LAmB (Ambisome) in Beagles at doses ranging from 0.25 to 16 mg/kg daily for 30 days, Bekersky and coworkers²² reported that no dogs died as a result of the drug; however, dose-dependent tubular nephrosis was present at 1 mg/kg, and 70% and 100% of dogs in the 8 and 16 mg/kg treatment group, respectively, were euthanized before the end of the study because of 25% or more body weight loss. Vomiting and diarrhea were evident in all groups, including a liposomal (i.e., without amphotericin B) control, but were worse in the 4, 8, and 16 mg/kg treatment groups. Azotemia was not present in the 1 mg/kg group. Azotemia was described as moderate and clinically significant toward the end of the 30-day treatment period in the 4 mg/kg group, with creatinine increasing from a baseline of $0.7.1 \pm \text{to } 2.3 \pm 0.4 \text{ mg/dl}$ by study end. Serum potassium was not clinically affected. The authors concluded that dogs tolerated up to 4 mg/kg well, despite peak amphotericin B concentrations ranging from 18 to 94 µg/mL.

Acute anaphylactic-type reactions such as vomiting, fever, and chills can occur with the use of amphotericin B and have been reported with lipid complex preparations as well.²⁵ Up to 30% of dogs receiving AmBD develop fever.²⁶ The frequent incidence of these reactions often leads to pretreatment for anaphylaxis (one-time use of a short-acting glucocorticoid does not enhance the toxicity of amphotericin B; see the discussion of "cocktail" in the following section).

Other side effects associated with amphotericin B include nausea and anorexia, thrombophlebitis, cardiac arrhythmias and related toxicities, hepatic dysfunction, and CNS signs (if given intrathecally) (see discussion on therapeutic use). Several side effects can be prevented by proper treatment (see following discussion of therapeutic use).

Drug Interactions

Amphotericin B interacts in an additive to synergistic fashion with a number of antifungal agents (see the discussion of combination therapy), although this effect seems to be most consistent with flucytosine. Although synergistic effects should be expected with azoles, this combination may be antagonistic if azole therapy is begun first.

In general, drugs that are renally active are not recommended for patients also receiving amphotericin B. In humans cyclosporine and tacrolimus (calcineurin inhibitors) will enhance nephrotoxicity. However, these immunomodulators tend to be safer, as far as nephrotoxicity is concerned, in both dogs and cats, and the combination may not be as dangerous. The nephrotoxicity of amphotericin also may be enhanced with catabolic drugs such as glucocorticosteroids, antineoplastic drugs, antiprostaglandins (glucocorticoids and nonsteroidal antiinflammatory drugs), and other nephrotoxic antibiotics. One study demonstrated that diuretic therapy during, but not just before, amphotericin B therapy increased the risk of nephrotoxicity more than twelvefold (as reviewed by Bagnis and Deray²³). Although diuretics have been used for a "protective" effect, the potential benefits are limited to mannitol, and even it may be associated with electrolyte disturbances. Combination with digoxin may enhance nephrotoxicity and hypokalemia. Declining renal function in association with amphotericin B therapy may affect clearance of co-administered drugs. Because it is renally excreted, 5-flucytosine toxicity may be enhanced if renal function declines with amphotericin B.

Therapeutic Use

Most of the advice and studies addressing the recommended method of administration of amphotericin B are based on the non-lipid preparation (AmBD).

Multiple strategies may help reduce toxicities or side effects to amphotericin B. The first focuses on prevention of an anaphylactoid reaction by pretreatment (to prevent vomiting, fever, chills, and anaphylaxis) with antihistamines (diphenhydramine 0.5 mg/kg, administered intravenously) and shortacting glucocorticosteroids (e.g., hydrocortisone sodium succinate, 0.5 mg/kg, administered intravenously). Because the reaction appears to be associated with direct mast cell degranulation (because of the cationic nature of amphotericin B), pretreatment with a small test dose (0.1 mg/kg for cats or 0.25 mg/ kg for dogs diluted in 10 mL infused over 15 minutes) may help identify animals that are likely to have an adverse reaction during infusion. Whereas lipid products may be characterized by less nephrotoxicity, they are more likely than nonlipid products to cause vomiting, nausea, and phlebitis.³⁸ As such, pretesting is indicated with their use as well.

In addition to dilution protocols (see discussion under Toxicity), strategies are intended to minimize amphotericin-B induced nephrotoxicity. Although what constitutes amphotericin B nephrotoxicity may vary, an increase in creatinine of as little as 25% may be considered significant in some patients.¹⁸ Azotemia precedes tubular dysfunction in humans, allowing for early detection (i.e., before irreversible damage). Urine sediment initially should be monitored for evidence of nephrotoxicity. Serum chemistries tend to be less sensitive indicators of nephrotoxicity. Urine γ -gt has been used to assess lipid-based amphotericin B toxicity. The drug should be temporarily discontinued (24 to 48 hours) if the blood urea nitrogen level becomes abnormal.²⁷

KEY POINT 9-5 Nephrotoxicity caused by amphotericin B might be minimized by several approaches, including pretreatment with sodium-containing fluids.

First and foremost, pretreatment with sodium-containing fluids is particularly important for preventing renal toxicity, including that associated with renal arterial vasoconstriction; posttherapy treatment might also be prudent. Secondly, amphotericin B can be administered with a "cocktail" intended to protect the kidney. Administration of the dose diluted in 5% dextrose is accompanied by mannitol (0.5 mg/kg) to maintain glomerular filtration rate and sodium bicarbonate (1 to 2 mg/kg) to prevent cellular acidification defects. The mannitol and sodium bicarbonate should not be added directly to the amphotericin B solution but given through another catheter in order to avoid precipitation of amphotericin B. The ability of cocktails to prevent nephrotoxicity is controversial. The treatment is based on one small study in dogs³¹ for which mannitol was demonstrated to protect the kidney. However, a subsequent study (using isolated perfused rat kidneys) found mannitol to impart a protective effect, presumably by reducing renal tubular edema by virtues of its osmotic effect.³² Binding of cellular cholesterol prevented toxicity, supporting the presumed mechanism of direct cytotoxicty. This study also demonstrated a synergistic toxic effect of amphotericin B in the presence of hypoxia. Only one clinical trial, in humans, has addressed renoprotection by mannitol, and it failed to identify an effect. However, this clinical trial, although randomized, involved only 11 patients and is probably not conclusive (as reviewed by Bagnis and Deray^{18,23}) Although such cocktails generally are not harmful as long as the solutions are not mixed with amphotericin B, mannitol has been associated with electrolyte abnormalities in the human-medicine literature.²³ Deray¹⁸ indicates that mannitol decreases renal medullary blood flow and PO2. As such, the use of mannitol remains controversial. A relatively recent study describes the nephroprotective effects of N-acetylcysteine (10 mg/kg daily) in a rat model of amphotericin-induced nephrotoxicity;³³ administration began 1 day before amphotericin was started. As previously described, amphotericin should not be mixed with solutions containing electrolytes, acidic solutions, or preservatives because these materials may cause drug precipitation. The rate at which amphotericin B is administered may also reduce the incidence of nephrotoxicity.

The third strategy by which amphotericin B toxicity might be reduced is administration with lipids or as a specialized delivery system (in lipids). Conventional amphotericin B is not recommended in humans in the presence of renal insufficiency, hypokalemia, hypomagnesemia, tubular acidoses, or polyuria.¹⁸ Lipid preparations are designed to deliver more drug selectively to the site of infection,³⁴ thus allowing higher doses (see the section on preparations). The liposomal products tend to be very expensive. In contrast to liposomes, fat emulsions are easy to prepare and administer and tend to be more cost effective. These products appear to be equal in efficacy to nonliposomal products but safer with regard to nephrotoxicity. However, the use of intralipid as the vehicle (AmB-IL) is associated with other difficulties that limit its use (see previous discussion).

The safety of liposomal or lipid-based products may allow delivery of higher doses without an increased risk of nephrotoxicity, with the incidence of nephrotoxicity reduced by 8% to 28%, depending on the preparation.^{18,23} Although several studies are available that address the safety of these products individually, and LAmB (Ambisome) in particular,³⁵ none appears to have compared all three products. However, in general, the liposomal product LAmB (Ambisome) is recognized to be the safest with regard to nephrotoxicity. Ambisome achieves the highest concentrations in humans compared with other amphotericin preparations but is well tolerated renally.^{17,19} In general, efficacy of LAmB is equal to or exceeds that of AmBD and is consistently better tolerated. Survival rates in humans for the product ranges from 99% to 100% (visceral leishmaniasis; three studies, $n \approx 400$), 37% to 78% (aspergillosis; five studies, $n \approx 400$), 84% to 93% for cryptococcosis (two studies, $n \approx 280$), 98% for histoplasmosis (one study, n = 55), and 20% to 69% for zygomycosis (three studies, $n \approx 130$).³⁵ That LAmB may be preferred for CNS infections is supported by the study and review of Ibrahim and coworkers,²¹ who found LAmB generally superior to ABLC in treating CNS infections, as indicated by response and decrease in fungal load. Abelcet (ABLC) and LamB were generally characterized as having the lowest incidence of all side effects (fever, chills, nausea, dyspnea, hypertension, hypotension, tachycardia, and nephrotoxicity) with the exception of hypokalemia (42% with LamB). Ambisome was associated with abnormal hepatic function tests in approximately 20% of human patients.¹⁷ Abelcet causes fewer infusion-related side effects in humans, and therefore a test dose is not necessarily indicated, whereas Amphotec is more likely to cause infusion side effects and should be given as a short infusion only.

One study reports the efficacy and safety of a liposomal product when used at higher than recommended cumulative doses for treatment of canine blastomycosis.³⁶ In another study, although the products were equally efficacious, the degree of nephrotoxicity between a fat emulsion and standard amphotericin B was no different.³⁷ Amphotericin B also has been administered with a lipid vehicle (intralipid) rather than 5% dextrose. Although nephrotoxocity appears to be reduced in some patients, it does not appear to be decreased in the patients at most risk for toxicity, and therefore liposomal lipidbased products should be considered.¹⁸ Further studies documenting the efficacy and safety of liposomal or fat emulsion products containing amphotericin B are needed.

A fourth strategy that can be used to minimize adverse events associated with amphotericin B is administration using alternative routes. Localized mycotic infections have been treated with localized administration of amphotericin, which may reduce the incidence of nephrotoxicity. Subconjunctival, intravitreal, intrathecal, intranasal (human aspergillosis: 5 mg/mL in water administered as aerosol), and intraperitoneal routes have been reported. Oral administration has been used for treatment of gastrointestinal candidiasis and presumably might be used for other gastrointestinal fungal disorders.²⁹ Both LamB and ABLC have been demonstrated to have enhanced efficacy when administered as an aerosol for pulmonary infections (as reviewed by Adler).¹⁹ Amphotericin B (AmBD) can be mixed in sterile water to 200 mg/kg and infused into the bladder for fungal cystitis. For fungal infections of the CNS, the drug can be given (0.2 to 0.5 mg in either 5 mL of CSF or 10% dextrose) intrathecally (under general anesthesia) two to three times per week.27

Combination antifungal therapy is a fifth stategy that is strongly encouraged to enhance efficacy and thus decrease the duration of antifungal exposure to the host. For example, as reviewed by Adler,¹⁹ efficacy of LamB is enhanced when combined with micafungin (zygomycosis, aspergillosis) and voriconazole (aspergillosis).

Although a sixth strategy whereby amphotericin B toxicity can reduced includes variation in doses, frequency of administration, concomitant therapy, and duration of therapy, no protocol has proven to be superior to others. Some literature supports rapid intravenous administration (bolus) in less debilitated dogs; slow intravenous administration might be more prudent in cats. A dose (0.25 to 0.5 mg/kg) can be diluted in 300 to 1000 mL of 5% dextrose and administered in an indwelling catheter over 2 to 6 hours, or it can be diluted in as little as 10 to 60 mL (30 recommended) and given over 2 to 10 minutes through a butterfly catheter²⁷ (flush catheter after infusion). The slow infusion method has the added advantage of additional fluids, which may reduce the incidence of nephrotoxicity,²⁸ especially in debilitated animals. The advantages of dilution and slow infusion is preferred and was previously discussed (see Toxicity). It is recommended that the small bolus be preceded or followed up with supplemental fluid, preferably normal saline. One report of an uncontrolled clinical trial describes the successful and apparently safer administration of amphotericin B after twice- or thrice-weekly subcutaneous administration (0.5 to 0.8 mg/kg diluted in 400 to 500 mL of fluid such that amphotericin B is less than 20 mg/L) for several months for treatment of cryptococcosis in dogs and cats.³⁰ However, only five successful cases were described, and further confirmation should be expected before this route is routinely embraced.

The sequence of repetitive treatments is also controversial. Some authors recommend alternate-day therapy, whereas others recommend daily therapy at a smaller dose. Doses also vary. Daily doses range from 0.15 to 0.5 mg/kg every other day (e.g., on Monday, Wednesday, Friday) until a cumulative dose of 4 to 12 mg/kg (depending on the organism or if therapy is combined with another antifungal) AmBD has been reached. Starting at a low dose (0.15 to 0.25 mg/kg) and gradually increasing the dose until the desired daily dose has been reached may reduce the severity of side effects. For particularly resistant infections, a dose of 1 mg/kg has been used on an alternate-day basis.

Other Polyenes

The spectrums of piramicin (natamycin) and nystatin are similar to that of amphotericin B. Pirimacin is used primarily to treat fungal keratitis, although efficacy toward *Aspergillus* may be questionable.³ Aerosolization of piramycin for treatment of susceptible fungal disorders also should be considered. The toxicity of nystatin precludes parenteral administration, although a liposomal product is being formulated. Currently, use of nystatin is limited to superficial and mucosal mycoses.

AZOLE DERIVATIVES

Structure–Activity Relationship

The azole derivatives (imidazoles and triazoles) include a large number of predominantly synthetic drugs. These drugs consist of a five-member ring with other aromatic rings attached by a carbon nitrogen bond. Imidazoles contain two nitrogen atoms and include clotrimazole, econazole, enilconazole, miconazole, and ketoconazole. Triazoles contain three nitrogen atoms and include fluconazole, itraconazole, and voriconazole (see Figure 9-1).^{4,39-41} Among the newer azoles are posaconazole and voriconazole. Voriconazole, a synthetic deriviative of fluconazole, is the first of the second-generation triazole compounds to be approved by the Food and Drug Administration. Voriconazole contains a fluorine molecule and a methyl group, which greatly enhances its spectrum compared with that of fluconazole.⁴² Other triazoles have been patented. Most compounds generally are not available as solutions because they tend to be insoluble in water (an exception is fluconazole). They are, however, soluble in organic solvents such as propylene glycol.

Mechanism of Action

The azoles target fungal sterol ergosterol. However, in contrast to amphotericin B, the imidazole derivatives do not bind to ergosterol but rather block its synthesis. The azoles inhibit fungal cytochrome P450 enzymes with sterol14 α -demethylase as the primary fungal target; however, other synthesizing enzymes also are targeted.³ Decreased cell membrane ergosterol alters cell membrane function but also is accompanied by an increase in 14-methylsterols, compounds that are potentially toxic. Cell membrane function fluidity decreases as cell permeability increases, resulting in a fungistatic effect (fluconazole and ketoconazole). At higher concentrations, selected drugs (miconazole, econazole, clotrimazole) also interfere with cell membrane fluidity and physiochemical intracellular processes (e.g., secretory vesicles, mitochondrial respiration), resulting in fungicidal effects. Efficacy of selected agents against gram-positive organisms may reflect this latter effect.³ Chitin synthesis increases in concert with decreased ergosterol synthesis, but its irregular distribution contributes to altered cell wall function. Because azoles also generate and detoxify intracellular hydrogen peroxide, selected drugs also express antibacterial, antiprotozoal, and anthelmintic activities. The imidazoles are also characterized by immunomodulatory effects, which may facilitate effective therapy.⁵ Because their mechanism of action depends on cell wall synthesis, the onset of action of the imidazoles may result in a lag time to therapeutic efficacy. In addition, a long elimination half-life of some members of this class (e.g., itraconazole) results in a lag time as steady-state concentrations are achieved.

KEY POINT 9-6 The mechanism of action of the azoles will result in a lag time to efficacy, which may be prolonged further because of the time that must elapse before steady state concentrations are reached.

Spectrum of Activity and Pharmacodynamics

Although the imidazole derivatives are more selective in their cellular activity than amphotericin B (i.e., impairing the synthesis of rather than binding to ergosterol), their spectrum of activity is broad and includes the dermatophytes ("ringworm": *Microsporum* and *Trichophyton* species), yeasts, dimorphic fungi (blastomycosis, histoplasmosis, cryptococcosis, coccidioidomycosis), *Eumycetes*, *Actinomyces*, and some *Phycomycetes*.^{1,4,11,27,40,43} The efficacy against these organisms varies. Studies comparing the efficacies of the azoles in animals are limited at the time of this publication, although several are pending in the human-medicine literature.

KEY POINT 9-7 Although not as efficacious as amphotericin B, the spectrum of the imidazoles is the broadest of the clinically used antifungal drugs.

In vitro MIC data regarding the relative susceptibility of selected organisms to itraconazole emphasize the variable susceptibility of fungal organisms to these drugs. Table 9-2 provides MIC₉₀ data for selected organisms and itraconazole. For dermatophytes, the MIC₉₀ for *Microsporum* species is 250 µg/mL versus for Trichophyton species 4 µg/mL. For other *Eumycetes*, MIC₉₀ concentrations range from 0.130 μ g/mL to more than 128 µg/mL.11,44 Fluconazole generally is considered to be fungistatic in action. This has been demonstrated for Candida sp. and C. neoformans.¹⁰ However, more recent data suggest that fungicidal activity may occur toward Candida. Like fluconazole, itraconazole more consistently exerts a time-dependent, fungistatic effect toward most organisms. The MFC₅₀ and MFC₉₀ (µg/mL) have been reported for B. dermatitidis (0.125, 3, respectively), H. capsulatum (2, 16), and C. immitis (>16 for both).¹⁵ However, it may exert fungicidal effects towards Aspergillus. The long half-lives of the imidazoles will facilitate convenience of dosing despite their timedependent killing effects. Efficacy of itraconazole will be enhanced by the formation of its active metabolite, hydroxylitraconazole, which may surpass the parent.⁴⁵ As with other azoles, the spectrum of the third-generation imidazoles, posaconazole (similar in structure to itraconazole) and voriconazole (similar in structure to fluconazole), includes a variety of infecting fungal organisms. Their spectrums are very similar.¹⁰ Posaconazole has been demonstrated to be more potent than fluconazole toward Candida and should be effective against the dimorphic fungal organisms,⁴⁶ although little information is available regarding its use. As with other azoles, voriconazole is fungistatic toward yeasts, exhibiting timedependent killing, but for some filamentous organisms may be -cidal. Its spectrum includes Candida sp., with MIC generally being 1 to 2 log lower than fluconazole; however, MICs are higher for fluconazole-resistant strains than for nonresistant strains. Voriconazole also is effective against C. neoformans, Trichosporon beigelii, and Saccharomyces cerevisiae. Additionally, it is very effective against Aspergillus sp., including some strains resistant to amphotericin B; indeed, it is approved for the treatment of Aspergillosis in humans. Time-killing studies with Aspergillus demonstrate that, in general, amphotericin B is more efficacious but itraconazole less efficacious than voriconazole. Activity against B. dermatitidis, C. immitis, and H. capsulatum appears to be "reasonable" but "less" toward S. schenckii. Li15 compared the MICs of amphotericin B, itraconazole, and voriconazole and found voriconazole to be more active in vitro than amphotericin B for the mold forms of H. capsulatum, B. dermatitidis, and C. immitis, with activity being fungicidal (MFC₅₀, MFC₉₀, respectively) toward B. *dermatitidis* (0.125, 4) and some *H. capsulatum* ($8, \ge 32$) (see Table 9-2). Fungicidal activity toward C. immitis is difficult to achieve (>32 for the MFC₅₀). Activity Aspergillus also is fungicidal (MFC not provided) toward several dematiaceous molds.¹⁵ Many dematiaceous and hyaline molds resistant to amphotericin B (e.g., Scedosporium, Fusarium, Paecilomyces, Alternaria) are susceptible to voriconazole. However, zygomycetes are not susceptible.42 Cutaneous infections by Leishmania species are clinically susceptible to ketoconazole.47 Clotrimazole and miconazole are common drugs used topically for treatment of dermatophytosis (e.g., Conofite) or yeast (e.g., otic preparations such as Otomax). Both drugs, as well as other imidazoles (e.g.) appear to exhibit efficacy against grampositive organisms including staphylococci and anaerobes.

Resistance

Resistance to the azoles has been sporadic, generally occurring in immunocompromised patients receiving long-term therapy. Failed drug accumulation in the cell is a major mechanism of resistance (e.g., *Candida* sp., *C. neoformans, Aspergillus flavus,* and *A. fumigatus*), caused by either decreased influx or formation of efflux proteins. Two major efflux transport proteins have been identified, particularly for *Candida* sp. toward fluconazole: the multidrug-resistant protein, major facilitator superfamily (MFS; a proton-motive-force-based mechanism; e.g., CaMDR1) and the ATP-binding cassette (e.g., CDR1 and 2). Resistance to azoles also may reflect altered interaction between the drug and targeted fungal CYP 450 enzyme; fluconazole appears more susceptible than itraconazole to mutations that alter drug-receptor fit. Gene amplification leading to enhanced synthesis of the target protein also has been identified as a mechanism of resistance to azole derivatives. Finally, fungal organisms may circumvent the synthetic pathway inhibited by azoles or compensate for altered enzyme activity; for example, inhibition of ergosterol may result in the accumulation of 14-methylated sterols that are less toxic than other compounds.³ Resistance to fluconazole appears to be increasing. Widespread use of fluconazole for treatment of Candida has been associated with increased resistance of the drug for selected species. Whereas many molds (e.g., A. fumigatus) are inherently resistant to fluconazole,³ resistance of Aspergillus isolates to itraconazole is rare. Combinations with nonantagonistic antifungal agents might be considered for treatment of infections by organisms associated with antifungal resistance.

Pharmacokinetics

Only selected pharmacokinetic information is available for the imidazoles in dogs or cats (Table 9-5).Oral absorption of the imidazole derivatives varies with the drug and among animals. For many drugs oral preparations are not available. For example, enilconazole (imazalil) is not orally bioavailable. For other imidazoles the rate of absorption varies from 1 to 4 hours. Oral absorption often depends on gastric pH, product preparation, and the presence of other drugs.⁴⁸ Absorption of itraconazole and ketoconazole is enhanced by gastric acidity; these drugs should be administered with food.⁴⁹ Alkalinizing drugs administered orally will decrease their absorption. Cyclodextrins are used to form complexes with the drugs, thus rendering the liphophilic drug soluble in solution, making oral solutions available for some drugs (e.g., Sporonix solution). In general, oral bioavailability should be anticipated to be better for these solutions than for capsules. Peak PDCs of itraconazole occur between 1 to 5 hours in cats and dogs. Bioavailability of capsules is approximately 20% in dogs and may be as little as 10% in cats, compared with close to 50% for the solution in cats and dogs.^{50,51} Decreased bioavailability may be responsible for therapeutic failure associated with low PDCs in some animals (cats and dogs). Unpredictable oral administration of itraconazole prepared as a capsule limits its usefulness in humans; the solution, on the other hand, generates more predictable concentrations.¹⁷ Care should be taken with compounded preparations; oral absorption generally is not verified for these products, and adequate oral bioavailability should not be assumed. Fluconazole is characterized by the best oral bioavailability among the imidazoles, being completely absorbed in cats;52 however, its efficacy, compared with that of itraconazole, is limited.

KEY POINT 9-8 Absorption of itraconazole and ketoconazole is enhanced by gastric acidity; these drugs should be administered with food.

Table 9-5	Pharmacokinetic Data for Selected Imidazoles in the Dog					
	Dose (PO, Once)		AUC (infinity)			
Drug	mg/kg	C _{max} μg/mL*	μ g hr/mL	Half-Life hr	Oral Bioavailability %	
Itraconazole ⁵²	5	3.55 ± 2.81		51	20 capsule	
	10	13.5 ± 8.5				
Voriconazole ⁵⁵	3	6.5*	32 (IV); 89(PO) [†]	6.3	138	
	3 (30 days)	$1.69 \pm 0.83^{\dagger}$	18 (IV);52			
	6 (30 days)	4.54±2.22				
	12 (30 days)	10.34 ± 5.1				
Posaconazole ⁵⁶	10	3-3.5+	43-57	7	65-72 (cyclodextrin)	
	10	0.2 (± 22%) at 7.6 hr	7.5	15	37-48 (methylcellulose)	
	10 (fed)	0.7 (± 28%) at 8 hr	27		· · ·	
	40 (fed)	2.1 (±31%) at 9 hr	105			

AUC, area under the curve; D, dog; IV, intravenous; PO, By mouth.

*50% protein bound.

[†]The lower C_{max} and AUC after 30 days of dosing reflects autoinduction.

Vehicle dependent+

Distribution to tissues also varies among the imidazoles. Ketoconazole is up to 99% protein bound; the highest tissue levels occur in the liver, lung, and kidney (and cerumen). Itraconazole is also very highly protein bound in humans.⁴ There is minimal penetration of the CSF by ketoconazole, although fluconazole penetrates the CSF well, with serum to CSF PDCs ranging from 0.58 to 0.89 µg/mL. The volume of distribution of ketoconazole is only 0.87 L/kg in dogs compared with 17 L/kg 5 L/kg for itraconazole in dogs⁵¹ and cats, respectively.50 The volume of distribution of fluconazole is 1.14 L/ kg in cats, with high concentrations occurring in the CSF and aqueous humor.⁵² The difference in distribution volume reflects, in part, distribution and accumulation to fat.⁵¹ Drug concentrations of itraconazole in the skin may exceed that in plasma by threefold to tenfold, with drug detectable 2 to 4 weeks after therapy is discontinued.⁵¹ Although distribution of itraconazole to the CSF appears to be limited, therapeutic concentrations appear to be achieved in patients suffering from cryptococcal meningitis. Among the azole derivatives, fluconazole has the best tissue distribution pattern and can achieve effective concentrations in CSF.

KEY POINT 9-9 Among the imidazoles, fluconazole is characterized by the best oral bioavailability and distribution into the central nervous system.

With the exception of fluconazole, the azole derivatives are eliminated by extensive oxidative (cytochrome P450) metabolism with excretion as inactive metabolites into the bile and urine. However, metabolism of itraconazole generates an active hydroxylated metabolite, whose AUC may exceed that of the parent compound.⁵³ Metabolism may be dose dependent; elimination rate constants are lower and half-lives are longer at higher doses and with longer therapy. In contrast to the other imidazoles, fluconazole is eliminated principally (70%) in the urine. The half-life of the imidazoles varies, with that of ketoconazole being relatively short (1.4 hours in dogs). Fluconazole and itraconazole have longer half-lives, ranging from 22 to 32 hours in humans. The half-life of fluconazole in cats is 25 hours.⁵² The half-life of itraconazole in dogs is 51 hours (itraconazole)⁵² versus 40 to 70 hours in cats (itraconazole);⁵⁰ The longer drug elimination half-life must be taken into account because it results in a longer time to steady-state concentration and maximum therapeutic effect. However, it also allows the flexibility of once-daily (10 mg/kg) rather than twice-daily (5 mg/kg) dosing.

The disposition of voriconazole is complicated. Its disposition has been reported in dogs as part of a preclinical study (see Table 9-5).⁵⁵ Beagles (n = 4) received multiple doses (8) of 6 mg/kg orally or 3 mg/kg intravenously using a crossover design; disposition was studied on day 1 and day 30 for each route. The AUC after single and multiple dosing (µg*h/mL) after the intravenous dose was 32 and 18, respectively, and after the oral dose 89 and 52, respectively, suggesting autoinduction. Other relevant parameters after single oral dosing were as follows: Cmax, 6.5 µg/mL at Tmax of 3 hours and apparent bioavailability of 138%. The drug was 51% protein bound, indicating a concentration of approximately 3.25 µg/mL of active drug. For a safety study, Beagles (n = 6) also received oral doses of 3, 6, or 12 mg/kg for 1 month. The apparent volume of distribution was 1.3 L/kg and clearance was 24 mL/min/kg, resulting in a calculated half-life of 6.3 hours. The C_{max} increased in a slightly disproportionate dose-dependent manner, being 1.69 \pm 0.83 µg/mL at 3 mg/kg and 10.3 \pm 5.1 µg/mL at 12 mg/kg 30 days after oral dosing. However, cytochrome P450 increased in a dose-related manner, resulting in a 1.7-fold increase in relative liver weight at the highest compared with the lowest dose. Autoinduction in dogs, which does not occur in humans, resulted in an increased clearance after multiple dosing, with these effects dissipating approximately 1 month after the drug was discontinued. For example, the mean C_{max} after a single oral dose of 3 mg/kg in dogs was 6.5 µg/mL but only 1.7 after 30 days dosing at the same dose. Although 55% to 87% of the drug ultimately was eliminated in the urine in dogs, only 5% was as the parent drug, indicating extensive hepatic metabolism. A major pathway of metabolism was generation of the N-oxide and hydroxylation metabolites as well as glucuronidation. The dose of voriconazole recommended for dogs can be based on pharmacokinetic-pharmacodynamic integration. The MIC₉₀ of most infecting microbes for which data are available will be achieved after 30 days at 3 mg/kg, even accounting for 50% protein binding in dogs. An exception occurs, however, for H. capsulatum, for which a higher dose is indicated. With a halflife of 6 hours, based on time-dependent killing, at least twice the MIC of the infecting microbe should be targeted to allow for a 12-hour dosing interval. In humans dosing regimens are designed to reach 3 to 6 µg/mL in the plasma; accordingly, a dose of 3 to 6 mg/kg twice daily is recommended. However, the half-life in humans is long (6 to 24 hours, depending on the dose), and steady-state concentration requires 5 to 6 days of dosing. As such, a loading dose consisting of a double daily dose is recommended for the first day of therapy. This is not necessary in dogs: the shorter half-life precludes accumulation to a steady state. However, the shorter half-life will necessitate twice-daily dosing. Because of autoinduction in dogs, dosing regimens should not be extrapolated for cats from dogs without the support of pharmacokinetic studies.

Voriconazole is cleared primarily by hepatic metabolism to inactive metabolites by CYP 2C19 (the primary isoenzyme), 2C9, and 3A4 being involved. Selected humans are considered "poor metabolizers" of the drug because of variation in CYP 2C19. In humans the dose is halved in the presence of mild to moderate liver disease. The relevance of this to dogs, which autoinduce, is not known.

Very limited pharmacokinetic information is available for dogs receiving posaconazole (see Table 9-5).⁵⁶ It was studied in two different vehicles (cyclodextrin or methylcellulose) during preclinical investigations. Absorption from the cyclodextrin vehicle was better, resulting in a higher C_{max} , greater AUC, and better oral bioavailability. Although the half-life following intravenous administration was approximately 8 hours, the effective half-life is 15 hours after oral administration, probably reflecting slow absorption, as is indicated by a T_{max} of 8 to 9 hours. Food enhanced absorption, increasing C_{max} and AUC fourfold. Although C_{max} increased more than two fold with multiple dosing, AUC was the same, indicating accumulation is not likely to be a clinical concern.

Preparations

Ketoconazole, itraconazole, and fluconazole are available for oral administration. Solutions are available for some products. Although their safety has not been documented for animals, fluconaozle (Diflucan) is available as an intravenous preparation that appears to be safe in cats when administered as a slow intravenous drip at 5 mg/kg. The solubility of imidazoles is poor and potentially toxic; solubilizing agents may cause adverse reactions. Cats also appear to tolerate a slow intravenous drip of itraconazole (5 mg/kg) with no adverse effects, although neither product is commercially available. Ketoconazole also is available in a topical preparation and a shampoo. Clotrimazole and miconazole are recommended only for localized dermatophyte or yeast infections susceptible to topical treatment. Clotrimazole has been used topically to treat nasal aspergillosis. Enilconazole is a topically effective azole that has been used to treat nasal aspergillosis but is available in the United States only as a 13.8% poultry dip. It is available in Canada as a 10% solution approved for use in dogs and horses. The poultry dip has been used topically in the United States at a dilution of 1:50 in water in dogs and cats with no apparent adverse effects. Terconazole is a new, topically active triazole that apparently has not yet been used for animals. However, an otic preparation containing posaconazole (with orbifloxacin and an anti-inflammatory) has recently been approved for dogs.

Drug Interactions

The azoles may interact synergistically with a number of antifungal agents. Synergism with polymyxin B is benefited in otic preprations.³ Ketoconazole and, presumably, other azole antifungals have synergistic antifungal activities with 5–flucytosine against *Candida* and *Cryptococcus* and with amphotericin against a variety of organisms. However, timing of amphotericin B and azole therapy is important. Azoles impair ergosterol synthesis, and therefore their use before amphotericin B may decrease its efficacy which is dependent on active cell wall synthesis. Amphotericin B should begin either simultaneously with (azoles are characterized by a lag time to effect) or before azole administration. Enhanced efficacy has also been demonstrated for terbenifine and topical therapy (see Therapeutic Use).

Because the efficacy of the azoles depends on interaction with P450 (an oxidative enzyme responsible for drug metabolism), drug interactions at the level of drug or steroid metabolism should be anticipated in the patient. The azoles are both inhibitors and inducers of CYP isoenzymes; the extent to which an azole inhibits metabolism often depends on its relative affinity for host compared to fungal CYP 450.3,57 All of the clinically relevant imidazoles inhibit some CYP. These include: CYP3A4 (ketoconazole, itraconazole, fluconazole, voriconazole; (ketoconzole has a higher affinity than itraconazole); 2C19 and 2C9 (ketoconazole, fluconazole, voriconazole); 2D6 (ketoconazole); 2C8 (ketoconazole and voriconazole); and 1A2 and 2E1 (ketoconazole). However, as has been demonstrated in dogs, voriconazole is an autoinducer and species differences in CYP interactions may be profound. When present, inhibition can be clinically relevant. It can be beneficial (e.g., the combination of ketoconazole with cyclosporine in an attempt to prolong cyclosporine clearance in order to decrease the daily cost of this drug (see Chapter 31).58 In the author's laboratory, the effect of ketoconaozle on cyclosporine concentrations appears to be quite variable, ranging from no effect to a dramatic increase. Kukanich and Borum⁵⁹ found that ketoconazole (approximately 13 mg/kg for 5 days) did not appear to affect the intravenous disposition of morphine in Greyhounds.

However, more commonly, inhibition is associated with adverse reactions. The author is aware of two cases of marked increases in phenobarbital concentrations (to over 85 μ g/mL) in epileptic dogs receiving fluconazole or itraconazole, respectively, for treatment of Malassezia; one of the dogs was euthanized resulting from (assumed) liver disease. More recently, a dog receiving deracoxib and also developed a perforated duodenal ulcer receiving ketaconazole for a skin yeast infection.

Itraconazole appears to cause autoinhibition; changes in the elimination half-life of intractonaozle have been documented in cats receiving long-term therapy (>6 weeks).⁵⁰ In humans, the risk of drug interactions involving voriconazole is high, perhaps more so than with the other azoles. Their magnitude and impact in dogs and cats needs to be clarified. Clinically relevant drug interactions have been documented for a number of drugs administered in concert with voriconazole; avoidance of other drugs administered by the liver would be prudent.⁴²

KEY POINT 9-10 All imidazoles appear to impact drugmetabolizing enzymes, with inhibition being most common and clinically relevant.

Not all drug interactions involve inhibition of CYP. Clotrimazole is a potent inducer of CYP3A and miconazole of CYP 1A and 2E; even ketoconazole is an inducer of CYP 2, although it is less potent than clotrimazole (see Chapter 2 for drugs metabolized by CYP isozymes). As previously discussed, voriconazole is an inducer of CYP in dogs. Ketoconazole interferes with sex hormones and corticosteroids by displacing them from globulins and perhaps by interfering with their synthesis. Ketoconazole inhibits lanosterol14-demethylase (cholesterol synthesis; CYP51) and two hydroxylase enzymes responsible for steroid metabolism as well as a key enzyme involved in testosterone synthesis. As a result of its effects on steroid synthesis, ketoconazole has been used to treat hyperadrenocorticism and to impair testosterone synthesis in patients with prostatic hypertrophy or prostatic cancer. Ketoconazole has caused lightening of the hair coat of some dogs.⁶⁰ Willard and coworkers⁶⁰ reported depressed basal cortisol and testosterone concentrations and ACTH response by cortisol at 30 mg/kg/day. A rebound response was seen after ketoconazole was discontinued. Serum progesterone concentrations were also decreased. Aldosterone was not decreased. Cats receiving 30 mg/kg/ day for 30 days developed dry hair coat and weight loss but no changes in testosterone or progesterone concentrations.⁶¹

Finally, not all clinically relevant drug interactions involving imidazoles reflect effects on cytochrome P450. The imidazoles in general are substrates for P-glycoprotein, and ketoconazole is a known inhibitor.⁶² Accordingly, other drugs that serve as substrates for P-glycoprotein are likely to be absorbed to a greater extent. Thus ketoconazole can affect (increase) cyclosporine A concentrations following oral administration without affecting cyclosporine elimination half-life as has been documented in the author's laboratory.

Toxicities and Side Effects

In general, the imidazoles are not characterized by the complex toxicities that are associated with amphotericin B. Because the azoles interfere with synthesis of ergosterol rather than binding the sterol, the host toxicities typical of those induced by amphotericin do not occur.⁶³ Gastrointestinal toxicities are the most common and are not severe.^{4,40,27,54,64} Nausea and vomiting can usually be prevented by administration of the drug with food. Hepatotoxicity with ketoconazole has been reported in humans. Mayer and colleagues⁶⁵ retrospectively reported

adverse effects of ketoconazole in dogs. Medical records in Australia (n = 296), Germany (n = 35), and the United States (n = 301) were reviewed, and adverse events were reported in 92 (14.6%). Doses ranged from 2.6 to 33.4 mg/kg, with an average daily dose of 11.2 mg/kg. The frequency of adverse events was as follows: vomiting (7.1%), anorexia (4.9%), diarrhea (1.1%), and lethargy (1.9%). Uncommon side effects included pruritis (0.6%) and ataxia, polyuria, and polydipsia; causal relationships were difficult to establish for the uncommon reactions.

Side effects to itraconazole are limited to gastrointestinal symptoms (nausea and vomiting), which may be related in part to the vehicle if associated with the oral solution (a cyclodextrin carrier).³ One case of cutaneous drug eruption typical of erythema multiforme caused by itraconazole has been reported in a dog;⁶⁷ idiopathic vasculitis has also been reported.⁵⁴ Fluconazole is associated with very few side effects; hematologic disorders may occur particularly in profoundly ill patients; otherwise, side effects appear to be limited to gastroinestinal and cutaneous reactions.

Isolated cases of hepatotoxicity have been reported with itraconazole and fluconazole. A retrospective study of dogs with blastomycosis found 5% to 10% of dogs treated with itraconaxole (5 to 10 mg/kg bid) developed hepatotoxicity with the effect dose dependent.¹¹⁹ A dose dependency has been documented in one case with fluconazole. Patients with impaired liver function may be predisposed to worsening hepatic function induced by the azole antifungal drugs. The occurrence of liver disease in animals treated with itraconazole is controversial. Cats receiving 5 and 10 mg/kg twice daily showed no adverse effects (including weight loss) after receiving itraconazole for 6 weeks.⁵⁰ However, one study of enilconazole applied as a 0.2% solution once every 3 days to Persian cats in a cattery indicated potential gastrointestinal signs in the cats, including salivation, anorexia, increased liver enzymes, and emesis and muscle weakness.⁶⁶ Nausea, vomiting, skin rash, thrombocytopenia, and hypokalemia have also been reported with fluconazole therapy. The author dealt with acute hepatopathy in a cat treated topically with a commercial over the counter preparation of clotrimazole; the owner treated a large cutaneous wound topically several times a day. The hepatopathy resolved within several days of discontinuing therapy.

Voriconazole is associated with a number of side effects. Interestingly, voriconazole (but no other azole) causes vision disturbances in humans. Disturbances are characterized by loss of color discrimination, blurred vision, bright spots, wavy lines, and photophobia; up to 30% of human patients are afflicted, although the drug rarely is discontinued because of this effect. Visual hallucinations are reported in 5% of human patients. Experimentally, voriconazole produced dosedependent changes in the electroretinogram of dogs at plasma levels comparable to those in humans.⁶⁸ Skin rashes also commonly occur; although most are mild, occasional severe reactions (e.g., Stevens-Johnson syndrome) occur. Clinical signs resolve when the drug is discontinued. As with other azoles, voriconazole is associated with increased hepatic leakage enzymes as well as serum alanine phosphatase; increased liver weight occurred experimentally in dogs after 1 month of dosing at 3 mg/kg.⁶⁸ Hepatotoxicity should be assumed to be dose and duration dependent. Although most changes are asymptomatic, severe hepatopathy has been reported in humans receiving voriconazole, with effects apparently dose dependent. Hepatic function might be measured before and 2 weeks into therapy and then every 2 to 4 weeks. The use of *N*-acetylcysteine, *S*-adenosylmethionine, or other hepatoprotectants might be considered. Again, because dogs appear to autoinduce, the impact of voriconazole on the liver is not clear. Other gastrointestinal side effects include nausea, vomiting, diarrhea, and abdominal pain.⁴² Although voriconazole is not nephrotoxic, nor is it eliminated in the urine, the carrier of the intravenous preparation may accumulate in patients with impaired renal function, and therefore the intravenous preparation should not be used in these patients.⁴²

Therapeutic Use

In general, itraconazole and fluconazole are more efficacious against many organisms than ketoconazole; however, the spectrum of fluconazole is limited compared with that of itraconazole. Ketoconazole has been used effectively for dermatophyte infections; mucocutaneous candidiasis; and many systemic mycoses in both dogs and cats. Ketoconazole has been reported to be effective in the treatment of dermatophytosis,^{70,71} blastomycosis,⁷² histoplasmosis,⁷³ coccidioidomycosis,⁷⁴ and cryptococcosis.75 Ketoconazole probably should not be used alone for treatment of canine blastomycosis; recommendations are to use amphotericin in addition to ketoconazole. Higher doses also are indicated for systemic cryptococcosis and coccidioidomycosis. Ketoconazole also has proved effective for treatment of Malassezia dermatitis, and candidiasis. It is available as a topical shampoo that can be useful for treatment of dermatophytosis or Malassezia. Ketoconazole has little efficacy (43%) against Aspergillosis species, fluconazole more efficacy (although some isolates, including A. fumigatus, are inherently resistant), and itraconazole most efficacy (60% to 70%). Fluconazole has been used successfully to treat ketoconazoleresistant strains of Candida. Equal efficacies of itraconazole and fluconazole have been shown for cryptococcal meningitis, despite relatively poor penetration of the CSF by itraconazole. Both are equally effective in Candida-induced pyelonephritis. Comparison of ketoconazole and fluconazole reveals fluconazole to be more active against coccidioidal meningitis.

Among the imidazoles, itraconazole and fluconazole are being used more consistently than the others for systemic treatment of susceptible fungal infections. For itraconazole⁷⁶ conditions successfully treated include blastomycosis⁵⁴ (including ocular⁷⁷), histoplasmosis,⁷⁸ cryptococcosis (including meningitis),⁷⁹⁻⁸¹ sporotrichosis,⁸² aspergillosis,⁸³ dermatophytosis,⁶⁴ dermatophytic pseudomycetomas,^{84,85} phaeohyphomycosis,⁸⁶ and cutaneous *Alternaria*.⁸⁷ Efficacy against *Aspergillosis* is better than that clinically recognized for any other agent (not including newer drugs), and although resistance is rare, treatment failure rates of up to 50% have been reported for itraconazole. In animals administration of itraconazole at a rate of 5 mg/kg twice daily is efficacious in the treatment of blastomycosis and histoplasmosis. After administration of

10 mg/kg, the C_{max} for itraconazole in dogs was $13.5 \pm 8.5 \ \mu$ g/ mL versus $3.55 \pm 2.81 \,\mu\text{g/mL}$ at 5 mg/kg. Although the MIC₉₀ of most infecting fungal organisms will be achieved at 5 mg/ kg, at the higher 10 mg/kg dose, the MFC for itraconazole will be achieved for B. dermatitidis, almost reached for H. capsulatum, but not reached for C. immitus. However, the incidence of adverse effects may be greater at this higher dose.⁵⁴ Concentrations will be higher at steady state. The efficacy of itraconazole against coccidioidomycosis is equivocal, requiring long-term therapy. Relapse of disease appears to be common. Despite the larger MIC for dermatophytes compared to other susceptible fungal organisms, itraconazole at 1.5 to 3 mg/kg every 24 hours was effective in 8 of 15 cats in one uncontrolled clinical trial for treatment of dermatophytosis.⁶⁴ Fluconazole is only modestly effective toward sporotrichosis; itraconazole should be considered first-line therapy.⁶⁹

KEY POINT 9-11 In general, itraconazole and fluconazole are more efficacious against many organisms than ketoconazole; however, the spectrum of fluconazole is limited compared with that of itraconazole.

Itraconazole has been used to treat canine blastomycosis (5 mg/kg/day); sporotrichosis (7.5 mg/kg/day); and, in conjunction with surgery, nasal aspergillosis (10 mg/kg/day). In cats it has proved effective for treatment of cryptococcosis and histoplasmosis. The dermatologic pharmacokinetics of itraconazole support pulse therapy, which has been used in human medicine for treatment of selective dermatologic fungal disorders. Treatment occurs for 2 consecutive weeks of daily administration each month for 3 consecutive months.⁸⁸ One report of itraconazole used to treat dermatophytosis noted similar success with this technique.⁶⁴

There are few reports regarding the efficacy of fluconazole for treatment of fungal infections in animals; infections that have been treated include blastomycosis,⁸⁹ cryptococcosis,⁷⁴ and nasal aspergillosis.⁹⁰ Efficacy has, however, been demonstrated toward a variety of fungal disorders in humans. Pulse dosing (once weekly) of fluconazole also has been described for treatment of skin infections in people.

Enilconazole has excellent in vitro activity against a number of organisms, but its topical use is limited to dermatophytes and nasal aspergillosis. Miconazole also is limited to topical use; combination with polymyxin B yields synergistic activity.

Newer azoles are likely to prove even more efficacious than fluconazole and itraconazole for the treatment of aspergillosis and coccidioidomycosis. Voriconazole is approved for treatment of selected infections, but in particular aspergillosis. The maintenance dose in humans is approximately 2 to 5 mg/ kg twice daily. In human patients who have not responded adequately to traditional therapy for treatment of aspergillosis, 38% had a partial to complete response to voriconazole used as salvage therapy. In a study of invasive aspergillosis in humans, 53% of patients receiving voriconazole responded (partial to complete) within 12 weeks compared with only 32% of patients receiving amphotericin B; survival rates were 71% and 58%, for each drug, respectively.⁴² Because of superior clinical response, safety, and survival, treatment of immuncompromised human patients with voriconazole was demonstrated to be economically superior to treatment with amphotericin B.⁹¹ For *Pseudallescheria/Scedosporium*, major pathogens in human immunocompromised hosts normally resistant to amphotericin B and *Fusarium* sp., response rate was 30% to 63% and 50%, respectively, for the two species. Despite excellent in vitro efficacy against *C. neoformans* and good CNS penetration, voriconazole is not recommended for treatment of *Cryptococcosis*, in part because of its failure in human patients. The same may be true for blastomycosis, histoplasmosis, and coccidiodomycosis. Although effective in animal models, successful therapy with voriconazole for these organisms has not been demonstrated in humans. A salvage approach might be considered for these organisms.⁴²

A single case report describes the successful treatment with posoconazole of a fungal disorder caused by *Mucor* (Zygomycetes class; Mucorales order) species on the nose of a 15-year-old cat.^{91a} After poor response to fluconazole, the cat was treated at 5 mg/kg daily for 3 months, with initial response evident in 2 weeks and continued response for the remainder of the 3-month treatment period.

Terbinafine was shown to enhance efficacy when combined with itraconaozle or fluconazole when treating candidiasis characterized by low susceptibility to the azoles.⁹² Indeed, combination with benzoyl peroxide topically enhanced treatment of candidiasis associated with *Pseudomonas* and *Staphylococcus aureus* infections in humans.⁹³

BENZIMIDAZOLES

Benzimidazoles (e.g., thiabendazole) may be better known for their anthelmintic activity, but many also are characterized by a broad range of antifungal activity at relatively low doses. Benzimidazoles bind to β -tubulin of the microtubule. Not only is mitosis blocked, but selected organelles also are displaced, such as mitochondria in hyphal tips, which alters linear growth. Unfortunately, resistance generally caused by point mutations in the β -tubulin genes, limits the antifungal activity of the drugs. The spectrum of thiabendazole is limited to the dermatophytes (toward which activity can be -cidal) and, to a lesser degree, *A. fumigatus*, penicillinosis, and some *Fusarium* species. Thiabendazole also is effective against *Pneumocystis carinii*. Its use as an antifungal is largely limited to topical therapy (e.g., otitis externa).

ECHINOCANDINS

The echinocandins are the first new antifungal drugs to be developed in the last 15 years.⁹⁴ Originally elucidated from different fungal organisms, including *Aspergillus*, they are synthetically modified lipoproteins derived from fermentation broth of a number of organisms.⁹⁵ Included in the chemicals identified thus far are aculeacin A, echinocandin B, pneumocandin B, enfumafungin, and papulacandins. These chemicals inhibit the synthesis of β -D-glucan (the major glucan in the cell wall of *Aspergillus*), disrupting the fungal cell wall (see Figure 9-1).

Their novel mechanism of action results in rapid fungicidal effects for some organisms with minimal side effects.⁹⁶ Caspofungin (see Figure 9-2) is the first of the drugs to undergo approval in the United States. Its spectrum of activity is limited but does include *Candida* sp. and *Aspergillus* sp.; the drug is approved to treat the latter. Other drugs include micafungin and anidulafungin, both approved to treat candidiasis.
