The large molecular weight of the echinocandins and poor oral absorption limit use to intravenous administration. Drug does not distribute well into the urine or CNS. Concentrations in the lungs approximate those in the plasma. The compounds undergo phase I metabolism to inactive metabolites. Despite its metabolism by the liver,97 capsofungin does not serve as a substrate for major CYP 450. However, selected drugs will alter capsofungin, disposition, including cyclosporine (which increases it). In humans caspofungin acetate is characterized by an elimination half-life of 9 to 10 hours but is administered once daily. Capsofungin is involved in few drug interactions. Side effects are unusual but include phlebitis, fever, nausea, skin rash, and abnormal liver function. Despite low CNS concentrations, human cases of cerebral aspergillosis have responded to caspofungin treatment. The ability to kill Aspergillus is controversial; generation of cell wall-deficient colonies in vitro may be associated with organism viability. The optimal dose has not yet been established in humans; generally a loading dose of 70 mg is followed up by doses of 50 to 70 mg daily. A ceiling dose of 1 mg/kg has been suggested, but doses of micafungin as high as 300 mg daily (up to 8 mg/kg daily) was not associated with toxicity in humans.⁹⁴ Efficacy has been demonstrated against fluconazole-resistant strains of Candida. However, Cryptococcus is resistant. Although Fusarium is resistant, Scedosporium is moderately susceptible and Saccharomyces is susceptible.

FLUCYTOSINE

Structure–Activity Relationship

5-Flucytosine (FLU; 5-fluorocytosine) was originally developed as an anticancer drug much the same as its sister anticancer drug, 5-fluorouracil. It is a water-soluble powder.

Mechanism of Action

As an antimetabolite, FLU interferes with DNA synthesis after its conversion to 5–fluorouracil, a substitution compound that prevents synthesis in the fungal cell.^{4,40} The compound enters the cell by way of cytosine permease, which also takes up adenine, guanine, hypoxanthine, and cytosine.³ The enzyme responsible for conversion of FLU to 5–fluorouracil is a cytosine deaminase, an enzyme whose absence in mammalian cells renders FLU relatively specific for fungal cells. The effect of FLU depends on subsequent metabolism: if converted by pyrimidine processing enzymes to a uridine monophosphate derivative, inhibition of thymidylate synthase and DNA synthesis yields -cidal effects. Alternatively, it can be converted by way of a pyrimidine salvage pathway resulting in metabolism to a uridine-5'-triphosphate derivative. Subsequent incorporation into RNA results in impaired protein synthesis and fungistatic effects (*Candida, Cryptococcosis*). Many organisms are intrinsically resistant to FLU because they either lack the permease enzyme or have a defective deaminase enzyme. Resistance also develops relatively rapidly, particularly for aspergillosis followed by cryptococcosis and candidiasis (especially *Candida krusei*).³ Secondary resistance usually reflects a decrease in an enzyme responsible for formation of uridine monophosphate. Use in combination with another antifungal agent reduces the development of resistance.

Spectrum of Activity

The spectrum of activity of FLU is limited and includes cryptococcosis, candidiasis and some cladosporiosis, aspergillosis, chromomycosis, and sporotrichosis. It has been the treatment of choice for cryptococcosis in humans.^{4,40} Combination therapy is usually indicated (e.g., amphotericin, ketoconazole). When FLU is used alone, resistance develops rapidly. Synergism occurs with amphotericin B and probably with ketoconazole (or other imidazoles).

Pharmacokinetics

Oral absorption of FLU is rapid and close to complete. Peak plasma concentrations occur in 1 to 2 hours. Distribution is large, to total body water. Protein binding is minimal, and CSF concentrations reach up to 90% of plasma concentrations. Penetration of aqueous humor and joints is good. The half-life of FLU is 3 to 6 hours. Most of the drug is excreted into the urine unchanged. Renal clearance is similar to that of creatinine and thus may be significantly decreased if renal dysfunction is present. Doses will probably need to be modified for patients with renal disease.

Preparations

Flucytosine is available as an oral preparation.

Side Effects

Because FLU interferes with DNA synthesis, body systems composed of rapidly dividing cells are adversely affected. Bone marrow depression is manifested as anemia, leukopenia, and thrombocytopenia (pancytopenia). This toxicity may be serious and is more common in patients with renal disease. Gastrointestinal toxicity is manifested as nausea, vomiting, and diarrhea, but it is not usually serious. Reversible, erythemic, alopecic dermatitis has been reported in dogs.

GRISEOFULVIN

Structure–Activity Relationship

Griseofulvin (see Figure 9-1) is produced from a *Penicillium* species bacterium. The drug is insoluble in water.

Mechanism of Action

Griseofulvin enters fungi through an energy-dependent transport system. Griseofulvin inhibits fungal mitosis by binding to the microtubules that form the mitotic spindle. The formation of microtubules from tubulin is inhibited. Formation of cytoplasmic microtubules responsible for transport of endogenous compounds also is inhibited. Other drugs, such as colchicine and vincristine, which also bind to and inhibit the microtubule, do so at a site that is different from that of griseofulvin. Griseofulvin also probably inhibits nucleic acid and fungal wall synthesis. It is not certain if griseofulvin is fungistatic or fungicidal. Resistance probably reflects decreased drug uptake.

Spectrum of Activity

The spectrum of activity of griseofulvin reflects the presence of an energy-dependent transport system in the fungal organism. Those with prolonged energy-dependent transport systems are susceptible, whereas those with independent systems of short duration are not. Efficacy is limited to dermatophytes: *Microsporum, Trichophyton,* and *Epidermophyton.* Because of its distribution into keratin, griseofulvin remains the drug of choice for fungal infections of the nails.

Pharmacokinetics

Oral absorption varies because of water insolubility and depends on particle size and preparation. Absorption is increased in the presence of fat. The rates of dissolution and disaggregation alter the bioavailability of different products. Bioavailability of the ultramicrosize is at least 50% greater than that of the microsize. Although griseofulvin penetrates the stratum corneum, it does not achieve effective concentrations topically. Griseofulvin is widely distributed to most tissues, but it is deposited and concentrated in keratin precursor cells. Thus it is incorporated in new keratin of skin, nails, and hair and (in humans) is secreted in perspiration. Although new keratin formed during treatment with griseofulvin is resistant to fungus, griseofulvin does not destroy fungi that infect the outer layers of the skin. New hair, skin, or nail growth accompanied by shedding of older growth is necessary before the fungus is affected; new growth is the first to be free of disease. Thus skin infections require 4 to 6 weeks of therapy, whereas toenails may require up to a year of therapy. Long hair breeds probably should be treated for a longer period of time compared to short hair breeds.

KEY POINT 9-12 Treatment with griseofulvin must be sufficiently long for new growth to replace infected growth.

Hepatic metabolism of griseofulvin by dealkylation is significant; metabolites are not active. The half-life reportedly is 24 hours in the dog. Half of the drug is excreted as metabolites in the urine. The rest is excreted through the bile unchanged in the feces.

Preparations

Griseofulvin is available for oral use as either a microsize (particle size 10 μ m) or ultramicrosize (particle size 2.7 μ m; e.g., Fulvicin, Gris-PEG) tablets. The drug should be administered with a fatty meal, particularly if the microsize preparation is used. Duration of therapy is *at least* 4 to 6 weeks (new hair growth must occur) and possibly longer. The drug should be administered at least once a day despite initial reports that recommend one weekly administration.

Side Effects and Drug Interactions

Side effects to griseofulvin are not uncommon. Nausea, vomiting, and diarrhea can be minimized by administration of the dose in divided increments with a meal. Hepatotoxicity may occur, and use in liver disease should be avoided. Idiosyncratic toxicity has been reported in the cat, manifested as gastrointestinal upset, neurologic disease, and bone marrow suppression.⁹⁸ The reaction appears to be both dose and duration independent. Signs may not be reversible, depending on the severity. Cats with feline immunodeficiency disorders may be more likely to develop neutropenia.⁹⁹ Certain feline breeds (e.g., Persian, Siamese, Abyssinian) may be more commonly affected.⁹⁸ At very high doses, the drug is teratogenic and carcinogenic in animals. The drug should not be given during the first two trimesters of pregnancy. Use with a shampoo (miconazole or chlorhexidine) enhances efficacy.

Griseofulvin is a potent inducer of microsomal enzymes. The clinical sequelae of this drug interaction are not well known, although increased metabolism of other drugs should be anticipated.

ALLYLAMINES AND THIOCARBAMATES

The allylamines (e.g., terbinafine, naftifine) and the much older thiocarbamates (e.g., tolnaftate) competitively inhibit squalene epoxidase, blocking conversion of squalene to lanosterol, leading to squaline accumulation and ergosterol depletion in the cell membrane. Terbinafine has a much higher affinity for fungal compared with mammalian squaline epoxidase. Aviod uptake of terbinafine into body fat and epidermis enhances and potentially limits its efficacy to dermatophytes and superficial pathogens of the skin. Antifungal effects are -cidal in these organisms; it has proved more efficacious than griseofulvin for both acute and chronic dermatophyte infections in humans. Efficacy has also been demonstrated against S. schenckii and Aspergillus (A. flavus more so than A. fumigatus). Although it is not clear if effective tissue concentrations are acheived, in vitro activity toward B. dermatitidis, C. immitis, and H. capsulatum has also been described as excellent. Some strains of Crypotococus sp. also are susceptible. In vitro activity also has been demonstrated toward Rhizopus, Alternaria, Phialophora, Chrysosporium, and Exophiala spp.^{3,100} Fungistatic efficacy has been demonstrated against yeasts,¹⁰¹ with activity being poor toward Candida.³ Increasingly, terbinafine has enhanced the efficacy of other antifungal drugs when used in combination for treatment of a variety of fungal disorders and pythiosis.^{100b} Terbinafine expresses some antibacterial activity; for example, when combined with benzoyl peroxide, its topical spectrum (in human) is expanded to include Pseudomonas and Staphylococcus.^{100b} In contrast to terbinafine, tolnaftate is limited to treatment of dermatophytes. Resistance to the allylamines is rare, but the drugs potentially can be affected by multidrug resistance efflux mechanisms.³

Terbinafine, available in oral and topical preparations, is well absorbed (80% in humans) after oral administration, although fat facilitates absorption. High concentrations occur in the stratum corneum, sebum, and hair. The drug is metabolized by the liver in humans; the elimination half-life is sufficiently long to allow once-daily administration, with steady state not occurring for 10 to 14 days in humans.^{3,102} An abstract reporting pharmacokinetics in cats suggested that a dose of 20 to 40 mg/kg once daily provided sufficient concentration of drug in the skin. The drug was well tolerated at this dose.¹⁰³ Side effects of terbinafine after oral administration are limited to gastrointestinal and skin symptoms; hepatobillary dysfunction is a rare adverse event.³ Because inhibition of ergosterol synthesis occurs at a step before cytochrome P450 involvement, the allylamines do not affect steroid synthesis as do the imidazoles.

KEY POINT 9-13 Although the distribution of terbinafine supports its efficacy to treat dermatophytes, it may also enhance the efficacy of other antifungal drugs toward other organisms.

IODIDES

The mechanism of antifungal action of the iodides is not known. Iodide is rapidly and completely absorbed orally. Distribution is to the extracellular fluid. Thyroid uptake will concentrate the drug up to 50 times that in plasma. Iodide is available as a 20% Na and K⁺ salt oral or intravenous preparation. Both salts have been used successfully to treat canine and feline cutaneous or lymphocutaneous forms of sporotrichosis, and, as such, it remains the drug of choice.^{104,105} Oral Na⁺ preparations are usually used. Iodide toxicity is more common in cats and is manifested as sweating; tachycardia; dry, scaly coat; diarrhea; and polyuria/polydipsia. Cardiomyopathy has been reported in cats. Treatment causing clinical signs of iodinism should be discontinued for 1 week and then reinstituted at a lower dose. Iodine has also been reported to be effective for various other fungal diseases, particularly as a topical ointment for localized skin infections. Topical iodine preparations continue to be available and might be used to treat fungal rhinitis (discussed later).

LUFENURON

Lufenuron is a chitin synthetase inhibitor used for the control of fleas in dogs and cats. Its use for the treatment of dermatophytes is controversial. A retrospective study of dogs and cats found that dogs treated with once-daily administration of 50 to 60 mg/kg responded (based on skin scraping) within 21 days. Cats received doses that ranged from 50 to 266 mg/kg, with response in 8 to 12 days. However, clinical trials have not been able to accomplish what the retrospective study implied. A study describing efficacy at a single dose of about 80 mg/kg every 2 weeks until culture cure was followed by clinical trials that failed to eradicate or prevent infection at 140 mg/kg. When combined with weekly enilconazole shampoos, 60 mg/kg every 30 days caused clinical response in most cats in a cattery after several weeks of therapy; however, not all animals became culture negative, and relapse occurred.³ Several abstract reports have failed to demonstrate efficacy, despite differences in duration or dose. This includes studies using established animal models for which itraconazole is effective.¹⁰⁶ Moriello and colleagues¹⁰⁷ could not demonstrate a protective effect of lufenuron (30 or 122 mg/kg monthly for 2 months) when used before experimental infection of juvenile cats with *Microsporum canis*. Studies based on combination rather than sole therapy may provide more information.

KEY POINT 9-14 Several abstract reports have failed to demonstrate efficacy of lufenuron in the treatment of fungal infections, despite differences in duration or dose.

COMBINATION THERAPY

Combination antifungal therapy has been reviewed in human medicine,108 including the molecular basis.9 Indications include patients at risk (immunocompromised). Few clinical studies provide conclusive evidence for or against combination therapy.¹⁰⁸ In vitro studies examining combination therapy often used different methods, limiting the ability to determine a consensus. Among the difficulties with clinical studies is the more common use of combinations in patients with greater severity of disease, thus biasing results. Not surprisingly, sample size is often too small to demonstrate significant differences. In vitro data for C. neoformans exposed to ampohtericin B, when combined with imidazoles, indicates, in order of minimal to most synergistic effect, fluconazole = itraconazole < posaconazole.9 The combination of flucytosine with itraconazole indicated the most synergistic activity toward C. neoformans. In contrast, for candidiasis, the order of least to most synergistic activity when imidazoles are combined with terbinafine was fluconazole < posaconazole < itraconazole < voriconazole.9 In animal (mice) models, the addition of fluconazole offered no benefit to amphotericin B for treatment of cryptococcosis. Flucytosine potentiated the effect of fluconazole but not posaconazole for treatment of C. neoformans. The most effective combination was amphotericin with flucytosine; the addition of fluconazole to this combination reduced the fungal burden even more. The efficacy of voriconazole toward aspergillosis was enhanced by caspofungin.

The combination of antifungals with other drugs not traditionally considered antifungal may offer enhanced clinical response. For example, combination therapy with antibacterials that target DNA may enhance efficacy. Examples include the fluroquinolones and the rifamycins.⁹ Rifampin has shown some efficacy against fungal microorganisms (*H. capsulatum, Aspergillus* sp., and *B. dermatitidis*) when combined with amphotericin B. Amphotericin B apparently facilitates movement of rifampin through the fungal cell wall into the organism, where RNA polymerase then can be accessed. A beneficial effect has been demonstrated in vivo (but not in vitro) for trovafloxacin combined with fluconazole or amphotericin G. In vitro efficacy has been demonstrated for the latter. The combination of traditional antifungal agents with terbinafine or chitin synthesis inhibitors (e.g., caspofungin) may also prove to be effective combinations for treatment of selected infections (e.g., coccidioidomycosis, aspergillosis, and others).

Among the drug combinations currently being actively researched are antifungal agents with immunomodulators. Included are cytokines such as granulocyte or macrophage colony-stimulating factors or interferon γ -1b. In contrast, the impact of calcineurin antagonists (e.g., tacrolimus and cyclosporine) is one of exacerbation, at least for cryptococcal meningitis.

THERAPEUTIC USE OF ANTIFUNGAL AGENTS

Dermatologic Fungal Infections: Dermatophytosis

A number of fungal organisms inhabit the hair coats of dogs and cats. *Alternaria, Cladosporium,* and yeasts may be associated with dermatitis. Dermatophytes can be isolated from normal animals or can be a cause of infection. Dermatophyte infections generally are self-limiting, with ability to mount an inflammatory response being an important determinant of infection control. Accordingly, drugs such as glucocorticoids, which mute the inflammatory response, predispose a patient to dermatophyte infection; dermatophytosis infection is 3 times more prevalent in cats infected with feline immunodeficiency virus than in noninfected cats.⁶⁶ The route of drug administration (topical versus systemic therapy) depends on the extent of infection, with the exception of *Trichophyton* infections, which should be treated systemically.

Topical therapy is indicated for all patients with dermatophytosis and may be the sole therapy for local, nondiffuse lesions. Hair coat preparation before medication should include clipping and bathing to remove hair and crusts. Several medicaments are available as shampoo, ointment, or cream formulations for topical therapy (see Table 9-5). Active ingredients include povidone–iodine, chlorhexidine, and imidazole. Other active ingredients that can be applied topically include captan, lime sulfur, and sodium hypochlorite. Short-term topical glucocorticoid therapy might be considered to control acute inflammation when present. Topical administration of enilconazole emulsion has been useful for treatment of feline dermatophytosis.

Moriello^{66,107} retrospectively evaluated in vitro and in vivo studies of treatments for dermatophytosis in dogs and cats. Topical treatments consistently found to be effective when administered once or twice weekly were lime sulfur (1:16), 0.2% enilconazole rinse (twice weekly; response in as early as 5 weeks), and a combined 2% miconazole–chlorhexidine shampoo. Captan, chlorhexidine (as sole agent), and povidine– iodine were generally ineffective.

Response to systemic therapy is likely to be more rapid if combined with topical therapy.⁶⁶ Systemic therapy should probably be preceded with a total body clip. Griseofulvin is the treatment of choice for long-term systemic antifungal therapy of dermatophytosis,¹⁰⁹ although expense mandates that a diagnosis of dermatophytosis be confirmed. Care should be

taken that the proper dose and duration of therapy are followed; treatment probably should be longer for longer-haired animals. Cure was reported in 63 to 70 days in one study with a mean of 41 days at 50 mg/kg in another study (as reviewed by Moriello).⁶⁶ For infections that do not respond to griseofulvin, an imidazole can be used. Ketoconazole has been used successfully, particularly when dosed at 10 mg/kg daily for 20 days. Itraconazole has, however, proved more efficacious for treatment of dermatophytes in human patients and has proved efficacious experimentally in cats infected with M. canis.¹¹⁰ Itraconazole was effective at 10 mg/kg once daily for 56 days or for 28 days followed by a week-on week-off pulse dosing for 56 to 70 days.¹¹¹ Interestingly, low-dose itraconazole (1.5 to 3 mg/kg) in 15-day cycles required a shorter time period at 1 to 3 cycles or 15 to 45 days. However, only 8 of 15 cats were successfully treated in this study, and two of these cats required a second cycle. Using an open clinical trial, a protocol using itraconazole (10 mg/kg once daily) and lime sulphur rinses (cat coat saturated with rinse at 8 ounces per gallon of water) every 7 days for 21 days was associated with successful treatment of dermatophytosis in shelter cats.^{111a} Cure was longer with higher fungal load (18.4+ 9.5 days) compared to smaller loads (14.5+5.7 days). Cats tolerated the rinses well. Efficacy of lufenuron was not substantiated in controlled studies. Terbinafine has demonstrated efficacy toward dermatophytosis in dogs and cats, although higher doses (>30 to 40 mg/kg) generally are required to achieve a mycologic cure. Time to cure in dogs varied from 21 to more than 126 days and from 28 to 84 days in dogs. A lower dose (10 to 30 mg/kg) may also be effective in both dogs and cats, although treatment should be expected to be approximately 60 to 90 days.¹⁰⁷ Use of terbinafine at 30 mg/kg for 2 weeks resulted in a cure of 11 of 12 cats with M. canis, and at 8.25 mg/kg daily, it eradicated spores from asymptomatic carrier cats (as reviewed by Bossche³). The use of systemic terbenafine at either a low (10 to 20 mg/kg) or high (30 to 40 mg/kg) dose once daily was compared with placebo treatment in cats (n = 9 per group) ranging between 1.5 and 4.5 months of age that were experimentally infected with M. canis. Cats were treated for 120 days. Response in the lowdose treatment group did not differ from that of the control group but did in the high-dose group; the number of cats cured per group was not provided. PDCs did not differ between the two dose groups, but concentrations in the hair were significantly higher with the higher dose.¹¹² Drug accumulated with multiple dosing, with concentrations at 3 months higher than at 2 months, suggesting peak effects may take up to 3 months (or more). Median concentrations in plasma at 9 and 120 days were 1.4 mg/L and 4.1 mg/L respectively, in the low-dose cats compared with 1.7 and 5.5 mg/L respectively, in the high-dose cats. Median concentrations in the hair at 9 and 120 days were 1 mg/L and 1.2 mg/L, respectively, in the low-dose cats compared with 1.9 and 3.6 mg/L respectively, in the high-dose cats. The highest concentration achieved in the hair in any one cat was 7.92 µg/mL; this compares with humans receiving only 6 mg/kg, for which concentrations reach 2.40 to 55 μ g/g.

Additional topical therapies for treatment of dermatophytosis or other dermatologic fungal disorders are also addressed in Chapter 22. Environmental cleansing may be important to treatment of dermatophytosis. This might be accomplished with either 2% chlorhexidine or 0.5% sodium hypochlorite.

Yeast or Yeastlike Infections

Malassezia

Malassezia (Pityrosporum) is a commensal organism that inhabits the skin, ear canal, anal sacs, vagina, and rectum of dogs. It is now recognized to be the causative agent of either localized or generalized pruritic inflammatory skin disease in dogs. The pathogenesis of the infection is controversial and appears to involve hypersensitivity to the organism. Postulated predisposing factors include allergic disease such as atopic dermatitis, diseases of cornification, chronic inflammatory skin disease, and previous therapy with antibiotics or glucocorticoids.

Therapy for Malassezia is directed toward removing predisposing factors and killing the causative agent.¹¹³ Antimicrobial therapy ideally should include both systemic and topical drugs. Ketoconazole and itraconazole are the systemic drugs of choice and should be given for at least 30 days. Topical therapy may be sufficient in some cases. Antifungal shampoos containing chlorhexidine, miconazole, or ketoconazole should be given at least twice weekly for a minimum of 6 weeks. Shampoos that resolve any exudate (e.g., benzoyl peroxide) may facilitate topical penetration of the antifungal drug. An acetic acid rinse (white vinegar and water at a ratio of 1:1) used twice weekly as a degreasing agent after shampooing may also prove beneficial as well as inexpensive. Application of eniloconazole emulsion may also be beneficial. The emulsion can be applied with a sponge or by whole-body immersion; the diluted product appears to remain stable for 4 to 6 weeks when protected against light, although use of a fresh dilution is recommended for each treatment.

Cole and coworkers¹¹⁴ studied in vitro the addition of 0.1% ketaconaozle to an ear rinse containing EDTA tromethamine and benzyl alcohol (T8 Solution) for treatment of canine otitis associated with *Malassezia*. The low concentration was sufficient to inhibit fungal growth. By itself, EDTA and thromethamine had no effect. Ahman and coworkers¹¹⁵ studied pulse dosing of itraconazole (5 mg/kg orally qd, 7 days on, 7 days off, 7 days on) for treatment of *Malassezia pachydermatitis* associated with greasy seborrheic dermatitis in Devon Rex cats (n = 6). Assessment was not blinding; control cats were not studied. Clinical signs associated with seborrhea resolved in all cats, with dramatic improvement recorded in the second week, supporting the role of *Malassezia* in the disease.

Negre and coworkers¹¹⁶ systematically reviewed the literature (before 2007) with regard to the treatment of skin disorders associated with *Malassezia*. Clinical trials in peerreviewed veterinary literature were considered if they focused on treatment of *Malessezia* associated with dermatitis and involved more than five dogs. Studies were assessed for quality based on methods intended to select subjects that adequately represented the target population and minimized bias. Trials were classified by size of the study groups. Outcome measure assessment had to include both clinical evidence of response as well as the extent of reduction in fungal colony counts. Only

Candidiasis

In the yeast phase, candidiasis normally occurs in the gastrointestinal, respiratory, or urogenital mucosa. The organism is acquired at birth and occurs at mucocutaneous junctions in the skin and in several organs inside the body. Factors that alter normal microflora (e.g., prolonged, high-dose, broadspectrum antimicrobial therapy) predispose to the development of candidiasis. Cell-mediated immunity is important in the control of disease, and prolonged immunosuppression increases the risk of further spread. Generally, microcirculation of the organs filters organisms, leading to embolization.

Topical infection can be treated with topical antifungal products, including polyene macrolides, imidazoles, and gentian violet (1:10,000). Systemic therapy can be treated with amphotericin B, 5-flucytosine (combined with another antifungal drug), or the imidazoles.

Systemic Fungal Diseases

Therapeutic success with antifungal drugs can be enhanced by long-term therapy, generally one to several months beyond the resolution of clinical signs; avoidance of immunosuppressive drugs; and use of combination therapy, particularly for infections that are difficult to penetrate or are life or organ threatening.

Blastomycosis

Blastomyces organisms become established in the lungs and then disseminate throughout the body. The presence of clinical signs in dogs is indicative of disseminated disease and the need for aggressive therapy. Preferred sites of infection in dogs are the skin, eyes, bones, lymph nodes, subcutaneous tissues, nasal passages, and brain. These tissues are difficult to penetrate with most antifungal drugs, thus increasing the likelihood of therapeutic failure. Immunosuppression is common in dogs with blastomycosis, further hindering therapeutic success. The use of radioimmunoassay tests based on the major surface protein W1-1 is predictive of active infection, confirming absence of infection 100% of the time.117 The authors concluded that the test is more accurate than those based on the A antigen and thus may be more relevant to assessing response to therapy. When the titer is used, concentrations are high initially but decline during therapy, persisting for months.¹¹⁷

Amphotericin B has been the treatment of choice for blastomycosis.¹¹⁸ Although high doses are more effective, the risk of nephrotoxicity may necessitate a less aggressive approach; lipidbased products should be considered particularly in patients at risk. The total cumulative dose for amphotericin B (AmBD) generally is 4 to 6 mg/kg for dogs and 4 mg/kg in cats; a higher dose should be anticipated for lipid-based products. A maintenance

dose of 0.15 to 0.25 mg/kg intravenously once monthly after the cumulative dose was reached was recommended in the early 1980s, but the scientific basis of this approach is questionable. Doses range from 0.15 to 0.5 mg/kg thrice weekly in dogs and cats, depending on renal function. Severe cases or intolerance to amphotericin B might be treated with a lipid complexed drug (see Table 9-3). Renal-sparing measures should be taken for patients with preexisting renal disease. Despite aggressive therapy, a relapse rate of 17% has been reported in dogs.²⁶ Combination therapy of amphotericin B with an imidazole should be considered whenever possible and is particularly important for infections in tissues that are difficult to penetrate, such as the brain and eye. However, because of mechanisms of action, it is important to begin the two drugs simultaneously. Of the imidazoles, ketoconazole has been used alone to treat blastomycosis in humans, but it is less successful for animals as a sole agent. Ketoconazole can be used at 10 to 10 mg/kg/day (up to 30 mg/ kg/day for difficult-to-penetrate tissues [e.g., eye, CNS]) when combined with amphotericin B. Because imidazoles are characterized by variation in drug disposition among animals, efficacy might be enhanced by increasing the dose. Although sequential use of amphotericin B followed by ketoconazole has been recommended, the two apparently can be used in combination immediately with little to no increased risk of toxicity. The rapid effects of amphotericin B are critical for life-threatening or organ-threatening infections. Itraconazole or possibly fluconazole are more likely to be effective than ketoconazole for the treatment of blastomycosis. Although itraconazole is more likely to be effective as sole therapy,¹¹⁹ combination therapy with amphotericin B is still recommended. Therapy should continue for at least 60 days or 1 month beyond resolution of disease indicators, whichever is longer. In their retrospective study of dogs with pulmonary blastomycosis, Crews^{119a} found 79 dogs survived, 38 died, and 8 were euthanized. Most dogs were treated with itraconazole alone (n = 89) with does in 14 of these dogs less than recommended. No information was provided regarding survival rates among the different treatments, including 20 dogs treated with a combination of amphotericin B and an imidazole. No significant effect could be demonstrated in dogs loaded for 5 days (dose not given) with itraconazole.

With proper therapy up to 80% of dogs with blastomycosis can be effectively treated.⁵⁴ The severity of pulmonary involvement appears to be a prognostic factor for both initial survival and the likelihood of relapse. Therapy may result in an initial worsening of respiratory disease, presumably because of an inflammatory response to dying organisms. A short course of short-acting glucocorticoids might be considered concurrently as therapy is initiated.¹²⁰ Of the remaining 20% of animals that survive initial therapy, some may die within the first 2 weeks of therapy. Relapse can occur in up to 20% of infected animals within the first 6 months after therapy, but relapse after 1 year is rare.

Histoplasmosis

Host macrophages phagocytize the yeast phase of *Histoplasma*, and the organism then undergoes replication. The intracellular location is a mitigating factor in the hematogenous and

lymphatic dissemination of the organisms from the lungs to other tissues. In most patients cell-mediated immunity brings the infection under control. The gastrointestinal tract may also be a primary site of infection, although dissemination from the lungs appears to be more likely.¹²¹ Although pulmonary infection may be self-limiting, therapy is indicated to prevent dissemination of infection.

Ketoconazole has been the drug of choice for mild pulmonary histoplasmosis.¹²¹ One study, however, reported that only itraconazole (5 mg/kg orally twice daily for 60 to 130 days; because the half-life is sufficiently long in cats, 10 mg/kg once a day for the same duration might be used) was effective against histoplasmosis in cats after ketoconazole had failed,⁷⁸ and consequently, it is the preferred treatment. Fluconazole might be considered if the CNS is involved. For more severe pulmonary infection or gastrointestinal infection, therapy should be more aggressive and include itraconazole combination therapy with amphotericin B (0.15 to 0.5 mg/kg intravenously 3 times a week, increasing to up to 1 mg/kg every other day to a total cumulative dose of 7 to 8.5 mg/kg). Both of the latter drugs are much more effective (up to a hundredfold) than ketoconazole against histoplasmosis. The prognosis for patients with pulmonary histoplasmosis is fair to good but guarded when the disease has disseminated. Acute respiratory distress might warrant a course of antiinflammatories. In a retrospective study of airway obstruction associated with chronic histoplasmosis in dogs,¹²² resolution of respiratory clinical signs occurred in less than 1 week in those dogs treated with glucocorticoids alone compared with a mean of 2.6 weeks if combined with an antifungal and 9 weeks if receiving an antifungal only. The use of glucocorticoids was not associated with development of active or disseminated histoplasmosis. Treatment should continue for at least 60 days or 1 month beyond resolution of disease indicators, whichever is longer.

Cryptococcosis

Cryptococcus organisms infect the upper respiratory tract or the alveoli, potentially causing granulomas at both sites. Once established in the respiratory system, they can disseminate to other tissues. Infection of the CNS by either dissemination or direct extension is common. Cutaneous and ocular lesions are common in cats.

Cell-mediated immunity is critical to the host's ability to overcome a cryptococcal infection Cryptococcal organisms have several features that affect their virulence. The capsule inhibits plasma cell function, phagocytosis, and leukocyte activity. Fever is uncommon (25% of dogs), particularly in cats. Immunosuppression is essentially necessary for cryptococcosis to develop in humans. Underlying diseases are, however, not often identified in cats or dogs with cryptococcosis. A risk factor for therapeutic failure in cats, which are generally more commonly infected with *Cryptococcus* than are dogs, is co-infection with immunosuppressive viruses.¹²³ The impact of the use of glucocorticoids in patients with severe *Cryptococcus* infection is not clear. Using a murine model of CNS and pulmonary cryptococcosis treated with fluconazole (5 or 15 mg/kg every 8 hours), investigators found that whereas dexamethasone (0.15 mg/kg every 8 hours intraperitoneally) for 3 days, 30 minutes before fluconazole) administration did not have a deleterious effect on successful therapy with fluconazole, response was much better with early (1 day) as opposed to later (8 days) into infection. Because pharmacokinetics confirmed that fluconazole concentrations in the plasma and tissue remained above the MIC at both time points and did not change across time, the authors concluded that the number of fungal organisms influenced outcome. Although dexamethasone was not associated with beneficial or deleterious effects, the authors did not address whether sufficient animals had been studied to detect a difference;¹²⁴ however, their study does support the early rather than later use of glucocorticoids.

Amphotericin B has been the treatment of choice for cryptococcosis.^{79,80,85} Doses should start at 0.5 to 0.8 mg/kg 2 to 3 times a week (0.25 to 0.5 mg/kg in cats); the drug can be given subcutaneously once diluted as long as the concentration does not exceed 20 mg/mL. A total cumulative dose at the higher end is recommended for cryptococcosis (4 to 8 mg/kg in one source, but up to 9 to 12 mg/kg in another for cats), reflecting longer duration of therapy. Initial therapy with a low dose and a subsequent increase in dose has been suggested for cats. Combination with 5-flucytosine or the imidazoles is likely to improve therapeutic success and is indicated for CNS infections because amphotericin B cannot sufficiently penetrate the blood-brain barrier. Ketoconazole has been used successfully to treat cryptococcosis. Itraconazole (10 mg/kg orally once daily), however, and fluconazole are more effective than ketoconazole against cryptococcosis. Cats appear to tolerate itraconazole better than ketoconazole.⁷⁹ Both drugs, but especially fluconazole, are characterized by better tissue penetrability and can be used to treat CNS infection. One study with cats reported that 16 of 28 were cured of cryptococcosis after treatment with itraconazole (100 mg orally once daily) for a mean of 4 to 16 months,⁸¹ with duration dependent on resolution of disease indicators. Combination with either flucytosine (50 mg/kg every 6 hours) or terbinafine should also be considered.¹⁰⁰ Response to therapy can be correlated to a decline in antigen titer.¹²⁵ The prognosis for recovery is favorable if the CNS is not involved.

Coccidioidomycosis

Coccidioidomycosis begins as an alveolar infection that spreads to peribronchiolar tissues and the lung surface. Cell-mediated immunity is important in overcoming the infection. In immunodepressed animals or in animals with massive exposure, pulmonary infection becomes extensive, and the infection disseminates first to mediastinal and tracheobronchial lymph nodes and then to other tissues. Organs that are subsequently infected include, in order of likelihood, bone, joints, visceral organs, the heart and pericardium, testicles, eyes, and brain.

Coccidiodomycosis is the most difficult of the dimorphic fungal infections to treat, and antifungal therapy is particularly long.¹²⁶ The duration varies with both the site of infection and the drug and can be for the life of the animal in some cases of disseminated disease. Whereas respiratory infections may spontaneously resolve, untreated disseminated infections will result in death. Ketoconazole has been the drug of

choice for treatment in the past and is associated with a 60% cure, with CNS or orthopedic involvement being associated with worse prognosis. Ketoconazole therapy should extend at least 1 year beyond resolution of clinical signs. However, itraconazole is more effective and should be considered; the duration is likely to be the same. Amphotericin B is also effective for the treatment of coccidioidomycosis; encapsulated or otherwise modified formulations should be considered such that therapy can continue for a longer period of time. A lower maintenance dose of either ketoconazole or amphotericin B has been recommended once clinical signs are in remission, although this approach (i.e., using lower doses) should be used very cautiously. Therapy with itraconazole may occur for a shorter time, although this has not been well established in animals. Fluconazole is indicated for CNS infections. Combination therapy (i.e., amphotericin B with an imidazole) should be strongly considered for treatment of coccidioidomycosis. Deterioration of clinical signs and a rising complement fixation test are both indications for combination therapy with amphotericin B. In general, duration of therapy should be at least 8 to 12 months; relapse is common, particularly in cats.¹²⁷

Paracoccidioidomycosis

Paracoccidiodomycosis, caused by *Paracoccidioides brasiliensis,* is a severe infection of the lungs and other body systems associated with granulamatous response in humans. Although rare in animals, one case was reported in South America in a Doberman Pinscher that presented with cervical lymphadenopathy.¹²⁸

Aspergillosis

Aspergillosis can occur as either the localized form, involving cavities of the ears, nose, or sinuses; or the disseminated form, occurring primarily in the lung of immunocompromised animals. Both systemic and topical therapy should be implemented with either form of the disease. Systemic therapy should consist of an imidazole; among the drugs itraconazole is the most efficacious against aspergillosis. Itraconazole was effective in treatment of aspergillosis or penicillinosis in two cats, although hepatotoxicity developed in a third; topical treatment with clotrimazole resulted in cure for this animal.¹²⁹ Itraconazole therapy for 10 weeks cured one dog infected with systemic and subsequent respiratory infection with Aspergillus niger.¹³⁰ Topical therapy has included amphotericin B; thiabendazole; and enilconazole, a topical imidazole available in Europe but not the United States. Enilconazole might be the most effective treatment when directly infused into the nasal passages through fenestrated tubes.¹³¹ The 10% solution is diluted 1:1 with water and administered through surgically placed nasal tubes within 2 to 3 minutes. The solution emulsifies within several minutes of mixing; nasal tubes must be flushed after treatment. The total daily dose of 20 mg/kg is administered in two divided doses daily. Topical clotrimazole might be considered instead of enilconazole. One study reported response of refractory fungal rhinitis to surgical débridement combined with a povodine-iodine (see Chapter 11 for definition) wound dressing changed every 2 to 3 days; treatment continued until granulation tissue was present.¹³²

Steinbach and coworkers¹³³ retrospectively examined the impact of combination or sequential antifungal therapy on invasive aspergillosis in humans or in experimental animals and found interactions ranging from synergy to antagonism. Amphotericin B combined with 5-fluorocytosine was the most commonly used combination (49%), with others including amphotericin B with itraconazole (16%) or rifampin (11%). Combination therapy was associated with improvement in 63% of patients, generally with amphotericin B combined with either 5-fluorocytosine or rifampin. However, combination of rifampin with the azoles was discouraged because induction by the former was apt to decrease concentrations of the latter, potentially below that considered effective. Combinations of amphotericin B with itraconazole were considered indifferent. In retrospective studies of animal model reports, amphotericin B plus 5-fluorocytosine, rifampin, or itraconazole was described as indifferent, whereas amphotericin B with micafungin was described as a positive interaction. Sequential therapy also was associated with benefits: Improvement was noted with amphotericin B or itraconazole followed by voriconazole but not with itraconazole followed by amphotericin B.133 Indeed, azoles followed by amphotericin B (rather than opposite sequence) were found to be antagonistic, as might be expected based on the mechanism of action of the two drug classes. The use of capsofungin alone or with other antifungal drugs may provide alternative therapies for treatment of aspergillosis; terbinafine might also be considered in combination.

The use of voriconazole in animals for treatment of aspergillosis is very appealing but has not yet been described. The potential side effects of voriconazole and its complex pharmacokinetics suggest that use should be based on scientific studies that establish dosing regimens necessary to achieve MICs demonstrated for targeted fungal organisms, as well as studies that establish safety after several weeks of therapy at that dose.

Subcutaneous Mycoses

Sporotrichosis

Sporotrichosis occurs in three clinical forms: cutaneous, cutaneolymphatic, and disseminated. Disseminated disease generally involves most internal organs. The treatment of choice for both dogs and cats is supersaturated potassium iodide (SSKI).¹³⁴ Itraconazole at 5 to 7.5 mg/kg every 12 to 24 hours has been recommended.¹²⁶ Cats are more sensitive than dogs to the side effects of SSKI. Treatment should continue for at least 30 days beyond clinical remission. Immunosuppressive drugs should be avoided, if possible, for the duration of the animal's life; recurrence in clinically cured animals has been reported after immunosuppressive doses of glucocorticoids. Imidazoles (e.g., ketaconazole or itraconazole) should be used to treat animals that cannot tolerate or do not respond to SSKI. Other antifungals (e.g., terbinafine) might be combined with iodine.

Rhinosporidiosis

Rhinosporidium rarely causes disseminated disease in animals and is essentially limited to the nasal tissues. Surgical excision is the treatment of choice.¹³⁵ For recurrences dapsone may be useful. Alternatively, ketoconazole or itraconazole may be successful.

Pythiosis

Originally referred to as phycomycosis, pythiosis, a granulomatous disease, is caused by a number of taxonomically diverse nonseptated hyphal Oomycetes. The cell wall of Oomycetes differs from that of true fungi. Most notably is the limited amount of sterols in the fungal cell wall; hence antifungal agents are often ineffective against infections caused by these organisms. No antifungal agent has proved efficacious against this organism. However, two cases of gastrointestinal pythiosis were treated postoperatively (and apparently successfully) with a combination of itraconazole (10 mg/kg daily) or combined with terbinafine (7.5 mg/kg qd).¹³⁶ Up to 20 mg/kg itraconazole daily has been recommended.¹²⁶ Brown¹³⁷ described the MIC of Pythium insidiosum and Lagenidium sp toward a number of antifungal agents and found that the relative efficacy to be azoles (limited) < terbinafine and caspofungin (minimal to moderate inhibition) < mefenoaxam (profound efficacy). The latter drug is a fungicide used in agriculture and is approved by the Environmental Protection Agency. Its mechanism is inhibition of RNA polymerase.

Antiviral Therapy

Dawn Merton Boothe

Chapter Outline

VIRAL REPLICATION ANTIVIRAL DRUGS Targets of Antiviral Therapy Antiviral-Induced Nephrotoxicity Antiherpesvirus Drugs Miscellaneous Antiherpes Drugs Antiretroviral Drugs Miscellaneous Antiviral Drugs Miscellaneous Alternatives or Adjuncts to Antiviral Drugs TREATMENT OF SELECTED VIRAL INFECTIONS

Treatment of Selected Canine Viral Infections Treatment of Selected Feline Viral Infections

Approximately 80 families and 4000 species of viruses are known to date, and more than 60% of illnesses afflicted humans in developed countries are caused by viruses. However, the development of drugs intended to prevent and treat viral diseases has been frustratingly protracted. Despite the long and intensive search for effective antiviral drugs, very few compounds have clinical applications. Currently, at least 23 antiviral drugs have been approved for use in human medicine; none is approved for use in animals. Unfortunately, unlike the situation with many other anti-infectious drugs, applications for human antiviral drugs in veterinary patients often have been limited because the etiologic agents of viral diseases vary so widely. In recent years, however, given the similarities between feline and human immunodeficiency viruses¹ and potentially other viruses, information regarding pathophysiology and drugs with potential efficacy are increasingly applicable to veterinary use. Further, trends have developed toward development of drugs that are broadly effective against viral diseases. The development of species-specific recombinant proteins (e.g., interferons [IFNs]) has increased our knowledge base and promises to improve the therapeutic armamentarium for viral disease afflicting dogs and cats. Although these drugs are discussed in greater depth in other chapters, their support of treatment for antiviral diseases will be addressed here.

For a number of reasons, the development of effective antiviral drugs is more difficult than development of other antiinfectious agents. Drugs that target the viral processes must penetrate host cells to be effective, potentially limiting their distribution. Because the mechanisms by which viruses replicate must involve the host genome, drugs that are effective against viruses also are likely to have a negative effect on the host, with most antiviral drugs subsequently being characterized by a narrow therapeutic window. Clinical signs during the stages of infection when viruses might be most conducive to pharmacologic therapy often being mild to absent, and the need for antiviral therapy is not recognized until antiviral response is unlikely. Therapy is further complicated by viral latency, the ability of the virus to incorporate its genome into the host genome such that clinical infection becomes evident again without re-exposure to the organism. Selection of the most appropriate antiviral drugs is handicapped by the lack of broad-spectrum antivirals and the lack of rapid tests to identify the infecting virus. Newer polymerase chain reaction tests have at least helped in the more rapid diagnosis of some viral disease (e.g., parvovirus in dogs).

KEY POINT 10-1 The development of effective antiviral drugs is limited by the latent nature of disease, inherent host toxicity to viral drugs, and rapid emergence of viral resistance. Differences in viral diseases limits application of human antiviral drugs to dogs or cats.

In vitro susceptibility testing of viruses requires sophisticated and expensive techniques such as cell cultures. In vitro inhibitory testing procedures have not been standardized, and results vary with the assay system, cell type, and viral inoculum. Additionally, results may not correlate with therapeutic efficacy of antiviral drugs.² The lack of correlation between in vitro testing and clinical efficacy reflects, in part, the requirement of some antiviral drugs for activation (i.e., metabolism of a prodrug, generally by the host).² Not only is the spectrum of antiviral drugs narrow, but additionally, a drug often targets a specific viral protein (usually a polymerase or transcriptase enzyme) involved in viral nucleic acid synthesis.² The limited mechanism of action tends to facilitate the development of antiviral resistance, which can occur rapidly, often reflecting substitution of only a single, although critical, amino acid in the target protein. Drugs that simply inhibit single steps in the viral replication cycle are virustatic. Consequently, viral replication is only temporarily halted, although in human medicine, chronic drug therapy may suppress reactivation of the disease caused by the virus and thus prevent clinical signs of disease. Because drugs often inhibit only active replication, viral growth often resumes once therapy is discontinued.

Antiviral drugs often cannot eliminate nonreplicating or latent viruses, and effective antiviral therapy generally also depends on an adequate host immune response. Consequently, those antiviral drugs that enhance the immune system of the host may be more likely to eradicate infection, as might combinations of antiviral and immune-enhancing drugs. Conversely, it is the overexpression of the immune response and the subsequent immune (e.g., feline immunodeficiency virus [FIV] and feline leukemia virus [FeLV]) or inflammatory response (e.g., feline infectious peritonitis [FIP]) that causes continued pathophysiology. The complex cascade of the immune system with dual pathways that balance a response renders pharmacologic management of just the right amount of immunomodulation in the right direction difficult in the face of viral diseases.

Prions (protein infectious virion) are infectious agents composed entirely of propagated misfolded protein that is resistant to endogenous straightening. The term prion refers to the unidentified unit of infection. The method of propogation is not clear but appears to involve abnormal refolding of protein such that aggregates of tightly packed beta sheets accumulate to form amyloid. Accumulation occurs only in neural tissues and is uncontrollable and invariably lethal. Among the diseases affecting dogs or cats that are thought to be associated with prions is feline spongiform encephalopathy. Because these agents are not treatable, they will not be considered further in this chapter.

VIRAL REPLICATION

Viruses are composed of a core genome consisting of either double-stranded or single-stranded DNA or RNA surrounded by a protein shell known as a *capsid*. Some viruses are further surrounded by a lipoprotein membrane or envelope. Both the capsid and lipoprotein membrane may be antigenic. Viruses cannot replicate independently and must usurp the host's metabolic machinery to replicate. Therefore viruses are obligate intracellular parasites. The host's pathways of energy generation, protein synthesis, and DNA or RNA replication provide the virus with the means of viral replication. For some viruses, replication is initiated by viral enzymes.² DNA viruses include poxvirus, herpesvirus, adenovirus, hepadnavirus, and papillomavirus. RNA viruses include rubella virus, rhabdovirus (rabies), picornavirus, arenaviruses, arboviruses, orthomyxovirus, and paramyxovirus (canine distemper) (Table 10-1).

Cells respond to viral infection in three ways: infection may have no impact on the cell or its function, cellular death may occur (which may preclude subsequent infection), or the cell may be transformed such that host control of cell growth is lost to viral activities. Viral replication occurs in five or six sequential steps (Figure 10-1): cell entry, including host cell attachment, generally through specific receptors, followed by host cell penetration; disassembly or uncoating resulting in release of viral genome; transcription of viral genome (or viral messenger RNA), which is dependent on virus-specified enzyme; translation of regulatory (early) or structural (late) viral proteins; post-translation modifications (including proteolytic cleavage, myristoylation, glycosylation); assembly of virion components; and release of the virus, generally by budding or cell lysis.² For DNA viruses, viral DNA is transcribed to host mRNA by host cell mRNA polymerase (or, for poxvirus, viral RNA polymerase). Replication of RNA viruses requires virion enzymes to synthesize mRNA. Double stranded RNA (dsRNA) viruses contain RNA molecules that are transcribed into proteins. Two groups of single stranded RNA (ssRNA) viruses exist. The RNA genome of positive-sense ssRNA viruses is directly translated as mRNA by the host. In contrast, the RNA genome of negative sense ssRNA viruses must first be translated to mRNA by viral RNA-dependent RNA polymerase; host ribosomes subsequently translate to the protein.

Retrovirues are unique viruses that contain a single strand of RNA that must first be translated, via reverse transcriptase, to a DNA copy of the viral RNA template. The DNA is then incorporated into the host genome (as a provirus), duplicated, and subsequently transcribed into genomic RNA and mRNA for translation into viral proteins.²

A number of host mechanisms protect against viral infection. However, the host response not only may fail to protect but also may perpetuate the disease. Antibodies will be generated in response to viral infection, but these do little to overcome the initial infection. Rather, in part because viral activity is generally intracellular and thus inaccessible to antibodies, antibodies generally protect against subsequent infection. Unfortunately, the presence of circulating antibodies can contribute to the disease process of some infections (e.g., FIP). Cell-mediated immunity (CMI) plays a critical role in overcoming and preventing viral infection. However, viruses that can avoid an effective CMI response may cause latent or, if the cell does not result in the loss of normal cellular housekeeping activities, persistent infections. Mechanisms by which this can be accomplished included downregulation of major histocompatibility complex production such that the infected cell is not recognized by T cells; cells are generated that are not detectable by the host immune system; and infection is limited to cells located in an immunoprivileged site, such as the brain. Viruses that are particularly adept at causing persistent, chronic infections include paramyxoviruses, selected herpesviruses, and retroviruses.

KEY POINT 10-2 Host response often cannot effectively eradicate infection, even in the presence of drugs, but often contributes to the diseases process.

In addition to the directed immune response, the host will mount a number of nonspecific protective mechanisms. These include increased body temperature, activity of natural killer cells and phagocytes, and hormones. The role of IFN increasingly is being revealed as a target of pharmacotherapy. Viral infection begins with interaction between the virus and its specific host cell receptor. It is this interaction that initiates the host activation of multiple signal transduction cascades that mount a host defense. Ultimately, these mechanisms cause the nucleus to activate diverse immunoregulatory genes and proteins that cause the intracellular environment to be antagonistic toward viral replication.³ Phosphorylations activate several

Table 10-1	Classificat	ion of Viruses by	Genome Type	
Genomic Type		Family (Viridae)	Genus (Virus)	Disease
DNA				
	ssDNA	Reoviridae		
		Parvoviridae	Parvovirus	Canine parvovirus, feline panleukopenia (distemper)
	dsDNA	Adenoviridae	Adenovirus	Canine infectious hepatitis, blue eye (CAV1), respiratory disease (CAV2)
		Herpesviridae	Herpesvirus	Canine herpes (CHV, reproductive), feline herpes (FHV-1; rhinotracheitis)
		Papillomaviridae		Canine papillomas
		Parvoviridae		
		Poxviridae		
RNA	dsRNA	Reoviridae	Rotavirus	
	(+)ssRNA	Coronaviridae	Coronavirus, feline coronavirus (FoCV)	Canine corona virus (gastrointestinal), feline infectious peritonitis
		Caliciviridae	Vesivirus	Feline calicivirus (respiratory)
		Flaviviridae	West Nile virus	
		Hepeviridae	Hepatitis virus E	
		Picornaviridae	Enterovirus	Polio, bovine, and porcine enterovirus
			Rhinovirus	
			Hepatitis virus A	
			Erbovirus	Equine rhinitis virus B
			Aphthovirus	Foot and mouth disease
	(-)ssRNA	Filoviridae	Ebola, Marburg

			Mumps virus	Mumps
			Morbillivirus	Measles, canine distemper
			Newcastle virus	Newcastle disease
		Rhabdoviridae	Rabies virus	Rabies
		Orthomyxoviridae	Influenza A (including canine), B, C virus	Canine influenza (respiratory)
	ssRNA	Retroviridae*	Lentivirus (HIV, FIV)	Human, feline AIDS
			Gammaretrovirus	Feline infectious leukemia

*Many virus members contain oncogenes. *ds*, Double strand; *ss*, single strand.

families of transcription factors. Among the antiviral genes regulated are those encoding interferon (IFN), including α -1 and -\beta regulators. Several viral cell receptor-initiated events have been identified for their ability to induce activation that ultimately involves IFN. For example, chemokine receptor binding to human immunodeficiency virus (HIV) envelope or glycoproteins, and poxvirus and measles virus binding to T and B cell membrane-bound glycoprotein each initiate such events. The 2-5A pathway is an example of an endogenous antiviral protective system that induces IFN through dependent RNase and 2'-5' oligoadenylate synthetase (OAS). Viral infection stimulates OAS, which ultimately leads to destruction of both viral and cellular rRNA. Subsequent cell death is similar in appearance to that caused by apoptosis. Viral replication is subsequently prevented.⁴ Activation of IFNbased and other defense mechanisms also can occur through nonreceptor–mediated mechanisms.³ Not surprisingly, viruses have developed several mechanisms that evade IFN-mediated cell responses. An example includes production of soluble IFN receptors that preclude interaction with normal receptors (e.g., poxviruses and herpesviruses) that would otherwise activate the cascades, downregulation of IFN synthesis (adenovirus), and blocking of phosphorlyations.³

The pathophysiology of infection, including molecular mechanisms, has recently been described for FeLV⁵ and FIV,¹ including the role of selected cytokines in the immune response.⁶

ANTIVIRAL DRUGS

Few antiviral drugs have been studied in animals (Tables 10-2, 10-3), and widespread clinical use of antiviral drugs is not common in veterinary medicine. Only a selection of the

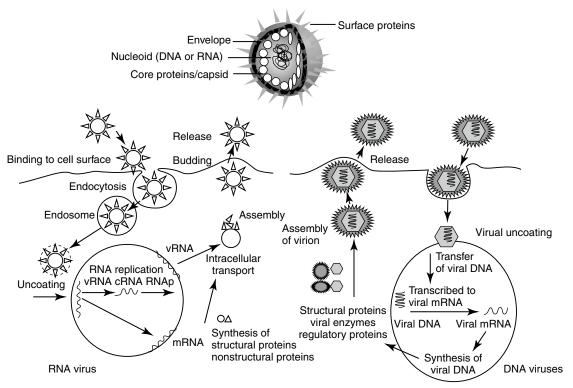

Figure 10-1 Replication of a representative RNA virus and DNA virus. Targets of antiviral drugs are presented before or during infection (including cell penetration), inside the cell (including viral replication, assembly and release), and during dissemination of progeny. The latter also includes preventing immunosuppression or the overzealous host response. *cRNA*, Replication intermediate; *mRNA*, messenger RNA; *RNAp*, RNA polymerase; *vRNA*, viral RNA.

more promising agents and their purported attributes are briefly discussed; alternatively, when pharmacokinetic information is available, because such information is so limited, it also is provided even if the drug is not an accepted therapy for canine or feline viruses.

Antiviral drugs are most practically categorized by the major viruses targeted by the drug, which tends to limit direct applicability to animal diseases. Although data specific to veterinary use are increasing, much information regarding antiviral drugs continues to reflect extrapolation from the human-medicine literature. This is particularly true for pharmacokinetics, and unless stated otherwise, such information is human in origin. Yet the disposition of antiviral drugs tends to be complex, often requiring prodrug activation, protein binding, and hepatic clearance, all of which tend to vary among species. The drugs are often characterized by a narrow therapeutic window. As such, extrapolation of dosing regimens should be done cautiously. Immune-modulating drugs in particular are not well understood, and mechanisms of action have not yet been fully elucidated. Very few human antiviral drugs have been studied or reported to be used for treatment of viral disorders in dogs or cats and the evidence provided by the few clinical trials performed in animals often is characterized by limitations in study design. Consequently, the inclusion in this chapter of information regarding antiviral drugs should not be interpreted as justification for use but rather treated as a springboard for additional studies. Two categories of drugs have been and are currently being pursued for the

pharmacologic treatment of viral diseases. *Antiviral chemicals* directly interfere with the virus, whereas *biologic response modifiers* stimulate the host's immune system, thereby increasing the host's ability to overcome viral invasion. The latter are discussed in greater depth elsewhere in this book.

Targets of Antiviral Therapy

Potential targets in the viral life cycle that might be pharmacologically inhibited are expressed during extracellular stages of viral infection (i.e., penetration), intracellular stages (i.e., replication, assembly, and viral release), and dissemination. Those expressed during extracellular stages include specific enzymes whose release is required for skin and mucosal barrier penetration by some viruses, specific cell receptors required for penetration by other viruses, and specific precursor "fusion" proteins that must be activated before cell penetration by some viruses. Antivirals that diminish penetration of host cells by the virus are more viral specific and thus not as inherently toxic as those that prevent viral replication by interfering with viral nucleic acid, DNA, and protein synthesis. Because cell penetration is enhanced by viral-induced immunosuppression, pharmacologic immunomodulation may also help prevent viral penetration.⁷ Thus these drugs are inherently more useful during the early stages of infection, which are often missed because of the lack of clinical signs. Classes of antivirals that target cell entry include soluble receptor decoys and antireceptor antibodies. Uncoating of the virus can be targeted by ion channel blockers, capsid stabilizers, and fusion protein inhibitors.²

Class	Drug	Mechanism	Viral Target	Veterinary Indications	Comments
Pyrimidine nucleoside	Idoxurine	Incorporated into DNA as thymidine analogue	Herpesvirus	Herpetic keratitis	Neoplasia and infertility limits to topical
	Trifluridine	Incorporated into DNA as thymidine analogue	Herpes simplex virus Cytomegalovirus Adenoviruses	Herpetic keratitis	Topical
	Sorivudine	DNA: thymidine analogue (thymidine Kinase)	Varicella-zoster virus		
Purine nucleoside	Vidarabine	Host phosphorylation; analogue of adenosine; competitive inhibition DNA polymerase; ribonucleoside reductase, other RNA activities	DNA viruses: herpesvirus Poxvirus Rhabdoviruns Hepadnavirus Selected RNA tumor viruses	Herpetic keratitis	Toxicity limits IV adminis- tration to life-threatening situations.
	Acyclovir Valacyclovir (prodrug)	Acyclovir: Synthetic analogue of guanosine; viral activation (thymidine kinase) and host phosphorylation: inhibition of DNA polymerase	DNA viruses Herpes virus	Feline rhinovirus? Veterinary use limited by dif- ferences in viral thymidine kinase	Topical, oral, parenteral (acyclovir). Oral (valacyclovir). Acyclo- vir associated with renal disease in dogs
	Penciclovir Famiciclovir (prodrug)	Guanine nucleoside, targeting thymidine kinase (herpes) or phosphotransferase (cytomegalovirus)	DNA viruses Herpesvirus Cytomegalovirus	Feline herpes virus	Less potent than acyclovir but accumulated in cell
	Ganciclovir	Guanine nucleoside			
	Ribavirin	Multiple enzymes inhibited, capping and polypeptide synthesis	DNA and RNA viruses (broad spectrum) Herpesvirus Orthomyxovirus Poxvirus Picornavirus Rhabdovirus Rotavirus Retrovirus	Feline calicivirus (limited efficacy against rhinovirus)	Oral, Aerosol Lesions worsened in cats with calici
Antiretroviral	Zidovudine (AZT)	Thymidine analogue; inhibition of RNA dependent DNA polymerase (reverse transcriptase)	Retroviruses		Relatively safe in cats; studied alone and in combination with lamivudine
	Lamivudine		Retroviruses HIV, FIV	FIV	Relatively safe in cats; studied in combination with AZT
	Didanosine	Purine nucleoside	HIV, FIV (including AZT resistant strains)		
Miscellaneous	Foscarnet Amantadine Rimantadine	DNA polymerase Interference with viral attachment, penetration or intracellular releases; viral mRNA transcription, assembly	Herpes Influenza A Influenza C Sendai virus Pseudorabies	Rhinovirus (prophylaxis); FeLV?	Oral, intranasal, subcutane- ous, aerosol
	Oseltamivir (prodrug)	Neuraminidase inhibitor	Influenza A Influenza B		
	Suramin Inosiplex	Inhibition of reverse transcriptase Suppression of viral mRNA; induce T-cell		FeLV?	

Table 10-3 Dose	l	Deer	Davida	
Drug Famciclovir	Indication	Dose	Route	Interval (hr)
Foscarnet sodium	See text	20.30 mg/kg(D)	IV, PO	8
Idoxuridine 0.1%	O aulan h ann ag vinug	20-30 mg/kg (D) 1 drop in each		-
solution	Ocular herpes virus infection	eye (C)	Topical (ophthalmic)	4-8
Idoxuridine 0.5% ointment		Apply to local lesion	Topical	4-8
Interferon alpha-2 (human recombinant)	Non-neoplastic feline leukemia virus– FeLV-associated disease (low dose)	15-30 IU/cat	IM, PO, SC	$24h \times 7$ days on and off cycles
		0.5-5 IU/kg (C)	PO, SC	$24h \times 7$ days on and off cycles
	FeLV appetite stimulation	1 IU/cat	РО	24h \times 7 days on and off cycles
	Feline infectious peritonitis (nonexudative)	30 IU/cat (C)	РО	$24h \times 7$ days on and off cycles
	Feline infectious peritonitis (exudative)	2000 IU/Cat	IM	24
	Ocular herpes	10 IU	РО	24
		25-50 IU/mL saline	Topical (both eyes)	4-6
	Indolent ulcers	60-100 IU	PO, SC	24
Interferon bovine beta	Non-neoplastic FeLV- associated disease (high dose)	10,000-1,000,000 IU/kg	PO, SC	24h \times 7 days on and off cycles
	Feline infectious peritonitis (exudative)	20,000 IU/C	IM	24h × 14-21 days
	Acute feline herpesvirus in kittens	10,000 IU/kg	SC	$24h \times 21 \text{ days}$
Interferon, feline recombinant	Immunostimulation	1 million IU/kg	SC	48h; reduce to 7 d when responding
Lactoferrin	Feline immunodeficiency virus stomatitis	40 mg/kg (C)	Topical	24
Lysine	Immunostimulation	500 mg/cat	РО	24h or divide dose and adminis- ter q 12h for life
Oseltamivir	Susceptible virus infections	2 mg/kg (D)	РО	$12h \times 10$ days
Propionibacterium acnes	Immunostimulation	<7 kg: 0.1-0.2 mg/dog	IV	4 × per week in first week, 2 × per week at 3- to 4-day intervals, followed by 1 × per week until clinical signs abate or stabilize. Maintenance dose once per month.
Propionibacterium acnes	Feline retrovirus infection	15 μg/kg	IV	Biweekly for 2-3 weeks
Ribavirin	Susceptible virus infections	11 mg/kg	IM, IV, PO	$24h \times 7 \text{ days}$
Trifluridine ophthalmic solution	Ocular herpesvirus infection	1-2 drops of a 0.1% solution	Topical	3-8
Vidarabine	Ocular herpesvirus infection	Apply 0.3 cm (0.125 inches)	Topical	4-8
Zidovudine	Susceptible virus infections	5-25 mg/kg (C)	PO, SC	8-12

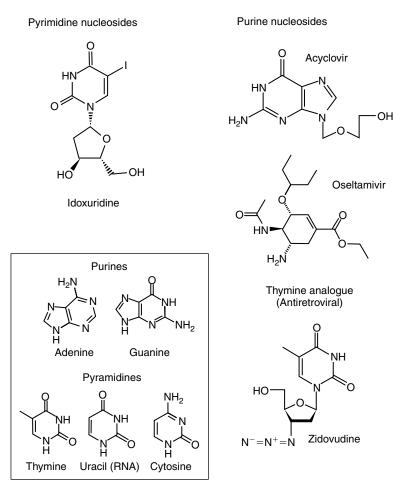

Figure 10-2 Structures of selected antiviral drugs. Structural similarity to purine or pyrimidine bases of host RNA or DNA (box) results in limited host safety.

Currently, targets expressed during intracellular stages of viral infection are the most common sites of pharmacologic intervention. Drugs include antivirals as well as a number of other classes of drugs (e.g., immunomodulators). Viral replication depends on macromolecular synthesis (by the host) of viral genome and on genome replication, transcription, and translation. Classes of drugs that inhibit transcription include inhibitors of viral DNA or RNA polymerase, reverse transcriptase, helicase, primase, or integrase. Natural substances capable of inhibiting viral transcription and translation (e.g., IFN) are much more potent than synthetic compounds. Viral replication is targeted by antisense oligonucleotides and ribozymes. Many antiviral drugs are nucleoside or nucleotide analogs, whose chemical structures allow prevention of viral replication by blocking nucleic acid metabolism (Figure 10-2; see also Figure 10-1). However, viral replication is so closely connected to vital functions of the host cell that agents capable of inhibiting viral replication usually injure host cells as well. Although such drugs are more likely to be broad in their antiviral spectrum, most also are potential teratogens, mutagens, and (particularly in humans) carcinogens. Further, they are associated with a variety of other host toxicities, with bone marrow suppression a not uncommon occurrence.⁷

Fewer agents have been developed that block viral translation. Classes of drugs that inhibit viral translation include IFNs, antisense oligonucleotides, and ribozymes. In addition, regulatory proteins might be inhibited. Another category of intracellular targets are specific enzymes, such as RNA or DNA polymerase, or reverse transcriptase of retroviruses, whose expression is required for the maintenance of the viral life cycle. Antiviral agents designed to block expression of these enzymes may have increased selectivity for viruses compared with the host, although their antiviral spectrum frequently is limited. Finally, assembly of synthesized viral macromolecules and release of the assembled virus may be pharmacologically inhibited. For example, IFN-induced inhibition of RNA tumor viruses occurs at assembly, although the mechanism is unknown.⁷

Posttranslational modifications such as proteolytic cleavage may be targeted by some drug classes (e.g., protease inhibitors). IFNs and drugs that inhibit specific proteins target viral assembly. Finally, antiviral antibodies and cytotoxic lymphocytes target the release of viruses from the host cell.

The final stage of viral infection that might be targeted pharmacologically is release of the new viral progeny from the infected host cell. Viruses can leave cells by causing cellular lysis or budding. With lysis, virus leaves in a sudden burst that kills the host cell. With budding, interaction between the virus and cell receptor induces changes that allow fusion of viral and cellular membranes, thus allowing the progeny to gradually leave the infected cell by budding. An example target for drugs during viral release is the neuraminidase in influenza viruses, a virulence factor that cleaves the sialic acid (neuraminic acid) residues from the glycan portion of cell receptors recognized by viral hemagglutinin.⁸

Viral infection may be also be pharmacologically inhibited during dissemination, which for some viruses appears to depend primarily on virally-induced host immunosuppression. Thus dissemination is another stage in which modulation of the immune system may help the host overcome viral infection.⁷ Biological response modifiers emerge with a role in modification of host response, whether it be inhibition of viral-induced immunosuppression or inhibition of an overzealous host response. The biological response modifier most commonly studied for its effect on viral infections and showing the most promise in efficacy has been IFN.

Antiviral-Induced Nephrotoxicity

Among the toxicities caused by antiviral drug is nephrotoxicity. The risk of antiviral drug-induced nephrotoxicity has increased as drugs have become more effective and novel in their action and as combination drug therapy has been implemented in response to increasing viral resistance.9 Acute tubular necrosis has been associated with a number of antiviral drugs (e.g., foscarnet, acyclovir, IFN, and cidofovir). However, variable renal lesions have been ascribed to a number of drugs, reflecting three major mechanisms: transporter defects, apoptosis, and mitochondrial injury. Glomerular disease resulting in proteinuria and, occasionally, the nephrotic syndrome has been mediated by either immune-mediated complexes (IFN) or crystal deposit (foscarnet). Crystalline deposits in the renal tubule (e.g., acyclovir, ganciclovir, and indinavir) can cause intrarenal obstruction. Isolated tubular defects may occur; examples include a Fanconi-like syndrome (cidofovir, tenofovir), distal tubular acidosis (e.g., acyclic nucleotide phosphonates, foscarnet), and nephrogenic diabetes insipidus (NDI: foscarnet).9 A major contributor to toxicity is intratubular cell drug accumulation mediated by ion-transport systems. For example, nephrotoxicity associated with cidofovir and adefovir appears to be facilitated by transport mediated by a transport protein.¹⁰ Limited use of antiviral drugs in veterinary medicine probably precludes effective evaluation of the advent of nephrotoxicity in animals with viral infections subsequently treated with antiviral drugs. However, among the clinical signs of toxicosis to accidentally ingested acyclovir in dogs were signs consistent with acute renal failure.11

Antiherpesvirus Drugs

Pyrimidine Nucleosides

A variety of pyrimidine nucleosides (both halogenated and nonhalogenated) effectively inhibit the replication of herpes simplex viruses with limited host cell toxicity. The exact mechanism of action of these compounds appears to reflect substitution of pyrimidine for thymidine, causing defective DNA molecules.

ldoxuridine. Idoxuridine (5-iodo-2-deoxyuridine, IDU; Stoxil) was the first of the nucleoside analogues to prove useful

in the treatment of viral diseases. Idoxuridine resembles and is substituted for thymidine. After phosphorylation, it is incorporated into both viral and host cell DNA. Altered DNA is susceptible to breakage, resulting in faulty transcription and altered viral proteins. The spectrum of antiviral activity is limited to DNA viruses, particularly members of the herpesvirus group. Resistance to IDU develops rapidly.² The ability of IDU to cause neoplastic changes, genetic mutation, and infertility limits its use to topical, primarily ophthalmic, infections. IDU is available as an ophthalmic ointment or solution. It is currently approved for use in the treatment of herpes keratitis in humans and has proved useful for the treatment of feline herpetic keratitis. One drop of a 0.1% solution is usually applied to the affected eye every hour; the 0.5% ointment can be applied every 2 hours.^{12,13} Topical application of IDU to the conjunctiva has been associated with irritation, pain, pruritus, inflammation, and edema of the conjunctiva and punctate areas on the cornea. Resistance of viruses to the drug develops readily both in vitro and in clinical cases.

Trifluridine. Trifluridine (triflurothymidine; TFT; Viroptic) is a halogenated (fluorinated) pyrimidine that is similar and often considered superior to IDU. TFT monophosphate irreversibly inhibits thymidylate synthetase, and TFT triphosphate competitively inhibits DNA polymerase incorporation of thymidine into DNA. Like IDU, it is preferentially incorporated into both viral and host DNA, and late virus-specific DNA transcription is inhibited.² Trifluridine has in vitro inhibitory effects against herpes simplex virus (types 1 and 2), cytomegalovirus, and selected adenoviruses. Clinical resistance to TFT has been reported. As with IDU, the primary therapeutic indication for TFT is herpetic keratitis. TFT is prepared as a 0.1% ophthalmic solution and is usually applied 6 to 8 times per day. Trifluridine is frequently preferred to IDU for the treatment of human and feline herpetic keratitis in order to prevent toxicities associated with IDU.12,13 Adverse reactions include discomfort on application and palpebral edema.²

Sorivudine. Sorivudine is a pyrimidine nucleoside analog characterized by potency that results in a relative selectivity for varicella-zoster virus (VZV). The drug is initially phosphorylated by viral thymidine kinase and then metabolized to diphosphate by viral thymidylate kinase. As such, sorivudine triphosphate is a competitive inhibitor of viral DNA replication. Unlike acyclovir, however, sorivudine is not incorporated into viral DNA. Inhibitory concentrations of sorivudine are 1000-fold lower for VZV than are those of acyclovir. Cellular uptake in cells infected with herpesvirus is fortyfold greater than in uninfected cells. Clinical resistance has not yet been detected.²

Sorivudine (in humans) is well absorbed after oral administration and is characterized by 98% protein binding. The elimination half-life is 5 to 7 hours, although half-life increases with age. Elimination appears to be urinary, with minimal hepatic metabolism. Side effects are primarily gastrointestinal (nausea, vomiting, and diarrhea). Hepatic enzymes may increase. Long-term administration has caused hepatic neoplasms in rodents. Sorivudine (probably its metabolite) appears to negatively interact with 5-fluorouracil by inhibiting the enzyme responsible for fluorouracil metabolism.² Sorivudine is available in both oral and intravenous preparations but only as investigational drugs.

Purine Nucleosides

Certain purine nucleosides have proved to be effective antivirals and are used as systemic agents. Several of these antiviral drugs deserve special mention.

Vidarabine. Vidarabine (Vira-A) was initially investigated for its efficacy as a cancer chemotherapeutic drug. An analog of adenine, vidarabine is phosphorylated by host enzymes and competitively inhibits viral DNA polymerase. It is substituted for adenine into DNA, thus inhibiting viral DNA polymerase. Mammalian DNA is also inhibited, although to a lesser extent. Ribonucleoside reductase, RNA polyadenylation, and transmethylation reactions also are inhibited.² Vidarabine selectively inhibits DNA viruses, particularly herpesviruses. It is also effective against poxviruses, rhabdoviruses, hepadnaviruses, and selected RNA tumor viruses.² Until recently, the drug was prepared as an injectable suspension. It is poorly water soluble, however, and must be dissolved in large volumes of fluid before intravenous use. A 3% ophthalmic ointment continues to be available. On intravenous administration, vidarabine is deaminated to hypoxanthine arabinoside which has 10% of the potency of the parent compound, but reaches concentrations that exceed the parent compound by fifteenfold after constant intravenous infusion. The drug is eliminated renally but predominantly as the hypoxanthine metabolite. The elimination half-life of the metabolite is approximately 3.5 hours. Adverse reactions are more likely with intravenous administration and include gastrointestinal upset (vomiting, diarrhea) and central nervous system (CNS) derangements (hallucinations, ataxia, tremors, and painful peripheral neuropathies with long-term use). In addition, vidarabine is probably mutagenic and carcinogenic. Phlebitis, hypokalemia, rash, elevated transaminases, and pancytopenia as well as inappropriate concentrations of antidiuretic hormone have been reported in humans. Systemic use in humans is reserved for life-threatening infections (e.g., herpes encephalitis). Although vidarabine is preferred over IDU for topical therapy of herpetic keratitis, the advent of acyclovir has reduced its use. Vidarabine can be useful for patients that have developed resistance to acyclovir or in combination with acyclovir for life-threatening infections.² Literature regarding its use in the cat is limited, but topical administration of the 3% ointment appears to be well tolerated in cats.12,13

Acyclovir and Valacyclovir. Acyclovir is an acyclic synthetic purine nucleoside analog that substitutes for guanosine in DNA synthesis. Valacyclovir is an L-valyl ester prodrug of acyclovir. Efficacy of acyclovir depends on activation of the drug to its monophosphate derivative by viral thymidine kinase. Subsequent phosphorylation to the diphosphate and then triphosphate form is mediated selectively by cells infected with herpesvirus. The formation of acyclovir-GTP results in the inhibition of viral DNA polymerase and incorporation of acyclovir-GTP into viral DNA, which terminates viral DNA synthesis. The drug has a greater affinity for viral (versus host) thymidine synthetase. Antiviral activity of acyclovir is limited essentially to herpesviruses. The in vitro activity of acyclovir is 100 times that of vidarabine and 10 times that of IDU. Viral resistance to acyclovir results from mutation to strains that are characterized by a reduction in viral thymidine kinase (the most common mechanism), altered substrate specificity, or altered viral DNA polymerase.²

Acyclovir is available in topical, oral (capsule), and parenteral (powder to be reconstituted) preparations. The bioavailability of the oral preparations (in humans) is poor (10% to 30%) and decreases with increasing doses.² In contrast, valacyclovir, which is rapidly and completely converted to acyclovir, increases bioavailability of acyclovir to 50% (in humans). Acyclovir distributes to all body fluids, including cerebrospinal fluid. It is eliminated primarily unchanged by glomerular filtration and tubular secretion and accumulates in patients with renal failure. The elimination half-life in adults with normal renal function is 1.5 to 6 hours; this can increase to 20 hours in anuric patients.

Toxicity of acyclovir, regardless of the preparation, is limited. Oral administration (of both acyclovir and valacyclovir) is associated with gastrointestinal upset. Intravenous administration may cause renal insufficiency and (rarely) CNS side effects. Cats experimentally infected with feline herpesvirus type 1 (FHV-1) that received 60 mg/kg daily of valacyclovir orally became ill within 6 to 9 days of therapy, necessitating termination of the study in 12 days. White blood cell counts declined, yet no difference was found in viral pathology in treated versus untreated cats, leading the authors to assess valacylovir as an unlikely option for treatment of FHV-1.14 Renal dysfunction is reversible and may reflect concentration in urine to the point that crystallization occurs² (see previous discussion). Rapid infusion, dehydration, and inappropriate urine flow increase the risk of renal damage. Phlebitis also may accompany intravenous administration. A retrospective review (January 1995 through March 2000) of acyclovir toxicoses in dogs (n = 105) following accidental ingestion reported by The American Society for Prevention of Cruelty to Animals National Animal Poison Control Center found clinical signs developing in 6 of 10 dogs within 3 hours of ingestion of doses ranging from 40 to 2195 mg/kg. ¹¹ The most common clinical signs were vomiting, diarrhea, anorexia, and lethargy, with polyuria and polydipsia reported in only 1 dog. Treatment included standard decontamination procedures, (i.e., induction of emesis, administration of activated charcoal), diuresis, and supportive care.

Veterinary use of acyclovir may be limited, probably because of differences among infecting viruses in viral thymidine kinase for acyclovir. In addition, antiviral resistance is increasing. Acyclovir is unable to eliminate latent infections. It is available as an ophthalmic ointment, a topical ointment and cream, an intravenous preparation, and various oral formulations.

KEY POINT 10-3 Veterinary use of acyclovir may be limited, probably because of differences in viral thymidine kinase for acyclovir.

Penciclovir and Famciclovir. Like acyclovir, penciclovir is an acyclic guanine nucleoside. Its spectrum of activity (herpes simplex virus and VZV) is also similar to that of acyclovir. Penciclovir (up to 77% bioavailable) is formed from its prodrug famciclovir. Penciclovir is a hundredfold less potent than acyclovir but is accumulated to higher concentrations than is acyclovir in infected cells.² Plasma elimination half-life in humans is approximately 2 hours, and elimination is renal. Although, like acyclovir, the drug is well tolerated orally, chronic administration appears to be tumorigenic, causing testicular toxicity in animals.

The pharmacokinetics and safety of penciclovir resulting from oral administration of famciclovir have been reported in cats (n = 8) at 62.5 mg (half of a 125-mg tablet; 9 to 18 mg/kg) orally after single and multiple dosing (every 8 or 12 hours; 4 cats per group) for 3 days.¹⁵ The maximum drug (C_{max}; ng/mL) concentration following a single dose was 330 ± 120 , and the elimination (disappearance) half-life was 3.1 ± 0.9 hr. Using a multiple-dosing, 12-hour dosing regimen, the C_{max} of penciclovir (ng/mL) did not change significantly from single dosing (multiple 12-hour dosing C_{max} [ng/mL] of 330 ± 180 at a T_{max} of 5 hours) but did with 8-hour dosing (multiple 8-hour dosing C_{max} of 680 ± 290) µg/mL. This increase is practically expected with a 3-hour half-life in the face of an 8-hour dosing interval (accumulation ratio of 1.4), but altered clearance cannot be ruled out without intravenous pharmacokinetic studies. The half-life did not change with multiple dosing, although the duration of dosing may not have been enough to allow emergence of drug interactions and the sample size may not have been sufficient to detect a difference. Dose normalization of C_{max} and area under the curve (AUC; 24 hours) yielded no significant differences between the two dosing intervals; again, limitations in sample size may have precluded detection of differences. Adverse effects may have included decreases in packed cell volume (by 27%) and total protein (by 10%). However, these changes may have reflected frequent blood draws during the study. White blood cell counts increased (neutrophils and monocytes) by 54% after the last dose. Although the cats tolerated dosing well, the target concentration suggested for treatment of FHV-1 is 3500 ng/m (based on the review of Thomasy et al.¹⁵), which was approximately tenfold higher than the C_{max} achieved in this study. Further studies must verify the safety of the drug at doses necessary to achieve this concentration.

Ganciclovir. Ganciclovir is structurally similar to acyclovir, with the addition of a hydroxymethyl group on the acyclic side chain. Its spectrum includes herpesvirus, with particular efficacy against cytomegalovirus; effective concentrations are tenfold to a hundredfold lower than the concentrations effective against other herpesviruses.²

Unfortunately, similar concentrations are inhibitory to bone marrow progenitor cells. As with other guanine nucleosides, ganciclovir inhibits viral DNA synthesis after monophosphorylation mediated by viral thymidine kinase (herpes) or phosphotransferase (cytomegalovirus). Diphosphates and triphosphates of ganciclovir are formed by cellular enzymes. The triphosphate competitively inhibits deoxyguanosine triphosphate incorporation into both viral and host DNA, with preferential inhibition of viral over host DNA polymerase. Intracellular concentrations (which exceed acyclovir concentrations by at least tenfold) decline much more slowly than those of acyclovir, resulting in a cellular elimination halflife of approximately 24 hours. Hence the drug is given once daily in humans.² Resistance most commonly reflects point mutations or deletions in viral DNA, resulting in reduced formation of viral phosphotransferase.

Ganciclovir is poorly bioavailable in humans (9%, with food). More than 90% of the absorbed drug is eliminated renally, with an (plasma as opposed to cell) elimination halflife of 2 hours. Elimination half-life increases proportionately with creatinine clearance. The primary adverse effect is myelosuppression, with neutropenia occurring in up to 40% and thrombocytopenia in 5% to 20% of patients. Myelosuppression more commonly occurs with intravenous administration and is generally reversible by 1 week after discontinuation of therapy, but it can be persistent and fatal. Treatment with granulocyte colony-stimulating factor may minimize neutropenia.² The risk of myelosuppression is increased when ganciclovir is combined with other cytotoxic drugs. Side effects in the CNS also are frequent, occurring in up to 15% of human patients. Clinical signs include convulsions and coma. Other adverse effects include infusion-related phlebitis, azotemia, anemia, fever, hepatic dysfunction, nausea, vomiting, and eosinophilia. Therapeutic use of ganciclovir includes cytomegalovirus retinitis, particularly in humans with acquired immune-deficiency syndrome-induced immunodeficiency. Ganciclovir is also used for treatment of any infection or prevention of infection (particularly in transplant recipients) associated with cytomegalovirus.

Ribavirin. Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide; Virazole) is a purine nucleoside analog that is activated by viral phosphorylation and subsequently prevents the formation of mRNA and translation of viral genome.^{12,13} The action of ribavirin involves specific inhibition of virusassociated enzymes, inhibition of the capping of viral mRNA, and inhibition of viral polypeptide synthesis. Thus it is effective against both DNA and RNA viruses and is a broad-spectrum antiviral drug. Susceptible viruses include adenoviruses, herpesviruses, orthomyxoviruses, poxviruses, picornaviruses, rhabdoviruses, rotaviruses, and retroviruses. Viral resistance to ribavirin is rare. Ribavirin is well absorbed in humans, widely distributed in the body, and eliminated by both renal and biliary routes as both parent drug and metabolites; it has a plasma half-life of 24 hours in humans. It does not have a wide margin of safety in domestic animals. Toxicity is manifested by anorexia, weight loss, bone marrow depression, anemia, and gastrointestinal disturbances. It has been successfully administered by topical, parenteral, oral, and aerosol routes. Ribavirin is administered as an aerosol to human patients afflicted with respiratory viral infections, thus avoiding the hematopoietic toxicities associated with systemic use of the drug. In the cat, in vitro investigations revealed marked antiviral activity against a strain of calicivirus but little efficacy for rhinotracheitis.^{12,13} However, Povey¹⁶ studied the oral administration of 25 mg/kg every 8 hours for 10 days in cats that had been experimentally infected with calicivirus. Pathologic lesions in infected cats worsened, primarily because of severe thrombocytopenia that presumably was drug induced. Cats also developed liver disease, although clinical signs resolved 1 week after the drug was discontinued.

Miscellaneous Antiherpes Drugs

Foscarnet

Foscarnet (phosphonoformic acid) is an inorganic trisodium salt that interferes directly with herpes viral DNA polymerase. The drug may also be effective in treating retroviral infections owing to similar interference with reverse transcriptase. Direct actions preclude the need for intracellular activation. Foscarnet has a hundredfold greater affinity for viral as opposed to host DNA polymerase- α .² Point mutations in DNA polymerase are responsible for resistance. Foscarnet is poorly bioavailable after oral administration. The drug is concentrated in bones, resulting in complicated plasma elimination. Elimination (in humans) is bimodal with an initial 4- to 8-hour elimination half-life followed by a 3- to 4-day half-life. It is eliminated primarily by the kidneys, with clearance decreasing proportionately with creatine clearance.

Major side effects in human patients include nephrotoxicity and hypocalcemia, which can become symptomatic. Serum creatinine increases in up to 50% of patients but decreases after therapy is stopped. Acute tubular necrosis, crystalluria, and interstitial nephritis have occurred. Sodium loading before therapy may decrease the risk of renal toxicity. Because foscarnet is highly ionized at physiologic pH, metabolic abnormalities are common in human patients. Calcium and phosphorus may decrease or increase. Decreases in ionized calcium may be sufficient to cause clinical signs consistent with tetany. Other CNS side effects reported in human patients (up to 25%) include tremors, irritability, seizures, and hallucinations. Fever, nausea, vomiting, anemia, leukopenia, and hepatic dysfunction also have been reported. Indications in human patients include cytomegalovirus retinitis and herpes infections that are resistant to acyclovir. The disposition of foscarnet and its precursor, thiophosphonoformate (TPFA), have been studied in normal cats. Whereas foscarnet was only 8% bioavailable, TPFA was 44%; however, only 14% of the drug is converted to foscarnet.^{16a} The half-life of foscarnet was approximately 3 hrs with clearance of 1.88 ml/min/kg, being similar to renal clearance. Foscarnet has been shown to be effective prophylactically in the treatment of feline rhinotracheitis. Its efficacy against retroviruses warrants further investigation for the treatment of FeLV. Currently, foscarnet is given to immunocompromised human patients and is being studied in the cat for treatment of retroviral infections.

Antiretroviral Drugs

Zidovudine

All clinically used (human-approved) antiretroviral agents are 2',3'- dideoxynucleoside analogs. Zidovudine (AZT; Retrovir) is a thymidine analog. Within the virus-infected cell, the 3'-azido group substitutes for the 3'-hydroxy group of thymidine. The azido group is then converted to a triphosphate form, which is used by retroviral reverse transcriptase and incorporated into DNA transcript.^{12,17} The 3' substitution prevents DNA chain elongation and insertion of viral DNA into the host cell's genome, preventing viral replication. Thus the shared mechanism of action of these drugs is inhibition of RNA-dependent DNA polymerase (reverse transcriptase). This enzyme is responsible for conversion of the viral RNA genome into double-stranded DNA before it is integrated into the cell genome. Because these actions occur early in replication, the drugs tend to be effective for acute infections but relatively ineffective for chronically infected cells.² Cellular α-DNA polymerases are inhibited only at concentrations a hundredfold greater than those necessary to inhibit reverse transcriptase, thus rendering this drug relatively safe to host cells. Cellular y-DNA polymerase, however, is inhibited at lower concentrations. Zidovudine is effective against a variety of retroviruses at low concentrations (<0.001 to 0.04 µg/mL. The intracellular elimination time of AZT is 3 to 4 hours.²

In human patients AZT is rapidly absorbed, with a bioavailability of 60% to 70%. Food impairs absorption. Concentrations in the cerebrospinal fluid are approximately 50% of those in plasma. The plasma elimination half-life is 1 to 1.5 hours. In human patients AZT undergoes first-pass metabolism.

Among the toxicities caused by AZT is myeloid suppression. The concentration necessary to suppress (human) myeloid cells is higher than that associated with antiviral activity, but nonetheless is still relatively low at 0.3 to 0.6 μ g/mL.² Although metabolites appear to be void of antiviral toxicity, at least one may contribute to myeloid toxicity. Granulocytopenia and anemia are the major adverse effects of AZT in human patients. The risk of toxicity increases in human patients with low (CD4⁺) lymphocyte counts, high doses, and prolonged therapy. Idovudinzidovudine may cause Heinz body anemia in cats,²¹ suggesting that complete blood counts should be performed on cats receiving AZT. Granulocyte colony-stimulating factor is indicated for management of granulocytopenia. CNS side effects are more likely as therapy is begun. Other side effects reported in humans include myopathy (characterized by weakness and pain), neurotoxicities, hepatitis (uncommon), and esophageal ulceration. Resolution of myopathy occurs slowly after drug therapy is discontinued. The risk of myelosuppression is increased by drugs that inhibit glucuronidation or renal excretion. Therapeutic indications for AZT in humans include treatment of HIV infections. Treatment with AZT prolongs survival, decreases the incidence of opportunistic infections, increases measures of immune function, and decreases HIV antigens and RNA. Zidovudine has been combined with didanosine or zalcitabine for more sustained CD4+ lymphocyte response.

The disposition of AZT has been studied in cats. It is rapidly absorbed in cats after intragastric or oral administration. Administration of a single dose of 25 mg/kg in normal cats by either route generates maximum serum concentrations of 28 \pm 7 and 29 \pm 15 µg/mL, respectively. Bioavailability for the intragastric route is 70 \pm 24%, and for the oral route 95 \pm 23%. The elimination half-life is approximately 1.5 hours and volume of distribution 0.82 L/kg. Drug concentrations were above the effective concentration 50 (EC₅₀) of 0.19 μ g/mL for FIV for at least 24 hours after either intravenous or oral administration.¹⁸ The drug appears safe at this dose despite drug concentrations being well above that associated with myeloid suppression of human cells. Side effects in cats at 25 mg/kg (administered intravenously) were limited to transient restlessness, mild anxiety, and hemolysis.¹⁸

KEY POINT 10-4 The disposition and safety of AZT support its use in cats.

Lamivudine

Lamivudine is among the more potent drugs against human immunodeficiency virus (HIV) and also has been studied in cats. As with AZT, it is rapidly absorbed in cats after intragastric or oral administration. Administration of a single dose of 25 mg/kg in normal cats by either route generates maximum serum concentrations of 50 ± 38.5 and $40 \pm 40 \ \mu g/mL$, respectively, with bioavailability for the intragastric route being $88 \pm 45\%$, and for the oral route $80 \pm 52\%$. The elimination half-life is approximately 2 hours and volume of distribution is 0.6 L/kg. The effective concentration $50 \ (EC_{50})$ for lamivudine ranges from 0.8.7 (mutant) to $11 \ \mu g/mL$ (wild type) for FIV and is present for at least 24 hours after either intravenous or oral administration.¹⁹ As with AZT, lamivudine appears safe in cats at 25 mg/kg with similar side effects.¹⁹

The disposition of the combination of AZT (5 mg/kg) and lamivudine (3 mg/kg) has also been studied in normal and FIV-infected cats after single and multiple (7-day) dosing.²⁰ Median AZT concentrations (ng/mL) were (median followed by range) 3.67 (2.67 to 4.66) at first dose and 3.65 (3.54 to 3.76) at steady state for AZT and 2.86 (2.62 to 3.08) at first dose and 3.89 (3.27 to 3.08) ng/mL (31.7 to 102.4 ng/mL) at steady state. These concentrations were comparable to those achieved in humans, although direct comparisons are precluded by different doses. Volume of distribution, clearance, and half-life were similar with combined therapy to that reported for individual therapy by Zhang and coworkers.^{18,19}

Didanosine

Didanosine is a purine nucleoside effective against HIV, including strains that have developed resistance to AZT. Although it is tenfold to a hundredfold less potent than AZT, it is more active in quiescent cells and in nondividing (human) monocytes and macrophages. It also is not toxic for hematopoietic precursor cells or lymphocytes at clinically relevant concentrations. It is metabolized inside the cell to its active derivative (ddATP), which competitively inhibits virus preferentially to host reverse transcriptase. Oral bioavailability of didanosine is about 40% in humans. Because it is very acid labile, food decreases absorption by 50% or more. Didanosine is available as both tablets and powder, with the tablet being 20% to 25% more bioavailable than the powder. Only about 20% of drug in plasma distributes to the cerebrospinal fluid. Up to 60% of the drug is excreted unchanged through the kidneys, with a plasma elimination half-life of up to 1.5 hours. Intracellular metabolism may be responsible for some plasma elimination. Side effects include painful peripheral neuropathy and pancreatitis. High doses increase the risk for both. A history of pancreatitis predisposes the patient to this side effect. Up to 70% of human patients develop pancreatitis, although hyperamylasemia will occur in up to 20%. Other adverse effects include diarrhea; rashes; CNS signs, including insomnia and seizures; optic neuritis; and, rarely, hepatic failure or cardiac dysfunction. Animal studies also have found gastrointestinal, bone marrow, hepatic, and renal dysfunction. Didanosine (33 mg/kg orally per day for 6 weeks) was used to develop a model of antiretroviral peripheral neuropathy in normal and infected SPF kittens.^{21a} Didanosine is approved for treatment of advanced HIV infections in human patients intolerant of or resistant to AZT. Stavudine, a thymidine nucleoside, and zalcitabine, a cytosine nucleoside, are alternatives to AZT therapy for human patients.²

Miscellaneous Antiviral Drugs

Amantadine

Amantadine and its derivative rimantadine are synthetic antiviral agents that appear to act on an early step of viral replication after attachment of virus to cell receptors. Interference of release of infectious viral nucleic acid into the host cell through the transmembrane domain of the viral M2 protein is proposed. The effect seems to lead to inhibition or delay of the uncoating process that precedes primary transcription. Amantadine may also interfere with the early stages of viral mRNA transcription. Amantadine also prevents virus assembly during virus replication. Viruses affected at usual concentrations include different strains of influenza A and C (but not B) virus, Sendai virus, and pseudorabies virus. It is almost completely absorbed from the gastrointestinal tract, and about 90% of a dose administered orally is excreted unchanged in the urine over several days (according to data for humans). The main clinical use has been to prevent infection with various strains of influenza A viruses. In humans, however, it also has been found to produce some therapeutic benefit if taken within 48 hours after the onset of illness. Amantadine and its derivatives may be given by the oral, intranasal, subcutaneous, intraperitoneal, or aerosol routes. It produces few side effects, most of which are CNS related; stimulation of the CNS is evident at very high doses. Acute toxicity generally reflects its anticholinergic effects and includes cardiac, respiratory, renal, or CNS toxicity.

Oseltamivir

Oseltamivir is prepared as an ester prodrug. On release by esterases in the gastrointestinal tract, the carboxylate form acts as a selective inhibitor of influenza A and B viral neuraminidases by inducing a conformation change at the enzymatic active site. The viruses cannot leave the infected cell and therefore aggregate at the cell surface and are unable to spread. Concentrations achieved in humans after oral administration of a therapeutic dose is $0.35 \ \mu\text{g/mL}$ of the carboxylate form. In humans the half-life is approximately 6 to 10 hours. It is excreted by renal tubular excretion; probenecid prolongs the half-life by twofold. The drug has not yet been studied in dogs or cats despite its anecdotal use for treatment of parvovirus in dogs.

Suramin

Suramin is a polysulfonate hexasodium salt capable of inhibiting reverse transcriptase; it has been studied for use in treating FeLV (discussed later).

Inosiplex

Inosiplex (Isoprinosine) is a compound formed from inosine and the para-acetamidobenzoate salt of 1-dimethylamino-2propanol. Inosiplex can inhibit cytopathic effects of several viruses in culture. In vivo experiments, however, suggest that optimal activity of inosiplex occurs with therapeutic administration after viral infection and requires an adequate host immune response. The mechanism of antiviral activity appears to involve specific suppression of viral mRNA. Inosiplex does not appear to be as efficacious as several antimetabolite antiviral compounds. Inosiplex can also induce T-cell differentiation similar to that induced by thymic hormones, apparently by augmenting RNA synthesis. Thus inosiplex may be more useful as an immunopotentiator in immunodeficient patients (see earlier discussion of biologic response modifiers).^{12,17,22}

Interferon and Its Inducers

Interferons (IFNs) are addressed in greater depth in Chapter 3. They are a group of multiple-gene inducible cellular glycoproteins that interact with cells and render them resistant to infection by a wide variety of RNA-containing and DNA-containing viruses. In addition, IFNs have numerous other effects on target cells, including a reduction in the rate of cell proliferation and alterations in the structure and function of the cell surface, the distribution of cytoskeletal elements, and the expression of several differentiated cellular functions. Interferons induce the synthesis of new proteins that are responsible for the activation of cellular endonucleases that degrade viral mRNA. Human IFNs are classified as α , β , or γ , depending on their physical stability, immunologic neutralization properties, host range, and homology in amino acid sequence. Viral infections generally are associated with the expression of IFN α and β genes. Those used in clinical trials have been produced by induction of synthesis by human white blood cells; fibroblasts; lymphoblasts; and, more recently, recombinant DNA techniques in bacteria. Numerous modes of antiviral action have been proposed. In addition to their ability to establish an antiviral state in host cells, they also appear to modulate the immune system of the host.

Interferons inhibit the replication of a wide variety of viruses. Among the RNA-containing viruses, the togaviruses, rhabdoviruses, orthomyxoviruses, paramyxoviruses, reoviruses, and several strains of picornaviruses and oncornaviruses are sensitive to inhibition by IFNs. Among the DNA-containing viruses, the poxviruses and several strains of herpes simplex types 1 and 2 viruses, as well as cytomegalovirus, are inhibited by IFNs. Adenoviruses are generally resistant. There are extreme variations in sensitivity to IFNs among different types and even strains of virus. In addition, the responses in different model and test systems can be extraordinarily variable. Interferons appear not to be as useful in the therapy of viral infections as was hoped initially. Interferons are usually administered parenterally but recently also have been used orally with some success. Although rare at recommended dosages, side effects may occur at higher levels.

To date, at least five feline IFN-alpha (feIFN) subtypes have been encoded,²³ each of which (1, 2, 3, 5, and 6), when expressed in a Chinese hamster ovary cell line, has exhibited antiviral activity against vesicular stomatitis virus– and feline calicivirus–infected cells.²⁴A recombinant feline IFN omega (rFeIFN- ω) is an insect- (silkworm-) generated (rather than microbial-based) product (Virbagen Omega) that is licensed by the U.S. Department of Agriculture for the treatment of retrovirus infections in cats.

Several substances induce IFN and have been tested for the prevention and treatment of viral infections and for treatment of neoplastic diseases. Although effective in some model systems, IFN inducers have not yet been found to be clinically useful because of their toxicity. High-molecular-weight inducers include polyriboinosinic acid/polyribocytidylic acid or poly(I)/poly(C); low-molecular-weight inducers include tilorone, aminobromophenylpyrimidinone, and aminoiodophenylpyrimidinone.

Miscellaneous Alternatives or Adjuncts to Antiviral Drugs

Lymphocyte T-Cell Immune modulator is an immuneregulating single polypeptide extracted and purified from bovine-derived stromal cells (ProLab manufacturers). The product package insert indicates that lymphocyte counts rapidly increased in cats (n = 23) with FIV or FeLV after treatment (1 mL) at 0, 7, and 14 days followed by monthly doses. Clinical scores became significantly better after the third dose. Red blood cell counts also increased in severely anemic cats. A clinical trial was not available for review, and no information was provided regarding control animals. As a biologic, the product has not been considered for approval by the Food and Drug Administration but had received conditional licensing by the United States Department of Agriculture as of November 2009.^{24a}

Several drug classes continue to be investigated mainly because of their in vitro antiviral activities. Their potential clinical usefulness remains obscure in most instances. Included among these agents are thiosemicarbazones, guanidine, benzimidazoles, arildone, phosphonoacetic acid, rifamycins and other antibiotics, and several natural products.

Lysine is an essential amino acid. Herpes simplex viral proteins are rich in L-arginine, and in vitro tissue culture studies suggest that viral replication is enhanced in the presence of a high L-arginine to L-lysine ratio. In contrast, when the ratio is low (i.e., lysine > arginine), viral replication and the cytopathogenicity of herpes simplex virus have been found to be inhibited. The effects of lysine may reflect antagonism of arginine-growth promoting effects, although the site of interaction is not known. Replacement of viral arginine with lysineyielding nonfunctional proteins also has been proposed.

Mycophenolic acid (MPA) is a non-nucleoside noncompetitive, reversible inhibitor of eukaryotic inosine monophosphate dehydrogenase. Inhibition of lymphocyte proliferation has led to its use to treat host versus graft rejection in human transplant recipients. Because microbial RNA and/or DNA synthesis also is inhibited, MPA has the potential for inhibiting infecting parasites and microbes, the latter including viruses. Mycophenolic acid appears to impair viral replication of a variety of viruses, including Sindbis virus, HIV herpesvirus, hepatitis B virus, orthopoxviruses, dengue virus, West Nile virus, and double-stranded RNA avian reoviruses.²⁵ It also appears to potentiate the inhibitory effects of cyclic guanosine analogs (e.g., acyclovir, penciclovir, and ganciclovir) against herpesviruses, the nucleoside analogs against HIV. However, its use as a broad-spectrum antiviral agent against positive- and negative-stranded RNA viruses has not been established.²⁵

TREATMENT OF SELECTED VIRAL INFECTIONS

Treatment of viral diseases in small animals is nonspecific and seldom includes antiviral drugs. Therapy tends to be supportive, focusing on fluid and electrolyte supplementation, prevention or treatment of secondary bacterial infection, and treatments that support the function and structure of the organ targeted by the infection. By far, the most important approach to management of viral diseases in dogs and cats is prevention and, in particular, an effective vaccination program. In addition, isolation of infected animals and cleansing of environments contaminated with potentially infecting viruses are important ways to limit the spread of viral infections.

Treatment of Selected Canine Viral Infections

Canine Parvoviral Enteritis

Parvoviral enteritis, caused by canine parvovirus-2 (CPV-2), is among the most common and fatal viral infections afflicting dogs, including most members of the family Canidae. Infection by this highly contagious virus generally reflects contact with infected feces. Animals, humans, and objects can serve as vectors. After exposure viral replication begins in the lymphoid tissue of the gastrointestinal tract, from where it disseminates to the intestinal crypts of the small intestine. The virus localizes in the epithelium of the tongue, oral and esophageal mucosa, small intestine, and lymphoid tissue. Because CPV-2 infects the germinal cells of the intestinal crypt, cell turnover is impaired and villi shorten. Mitotically active myeloid cells and lymphoid cells are also targeted, leading to neutropenia and lymphopenia. Complications of intestinal damage include bacteremia, endotoxemia, and disseminated intravascular coagulation (DIC). Infections are most severe in puppies younger than 12 weeks of age because of their immature immune system. Clinical signs include vomiting (which can be severe), diarrhea, and anorexia. Animals may be febrile. Clinical pathology may reveal leukopenia. Myocarditis can develop in patients infected in utero or less than 8 weeks of age. Diagnosis is based on clinical signs, leukopenia (generally proportional to the severity of illness), and enzyme-linked immunoassay (ELISA) antigen testing.

The clinical efficacy of rfeIFN-omega has been evaluated for the treatment of dogs with experimental and spontaneous parvoviral enteritis. Martin and coworkers²⁶ treated experimentally infected Beagle puppies with rFeIFN-omega (2.5 MU/kg) for 3 consecutive days and reported 1 of 5 deaths compared with 5 of 5 in untreated controls. De Mari and coworkers²⁷ studied spontaneous disease using a multicentric, doubleblind, placebo-controlled study. Clinical signs of the IFNtreated (2.5 million units/kg/day for 3 consecutive days) animals (n = 43) improved significantly during the 10-day study period compared with those of control animals (n = 49). Only 3 deaths occurred in the IFN group compared with 14 deaths in the placebo group, resulting in a 4.4 reduction in mortality. This increased to a 6.4–fold reduction in mortality in unvaccinated dogs.

Oseltamivir has been used to treat parvovirus, although this use is not based on a randomized clinical trial. One (abstract form) study reports a decrease in mortality of parvovirus by 75% to 100% (2 mg/kg orally every 12 hours); cost will be approximately \$0.25/kg. However, neuraminidase does not appear to be a virulence factor for parvovirus, including the release of viruses from the cell. In contrast, bacterial neuraminidases are also produced by a large number of respiratory mucosal pathogens and are necessary for biofilm formation by *Pseudomonas aeruginosa*. Use of viral neuraminidase inhibitors prevents biofilm formation by microbial organisms. Accordingly, the use of oseltamivir for its *nonviral* indications warrants further consideration for its potential impact on intestinal bacterial translocation; well-designed clinical trials are needed to demonstrate efficacy.

KEY POINT 10-5 Efficacy of oseltamivir for treatment of parvovirus, if it is scientifically demonstrated, may reflect its impact on bacterial translocation rather than viral inhibition.

Symptomatic therapy for canine parvoviral enteritis focuses on restoration of fluids and electrolytes and on prevention or treatment of bacteremia or endotoxemia. Fluid therapy is the single most important treatment and should be aggressive and continued as long as the patient is vomiting or diarrhea is present. Among the antiemetics, metoclopramide originally was among the most successful, with ondansetron considered for animals that fail to respond. Maropitant may be the better choice. Treatment of diarrhea is generally not indicated. The use of narcotic motility modifiers (e.g., loperamide, diphenoxylate) has been recommended if necessary,²⁸ but their use may prolong the presence of undesirable toxins in the gastrointestinal lumen. Thus their use is discouraged. Antimicrobial therapy should focus on both gram-negative coliforms and anaerobic organisms. In general, an injectable beta-lactam combined with an aminoglycoside has proved efficacious. Fluid therapy, once-daily dosing, and the immature nature of pediatric canine kidneys provide protection against aminoglycoside-induced renal disease. Fluorinated quinolones should not be used if possible because of the risk of cartilage damage. Ceftiofur has been used because of its potential for intravenous administration and its efficacy against Escherichia coli, one of the major contributors to secondary bacterial complications of parvovirus. Note, however, that efficacy and safety at doses necessary to control the systemic bacterial complications of parvovirus have not been documented. In addition, efficacy against anaerobic organisms of the gastrointestinal tract has not been studied. Cefazolin should be equally effective as ceftiofur against *E. coli* associated with translocation, although more frequent administration may be necessary and efficacy against anaerobes may be less.

Parvoviruses are extremely stable, being resistant to environmental conditions and many chemical disinfectants. Canine parvovirus is susceptible to sodium hypochlorite (1 part household bleach to 1:32 parts water). Exposure to diluted bleach must be long in duration.

Canine Distemper

Canine distemper²⁹ spreads by aerosolization to the epithelium of the upper respiratory tract. Multiplication in tissue macrophages leads to spread to lymphatics; tonsils; bronchial lymph nodes; and ultimately to lymphatic tissues of the gastrointestinal tract, liver, and other organs. Additional spread generally is hematogenous. Leukopenia characterized by lymphopenia develops as the virus proliferates in lymphoid tissues. Animals with adequate immunity are able to clear infection within 8 to 9 days. In dogs with an insufficient immune response, the virus spreads to other tissues, including the skin and other organs. Persistent viral infection of the CNS appears to develop in dogs that are not able to generate circulating IgG antibodies to the viral envelope. Immune complex deposition in the CNS may facilitate viral infection. Lesions and their sequelae in the CNS vary with the age and immunocompetence of the dog, the pathogenicity of the virus, and the duration (acute versus chronic) of infection. Acute encephalitis is more likely in young or immunosuppressed dogs and reflects direct viral damage. Demyelinating polioencephalomalacia is characterized by minimal inflammation. Continued infection in the CNS leads to progressive increases in the immune response, ultimately contributing to continued and widespread damage. Chronic infection is associated with increased concentrations of antimyelin antibodies, activation of macrophages, and release of reactive oxygen radicals. Despite resolution of inflammation in surviving animals, canine distemper virus can persist in infected brain tissues.

Clinical signs vary with the extent of infection and include general listlessness; fever; upper respiratory tract infection (similar to kennel cough); keratoconjunctivitis sicca; serous to mucopurulent discharge; and vomiting and diarrhea, often associated with tenesmus. Animals may become severely dehydrated. Neurologic signs generally develop after recovery (generally at 1 to 3 weeks but potentially up to several months) and tend to be progressive. Mature animals can abruptly develop neurologic signs despite prior vaccination and no previous evidence of disease. Clinical signs of CNS involvement vary with the area of the CNS affected and with the magnitude of damage and include hyperesthesia, cervical rigidity, seizures, cerebellar signs, paraparesis or tetraparesis, and myoclonus. Diagnosis is based on immunologic testing of IgM (ELISA). Measurements of IgG in both serum and cerebrospinal fluid may be useful for detecting chronic CNS infections. Immunocytology may also be helpful in the diagnosis of canine distemper, although the need for special equipment renders this aid less practical.

The most appropriate approach for limiting morbidity and mortality associated with canine distemper is proper vaccination.²⁹ Treatment continues to be largely supportive and focuses on prevention or treatment of bronchopneumonia (usually caused by Bordetella bronchiseptica), fluid and electrolyte support with supplementation of B vitamins as needed, and treatment of neurologic signs. Progression of neurologic signs may provide justification for treatment of cerebral edema (e.g., single administration of dexamethasone).²⁹ Seizures should be treated with anticonvulsant medications (diazepam for immediate control, phenobarbital or bromide for long-term control). Myoclonus is not treatable. Chronic inflammatory forms of distemper (including optic neuritis, encephalitis) may require long-term glucocorticoid therapy. Glucocorticoids that are more effective in their ability to control oxygen radicals (e.g., methylprednisolone) may offer an advantage, although this has not been clinically addressed with controlled studies. Therapy with ascorbic acid intravenously has not been proved to be clinically useful but nonetheless has been recommended.²⁹ Infections associated with measles in children apparently have responded favorably to two treatments with vitamin A (200,000 IU or 60 mg) if given within 5 days of the onset of clinical signs.²⁹ Canine distemper virus is extremely susceptible to common disinfectants.

Infectious Canine Hepatitis

Infectious canine hepatitis³⁰ initially localizes in the tonsils and spreads to regional lymph nodes and then to the bloodstream. The virus rapidly disseminates to all tissues, with hepatic parenchymal cells and vascular endothelial cells serving as the primary targets. Cytotoxic effects of the virus cause injury to the liver, kidney, and eye. In immunocompetent animals, infection is cleared within 7 days. Acute hepatic necrosis tends to develop in immunoincompetent animals. Although acute necrosis is the most common cause of death in animals surviving the initial phases of infection, it also can be self-limiting. Animals that respond with a partial neutralizing antibody tend to develop chronic active hepatitis, which can progress to fibrosis. Although renal lesions may develop with acute infection, progression to chronic renal disease apparently does not occur. Animals, however, remain prone to pyelonephritis. Ocular location of the virus occurs in about 20% of animals and can cause severe anterior uveitis and corneal edema. Ocular lesions tend to be self-limiting unless complications develop. DIC is a frequent acute complication of infectious canine hepatitis, probably triggered by widespread endothelial damage and activation of the clotting cascade. Decreased hepatic function and inability to clear products of degradation and to synthesize clotting factors contribute to DIC. Clinical signs in the acute stages of infectious canine hepatitis include enlargement of lymphoreticular tissues, fever, coughing, abdominal tenderness associated with hepatomegaly, and hemorrhagic diathesis. Less commonly, icterus and CNS signs may develop. Ocular lesions may be associated with blepharospasm, photophobia, cloudiness of the cornea, and ocular discharge. Diagnosis is based on clinical laboratory changes consistent with damage caused by infectious canine hepatitis and serologic testing.

Therapy is supportive and should continue until the liver has adequately healed from acute damage. Among the alternative therapies that might be considered is lactoferrin. Inhibition of growth has been demonstrated toward a number of viruses by the iron-binding protein lactoferrin. This endogenous compound is found in mucosal membranes, milk, and other tissues where it imparts other antimicrobial effects. Among the viruses targeted is canine herpesvirus, as has been demonstrated using in vitro techniques (canine kidney cells). The effects targeted viral replication and were independent of the iron-binding effects of the drug.³¹ Impaired interaction between the virus and cell receptors leading to altered viralhost cell attachment was a suggested mechanism.

Therapy focuses on fluid and electrolyte support, treatment as indicated for DIC (including both replacement therapy and anticoagulant therapy), and treatment for hepatic encephalopathy as needed in acute stages. Hypertonic glucose (0.5 mL/kg of a 50% solution given intravenously over 5 minutes) may be helpful in the presence of hypoglycemia. Polyinosinic–polycytidylic acid, an IFN inducer, has been used experimentally but is not a practical therapy. Persistence of chronic liver disease should be treated appropriately.

Infectious canine hepatitis is very resistant to many chemical disinfectants, including chloroform, ether, acid, and formalin. Chemical disinfectants that appear to be useful include iodine, phenol, and sodium hydroxide. The application of steam (5 minutes at 50° to 60° F) may be a reasonable method of disinfection for instruments.

Canine Infectious Tracheobronchitis (Kennel Cough)

The most common causative organisms of kennel cough are canine parainfluenza virus, a single-stranded RNA virus, and B. bronchiseptica.³² Other viruses and bacterial infections are also associated with the syndrome. Bacterial causes of tracheobronchitis are discussed in Chapter 8. Viral transmission occurs primarily by aerosol or, for some viruses, oronasal contact. The lack of viral replication in macrophages limits infection of the virus to the upper respiratory tract, although it is the viral-induced damage to the respiratory epithelium that allows secondary bacterial infection. B. bronchiseptica preferentially attaches to the respiratory epithelium, replicates on respiratory cilia, and releases potent toxins that impair phagocytosis and cause ciliostasis, allowing infection by opportunistic organisms. The most common clinical signs associated with canine infectious tracheobronchitis (ITB) is paroxysmal nonproductive coughing, often associated with retching. Edema of the vocal folds is responsible for the characteristic honking sound of the cough. History includes exposure to other dogs, often at a boarding facility. Diagnosis is based on history and clinical signs. Culture of the upper airways (by bronchoscopy or transtracheal wash) can support diagnosis of a bacterial component. Rising antibody titers may be helpful in identifying a specific viral etiology. Therapy focuses on control of cough and, in cases complicated by persistent bacterial infection, (as evidenced by mucopurulent discharge that emerges after viral phase) antimicrobials. Glucocorticoids may be helpful for controlling cough but do not appear to shorten the clinical outcome. Antitussive therapy should include both peripheral bronchodilators and centrally active drugs. Narcotic derivatives are more likely than non-narcotics to control cough associated with ITB. Aerosol therapy may be helpful in cases associated with marked accumulation of respiratory secretions or pneumonia. Mucolytics, such as *N*-acetylcysteine, may be very irritating to the respiratory tract and can be given orally or parenterally.

Parainfluenza virus is susceptible to sodium hypochlorite, chlorhexidine, and benzalkonium solution. Control of outbreaks in a kennel may require isolation of the entire facility for up to 2 weeks. Vaccines are available; intranasal vaccination may lead to clinical signs typical of ITB.

Canine Papillovirus

Papillovirus is a largely self-limiting infection. However, antiviral therapy might be considered in nonresponders or in the interest of improving the comfort of animals. One uncontrolled clinical trial reported response of infection with nonspecific immunomodulation. Dogs (n = 16) presenting with papillomas in the oral mucosae and palate were treated with 2 mg Propionibacterium acnes intramuscularly once per week. Response was realized in 2 weeks, with resolution of lesions occurring within 5 weeks in younger animals. However, in older animals response required treatment 3 times per week, with regression of lesions beginning at week 3 and completed by week 6. No significant side effects of therapy were reported, leading the authors to conclude that P. acnes would be a reasonable alternative for treatment of canine papillomas that have not naturally regressed.³³ Other anecdotal treatments have included IFN-alpha-2a, 1-3 million IU/dog, orally 3 times per week.

Yagci and coworkers³⁴ prospectively studied the positive effects of azithromycin (10 mg/kg once daily for 10 days) for treatment of canine oral (n = 12) or cutaneous (n = 5) papillomatosis using a double-blinded controlled design. Dogs were assigned to treatment groups based on entry into the study; 10 dogs (7 oral and 3 cutaneous) received treatment, whereas 7 did not. Cutaneous lesions on 1 dog in the placebo group spontaneously resolved at day 41. However, skin lesions in the 10 dogs with cutaneous lesions in the treatment group resolved in 10 to 15 days (although not stated in the report, it is assumed that all dogs with oral lesions also had skin lesions). The number of animals with oral lesions was not evident during the 8-month follow-up period of the study.

Treatment of Selected Feline Viral Infections Feline Panleukopenia

Feline panleukopenia³⁵ is caused by parvovirus transmitted by direct contact between cats or between cats and vehicles acting as vectors. As with other parvoviruses, cells that are rapidly

dividing are particularly susceptible to infection, including bone marrow, lymphoid tissue, and intestinal mucosal crypt cells. In utero infection can cause a number of reproductive disorders in the pregnant cat, ranging from loss of fetuses if infection occurs early in the pregnancy to birth of affected kittens. Injuries in kittens occur in the CNS, particularly the cerebellum, optic nerve, and retina. Panleukopenia causes acute signs, including fever; depression; anorexia; and, less frequently, vomiting. Dehydration can be extreme. Other potential clinical signs include ulceration, bloody diarrhea and icterus, and signs indicative of DIC. Queens infected during pregnancy may be diagnosed with infertility, and dead fetuses may mummify. Kittens affected in utero present with classic signs of cerebellar hypoplasia.

Diagnosis generally is based on a complete blood count. Therapy is symptomatic and focuses on fluid and electrolyte replacement (with vitamin B) and maintenance, antiemetics (generally metaclopramide), and broad-spectrum antimicrobials to control secondary infection. The use of antivirals has not been established. Diazepam or other appetite stimulants can be attempted in anorectic cats that are not vomiting. Blood transfusions may be indicated in the presence of severe anemia.

Feline Infectious Peritonitis (FIP)*

The treatment of FIP has recently been reviewed.³⁶ Although caused by a coronavirus, the pathophysiology of infection is complex, in part because a variety of coronaviruses are capable of infecting cats. Further, cat susceptibility to infection and subsequent development of FIP vary unpredictably.³⁷ The underlying relationship between FIP virus and non-FIP feline corona virus (FeCoV) cannot yet be discriminated based on current serology methods alone. The role of polymerase chain reaction based assays has to be defined; the ABCD Guidelines for FIA indicates that it cannot diagnose FIP in that positive results have been obtained in healthy carriers and negative results may occur in cats with FIP. Rivalta's test-based on high protein content, inflammatory mediators, and fibrinogen present in fluids of the effusive form-is characterized by a high predictive value.^{37a} Among the feline corona viruses are strains whose pathogenicity and virulence vary from minimal, with replication limited to the gastrointestinal epithelium, to the virulent strains causing (FIP). Variability in virulence exists even within strains causing FIP. Cats infected with non-FIP corona virus are at risk to develop FIP as some strains appear to rapidly mutate to the virulent form. Virulence may be related to the ability of the virus to infect and replicate within macrophages. The "S" protein on the viral envelope appears to be responsible for viral attachment, membrane fusion, and virusneutralizing antibody production. Infection and subsequent reinfection among carrier cats (e.g., in catteries or multiple-cat households) probably facilitates mutation. Cats do not develop FIP unless preexisting corona antibodies exist. Antibodies to the virus facilitate monocytes and macrophage infection (antibody-dependent enhancement), leading to dissemination. Cats that develop antibodies before mounting an effective cellmediated response to FeCoV appear to develop the effusive form of FIP on reinfection; a partial cell-mediated response may result in the noneffusive form of the disease.

Clinical signs of FIP reflect immune-complex deposition (Arthus-type reaction) in smaller vessels. Clinical signs of FIP vary with the site of virus and immune complex deposition and generally reflect either an effusive or noneffusive form. Immune complexes that form in response to the virus or the specific viral antigen include both antiviral antibodies and complement. Activation of complement leads to the release of vasoactive amines, endothelial retraction, and increased epithelial permeability, which in turn allows exudation of the protein-rich exudate typical of FIP. If vascular permeability is the predominant effect, the effusive form develops. Less severe permeability with subsequent recruitment of inflammatory cells appears to lead to the pyogranulomatous inflammation characteristic of the noneffusive form. Neutrophil accumulation and subsequent release of lysozymes cause vascular necrosis. Systemic involvement may reflect spread of viral-infected macrophages and subsequent complement activation or deposition of immune complexes from circulation into tissues. Pyogranulomata develop, the magnitude of which reflects the size, number, and amount of antibody and antigens. Regions of high blood pressure and turbulence appear to be more common sites of deposition. Effusive FIP causes ascites with or without pleural effusions. Noneffusive FIP tends to be vague in presentation and includes fever, weight loss, anorexia, and depression. Ocular lesions are common, characterized by iritis, hypopyon, and hyphema. Pyogranulomata may be present in the vitreous or the retina. Neurologic signs are not uncommon and include ataxia, nystagmus, and seizures. Meningitis may lead to tremors, hyperesthesia, behavioral changes, or cranial nerve defects. Hydrocephalus also may develop.

Investigations into treatment of FIP have focused on both antiviral therapy (particularly IFN) as well as control of the immune response. A number of drugs have been studied for potential efficacy against FIP, some with little hope of being clinically applicable. For example, in one in vitro study, the rank of CD_{50} : ED_{50} (the ratio of a cytotoxic to effective dose) of drugs toward FIP was pyrazofuin > 6-azauridine > 3-deazaguanosine > hygromycin B > fusidic acid > dipyridamole. Compounds with no effect were caffeic acid, carbodine, 3-deazauridine, 5-fluoroorotic acid, 5-fluorouracil, D(+)glucosamine, indomethacin, D-penicillamine, rhodamine, and taurine.³⁸ More recent in vitro studies have demonstrated the potential efficacy of ribavirin or adenine arabinoside, but neither acyclovir nor AZT.

A variety of studies (as reviewed by Hartmann and others³⁶) have focused on minimizing the immune and thus inflammatory response. However, studies have been characterized by a number of limitations, including failure to accurately diagnose FIP and limited sample size. Glucocorticoids with or without

^{*}The European Advisory Board and Cat Diseases (ABCD) has published guidelines for the viral disease of major feline or human public health significance. Each guideline provides an excellent review of the pathophysiology of the disease and an evidence-based approach to the diagnosis, prevention, and treatment of the diseases (Table 10-4). Although the availability of diagnostic and treatment aids will vary among countries, the principles and applications are relevant to all.

cyclosphosphamide have been associated with variable success in uncontrolled studies. Despite in vitro studies, ribavirin has not been proven effective and appears to be too toxic at doses that are necessary to achieve effective concentrations. Case reports have described variable success with thrombox-ane synthetase inhibitors, melphalan, chlorambucil, tylosin (for its immunomodulatory effects), promodulin, human IFN, *P. acnes* and the "paraimmunity" inducer Baypamum have all been reported either as single cases or in clinical trials. No clear effective treatment has emerged.

According to the ABCD, low dose human IFN- α is contraindicated and SC high dose was ineffective in cats with FIP. Most recently, efficacy of feline recombinant-omega IFN has been studied. A series of 12 cases of spontaneous FIP treated with a combination of glucocorticoids and recombinant feline-omega IFN (106 IU/kg administered subcutaneously every 48 hours until clinical improvement followed by once weekly); complete remission (over 2 years) was reported in 4 cats and partial remission (2 to 5 months) in another 4. However, all survivors were older cats (older than 5 years), with the effusive form of the disease.³⁹ Hartmann and coworkers Ritz and coworkers³⁹⁹ failed to find a treatment effect compared to placebo for rF-INF ω in cats (n = 37) whose FIP was confirmed histologically and immunohistochemically (ability to detect a significant difference may have been limited by sample size). Effusive disease was also treated with dexamethasone or prednisolone. rF-INFω was administered at 10⁶ IU/kg subcutaneously daily for 8 days and then weekly thereafter. Despite ongoing and historical studies, effective treatment of FIP remains elusive. Anecdotal reports suggest efficacy of pentoxifylline for the effusive form of FIP. Supportive therapy includes fluids as necessary, antimicrobials, ascorbic acid, vitamin B, and vitamin A.

Options for treatment of ocular FIP (Table 10-4) include topical and oral glucocorticoids (prednisolone or dexamathasone) or a combination thereof. As a primary T-cell, rather than B-cell inhibitor, cyclosporine is not recommended. As with systemic disease, anecdotal reports suggest efficacy of pentoxifylline. Intracameral tissue plasminogen activase has been anecdotally suggested if fibrin does not resolve.

Preventive efforts toward FIP infection are also complicated by the futility of identifying and removing carriers: serologic testing will identify only previous exposure to coronavirus, which will be true for the majority of cats. Vaccines thus far have proved ineffective because antibodies sensitize to rather than protect from the disease. Strains and route of inoculation will influence outcome of vaccination. Because animals will have been exposed by the time diagnosis is made, isolation is not necessary. However, environmental cleansing should be relatively easy. Although FeCoV is relatively stable in the environment, it is easily destroyed by most common detergents and disinfectants, including diluted (1:32) sodium hypochlorite solution.

Feline Respiratory Disease

Feline rhinovirus (FRV) and calicivirus (FCV) are the major viral causes of respiratory disease in the cat,⁴⁰ but a number of bacterial organisms contribute to the pathogenesis, including

B. bronchiseptica, Mycoplasma spp., and Chlamydia psittaci. Other viral organisms (e.g., reovirus, poxvirus) also may contribute. Rhinovirus is a herpesvirus. Natural routes for both viral infections are by way of the nasal, oral, and conjunctival mucosae. Viral replication of rhinovirus occurs primarily in the nasal mucosal epithelium and, for calicivirus, throughout the respiratory epithelium. Growth of rhinovirus tends to be restricted to areas of lower body temperature; thus lesions tend to be limited to the nasal mucosa and the pharynx. Lesions reflect necrosis and result in the typical clinical signs of marked sneezing, pyrexia, depression, and anorexia; cats may salivate. Conjunctivitis with chemosis and hyperemia are common, with mucopurulent discharge of the nares and eyelids developing. Oral ulceration is rare. Several syndromes have been described, including the classical acute rhinosinusitis and corneal disease; an atypical disease that may be accompanied by a systemic response (including fading kitten syndrome), and chronic rhinosinusitis disease. For the latter, damage to nasal turbinates can be extensive and permanent, leaving the infected cats susceptible to lifelong chronic upper respiratory tract infections (e.g., rhinitis, sinusitis) and conjunctivitis. Rhinosinusitis may also reflect a chronic allergic inflammatory response.^{40b} Calicivirus infection has variable clinical signs because it is more likely to affect the lungs. Oral lesions (tip of the tongue, mouth, and nose) are the most predominant sign, reflecting epithelial necrosis; fever and mild respiratory and conjunctival signs also occur. Feline calicivirus also has been associated with chronic gingivitis and stomatitis. Sneezing and ocular and nasal discharge are not as common as with rhinovirus. Pulmonary lesions begin with alveolitis. Lameness also may occasionally develop. An often lethal, highly virulent form of FVC resulting in systemic disease has been reported, with the disease more severe in adults compared to kittens.^{40a} The syndrome is associated with a systemic inflammatory response syndrome. Diagnosis using molecular-based assays should be made only cautiously for FVC as the presence of virus and clinical signs are poorly correlated.

Similarities between human and feline herpesvirus infection justifies the potential application of human antiherpetic drugs to treatment of feline infections. Accordingly, information regarding their use for treatment of feline respiratory infections is increasing. For example, using infected feline kidney cells, the inhibitory concentration (50%) was determined for a number of antiviral drugs toward FHV-1. In vitro efficacy of IDU and that of ganciclovir were approximately equivalent and approximately twice that of cidofovir and penciclovir. Foscarnet appeared to be comparatively ineffective.⁴¹ Also using in vitro techniques, cidofovir decreases cytopathic effects and viral load FHV-1 of feline corneal epithelia at concentrations of 0.05 and 0.02 mg/mL. However, cytotoxic effects also were evident in cultured cells.⁴² Van der Meulen and coworkers⁴³ reported on the in vitro efficacy of six antiviral drugs [acyclovir, ganciclovir, cidofovir, foscarnet, adefovir, and 9-(2-phosphonylmethoxyethyl)-2, 6-diaminopurine (PMEDAP)], using an in vitro plaque reduction assay (embryo-derived feline kidney cells). Of the six drugs, ganciclovir, PMEDAP, and cidofovir were most effective in reducing

Disease	Cause	Diagnosis	Vaccine	Prevention	Treatment
FVC	Calicivirus	PCR?	Two injections, at 9 and 12 weeks (4 weeks accept- able with repeat every 2 weeks until 12 weeks of age); third at 16 weeks in high risk situations; 52 weeks; then yearly (high risk) or every 3 yr booster queen before mating.	Sodium hypochlorite (5% bleach; 1:32). Individual cages for non-household member cats.	Antivirals: None Immunomodulators: rFINFω (IV) Stomatitis: Immunosuppressants (glucocorticoids, others [IV]), human or rfIFNω (IV), including intralesional Highly virulent strain: glucocorticoids, IFN (III) Supportive therapy: Stomatitis: Stomatitis: cleaning-extraction, antimicrobials Highly virulent: fluid therapy, antimicrobials
Rhinotracheitis	Feline herpes virus (alpha)	PCR; positive may indicate low level shedding or viral latency	All kittens: at 9 weeks and 12 weeks. Unvaccinated adults: two vaccina- tions, 2 to 4 weeks apart. Booster: annual for high risk; if > 3 yr between boosters, two vaccina- tions 2-4 weeks apart. Otherwise booster every 3 yr.		Antivirals (III): Trifluridine topically every hr × 24 then every 4 hr Idoxuridine topically every 2 to 4 hr Ganciclovir topically Acyclovir topically and oral L-lysine 250 mg bid to 400 mg once daily Immunomdulators (III): rfIFNω: 1 MU/kg every 24 to 48 hr 50,000-100,000 U PO every 24 hr 10 MU/19 ml 0.9% NaCl: 2 gtt OU 5×/day for 10 days Supportive (fluids etc): Appetite stimulants (feeding tube if necessary) Antimicrobials Mucolytics, including nebu- lization with saline
Panleukopenia	Feline parvovirus	Latex aggluti- nation based tests; PCR	All kittens: Start at 4 weeks with inactivated product (if exposed), or 6 to 9 weeks otherwise. Repeat every 3 to 4 weeks until 12 weeks (if started at 4 weeks) or 16 weeks. Booster at 1 yr and then 3 yrs or more. Adult cats: one vaccination; booster at 1 yr. Booster queens before breeding; kittens may require extra vaccination at 16 to 20 weeks. Avoid modified live in pregnant queens.	Isolate from susceptible kittens. Passive immunization of exposed young kittens, unvaccinated adults. Virus extremely stable; cleanse with sodium hypochlorite, formal- dehyde (gas for room disinfection), sodium hydroxide or peracetic acid.	Antivirals: None Immunomodulators: Immune serum rFINFω (IV) Supportive: Fluids, antimicrobials (including anaerobic spectrum) Enteral or parenteral nutrition (IV?) Antiemetics Plasma or whole blood if hypoproteinemic

Table 10-4 Summary of the European Advisory Board on Cat Disease Guidelines for Feline Viral Diseases*37a, 40a, 40b, 69a, 73, 74

Disease	Cause	Diagnosis	Vaccine	Prevention	Treatment
Infectious peritonitis	Feline corona virus group 1	Clinical signs Rivalta's test Others?		Isolation of cats not nec- essary. Clean as with standard disinfec- tants. Wait 2 months after seropositive cats removed before intro- duction of new cat.	Antivirals: noneImmunodulators:rFINF ω (IV)Immunosuppression:Prednisolone orDexamethasone (III)Pentoxyfylline (IV)Cyclophosphamide (with glucocorticoids) (IV)Thromboxane synthetase inhibitors (ozagrel) (III)
Immunodefi- ciency virus	Retrovirus (lentivirus)	ELISA; West- ern blot for inconclusive results	Routine vaccination of FIV- positive cats controver- sial; inactivated vaccines recommended.	Neuter cats (to avoid fight-induced trans- mission). Shelters: segregate FIV+ cats.	Antivirals: AZT (5-10 mg/kg stomatitis: III); (do not use if anemic) Immunomodulators rf-IFNω(?) rh-IFNα (III) Stomatitis: Glucocorticoids others Neutropenia: Filgastrim (III) Anemia: rh-erythropoietin (IV: 100 IU/kg SC every 48 hr rh-insulin-like growth factor (III)
Leukemia	Gamma retrovirus	ELISA; PCR for inconclusive results	Generally recommended at 8-9 and 12 weeks; booster annually and then at 2 to 3 yr intervals in cats older than 3 to 4 yr. Note: response to other vac- cines may be insufficient. Do not vaccinate sick FeLV + Cats. Vaccinate healthy FeLV and FIV + Cats.	Neuter cats (to avoid fight-induced trans- mission). Hospital and shelters: segregate FIV+ cats Test and remove multi- cat households. Shel- ters: euthanize sick cats; house-positive cats individually.	Antivirals: AZT (I) Immunomodulators: rf-IFNω (I) Avoid immunosuppressants unless cancer or stomatitis Neutropenia: Filgastrim
H5N1 (swine flu)	Influenza type A	Clinical signs	NA	Strict isolation; standard medical disinfectants.	Supportive; contact regula- tory authorities

Table **10-4** Summary of the European Advisory Board on Cat Disease Guidelines

*The number (I-IV) by each treatment is the evidence number suggested by ABCD Guidelines for that disease where I = the highest level of evidence reflecting well designed randomized, controlled clinical trials in the target species; II = well-designed controlled studies in target species with spontaneous disease but an experimental setting; III = nonrandomized clinical trials, case series, uncontrolled studies with dramatic results; and IV = expert opinion, case reports, nontarget species studies or pathophysiologic justification.

plaque numbers and thus were cited as potentially viable candidates for treatment. In another in vitro study penciclovir was found to be much more potent (concentration by which plaques were reduced by 50% of 1.6 µg/mL) against FHV than acyclovir (24 µg/mL) and trifluorothymidine (5.7 µg/mL).44

Although in vitro studies are useful for identifying potential drugs, clinical trials are necessary to support their use. However, well-controlled clinical trials are limited. Stiles⁴⁵ retrospectively described the use of a variety of drugs for treatment of FHV-1 in cats (n = 17). Drugs included IDU (n = 7), vidarabine (n = 4), and trifluridine (n = 3) as well as recombinant human alpha-IFN (PO, n = 3) in conjunction with topical administration of antiviral agents. Williams followed up on his 2004 in vitro study⁴⁶ with a clinical trial involving cats (n = 30) with clinical signs associated with and demonstrated to be positive for FHV-1. Acyclovir ointment (0.5%) was applied 5 times daily; cats had been previously treated (for 21 days) with topical chlortetracycline three times daily for treatment of Chlamydia. No placebo or other control groups were studied. Cats that were FHV-1 positive did not respond to the 21 days of chlortetracycline therapy, but did respond to acyclovir in a median of 12 days of treatment. Cats that were treated only 3 times a day with acyclovir (due to poor owner compliance) did not respond initially, but did respond when the frequency of treatment was increased. Based on these studies and anecdotal reports, ocular herpetic infections can be treated topically with, in order of efficacy, trifluridine (1%) or idoxuridine (0.1%), vidarabine (3%), and acyclovir (3%). Each must be applied at 4-hour intervals for 1 week beyond the resolution of clinical signs.⁴⁷ Preference as to idoxuridine or trifulridine as first choice may depend on cost and tolerance (irritation).

Anecdotal reports suggest the potential efficacy of other drugs. For example, famciclovir (31 mg or ¼ of a 125-mg tablet orally twice daily for 10 days) has been used for acute flare-ups in cats not exhibiting systemic signs of illness associated with upper respiratory tract infections. In their review, Caney and coworkers⁴⁸ report that FHV-1 might be treated with topical use of trifluorothymidine (trifluridine; most potent; hourly the first 24 hours, then hourly during the waking hours, to every 4 hours as soon as re-epithelialization has occurred), IDU (every 2 to 4 hours for the first 24 hours, then 4 to 6 times daily until 1 week beyond clinical resolution of signs) and vidarabine. It is best if treatment is started early, but the duration of therapy should be limited to 2 to 3 weeks because of the risk of epithelial toxicity. Oral administration of AZT also should begin early, although it is a hundredfold less potent against FHV than it is toward human herpes simplex.

Other drugs might be considered for treatment of feline viral respiratory infections, although evidence for use is limited. Among those most commonly cited is lysine. Using a placebo-controlled design, L-lysine administration (400 mg in food once daily) was associated with a decrease in the incidence of conjunctivitis in cats with experimentally induced viral respiratory diseases.⁴⁹ Animals were infected 5 months before the study such that infections were latent. Viral expression was induced by either the stress of rehousing or administration of glucocorticoids. The drug caused a delay in onset of clinical signs (average delay of 7 days) and a decrease in episodes of viral shedding 5 months but only in rehoused cats and not glucocorticoid-treated cats. The 400-mg dose yielded a maximum plasma concentration of about 450 nmol/mL after single dosing (two cats; time not noted) and approximately 300 nmol/mL at 3 hours after 30 days of therapy.49 Stiles and colleagues⁵⁰ also studied the impact of lysine (500 mg orally twice daily) beginning 6 hours before experimental infection of cats (n = 4; an additional 4 cats received placebo). Because arginine is an essential amino acid, both arginine and lysine were analyzed in plasma. Lysine did not affect arginine concentrations, supporting its safe use in cats. Despite the small number of animals, clinical scores differed between the two treatment groups between days 5 and 15 after infection; however, the scores of the two groups were similar during the final week of the 21-day study, as resolution of clinical signs caused the scores to return to baseline (preinfection). This study provides some evidence of support; failure to maintain a significant difference at 21 days may reflect sample size. However, the efficacy of once-daily L-lysine (250 mg if less than 5 months or 500 mg if greater than 5 months) also was studied for its impact on emergent upper respiratory infection in animal shelter cats (n = 144 treated and 147 nontreated cats). No difference was found in the subsequent incidence of upper respiratory infection that emerged between the two treatment groups.51

KEY POINT 10-6 A consensus cannot yet be determined from clinical trials that address the efficacy of lysine for treatment of upper respiratory infections in cats.

Interferon also has been studied. Human recombinant drug has been used at 5 to 25 U per day orally, whereas rFeIFN- ω is recommended at 2 drops of 500,000U/mL saline topically 5 times a day. Sandmeyer and coworkers⁵² studied the in vitro effect of rFeIFN-w n cultured corneal epithelial cells infected with FHV-1. Concentrations of 100,000 IU/mL significantly reduced virus-induced pathology without causing cytotoxicity. Siebeck and coworkers53 also studied in vitro the impact of recombinant human IFN α -2b and rFeIFN- ω in FHV-1 using feline kidney cells. Both plaque number and size were reduced by 100,000 U/mL of both recombinant IFNs; neither product at any concentration (up to 500,000 U/mL) caused cytotoxicity. The feline product was more effective but only at higher concentrations. Ohe and coworkers53a demonstrated in vitro sensitivity to recombinant feline IFN (the IFN type was not provided but the product is produced in Japan) by 5 strains of FCV causing breakthrough disease in vaccinated cats. No well-controlled study has identified drugs useful for treatment of feline calicivirus.

Supportive therapy for respiratory disease associated with viral infections must also be directed toward the secondary bacterial infection associated with the syndrome. This includes both removing debris that might support bacterial growth at the site of infection and controlling bacterial infection and inflammation. Antimicrobial therapy is best based on an appropriately collected culture, which may be difficult. Empirical selection should target the most likely infecting organisms (e.g., fluorinated quinolones, doxycycline, azithromycin). Note that ineffectual antibacterial therapy is likely to contribute to infection by P. aeruginosa. Alternating antimicrobial therapy may reduce the development of resistance; higher doses should be used not only because penetrability is likely to be impaired but also because minimizing the advent of resistance is important. Combination therapy should be considered with acute flare-ups associated with bacteria (see Chapter 8). Because oral medication may be difficult to administer, injections and medications that can be given once daily may be preferred. Nasal decongestants may be helpful during the acute phases, but note that α -adrenergic decongestants may contribute to nasal mucosal necrosis owing to impaired blood flow. Antihistaminergic products are probably preferable; among them are newer drugs that may have better efficacy than older antihistamines if they preclude mast cell degranulation (Zyrtec [cetirizine], 2.5 mg/cat daily). However, their use should be discontinued in the presence of purulent secretions. At this point, liquefaction of secretions may be paramount to success; a dysfunctional mucociliary apparatus may contribute to infection by providing an optimal environment for microbial growth. Mucolytic drugs and mucokinetics may facilitate movement of accumulated respiratory secretions. *N*-acetylcysteine can be given by injection (125 mg), although oral administration (1/8 tsp sprinkled on food) might be helpful despite significant first-pass metabolism of the compound. Aerosolization or local installation of saline also may be helpful if lesions tend to predominate in upper airways.

The impact of glucocorticoids on viral-induced feline respiratory infections is not well studied. In general, immune suppression is discouraged because of the risk of recrudescence of latent infections. However, in one study, administration of methylprednisolone (5 mg/kg intramuscularly) did not statistically increase shedding of FHV in experimentally infected cats compared with pretreatment shedding, although the power of the study to detect a significant difference was low.⁴⁹

Feline Viral Neoplasia: Feline Leukemia Virus

FeLV is caused by an oncornavirus subfamily of retroviruses. Its pathophysiology has been well reviewed.⁵ Viral replication depends on the presence of reverse transcriptase (RNAdependent DNA polymerase). The enzyme makes a provirus (a copy of DNA) that is subsequently inserted into the host genome. The binding site of FeLV is the major envelope glycoprotein (gp70); antibodies to this envelope provide protective immunity. Malignant cells also contain the feline oncornavirus cell membrane antigen (FOCMA); high levels of FOCMA antibodies render the cat resistant to viral-induced leukemia or lymphoma. FeLV is contagious, with transmission occurring by way of the saliva after close contact between cats. Iatrogenic transmission can occur through contaminated blood or instruments that penetrate (e.g., needles). Initial infection is characterized by malaise and lymphadenopathy. Cats that mount an adequate immune response recover. FeLV spreads hematogenously to the bone marrow in cats that do not mount an immune response. Cats can become latently infected, with the virus residing undetected (by ELISA, fluorescent antibody testing, or viral culture) in the bone marrow.

Cats infected with FeLV die as a result of viral-induced neoplasia (lymphoma or leukemia), suppression of the bone marrow (anemia), or infections caused by FeLV-induced immunosuppression. Bone marrow suppression occurs because FeLV can block differentiation of erythroid progenitors. Other mechanisms may also be involved. Platelet and leukocyte abnormalities also may occur, and a panleukopenialike syndrome induced by FeLV has been described. Immunosuppression reflects disruption of T-cell function, ultimately affecting both cellular and humoral immunity. Immune complex disease has been described and can be induced experimentally with antibodies to gp70. Glomerulonephritis may be a sequela. Other disorders include those of the reproductive tract (infertility, abortions, endometritis), lymphadenopathy (most severe in submandibular lymph nodes), osteochondromas, and olfactory neuroblastomas. Diagnosis of FeLV is based on fluorescent antibody testing and ELISA. The indications and advantages for each are described elsewhere.54

Treatment of FeLV-related diseases varies with the syndrome resulting from the infection and, for most syndromes, is discussed in other chapters. Lymphoma is generally fatal in 1 to 2 months if not treated. Prognosis for complete remission is relatively good for the otherwise healthy cat.⁵⁴ Treatment focuses on combinations of chemotherapeutic drugs and, for selected cancers (e.g., nasal lymphoma), radiation therapy. Single-agent glucocorticoids are relatively ineffective and are palliative only. The most commonly used combination of chemotherapeutic agents is cyclophosphamide, vincristine, and prednisone. Other drugs that might be added to this regimen, depending on the cell type and response, include doxorubicin and, less commonly, L-asparaginase, cytosine arabinoside, and methotrexate. Antiemetics may be necessary, as might appetite stimulants (cyproheptadine, diazepam, megestrol acetate).

Treatment of the cancer component of viral diseases is addressed in Chapter 33. Bone marrow suppressive disease has been treated with repetitive blood transfusions. Prednisolone may increase the life span of erythrocytes if immune-mediated destruction is contributing to anemia, but glucocorticoids also will contribute to immune suppression. Human recombinant (and, when available, canine recombinant) growth factors may be useful for increasing bone marrow production of precursor cells despite the fact that most animals with anemia have high endogenous concentrations. Response to human recombinant erythropoietin (100 U/kg, subcutaneously 3 times weekly) requires about 3 to 4 weeks. This product should be reviewed before its use. Likewise, recombinant granulocyte colonystimulating factor may be of benefit in the treatment of leukopenias. Development of antibodies to both of these products may limit their use beyond several weeks.

No antiviral drug has been shown to clear a FeLV viremic cat. Drugs that target reverse transcriptase, such as AZT, offer the most promise for effective therapy. Zidovudine suppresses viral replication but will not eliminate the virus. Experimentally, the drug can prevent viremia when administered (60 mg/kg per day divided every 8 hours) within 96 hours of infection. Zidovudine (30 mg/kg per day) inhibited antigenemia in kittens and prolonged survival time from 35 to 102 weeks. Myelosuppression, however, occurred in 33% of the treated cats.

In another study AZT (10 to 20 mg/kg twice daily for 42 days) prevented retroviral infection in cats if administered immediately after virus exposure. Replication also may have been reduced when it was administered to previously infected animals.⁵⁵ Serum-neutralizing antibodies developed in some of the infected cats, and the cats became resistant to subsequent viral challenge. However, progression of disease was not altered in cats if treatment was withheld until day 28 after infection, although the level of viremia was much lower than in untreated cats. Zidovudine appeared to be nontoxic in uninfected cats, although 3 of 12 infected kittens became anorectic and icteric and were vomiting after 40 days of treatment. Zidovudine may be beneficial in reducing FeLV-associated diseases; one study reported improved health status and a reduction of oral lesions in cats with FeLV-associated stomatitis.

In their review of antiviral therapy in cats, Caney and coworkers⁴⁸ acknowledge the controversy regarding the efficacy of AZT for treatment of FIV and FeLV but report that positive cats with gingivitis or neurologic disorders have responded clinically to either oral or subcutaneous administration, with reversible anemia being the major side effect. Kociba and coworkers⁵⁶ studied the effect of leukocyte-derived human IFN- α on FeLV-associated erythroid aplasia but found no beneficial effects. Other drugs have been studied

for potential efficacy against FeLV. Phosphomethoxyethyl adenine (PMEA), another reverse transcriptase inhibitor, also has been studied in cats. Cats with stomatitis associated with FeLV responded better to PMEA (AZT was also given at 5 mg/kg every 12 hours), but adverse reactions to the drug are likely to limit its use. The combination of AZT with IFN (1.6×10^6) U/kg, SC, sid) or IFN by itself may reduce antigenemia, but antibody development may reverse the effect. Cogan⁵⁵ evaluated the efficacy and safety of suramin (10 to 20 mg/kg) in two FeLV-infected cats. Although toxic signs were limited to vomiting and anorexia (both resolving between treatments), viremia in both peripheral blood cells and serum did not resolve. Serum viral infectivity transiently decreased during treatment but was significantly higher 14 days after treatment was discontinued. Previous in vitro studies by the same author revealed a 90% inhibition of infectivity at drug concentrations of 100 mg/mL. Immunomodulating therapies also have been studied or reported after empiric use in cats with FeLV-related diseases. Immunomodulators may provide the most effective means of treating or controlling FeLV-related diseases.

KEY POINT 10-7 Although the efficacy of AZT for treatment of FIV and FeLV is controversial, gingivitis or neurologic disorders associated with disease may respond clinically.

A clinical case of feline epitheliotrophic T-cell lymphoma with paraneoplastic eosinophilia that failed initial therapy responded when rhINFa2b was added. Response was based on clinical, hematogenous, and sonographic evaluation. Relapse coincided with detection of antibodies directed toward the IFN.⁵⁸

Other immunomodulatory drugs have been studied for treatment of FeLV. Antibodies that target gp70 have proved useful experimentally only when given within 3 weeks of the initial infection. Immunostimulants including IFN-a, staphylococcal protein A (10 μ g/kg twice weekly for 10 weeks, then monthly), P. acnes (0.5 mL intravenously twice weekly for 2 weeks, then weekly), acemannan (2 mg/kg twice weekly), and evening primrose (550 mg daily) have been used with variable success, but no well-designed study has proved efficacy. Staphylococcal protein A has reversed viremia in a few cats, but only a small number of cats have been studied. Ultimately, combinations of therapies (e.g., antiviral drugs combined with immune modulators) may prove most beneficial. For example, response to Staphylococcals protein A (intraperitoneal) and IFN (oral) or the combination thereof was studied in a clinical trial of 36 cats with spontaneous FeLV infection (animals with tumors were excluded). No differences were found in clinical scores, clinical pathology, or survival time, although the authors reported that owners reported improved health more often in those cats treated with Staphylococcals protein A, leading the authors to recommend this form of immunomodulation in conjunction with supportive care.⁵⁹

Adoptive immunotherapy using autologous lymph node cells that have been activated and expanded ex vivo using interleukin-2 (IL-2) in short-term cultures resulted in clinical improvement within 2 to 4 weeks and lasting at least 13 months in 9 of 18 cats with FeLV; 4 of the 18 cats became antigen free.⁶⁰

Feline Immunodeficiency Virus

Pathophysiology of infection. FIV, like HIV, is caused by a lentivirus.²¹ The pathophysiology of infection with FIV has been reviewed.^{1,6} FIV continues to serve as a model for the study of human lentiviruses, and information regarding transmission, pathogenesis, host response, and immune dysfunction antiviral strategies is often shared among the two syndromes.⁶¹ As with FeLV, transmission of FIV among cats occurs by way of saliva or blood, presumably through bite wounds. Transmission also can occur in utero or through milk ingested by nursing infants. Whereas CD4 receptors on T-cells serve as receptors for HIV, CD4 is not the receptor for FIV. One group of investigators has identified CD134 (OX40) as a primary receptor.⁶² However, CD4 cells decrease early in infection, and therefore FIV causes progressive disruption of normal immune function. Viral replication begins in lymphoid tissues and salivary glands and spreads to mononuclear cells and nonlymphoid organs. Clinical signs may occur during the initial phases of viremia. The cause of the decrease is not known, but the result is an inversion of the normal CD4/CD8 ratio in infected cats. CD8 cells may increase, contributing to the inversion. Formation of immunoglobulins (dysregulation may lead to hypergammaglobulinemia in some cases) and cytokines also is disrupted. Several phases of infection have been described after infection with FIV: an acute phase, followed by a clinically asymptomatic phase that varies in duration, and a terminal phase. Other phases have been described by other investigators.

As with HIV, clinical signs of FIV are highly variable, reflecting different tissues and the role of secondary pathogens. Secondary bacterial infections reflect opportunistic microflora. Infections by fungal (e.g., Cryptococcus) and protozoal (e.g., Toxoplasma) organisms also should be anticipated. Abnormal neurologic signs are not uncommon and may reflect an inflammatory response to altered astrocyte metabolism. Changes in behavior are most commonly reported, followed by seizures, paresis, motor abnormalities, and disrupted sleep patterns. Direct damage is the most common cause of neurologic signs, although secondary infection by Toxoplasma or Cryptococcus spp. should be considered. Abnormalities in renal function and wasting disease also may reflect either abnormal function or an inflammatory response in the respective organs. Ocular diseases include anterior uveitis (caused by either FIV or opportunistic secondary organisms), glaucoma, vitreal changes, retinal degeneration, and retinal hemorrhage. Respiratory disease generally reflects secondary infection. Neoplasia is a common reason for presentation. A number of tumor types have been reported in FIV-infected cats, including lymphomas (usually B cell) and leukemias. Diagnosis is based on clinical signs and serologic testing.

Treatment. Therapy of FIV has largely focused on supportive care. Antiviral therapy thus far has been unrewarding, but newer information may provide potentially effective choices. Both AZT and PMEA have been studied; although neither drug thus far has prevented infection, onset to detectable viremia and immunologic changes can be prolonged. A trend toward normalization of inverted CD4:CD8 ratios and

clinical evidence of improvement in diseases such as stomatitis have occurred. Of the two drugs, AZT is most likely to improve the quality of life of a cat infected with FIV. In general, improvements in the cat's general condition, immune status, and quality of life can be expected, along with a longer life span. Benefits of immunomodulators in cats with FIV are not clear, and assessment of scientific studies is clouded by the additional use of antimicrobials and other drugs. Immunostimulation should be avoided, however, because of the association of enhanced immune response with enhanced production of FIV experimentally.

In human patients with AIDs, highly active antiretroviral therapy has essentially revolutionized therapy, often rendering the lethal disease into a chronic but often manageable disease. The combination therapy is designed to suppress viral replication while preserving and potentially repairing the host immune response. Combination therapy generally includes two antiretroviral drugs such as AZT or lamivudine, which target early viral replication, with an HIV-1 protease inhibitor that targets later stages of replication. Other antiretroviral drugs approved for use in humans include ddi (didanosine), ddc (zalcitabine), D4T (stavudine), 3TC (lamivudine), and most recently Ziagen (abacavir). The first protease inhibitor approved in the United States was saquinavir (late 1995); others approved since then include ritonavir, indinavir, nelfinavir, and amprenavir. This approach has proved to be effective in decreasing viral loads and improving the CD4:CD8 ratio in human patients with AIDS; mortality and morbidity of HIV infection have subsequently been reduced. However, treatment paradigms have shifted from "hit hard and early" to delaying aggressive therapy until clinical signs have progressed. Whether a similar approach should be considered for treatment of FIV is not clear, although the indications and criteria for decision making have been reviewed.⁶³ Unfortunately, although FIV, like HIV, is susceptible to nucleoside analogs, it may not be susceptible to currently prescribed HIV-1 protease inhibitors, although this may change for newer protease inhibitors.20

FIV is susceptible in vitro to a number of nucleoside analogs, including AZT, zalcitabine, didanosine, and lamivudine in vitro at concentrations similar to those necessary to inhibit HIV-1. However, identifying the proper dose will be important; for example, subinhibitory concentrations of AZT increased the (in vitro) mutation frequency of FIV in a dose-dependent manner.⁶⁴

As with patients with HIV, feline patients infected with FIV and subsequently treated with AZT show delayed onset of viremia, reduced plasma virus loads, and clinical improvement. Zivudine has been successfully used at 5 to 15 mg/kg orally every 12 hours to treat FIV-induced neurologic manifestations and 5 mg/kg subcutaneously every 12 hours to treat stomatitis, conjunctivitis, and alopecia; it improved the CD4:CD8 ratio. Quality and quantity of life also improved.¹⁸ However, Hayes and coworkers⁶⁵ studied the effect of AZT in kittens, focusing on pathophysiology of the disease at the thymus. The loss of thymic function in kittens infected with FIV appears to reflect an inflammatory process that continues even if viral burden is significantly reduced. In 8-week-old kittens experimentally infected with FIV, zidovudine monotherapy reduced viral load in peripheral blood lymphocytes, plasma, and thymus, compared with saline-controlled kittens. However, an impact on neither thymus lesions nor CD4 could be detected, and neither thymic involution nor CD4 cell decline were prevented.⁶⁵

According to Jordan and coworkers,²⁰ combination therapy with AZT and lamivudine demonstrated some clinical benefit in infected cats receiving experimental bone marrow transplants, although specifics were not provided. Using in vitro methods, AZT or lamivudine alone or in combination were somewhat effective in FIV-infected peripheral blood mononuclear cells, with the combination resulting in an additive or synergistic effect.⁶⁶ Follow-up in vivo studies were performed in specific pathogen-free cats receiving the combination before infection, at the same time as infection, or 2 weeks after infections. Doses were high (50 to 75 mg/kg every 12 hours). The authors found that the combination was helpful in preventing (five of six cats) but not treating infection. Both infection and antibody seroconversion were delayed in all treatment groups. However, adverse drug reactions (anemia and neutropenia) occurred at either treatment dose, although these resolved when the dose was dropped to 10 mg/kg twice daily.

Interferon. Using in vitro techniques, viral replication was decreased in feline cell lines infected with FIV and subsequently treated rFeINF-ω, but not rFeIFN-γ. A similar effect was found with simultaneous infection and treatment of peripheral mononuclear blood cells: replication was decreased with both rhIFN- $\alpha 2$ and rFeINF- ω , but not rFeIFN-y. Pretreating 3 days before infection did not improve efficacy of rFeIFN-y.67 The effect of subcutaneous administration of rFeIFN-v (1 million U/kg per day) for 5 consecutive days on day 0, 14, 60 was studied in 81 cats experimentally infected with FeLV or FeLV/FIV (based on ELISA) using a multicentric double-blinded placebo controlled design.68 All cats were exhibiting clinical signs associated with infection, but the study did not include cats with malignancy. The treatment group receiving IFN therapy was associated with less mortality, improvement in hematologic indicators, and improved clinical scores compared with placebo-treated cats.68 However, in another study, although well tolerated, rf-IFN α did not significantly alter CD4:CD8 ratios or proviral load in cats with experimentally induced chronic FIV infection after treatment at either a high dose at 10⁶ U/kg per day subcutaneously for 5 days or a lower dose of 10⁴ U/cat orally per day for 6 weeks.48

Pedretti and coworkers⁵⁷ reported on the administration of a low dose (10 IU/kg) of natural human IFN- α (a combination of at least 9 different α subtypes) in naturally infected cats (n = 24; six placebo-treated cats). The product was diluted in phosphate-buffered saline, fortified with bovine albumin, filtered, and administered over the gums. The product was administered using a 7-days-on, 7-days-off cycle for 6 months; after 2 months of no therapy, another round was instituted. Treatment was considered easy by practitioners and was well tolerated with no overt side effects in cats. All treated cats survived the treatment period except for one cat that was seriously ill at study start; in contrast, only one placebo-treated cat survived the initial 6-month treatment period. Fever and lymphadenopathy resolved in the treatment group by day 10 of therapy but persisted throughout the study in the placebo group. However, viremic counts (excluding two cats with outlying high counts) did not change among groups. Survivability of CD4 cells was better in treated cats, although CD8 counts slowly increased such that the balance between CD4 and CD8 cats was not maintained. White cell counts declined in placebo cats. The placebo group, but not the treatment group, was characterized by progressive liver disease and failure. The authors indicated that the favorable response probably reflected the downregulation of inflammatory cytokines realized only with low (1 to 10 IU/kg) doses and the loss of this control such that proinflammatory responses occur with higher doses.

In a study of 40 naturally infected FIV cats treated with AMD3100 (a bicyclam chemokine receptor inhibitor; 0.5 mg/kg every 12 hours, administered subcutaneously), PMEA (10 mg/kg twice a week), or a combination of the two drugs for 6 weeks, stomatitis improved with either PMEA or the combination therapy. Further, the provirus load decreased in the AMD3100group compared with other groups.^{69, 69a} However, treatment in either PMEA group was accompanied by decreased red blood cell, hemoglobin, and hematocrit counts; serum magnesium was decreased in the AMD3100 group. The authors concluded that the combination therapy was less effective than the use of the bicyclam alone. Guidelines of the ABCD recommend its use for treatment of FIV.

Bleomycin inhibits HIV viral replication apparent through oxygen-radical generation that also characterizes its anticancer effects. The use of bleomycin in combination with highly active antiretroviral therapy, particularly in those situations in which resistance has developed, has been recommended;⁷⁰ efficacy in cats infected with FIV has not yet been reported.

The efficacy of two acyclic phosphonyl adenine nucleosides, (fluoro, or FPMPA and methoxyethyl; PMEA) ameliorated clinical symptoms of FIV. Response included the incidence and severity of stomatitis, immunologic parameters such as relative and absolute CD4+ lymphocyte counts, and virologic parameters, including proviral DNA levels in peripheral blood mononuclear cells. However, of the two FPMPA was not associated with hematologic side effects, even at 2.5-fold higher dose, compared with PMEA.⁷¹

Because of its efficacy in mice, 16alpha-bromoepiandrosterone (epiBr), a synthetic derivative of the natural hormone dehydroepiandrosterone (DHEA), also has been evaluated for efficacy against experimentally induced FIV infection in cats.⁷² Two treatment regimens were studied: 5 consecutive days for weeks 0, 4, 8, and 16, or treatment 1 week before infection and continuing for 4 weeks after infection. All animals were studied for 20 weeks. For both groups, compared with control animals, CD4: CD8 T-cell ratio and total CD4 cell counts were less and CD8 cells higher from weeks 2 through 20 after infection. Although virus load was initially higher in treated cats, viremia subsequently declined to less than that of controls, and treated cats had higher FIV–p24 antibody responses.⁷²

Disinfectants, antiseptics, and biocides are expected to play an even more important role in the future in controlling microbes in both the veterinary patient and hospital.¹ When used properly, disinfectants, antiseptics, and biocides contribute to both the prevention and the treatment of disease. Despite the fact that there are as many as 300 biocidal products available, about 14 of these are in more than 90% of the registered products in the United States.² The veterinary clinician need be familiar with relatively few biocidal products to make an informed decision regarding their selection and use.

DEFINITIONS

Definitions of appropriate terms, characteristics of disinfectants and antiseptics by chemical type, factors affecting disinfection and antisepsis, and disinfection and antiseptic practices germane to veterinary practice are reviewed in this chapter (Box 11-1). It is hoped that through greater understanding of the properties of disinfectants and antiseptics, veterinary clinicians will use them appropriately.

The distinction between disinfectants and antiseptics is not always clear (Table 11-1). Antiseptics are usually the weakest and least toxic of the surface antimicrobials.³ Antiseptics may be used on intact skin or mucous membranes before a surgical procedure or in the treatment of open wounds. Regardless of their use, antiseptics should exert a sustained effect against microorganisms without causing tissue damage.⁴ Although some specific biocides may be used as both disinfectants and antiseptics (e.g., alcohols and iodines), it is not generally recommended that an antiseptic be used for the purpose of disinfection, and vice versa.

KEY POINT 11-1 Use of an antiseptic for the purpose of disinfection, and vice versa, is generally *not* recommended.

CHARACTERISTICS OF DISINFECTANTS AND ANTISEPTICS BY CHEMICAL TYPE

The characteristics of the following 10 types of disinfectants, antiseptics, and biocides are presented: alcohols, aldehyde compounds (formaldehyde and glutaraldehyde), chlorhexidine, chlorine and chlorine compounds, ethylenediaminetetraacetate (EDTA), ethylene oxide, iodine and iodine compounds, peroxygen compounds (including hydrogen peroxide), phenols (including bisphenols and halophenols), and quaternary ammonium compounds. Mechanism of action (presumed or established), classification as to level of biocidal activity, commonly available preparations, efficacy, and uses are presented for each chemical type (Figure 11-1).

Alcohols

Alcohols possess the following features desirable for a disinfectant: bactericidal action against vegetative forms, relative inexpensivness, ease of availability, and relative nontoxicity when used topically.⁵ Alcohols are used alone or in combination with phenols, chlorhexidine, iodines, and quaternary ammonium compounds.⁶ Alcohols appear to exhibit their antimicrobial effect by denaturing proteins. Lysis of some microorganisms may occur, although the bacteriostatic action of alcohols is due to the inhibition of cell metabolites. Some water is required for alcohols to be most effective. Alcohols are considered to have intermediate-level biocidal activity. Two forms of alcohol are used most commonly: ethyl alcohol and isopropyl alcohol. Ethyl alcohol has enhanced virucidal properties and reduced toxicity compared with isopropyl alcohol, which has slightly greater bactericidal action.

When used alone, alcohols are more effective antiseptics than disinfectants. Alcohols are not good cleaning agents and are not recommended in the presence of physical dirt.⁷

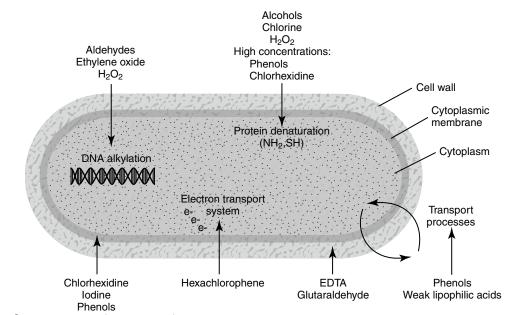

Box 11-1

Disinfection and Antisepsis Definitions

Sterilization: The act or process, physical or chemical, that destroys	Intermediate-level disinfectant: An agent that inactivates the tuber-
or eliminates all forms of life, especially microorganisms.	cle bacillus but does not necessarily kill bacterial spores. These
Disinfection: The killing of pathogenic agents by chemical or physi-	disinfectants may be used on semicritical items, which carry an
cal means directly applied. Disinfection processes differ from	intermediate risk of inducing infection in the patient.
sterilization procedures, primarily in their lack of sporicidal	Low-level disinfectant: An agent that rapidly kills vegetative forms
activity.	of bacteria and fungi but cannot be relied on within a practical
Disinfectant: An agent, usually chemical, that frees from infection	period of time to destroy bacterial endospores, tubercle bacil-
by destroying disease-producing or other harmful microorgan-	lus, or small nonlipid viruses. These disinfectants are indicated
isms. This term generally refers to substances applied to inani-	only for use on noncritical items that carry relatively little risk of
mate objects.	inducing infection in the patient.
High-level disinfectant: An agent that has effectiveness against	Antiseptic: A substance that prevents or arrests the growth or action
bacterial endospores under the proper conditions. High-	of microorganisms on living tissue either by inhibiting their
level disinfectants are to be used on critical items (items that,	activity or by destroying them.
if contaminated, impart a substantial risk of infection to the	Biocide: A chemical or physical agent, usually broad spectrum, that
patient).	inactivates microorganisms.

Biocides Most Appropriately Used as Disinfectants	Biocides Most Appropriately Used as Antiseptics	Biocides Effective as Both Disinfectants and Antiseptics	
Aldehyde compounds (formaldehyde and glutaraldehyde)	Chlorhexidine	Alcohols	
Chlorine and chlorine compounds	Dilute sodium hypochlorite solution (Dakin's solution)	Chloroxylenols	
Ethylene oxide	EDTA	Iodines	
Hydrogen peroxide	Iodophors		
Phenols			
Quaternary ammonium compounds			

Quaternary ammonium compounds

Figure 11-1 Diagram showing targets within the microbe for selected disinfectants, antiseptics, and biocides.

Alcohols are widely used for both hard-surface disinfections and skin antisepsis.⁸ In appropriate concentrations, alcohols provide the most rapid and greatest reduction in microbial counts on intact skin. Alcohols should not be used in open wounds. Alcohols should be allowed to evaporate thoroughly from the skin to be fully effective and to decrease irritation.⁷ Because of their inability to destroy bacterial spores, alcohols are not recommended for disinfection of surgical instruments.

Aldehyde Compounds (Formaldehyde and Glutaraldehyde)

Formaldehyde (3% to 8% solutions) exhibits intermediatelevel to high-level disinfection. It is sporicidal, with its mechanism of action being the ability to combine with protein, RNA, and DNA in the spore.⁹ Formaldehyde does not penetrate well, and its fumes are irritating.⁶ It is used infrequently as a disinfectant in veterinary hospitals.

Glutaraldehyde (1,5-pentanedial) has been used as a chemosterilizing agent for approximately 40 years.^{10,11} It displays potent bactericidal, fungicidal, virucidal, mycobactericidal, and sporicidal activity.¹¹⁻¹³ Glutaraldehyde acts on proteins by denaturation and on nucleic acids by alkylation.¹⁴ It is classified as an intermediate-level to high-level biocide.

Factors that influence the activity of glutaraldehyde include time of contact, temperature, concentration, pH, and the presence of soiling material.¹² Glutaraldehyde shows a very marked, temperature-dependent activity.¹² The pH affects the stability and biocidal activity of glutaraldehyde. Glutaraldehyde is more stable at acid pH, but it is more active at alkaline pH (around 8 to 8.5). As pH increases, the number of reactive sites to which glutaraldehyde binds is increased, thus enhancing its lethal effect.¹² At alkaline pH, glutaraldehyde penetrates more extensively into the spore, where it fixes the cortex.¹¹ The negative effect of organic matter is more apparent when lower concentrations of glutaraldehyde are used. Alkaline glutaraldehyde (2%) takes longer to be effective in the presence of organic matter.⁶ Glutaraldehyde has a dual role against bacterial biofilms (a characteristic of some bacteria that makes them more resistant to disinfection): an ability to penetrate the biofilm and inhibit microbial cells protected by the film and an acceleration of the detachment rate of bacteria from the biofilm.12

Disinfectants containing 2% glutaraldehyde are considered high-level disinfectants, with recommended contact times of 10 to 30 minutes. Exposure times of 6 to 10 hours frequently result in sterilization. Glutaraldehyde is used widely as a disinfectant for heat-labile equipment (e.g., endoscopes). Glutaraldehyde disinfectants are not as noxious, irritating to the skin, or corrosive as formaldehyde; however, precautions should be taken with their use. Gloves, safety goggles, and proper ventilation are recommended to minimize risks to those disinfecting the equipment, and glutaraldehydedisinfected equipment should be thoroughly rinsed with sterile water before use to reduce risk to the patient.¹¹ Stabilized glutaraldehyde solutions are safe and effective preoperative skin antiseptics for elective clean-contaminated surgical procedures in dogs.¹⁵ **KEY POINT 11-2** Under proper conditions, 2% glutaraldehyde is considered a high-level disinfectant.

Chlorhexidine

Chlorhexidine is a cationic bisbiguanide, not related to hexachlorophene, that was first synthesized in 1950.¹⁶ It is available as a solution and as a scrubbing agent. Chlorhexidine solution is used principally as a topical antiseptic on skin wounds and mucous membranes, but it is also used as a pharmaceutical preservative. Chlorhexidine scrub is used to preoperatively prepare the surgeon and patient. Chlorhexidine exhibits a broad spectrum of antibacterial activity, strong binding to the skin, ability to adsorb to negatively charged surfaces in the mouth (e.g., tooth and oral mucosa), persistence, low toxicity, and a minimal negative effect on activity by blood or other organic material.⁷ Chlorhexidine has its major antibacterial action by interference with the function of cellular membranes, with the primary site of action being the cytoplasmic membrane.^{8,13,14,16,17} Rupture of the cytoplasmic membrane of the microbe occurs without lysis of the cell wall. Chlorhexidine has low-level to intermediate-level biocidal activity.

Chlorhexidine has a very rapid bactericidal effect as well as persistence of action.¹⁴ It has limited fungicidal and virucidal properties.⁶ Chlorhexidine is more effective against grampositive than gram-negative bacteria and exhibits a bacteriostatic effect against some bacteria.^{6,7} Acquired resistance to chlorhexidine has been observed, notably in staphylococci.^{8,18} The optimum range of pH for activity of chlorhexidine is 5.5 to 7. Chlorhexidine is incompatible with anionic detergents and inorganic anionic compounds; ⁶ thus standing soap lather should be removed by rinsing before chlorhexidine solution is applied to the skin. Chlorhexidine forms a precipitate when diluted with electrolyte solutions, but this precipitate does not affect antimicrobial activity.¹⁹

Chlorhexidine is available as an alcoholic solution (scrub) that is used in the preoperative skin preparation of the surgeon and patient and as an aqueous solution. Two preparations that are used commonly in veterinary hospitals are chlorhexidine gluconate (scrub) and chlorhexidine diacetate or gluconate (solution). There are few reports of adverse reactions with chlorhexidine. Chlorhexidine scrub should be used only on intact skin, never in wounds. Negligible absorption from the alimentary tract occurs, and the incidences of skin irritation and hypersensitivity are low. Chlorhexidine is ototoxic when placed in the middle ear cavity, and its use on the brain or meninges is contraindicated. In general, chlorhexidine solution (0.05%) is an effective and well-tolerated wound antiseptic in veterinary patients.^{19,20}

KEY POINT 11-3 Chlorhexidine solution (0.05%) is generally an effective and well-tolerated wound antiseptic.

Chlorine and Chlorine Compounds

Chlorine disinfectants are readily available, inexpensive, have a broad antimicrobial spectrum, and present minimal environmental hazards.³ Mechanism of action appears to be through oxidation of peptide links and denaturation of proteins.¹⁴ Intracellular accumulation results in inhibition of essential enzyme systems.¹³ Chlorine compounds are classified as intermediate-level disinfectants. Two factors that affect the biocidal activity of chlorine are pH and the presence of organic material. The greatest influence on the antimicrobial activity of chlorine in solution appears to be pH. With decreasing pH there is increasing biocidal activity. This increased activity at lower pH is due to a higher concentration of undissociated hypochlorous acid, which has a greater bactericidal action than the dissociated form. Organic matter consumes available chlorine and reduces its antibacterial efficacy.²¹ This negative effect is particularly evident in solutions with low levels of chlorine. Small additions of iodine or bromine to chlorine solutions greatly enhance their bactericidal activity. ²¹

Sodium hypochlorite appears to be the chlorine compound most frequently used as a disinfectant in veterinary hospitals. It is an effective virucidal agent.²² Sodium hypochlorite was first introduced as an antiseptic in 1915 as Dakin's solution (0.4% available chlorine).²³ Although still used as a wound antiseptic, sodium hypochlorite is used more frequently as a disinfectant in veterinary hospitals as a 0.16% solution (1:32 dilution of 5.25% stock solution) of liquid bleach.

EDTA

EDTA, especially in combination with Tris buffer ([hydroxymethyl]aminomethane), has been shown to have antibacterial properties, particularly against certain gram-negative bacteria. Tris-EDTA acts by increasing cell wall and membrane permeability through chelation of divalent cations and by slowing degradation of ribosomes.^{13,24,25} The clinical use of Tris-EDTA has been limited largely to four major pathogens: *Pseudomonas aeruginosa, Proteus vulgaris, Escherichia coli,* and *Staphylococcus aureus.*²⁴ Tris-EDTA decreases the minimal inhibitory concentration for these bacteria when selected antimicrobials are added in vitro.²⁶ It also potentiates the antimicrobials effects of chlorhexidine diacetate in lavage solutions.²⁷

Tris-EDTA solution is inexpensive and readily available. It has been used as an irrigant in combination with antimicrobials in the treatment of otitis externa, bacterial rhinitis, and multiple fistulae in dogs.²⁴ Formulations of other biocidal agents (e.g., chloroxylenol) may contain EDTA. Such preparations have enhanced efficacy against *P. aeruginosa* organisms.²⁸

Ethylene Oxide

Recognition of the biocidal activity of ethylene oxide did not take place until more than 60 years after its discovery in the 1850s. Ethylene oxide was patented in the United States in 1936 for use as a gas-phase biocide.¹⁰ It is a high-level disinfectant when used under proper conditions. Variables that are critical to the action of ethylene oxide include prehumidification, temperature, and concentration. Ethylene oxide sterilization is used for heat-labile equipment. Ethylene oxide is an alkylating agent that exhibits its bactericidal and sporicidal activities because of its reaction with nucleic acids.^{8,29} It may be combined with either carbon dioxide or fluorocarbons. Because of its toxicity, mutagenicity, carcinogenicity, and capacity to irritate eyes and mucous membranes, ethylene oxide sterilization for heat-labile equipment is being challenged by other, safer techniques, such as plasma sterilization (see later discussion of peroxygen compounds).

Iodine and Iodine Compounds

The first reference to the use of iodine for wounds was made in 1839.^{10,30} Iodine is an excellent, prompt, effective biocide with a broad range of action. Of the seven different forms of iodine that are present in pure aqueous iodine solutions, only two play a role in the disinfection processes: molecular iodine (I₂) and hypoiodic acid (HOI). Molecular iodine has superior sporicidal and cysticidal properties compared with HOI. Iodine acts by decreasing the oxygen requirements of aerobic microorganisms.14 Iodine also interacts preferentially with thiol groups in proteins of the cytoplasmic membrane.14,30,31 Although bacterial resistance to iodine seems to be uncommon, bacterial resistance to povidone-iodine has been reported.¹⁸ Iodine has comparatively low reactivity with proteins, except blood, and pH has little effect on antimicrobial efficacy. Blood reduces the efficacy of iodine by converting it into nonbactericidal iodide.

KEY POINT 11-4 Use of iodophor in body cavities is *not* recommended.

Two main groups of iodine preparations are used clinically: preparations releasing free iodine and those containing complex-bound iodine. Preparations that release free iodine have intermediate-level biocidal activity. Preparations that release free iodine include *iodine topical solution*, an aqueous solution containing 2% iodine and 2.4% sodium iodide; *strong iodine solution (Lugol's solution)*, an aqueous solution containing 5% iodine and 2.4% sodium iodide; *inclure*, containing 2% iodine and 2.4% sodium iodide; *inclure*, containing 2% iodine and 2.4% sodium iodide; *inclure*, containing 2% iodine and 2.4% sodium iodide in aqueous ethanol (1:1); and *strong iodine tincture*, containing 7% iodine and 5% potassium iodide in 95% ethanol. Iodine tincture preparations are both more efficacious and more toxic than aqueous solutions, including iodophors.

Preparations containing complex-bound iodine have lowlevel to intermediate-level activity. Iodophors are the most commonly used preparations that contain complex-bound iodine. The iodine in iodophors is bound to a carrier of high molecular weight (e.g., polyvinylpyrrolidone). Such carriers tend to increase the solubility of iodine; provide a sustainedrelease reservoir; reduce the equilibrium concentration of free molecular iodine; improve the wetting properties of the iodine; and aid in penetration of iodine in organic soil, including fat.³⁰

The best known iodophor is povidone-iodine. Povidoneiodine compounds have a pH of about 5. The bactericidal properties of iodophors depend on the liberation of free iodine.³² The amount of free iodine in iodophor preparations depends on concentration, being greatest in a 0.07% solution of povidone-iodine.³³ Dilutions of iodophors demonstrate more rapid bactericidal action than a full-strength povidone-iodine solution.³⁴ Although in vitro studies have shown povidoneiodine to be highly effective against selective bacteria, including methicillin-resistant *S. aureus*,³⁵ in vivo studies provide conflicting data regarding efficacy.²³ LeVeen et al.³² conclude that on the basis of clinical and experimental evidence, free iodine is not liberated from povidone–iodine in therapeutic concentrations. Clinical studies indicate that povidone–iodine is suitable as an antiseptic on intact skin.³²

Iodine-containing preparations, particularly iodophors, are used frequently as antiseptics. Iodophors are available in a variety of forms, including 10% solution, 2% cleansing solution (scrub), and 2% aerosol spray. Presurgical skin disinfection of surgeon and patient, disinfection of mucous membranes, and wound disinfection are the most common uses of iodophors. Povidone–iodine also has been reviewed favorably as an oral antiseptic.³⁶ Cutaneous absorption of iodine, particularly in traumatized skin, can lead to increased serum iodine levels. Systemic iodine toxicity is also possible when iodophors are used to treat large, open wounds.²³ Also, iodophors produce adverse effects when placed in the peritoneal cavity; hence their use in the peritoneal cavity is not recommended.³²

Peroxygen Compounds

Hydrogen peroxide has historical and current application as a disinfectant and antiseptic. As a 3% solution, hydrogen peroxide has limited bactericidal effectiveness and is usually classified as an intermediate-level biocide.²³ It is an oxidizing agent and acts by denaturing proteins and lipids of microorganisms.^{14,29} Hydrogen peroxide (3%) provides an effervescent cleansing action; however, because of its cytotoxicity, hydrogen peroxide is inappropriate as an antiseptic.^{23,37} As a 58% solution, however, and in the presence of an electromagnetic field, hydrogen peroxide becomes a gas plasma. As a gas plasma, hydrogen peroxide destroys microorganisms and is classified as a high-level disinfectant. Hydrogen peroxide (58% solution) is sporicidal by virtue of its effect on the outer spore layers and the spore core.38 Because the process temperature associated with plasma sterilization does not exceed 50° C, plasma sterilization is particularly well suited to heatlabile materials that cannot be steam sterilized.³⁹ Because of its relative safety, plasma sterilization is emerging as an alternative to ethylene oxide gas in the sterilization of heat-labile articles. Other peroxygen compounds, such as peracetic acid and ozone, have limited use in veterinary medicine.

Phenols

Carbolic acid, a phenol, is the oldest example of an antiseptic compound.⁴⁰ Phenols have a wide spectrum of activity against bacteria, viruses, and fungi, but they have minimal sporicidal activity.⁶ They act on the cytoplasmic membrane, producing leakage and disrupting membrane transport.¹³ Phenols are classified as low-level to intermediate-level biocides. While used sparingly in veterinary medicine, phenolic biocides are still widely used throughout the world.⁴¹ Two classes of phenol derivatives that have potential interest are the bisphenols (e.g., triclosan and hexachlorophene) and halophenols (chloroxylenol).⁸

Triclosan, a broad-spectrum antimicrobial agent, is used as a topical antiseptic and is frequently formulated with EDTA.^{8,42} Hexachlorophene, a chlorinated phenol derivative, was used as a presurgical antiseptic primarily by surgeons, but its toxicity has limited its use.⁴³ Chloroxylenol has been used extensively as a preservative, disinfectant, and topical antiseptic.²⁸

Quaternary Ammonium Compounds

Introduced in 1916, quaternary ammonium compounds are surface-active cations that exhibit low-level biocidal activity.¹⁰ They bind irreversibly to the phospholipids and proteins of the cytoplasmic membrane of microbes, impairing permeability.^{13,14} Quaternary ammonium compounds are much more effective in preventing the growth of bacteria than in killing them, and they are far more effective against gram-positive than gram-negative bacteria.⁶ Quaternary ammonium compounds possess a narrow margin of safety and can fail when exposed to resistant microorganisms.⁴³

Quaternary ammonium compounds with a carbon chain length of 14 demonstrate the highest level of bactericidal activity.⁴⁴ They were used initially as an adjunct to surgery, such as in presurgical patient preparation, but this use has been curtailed, in part because of the observation that skin bacteria survive beneath the layer of applied quaternary ammonium compound. Additionally, quaternary ammonium compounds tend to be inactivated by lipids in organic matter, and their activity is adversely affected by soap, hard water, and gauze.⁴³ Quaternary ammonium compounds are currently used primarily for environmental disinfection of floors, walls, and equipment surfaces. Benzalkonium chloride is used as a topical antifungal agent for horses at a concentration of 0.15%.

FACTORS AFFECTING DISINFECTION AND ANTISEPSIS

A successful disinfection plan requires initial consideration of microbial susceptibility and environmental conditions.⁴⁵ Factors of importance when selecting a chemical biocide include the degree of microbial killing required; the nature and composition of the surface item or device to be treated; amount of organic matter present; number and resistance of microorganisms present; presence of microbial biofilms; and cost, safety, and ease of use of the available agents.² Critical items, which, if contaminated, impart a substantial risk of infection, must be sterilized. Noncritical items, which touch only the intact skin of the patient during routine use, can be disinfected. The greater the risk of infection associated with the use of a device, the more complete must be the degree of microbial killing on that device. The nature and composition of the device or surface to be treated affects the ease with which that device may be disinfected. Smooth, nonporous, and cleanable surfaces (e.g., table surfaces) are easiest to disinfect, whereas crevices, joints, and pores (e.g., surgical clamps) constitute barriers to the penetration of liquid biocides.²

The amount of organic material present has a major impact on the efficacy of most disinfectants. Physical cleaning before disinfection is often the most important step in the disinfection process.² Endoscopes and accessories are particularly challenging to clean properly. Organic material has an especially profound effect on the biocidal efficacy of chlorine and iodinebased disinfectants and quaternary ammonium compounds.² Negative effects of organic material are particularly profound with weak concentrations and with low-level disinfectants.

The number and resistance of microorganisms present can influence biocidal efficacy. In general, the higher the level of microbial contamination, the longer must be the exposure to the chemical biocide before the entire microbial population is killed.² Microorganisms vary widely in their resistance to chemical biocides, with bacterial spores being most resistant, then protozoal cysts, coccidial oocysts, tubercle bacilli, small nonlipid viruses, fungi, vegetative bacteria, and medium-size lipid viruses.³⁷ Differences in resistance exhibited by various vegetative bacteria are relatively minor, with staphylococci and enterococci being the more resistant gram-positive bacteria and Pseudomonas, Proteus, Klebsiella, Enterobacter, and Serratia spp. showing greater resistance than other gram-negative bacteria.^{2,8} The resistance of some bacteria, such as *Pseudomo*nas and Serratia spp., may relate in part to the production of a glycocalyx-based biofilm.8,43,46

Some bacteria (e.g., Klebsiella pneumoniae, Serratia and Pseudomonas spp.) produce biofilms.43,47,48 Biofilms are collections of bacteria in a community that form in an exopolysaccharide extracellular matrix.48 They surround bacteria and make them more resistant to disinfection. Biofilms may be encountered in medical implants, such as catheters, sutures, and orthopedic prostheses, and seem to present a barrier to penetration by disinfectants and antiseptics.^{8,25,43,46,48} Biofilms serve as nidi of contamination as well as sources of bacterial products, such as toxins.48 The reduced accessibility of the bacteria included in the biofilm appears to be the major factor in resistance development.⁴⁷ Resistance depends on the nature of the disinfectant, with greater resistance reported with selected quaternary ammonium compounds (e.g., benzalkonium chloride) and less resistance with oxidizing agents (e.g., sodium hypochlorite and hydrogen peroxide) and phenolic derivatives.⁴⁷ Intrinsic and acquired resistances to disinfectants have been observed, notably Staphylococci, Pseudomonas, and Enterobacter spp.3,8,18,46 Potential for acquired bacterial resistance is rated very low, low, and moderate for alcohols, triclosan, and chlorhexidine, respectively.⁴² Although concerns about the use of chlorhexidine, triclosan (a bisphenol), and quaternary ammonium compounds and possible bacterial resistance to them and to antimicrobials have been raised,49 antimicrobial-resistant pathogens (e.g., methicillinresistant S. aureus) did not demonstrate resistance to biocides at the currently used contact times and concentrations.³⁴

Cost may be a factor in selection of disinfectants and antiseptics. One of the major impacts on cost of a disinfection procedure is the dilution of biocide used. Although overdilution of a biocide will reduce its net cost, overdilution may also significantly reduce its biocidal potency. The manufacturer's recommendations should be followed when diluting a biocide. Selection of biocides should be based primarily on efficacy and safety, not cost. Ease of use of a biocide can affect disinfection practices. Those agents with wider safety margins are likely to be easier to use. Other causes of disinfection failure include poor disinfectant penetration or coverage, insufficient contact time, and inadequate temperature and humidity while the disinfectant is being applied.^{3,46}

DISINFECTION AND ANTISEPTIC PRACTICES

Veterinary Hospital Disinfection

Types of disinfection practices in a veterinary hospital include immersion disinfection; disinfection of surfaces, including cabinets, tables (examination, treatment, and surgery), kennels, lights, and chairs; and environmental disinfection.⁴⁰ Agents that have been used for immersion disinfection include 2% alkaline glutaraldehyde, isopropyl alcohol (thermometers), chlorhexidine diacetate, and quaternary ammonium compounds. Of these agents, only 2% alkaline glutaraldehyde is reliable. Because the disinfection of surgical instruments by immersion lacks the safety of heat-pressure sterilization, immersion disinfection is not recommended for instruments to be used during aseptic surgery.

Surface disinfection in a veterinary hospital can be particularly important in minimizing spread of disease. Thorough cleaning of the surface before disinfection is a critical step. Other factors that improve the efficacy of surface disinfection include adequately covering the surface with the disinfectant and maintaining contact for a sufficient time. Agents that are used as surface disinfectants include sodium hypochlorite and quaternary ammonium compounds. Sodium hypochlorite is used as a 0.16% solution (1:32 dilution of 5.25% solution) of liquid bleach to disinfect kennels and tables. Such a solution has been shown to be effective in neutralizing parvovirus.⁵⁰ Quaternary ammonium compounds are surfactants that have both cleansing and disinfecting properties. Despite their cleansing properties, quaternary ammonium compounds have reduced biocidal efficacy in the presence of organic material; hence cleaning of surfaces before their use is indicated. Quaternary ammonium compounds have been recommended for the routine disinfection of environmental surfaces.⁴³ Effective environmental disinfection of large-animal holding facilities using a peroxygen compound (4% peroxymonosulfate) has been described.51

Surgical Antisepsis

Surgical antisepsis is the application of antimicrobial chemicals to skin, mucosa, and wounds to reduce the risk of infection.⁵² Surgical antisepsis most commonly involves the removal or reduction of normal flora by the topical application of antimicrobial substances to the intact skin before a surgical procedure. Distinguishing between antiseptic use on intact skin and that on mucous membranes or in wounds is important. Different formulations and concentrations of antiseptics are indicated depending on their use. Preparations containing alcohol or detergents (scrubs) are to be used only on intact skin. The concentration of antiseptic used in wounds is less, in general, than that of preparations applied to intact skin.

Surgical Preparation of the Skin

The purpose of a surgical hand scrub or alcohol-based hand rub is to remove transient flora and reduce resident flora for the duration of surgery in case of glove tears.^{7,53} Regardless of the biocidal agent used, the technique of hand washing is important. The primary problem with hand hygiene is not a paucity of good products but rather the laxity of practice.⁷ Nails should be short, and artificial nails and nail polish are discouraged.⁷ Debris should be removed from under the fingernails with a nail cleaner after the hands and forearms have been washed thoroughly. The subungual area has higher microbial counts, and contamination of the hands can increase when gloves create a warm, moist environment.^{7,40} Duration of washing is important both for mechanical action and to allow antimicrobial products sufficient contact time to achieve the desired effect.⁷ Although the American College of Surgeons suggests that a surgical scrub of 120 seconds, including brushing of the nail and fingertip areas, is adequate,⁷ longer scrubs may be performed by veterinary surgeons.

Selection of an appropriate biocidal agent for surgical hand scrubbing should be made in three stages: One should determine what characteristics are desired, review and evaluate the evidence of safety and efficacy in reducing microbial counts, and consider the personnel acceptance of the product and the costs.⁷ Antiseptic treatment of the skin should not be toxic, should not cause skin reactions, and should not interfere with the normal protective function of the skin.⁵² Antiseptic agents used to prepare the skin of the surgeon or patient include alcohols, chlorhexidine, iodophors, and chloroxylenols.

Alcohols, in appropriate concentrations (60% to 90%), provide the most rapid and greatest reduction in microbial counts on skin.^{7,52} Alcohols are not good cleansing agents, and they are not recommended in the presence of physical dirt. They should be allowed to evaporate thoroughly from the skin to be fully effective and to decrease irritation.⁷ Immersion of the surgeon's hands and arms in alcohol has been shown to be an effective technique.⁷ Waterless, alcohol-based hand rinse products (rubs) effectively reduce microbial counts on skin.⁵⁴ Hand rubs have been shown to be effective within application times of 90 to 180 seconds.⁵³ Alcohol is also used on the intact skin of the veterinary patient before surgery as a defatting agent.⁵⁵

Chlorhexidine gluconate has both rapid and persistent antibacterial activity when used as a presurgical scrub. Its persistence is probably the best of any agent currently available for hand washing.⁷ The activity of chlorhexidine is not significantly affected by blood or other organic material.⁷ The incidence of skin irritation to chlorhexidine scrub seems low. Chlorhexidine scrub may be the ideal agent for surgical preparation of the skin.³³ Both 2% and 4% formulations in a detergent base are readily available.

Iodophors, particularly povidone–iodine, are used frequently in the presurgical preparation of surgeons and veterinary patients. The antimicrobial effects of iodophors are similar to those of iodine. Recommended levels of free iodine for antiseptics are 1 to 2 mg/L.⁷ Povidone–iodine scrub has been found to be equally effective as chlorhexidine gluconate scrub in reducing the number of bacteria on canine skin for up to 1 hour after application.⁵⁶ Iodophors are rapidly neutralized in the presence of organic materials such as blood.⁷ They have a propensity toward skin irritation, and cutaneous absorption can cause thyroid dysfunction. Iodophors are available as a surgical scrub (2%) and as a solution (10% and 2%). Chloroxylenols and bisphenols are synthetic phenol derivatives that have been used sparingly as a presurgical scrub of surgeons and veterinary patients. They are less effective than either chlorhexidine or iodophors in reducing skin flora, but chloroxylenols may have a lower incidence of skin irritation than iodophors.⁷ Their activity is only minimally affected by organic matter.⁷ Formulations used as a presurgical scrub include 3% chloroxylenol, 1.5% parachlorometaxylenol, and 1% to 2% triclosan.^{7,42}

Surgical Preparation of Mucous Membranes

Antisepsis of mucous membranes, particularly the oral mucosa, presents particular problems. The bacterial colonization of the oral cavity is very high, and the efficacy of oral antiseptics is affected by dilution effects as well as inactivation due to salivary proteins.³⁶ Also, an increase in antiseptic concentration is limited by local irritation and a high absorption rate with the risk of systemic intoxication.³⁶ Only a few solutions are useful as oral antiseptics: povidone–iodine, chlorhexidine, and hexetidine.³⁶ Povidone–iodine solution has been shown to reduce inflammation and the progression of periodontal disease as well as bacteremia after dental extractions.³⁶

Chlorhexidine solution is an effective agent for the prevention and treatment of oral disease.¹⁶ Its effectiveness stems from its ability to adsorb to negatively charged surfaces in the mouth, such as the tooth and mucosa. Hexetidine is used as a 0.1% solution for local infections and oral hygiene. It has been shown to have similar antimicrobial efficacy against common buccal organisms as 0.2% chlorhexidine.⁵⁷

Wound Antisepsis

When topically treating a contaminated wound with an antiseptic solution, the clinician should choose an appropriate type and concentration of antiseptic that has both antibacterial properties and minimal negative effects on wound healing. Antiseptics that appear to fulfill these criteria include chlorhexidine solution, povidone–iodine solution, and sodium hypochlorite solution (Dakin's solution). Chlorhexidine diacetate solution (0.05%) has a wide spectrum of antimicrobial activity as well as minimal deleterious effects on wound healing.⁵⁸ Its sustained residual activity seems to be an advantage in wound therapy. Dilution of the stock solution with sterile water, 0.9% sodium chloride, or lactated Ringer's solution does not adversely affect its antibacterial activity.¹⁹

Povidone–iodine solution appears to be most effective and least tissue toxic in concentrations of 0.1% to 1%.³³ Povidone–iodine concentrations greater than 0.5% are cytotoxic to the canine fibroblast in vitro.³³ Povidone–iodine should be used judiciously on large wounds because of the potential for systemic absorption of iodine.

A dilute Dakin's solution (0.005% sodium hypochlorite) has been shown to be both bactericidal and not damaging to fibroblasts.⁵⁸ Dakin's solution has been used as an effective irrigant for human wounds since World War I, and its use has persisted to the present. In vivo studies on the efficacy of Dakin's solution in canine wounds are not available.³³

Treatment Clindamycin Sulfa Plus Pyrimethamine Monensin *GIARDIA* Biology Treatment **MISCELLANEOUS DRUGS AND PROTOZOAL INFECTIONS** Drugs Miscellaneous Protozoal Infections **SUMMARY**

Protozoal infections can provide diagnostic as well as therapeutic challenges for the small animal clinician. The situations can range from the simple treatment of a young kitten with coccidiosis to the more robust challenges of chronic giardiasis in a breeding kennel. Although several of the protozoa are well characterized and relatively easy to treat, others are poorly understood and have no specific agents available for therapy. Three types of infections caused by major pathogens are presented here: common enteric coccidia, toxoplasmosis, and giardia. The pathogens are known to affect dogs and cats, and two are significant zoonotic agents.

This chapter does not include the protozoa that appear only sporadically in the veterinary literature (*Balantidium*, *Pentatrichomonas*, *Entamoeba*, *Hammondia*, *Besnoitia*, and *Sarcocystis* spp.). These organisms are not adequately documented as pathogens of dogs and cats and thus require no therapy. Also excluded are selected protozoal pathogens that are partially characterized but have no effective treatment available. Textbooks of parasitology or infectious disease should be consulted for a complete discussion of these sporadic, spurious, or untreatable pathogens.^{1,2}

Therapy of protozoal infections, which are often zoonotic, must include use of therapeutic agents along with supportive therapy and proper hygiene and husbandry to clean up the environment and prevent spread to other animals and people. No therapeutic agent, no matter how safe or effective, can be expected to treat these diseases without supportive therapy and hygiene. Table 12-1 lists the therapeutic agents discussed in the text. These drugs are discussed below as well as in specific chapters.

COMMON ENTERIC COCCIDIOSIS

Biology

The most common protozoa in small animal veterinary medicine are the coccidians, which cause a condition termed *coccidiosis*. Coccidia are very host specific. Dogs and cats are infected with several species in the genus *Isospora*. Diagnosis is readily made by conventional fecal floatation techniques using concentrated sugar or salt solutions. Careful identification of coccidia oocysts may reveal the presence of spurious coccidia from other genera, especially *Eimeria* spp., which commonly parasitize food animals, thus indicating coprophagy. Nevertheless, coccidia are ubiquitous in young dogs and cats and commonly cause disease, especially in those with suboptimal nutrition, immune status, or stress.

Coccidia are obligate intracellular parasites that depend on dispersion of fecal oocysts for transmission. This fact alone illustrates the importance of hygiene. There are four species that infect dogs (*Isospora canis, Isospora ohioensis, Isospora burrowsi,* and *Isospora neorivolta*) and two that infect cats (*Isospora felis* and *Isospora rivolta*). Although direct ingestion of the oocyst is the primary means of infection, rodents can serve as paratenic hosts if they ingest the oocyst and then are eaten by the definitive host.

Coccidia have life cycles that are more complex than other infectious agents (Figure 12-1). Each life cycle includes both sexual and asexual phases. This is important to remember because the therapeutic agents used to treat and control coccidia are primarily effective against the asexual stage of the life cycle.

KEY POINT 12-1 Hygiene must be addressed for effective resolution of coccidian infections.

Drug	Indication	Species	Dose (mg/kg)	Interval (hr)	Route	Duration (days)	Comments
Albendazole	Giardiasis	Dog	25	12	РО	2	
Allopurinol	Leishmaniasis	Dog Dog	20 15	24 24	PO PO		With meglumine antimoniate

*Clinical signs recur at lower dose; safety at higher dose not established.

§Use a 1% solution.

The oocyst is passed in the feces, and, after suitable exposure to air, heat, and moisture, the oocyst sporulates. This process may take only a few hours or a few days, depending on the species of coccidia and on the environmental conditions. During sporulation each oocyst develops into two sporocysts that contain four sporozoites each; thus each oocyst contains a total of eight infective sporozoites.

After ingestion the sporozoites are liberated from the oocyst and invade the enterocytes that line the small intestine. Once inside the enterocytes, the sporozoites turn into trophozoites, which undergo asexual fission (properly termed schizogony or merogony) to produce many daughter schizonts. After 4 days the enterocyte ruptures and releases the multiple schizonts (or meronts). This schizont stage is the place in the life cycle where therapeutic agents have a chance to break the life cycle. Because the schizonts are released from the cell only every 4 days, the therapeutic agent should be present in the gut for several multiples of this period, usually 14 to 21 days. The daughter schizonts are capable of infecting new enterocytes and repeating the cycle of fission into many daughters and rupture of the subsequent enterocytes. The number of asexual cycles has been determined for each species of coccidia; the small animal pathogens typically have

two or three asexual cycles before entering the sexual stage of the life cycle.

The schizont, produced by the last cycle of asexual fission, enters another enterocyte and develops into either a male or a female gametocyte. The female gametocyte enlarges and forms a singular large cellular structure within the enterocyte. The male gametocyte undergoes fission to produce many small biflagellate male sex cells. The enterocytes rupture, and the motile male sex cells fertilize the female gametocytes, which mature to a zygote and then pass out in the feces in the form of an oocyst. The fresh oocysts are exposed to the external environment, where they sporulate and infect new hosts.

The repeated intracellular invasion of enterocytes and subsequent rupture can produce substantial pathology to the gut, especially if the infected host is young, weak, malnourished, or stressed. Normal animals, in otherwise good health, usually experience coccidial infection followed by an effective immune response that limits and eliminates the infection without therapeutic intervention. Most clinicians prefer to intervene when coccidia are identified in a fecal floatation. Therapy is usually successful in eliminating the coccidial oocysts, although it is not known how many of these animals

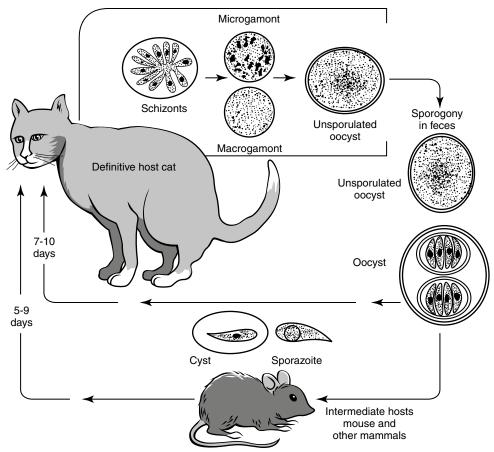

Figure 12-1 Life cycle of *Isospora felis,* which is typical of the *Isospora* spp. The mode of transmission may be direct, via ingestion of sporulated oocysts from the environment, or indirect, via ingestion of cysts in prey animals. Sexual and asexual reproduction of the parasite occurs in the intestines of the definitive host (in this case, a cat), and unsporulated oocysts are shed in the feces of definitive hosts. (From Dubey JP, Greene CE: Enteric coccidiosis. In Greene CE, editor: *Infectious diseases of the dog and cat,* ed 2, Philadelphia, 1998, Saunders, p. 511.)

would have spontaneously cleared the infection without intervention.

Treatment

Sulfas and Potentiated Sulfas

Use of sulfonamides is the treatment of choice for small animal coccidia as well as a number of other protozoal organisms. Unfortunately there is a paucity of research information to support their efficacy. Two pivotal studies on sulfamethoxine and sulfaguanidine against coccidia support their utility; however, these two agents are no longer available in the United States.^{3,4} Clinicians have empirically substituted more readily available sulfonamides and enjoyed apparent clinical success.⁵ Currently there is one simple sulfa and three potentiated sulfas that are commonly used in the United States: sulfadimethoxine (Albon), sulfadimethoxine with ormetoprim (Primor), sulfadiazine with trimethoprim (Di-Trim, Tribrissen), and sulfamethoxazole with trimethoprim (Bactrim, Septra).

KEY POINT 12-2 Use of sulfonamides is the treatment of choice for small animal coccidians.

Sulfonamide Chemistry and Mechanism of Action

The sulfonamides are discussed in more depth in Chapter 7. Each is a structural analog of para-aminobenzoic acid that competitively inhibits the dihydropterate synthetase step in the synthesis of folic acid, which is required for synthesis of RNA and DNA. Inhibition by sulfas impairs protein synthesis, metabolism, and growth of the pathogen. A vast array of sulfa agents have been created and described; all but a few have been lost in the sands of time. The important differences among these agents involve their solubility, duration of action, and activity against key pathogens. Fortunately, the three sulfas included in this discussion demonstrate acceptable performance in all three categories; solubility is adequate, they are given once or twice daily, and they have a reasonably broad spectrum of action. The sulfa drugs are primarily effective against the schizont stages of coccidian; thus prolonged treatment may be required for the drug to effectively block the life cycle.

Potentiator Chemistry and Mechanism of Action

The diaminopyrimidine potentiators (trimethoprim and ormetoprim) act in concert with sulfonamides by blocking the next step (dihydrofolate reductase) in folic acid synthesis. Chemically the diaminopyrimidines are related to pyrimethamine, which has antimalarial properties. The agents are highly selective inhibitors of dihydrofolate reductase. This sequential blockade produces significant potentiation of activity. It is a classic case of drug potentiation.

Drug Disposition

The sulfonamides are weak acids that are well absorbed from the gastrointestinal tract and are widely distributed in the body. Sulfadimethoxine and sulfamethoxazole have high serum protein binding, which provides decreased body clearance and long half-lives. They undergo metabolic alteration in the liver and subsequent renal clearance. Trimethoprim and ormetoprim are also well absorbed from the gut, widely distributed, and then hydroxylated and excreted through the urinary tract.

Toxicity and Adverse Effects

The long history of sulfa use in veterinary medicine has resulted in a wide array of toxic and idiosyncratic reactions in animals. Historically, the most common and most avoidable reactions result from crystallization in the urinary tract with secondary crystalluria, hematuria, and urinary obstruction. Recent reviews in human medicine indicate that the improved solubility of the modern preparations has decreased the risk of crystalluria; nevertheless, it is still prudent to ensure adequate water intake and proper hydration during sulfa therapy.⁶ The human-medicine literature also suggests that the sulfon-amides may be directly nephrotoxic.⁶ Hematopoietic disorders (thrombocytopenia and leukopenia) have also been reported as a result of sulfa therapy. Sulfaquinoxaline especially has been associated with hypothrombinemia, hemorrhage, and death in puppies receiving therapy for coccidia.⁷

Idiosyncratic reactions in animals and people often include immune-mediated phenomena such as hypersensitivity reactions, drug fever, urticaria, nonseptic polyarthritis, focal retinitis, and hepatitis. Fortunately, these reactions occur at very low rates when the drugs are used at recommended dose rates and for less than 2 weeks.

Preparations

There are four sulfa products that are currently available for use in small animal medicine: sulfadimethoxine, sulfadimethoxine with ormetoprim, sulfadiazine with trimethoprim, and sulfamethoxazole with trimethoprim. Each is available in a variety of formulations.

Sulfadimethoxine

Sulfadimethoxine is a rapidly absorbed, long-acting sulfonamide. It is not acetylated in the dog and is excreted unchanged in the urine. It is approved for treatment of coccidiosis in dogs and cats. It has a wide margin of safety; dogs given multiple oral doses of 160 mg/kg by mouth daily for 13 weeks showed no signs of toxicity.⁸

It is important that all treated animals receive adequate water intake to prevent dehydration and crystalluria, as well as proper nutrition, during therapy for coccidiosis. Therapy is available as a 40% injection (Albon); in 125-, 250-, and 500-mg tablets (Albon); as a pleasant-tasting 5% suspension (Albon); and as a 12.5% oral solution (Albon, Di-Methox). The approved therapy is an initial dose of 55 mg/kg, orally or by subcutaneous or intravenous injection, for the first day and subsequent doses of 27.5 mg/kg orally once daily for 12 to 21 days. It seems reasonable that, because coccidia are enteric pathogens, the oral route would be most effective.

Sulfadimethoxine with Ormetoprim

Sulfadimethoxine with ormetoprim is the most recently approved potentiated sulfonamide. It constitutes a rational combination that potentiates the action of both drugs by blocking two sequential steps in the synthesis of folic acid. Ormetoprim is a diaminopyrimidine potentiator with very low mammalian toxicity. The available tablets contain 100/20, 200/40, 500/100, or 1000/200 mg sulfadimethoxine/mg ormetoprim, respectively (Primor). The tablets are designated by the total weight of active ingredient in each tablet; thus Primor 120 contains 100 mg of sulfadimethoxine and 20 mg of ormetoprim. The approved starting dose is 55 mg/kg orally on the first day of treatment and then 27.5 mg/kg orally once per day for 14 to 21 days. Treatment should not extend beyond 21 days.⁸

It is interesting to note that the only recent controlled study of coccidiosis therapy for dogs was conducted with this drug combination. In that study, 32.5 mg/kg or 66 mg/kg was given continuously in the food for 23 days, subsequent to experimental oocyst infection. The higher dose of 66 mg/kg provided better results and did not produce any adverse reactions.⁹

Sulfadiazine or Sulfamethoxazole with Trimethoprim

Sulfadiazine with trimethoprim is the potentiated sulfa with the most years of actual use in veterinary medicine. For many years it was the only potentiated sulfa approved for use in animals. Trimethoprim is a diaminopyrimidine potentiator with very low mammalian toxicity. The available tablets contain 25/5, 100/20, 400/80, or 800/160 mg sulfadiazine/mg trimethoprim, respectively (Tribrissen, Di-Trim). The tablets are designated by the total weight of active ingredient in each tablet; thus Tribrissen 30 contains 25 mg sulfadiazine and 5 mg trimethoprim. The approved dose is 30 mg/kg orally or 26.4 mg/kg by subcutaneous injection daily for up to 14 days. The preferred dose for bacterial infections in dogs and cats is 30 mg/kg once or twice daily and may be indicated for severe coccidial infections. The manufacturer recommends that animals with marked hepatic parenchymal damage, blood dyscrasias, or previous sulfonamide sensitivity should not be given this product.8,10

Sulfamethoxazole with trimethoprim is a readily available product approved for use in people (Bactrim, Septra); it is not currently approved for use in animals. Because of its similarity to veterinary potentiated sulfonamides and because low-cost generics are available, it is widely used in veterinary medicine. There is some controversy regarding the appropriate dosing regimen for this human-labeled product in animals, but many clinicians gain acceptable clinical results using the same dose as sulfadiazine. Sulfamethoxazole with trimethoprim is available in a fixed combination of 5:1 sulfamethoxazole to trimethoprim as tablets and pediatric suspension. The available single-strength tablets contain 400/80 mg and double-strength tablets contain 800/160 mg trimethoprim, respectively (Bactrim, Septra). The pediatric oral suspension contains 40 mg sulfamethoxazole and 8 mg trimethoprim per milliliter. The dose for bacterial infections and coccidiosis in dogs and cats is 30 mg/kg once daily for 10 days¹⁰ and may be indicated in severe coccidial infections.

Amprolium

Amprolium (Amprol, Corid) is an antiprotozoal drug that is a structural analog of thiamine. It is freely soluble in water, methanol, and ethanol. The close structural similarity between amprolium and thiamine allows amprolium to compete with thiamine for absorption into the parasite. It is most effective against the first-generation schizont stage and thus is more effective for prevention than treatment.

At very high doses, amprolium may produce thiamine deficiency in the host. Thiamine deficiency can be treated by adding thiamine to the diet, although excessive thiamine supplementation may decrease the efficacy against the pathogen. In dogs adverse reactions are apparently rare and may consist of neurologic abnormalities, depression, anorexia, and diarrhea.¹⁰

Amprolium is approved for use in the drinking water or feed of poultry and cattle for the prevention and treatment of coccidia. Treatment for dogs and cats requires adapting the approved formulations to small animal use. The target dose for treatment of dogs is 100 to 200 mg/kg by mouth daily in food or water.¹⁰ Dogs may be treated by mixing 30 mL (2 Tbs) of 9.6% amprolium solution to 1 U.S. gallon (3.8 L) of drinking water and offering it as the sole source of drinking water.¹¹ Alternatively, 1.25 g of 20% amprolium powder can be mixed with daily ration sufficient for four puppies.¹² Amprolium should be provided in either the food or the water but not in both for a period of 7 days. It may be given as a treatment for coccidia or as a preventive measure for 7 days before puppies are shipped or to bitches just before whelping.

Cats may be treated at a dose of 60 to 100 mg/kg by mouth once daily for 7 days, which may be accomplished by direct oral administration.¹³ Placement of medication in food or water may be more unreliable for cats than for dogs owing to the finicky eating habits of many cats.

Furazolidone

Although the nitrofurans (nitrofurazone and furazolidone) have been reported in the literature as being effective in the treatment of coccidiosis and were once widely available for oral treatment of food animals, they have been systematically eliminated from the veterinary marketplace in the United States because of concerns regarding carcinogenicity. Furazolidone apparently inhibits numerous microbial enzyme systems, especially those related to carbohydrate metabolism, but the actual mechanism of action remains to be determined.¹⁴ Furazolidone is still available in a dosage form that is approved

for human use (Furoxone). Potential toxicity includes gastrointestinal disturbance, peripheral neuritis, decreased spermatogenesis, and weight gain.¹⁵ Dogs and cats can be treated with 8 to 20 mg/kg orally, 1 to 2 times daily, for 5 days.^{10,13} The product is available in 2 formulations approved for use in people (Furoxone): 100-mg tablets and an oral liquid containing 3.34 mg/mL.

Quinacrine

Quinacrine has demonstrated useful activity in the treatment of coccidiosis. Efficacy is variable, as is the relationship between plasma and tissue concentrations. Commercial production in the United States. (Atabrine) was discontinued in 1993.

TOXOPLASMOSIS

Biology

Toxoplasmosis is caused by *Toxoplasma gondii*, an obligate intracellular coccidian parasite. The parasite and the disease occur worldwide and have serious zoonotic impact. The domestic cat and other cats serve as the definitive hosts of this parasite. All other warm-blooded animals serve as intermediate hosts. In the United States, infection rates range from 0% to 100% in cats, 30% in dogs, and 30% to 60% in people. Although infection and seroconversion are common, clinical disease and diagnosis are rare.¹⁶

Enteroepithelial Life Cycle

The enteroepithelial life cycle of *T. gondii* in cats is similar to the life cycle of the common enteric coccidia (Figure 12-2). *Toxoplasma* oocysts are ingested from the environment; alternatively, tissue cysts may be ingested by carnivorism. Once ingested, bradyzooites are released that penetrate the epithelial cells and begin a cycle of asexual reproduction. The sexual stage of the cycle proceeds when the zooites differentiate into microgametes and macrogametes. The macrogametes are fertilized by the microgamete, and the resulting union produces an oocyst that is shed in the feces to begin the cycle again. It is believed that the enteroepithelial life cycle and the resulting oocysts occur only in cats; therefore only cats shed infective oocysts.

Extraintestinal Life Cycle

The extraintestinal life cycle occurs in all warm-blooded animals, including cats. This cycle begins when oocysts or infected tissues are ingested. The bradyzoites or sporozoites penetrate intestinal cells and undergo asexual reproduction and then break out of the gastrointestinal tract to infect virtually all other tissues, including the brain, striated muscle, and liver. After entering these extraintestinal tissues, they penetrate the cell and multiply until the cell is destroyed. The tachyzoites are released to infect other cells, and the cycle repeats. Eventually, the tachyzoites form tissue cysts that remain viable and infective for the life of the animal. These tissue cysts are infective to all warm-blooded animals and infect all animals who ingest the infected tissues. It is the ubiquitous tissue migration and replication across innumerable species that makes the pathogen so insidious and dangerous.

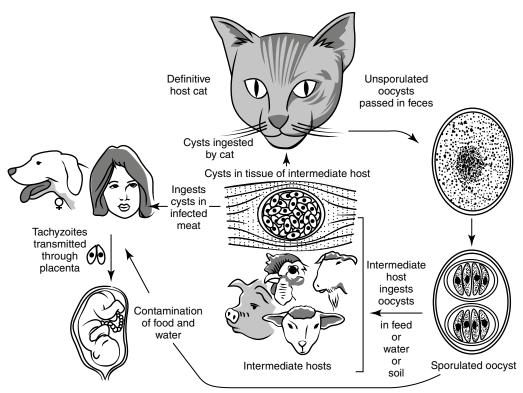

Figure 12-2 Life cycle of *Toxoplasma gondii*. (From Dubey JP, Lappin MR: Toxoplasmosis and neosporosis. In Greene CE, editor: *Infectious diseases of the dog and cat,* ed 2, Philadelphia, 1998, Saunders, p. 494.)

Congenital Transmission

If the host is infected during pregnancy, then the tachyzoites move across the placenta to infect the developing fetus. Infection during the first half of the pregnancy leads to more severe disease in the fetus. Women infected during pregnancy risk congenital malformation, mental retardation, and death of the unborn fetus. Women should be cautioned to avoid exposure to cat feces and to refrain from consuming undercooked meat during pregnancy.

Clinical Signs

Clinical signs in cats are most severe in prenatally infected kittens. Such kittens may be stillborn or die before weaning. Clinical signs relate to pathology in the liver, lungs, and central nervous system. Adult cats typically demonstrate anorexia, lethargy, dyspnea, weight loss, icterus, vomiting, diarrhea, stiff gait, shifting leg lameness, or neurologic deficits. Ocular lesions may include uveitis in the anterior and posterior chambers, iritis, iridocyclitis, and detached retina. In severe cases respiratory or central nervous system involvement may cause death.¹⁷

Infected dogs may show clinical signs related to respiratory, neuromuscular, or gastrointestinal pathology. Generalized toxoplasmosis is characterized by fever, tonsillitis, dyspnea, diarrhea, and vomiting.¹⁷ More devastating clinical signs may be seen in dogs with neurologic or muscular involvement. Seizures, neurologic deficits, tremors, ataxia, paresis, or paralysis may be seen in these animals. Ocular lesions in dogs are infrequently reported.¹⁷

Diagnosis

Antemortem diagnosis of toxoplasmosis is a significant diagnostic challenge primarily because of the usual lack of clinical signs in infected animals. Fecal floatation for infected cats may reveal small oocysts that are indistinguishable from other coccidia. It is also important to realize that infected cats shed oocysts for only 1 to 2 weeks after their first exposure, thereafter forming a protective immunity that prevents further shedding of oocysts. Many other tools have been applied to the diagnosis of toxoplasmosis, including clinical chemistry, which may reveal elevated liver enzymes; cytology, which may detect tachyzoites; radiology, which could suggest inflammation of target organs; serology, which would reveal a past infection; and parasite isolation. Unfortunately, no simple, specific, and timely diagnostic tool is available to detect an active case of toxoplasmosis.

Treatment

Treatment of toxoplasmosis may have several goals: to prevent shedding of oocysts from infected cats, to prevent transmission of toxoplasmosis by ingestion of infected tissues, to prevent tachyzoite replication in nonfeline host tissues, and to prevent prenatal infections. In some cases the goal may be to alleviate clinical signs of an active infection.

Clindamycin

Clindamycin is currently considered the drug of choice for treating toxoplasmosis. Structurally, clindamycin is a congener of lincomycin. Clindamycin is well absorbed (90%) after oral administration and is widely distributed in most tissues, except the central nervous system. It readily crosses the placenta and is extensively bound to plasma proteins. The drug is metabolized in the liver and excreted primarily in the urine and bile.¹⁸ Gastrointestinal upset is sometimes reported in animals receiving clindamycin. Severe, even fatal, pseudo-membranous enterocolitis has been reported in people, caused by overgrowth of *Clostridium difficile*.

KEY POINT 12-3 Clindamycin is currently considered the drug of choice for treating toxoplasmosis.

Treatment of systemic *Toxoplasma* infection in dogs can be accomplished with oral or intramuscular clindamycin at 10 to 20 mg/kg twice daily for 2 weeks.^{17,19} Cats can be treated for systemic infections with oral or parenteral clindamycin at 10 to 12.5 mg/kg twice daily for 2 to 4 weeks; this antimicrobial is also useful to control shedding of oocysts.²⁰ The drug should be given with caution to cats with pulmonic toxoplasmosis; parenteral administration to experimentally infected cats resulted in several deaths.¹⁰

Clindamycin is available in two veterinary formulations (Antirobe): capsules containing 25, 75, or 150 mg and an oral solution containing 25 mg/mL. Similar clindamycin formulations are available for use in humans (Cleocin): 75- and 150-mg oral capsules, an oral pediatric suspension (15 mg/mL), and an injectable solution containing 150 mg/mL.

Sulfa Plus Pyrimethamine

The more time-tested therapeutic regimen for toxoplasmosis is a combination of sulfonamide and pyrimethamine. The sulfonamides were discussed previously. Pyrimethamine is structurally and pharmacologically similar to the folic acid antagonist trimethoprim. Pyrimethamine is primarily used in veterinary medicine to treat toxoplasmosis and equine protozoal myelitis, or "equine toxoplasmosis." Little pharmacokinetic data are available for pyrimethamine use in dogs and cats, but in humans it is well absorbed after oral administration. It is well distributed to the kidneys, liver, spleen, and lungs. The metabolic pathway is unclear, but pyrimethamine metabolites may be found in the urine.

Pyrimethamine can cause anorexia, malaise, vomiting, depression, and myelosuppression. Concomitant oral administration of folinic acid or brewer's yeast may help alleviate some of these clinical signs. Because toxicity may develop rapidly in cats, they should have frequent hematologic monitoring. It is a teratogen in rats but is sometimes used by pregnant women.¹⁰

Dogs and cats are treated for systemic *Toxoplasma* infections at a dose of 30 mg/kg sulfa and 0.25 to 0.5 mg/kg pyrimethamine orally twice daily for 2 weeks. Cats may be treated to control shedding of oocysts at a dose of 100 mg/kg sulfa and 2 mg/kg pyrimethamine orally once daily for 1 to 2 weeks.¹⁷

Pyrimethamine alone is available in 25-mg tablets (Daraprim) and in combination tablets containing 25 mg pyrimethamine and 500 mg sulfadoxine (Fansidar). These dosage forms are likely to be difficult for most cat owners to administer.

Monensin

Monensin is an ionophore coccidiostat that is fed to poultry and cattle to enhance feed efficiency. It forms ionic complexes that move across biological membranes. The net effect is disturbance of mitochondrial function, which inhibits growth of the pathogen. It is not well absorbed from the gastrointestinal tract, and thus oral administration provides effective concentrations only in the gastrointestinal tract. It can be toxic if high doses are given. Shedding of *Toxoplasma* oocysts may be controlled in cats by mixing monensin in the feed at 0.2% on a dry matter basis and feeding for 1 to 2 weeks.¹⁷ Monensin is available in several feed-additive formulations designed for incorporation into a finished feed. Formulating such feeds for cats is beyond the capabilities of most cat owners.

Toxoplasmosis is the most common infection of the central nervous system in human patients with acquired immunedeficiency syndrome, resulting in a number of studies in human patients regarding efficacy. Standard regimens include combinations of pyrimethamine with either sulfadiazine or clindamycin, although side effects limit use. A potentially less toxic combination includes atovaquone suspension (approximately 20 mg/kg every 12 hours) and either pyrimethamine (1 mg/kg once daily after a loading dose of approximately 3 mg/ kg) or sulfadiazine (20 mg/kg every 6 hours). In one study up to 82% of patients receiving atovaquone as part of combination therapy responded therapeutically, with 28% discontinuing therapy as a result of gastrointestinal adverse events (including taste of atovaquone). The combination of atovaquone and pyrimethamine was recommended as the first-choice combination, with sulfadiazine substituting for pyrimethamine in patients unable to tolerate the former.²¹

GIARDIA

Biology

Giardia (Giardia duodenalis = Giardia lamblia) are protozoan parasites that are motile by means of flagella. They exist extracellularly in the lumen of the gastrointestinal tract. They are ubiquitous pathogens that can inhabit and cause disease in most mammals and are well-known pathogens in dogs, cats, and people. Recent surveys show that 36% of puppies in the United States are infected with *Giardia*.²² Despite this prevalence, the condition in pet animals remains underdiagnosed on account of inappropriate fecal examination techniques. It is a pathogen with zoonotic potential, insofar as *Giardia* frequently causes disease in people, but there is some uncertainty as to whether the same species and strains infect people and pets. More extensive information about this issue can be found elsewhere.^{1,23-26}

The life cycle of *Giardia* is direct and simple (Figure 12-3). The cyst of the *Giardia* is passed in the feces. It is nonmotile and protected by a distinct wall. Although very susceptible to drying, the cysts can survive for weeks or months in cool water. Infections are often traced back to contaminated drinking water. Once ingested, the cysts break open and trophozoites are released into the small intestine. The trophozoites are flattened on one side with a ventral sucking disk that attaches

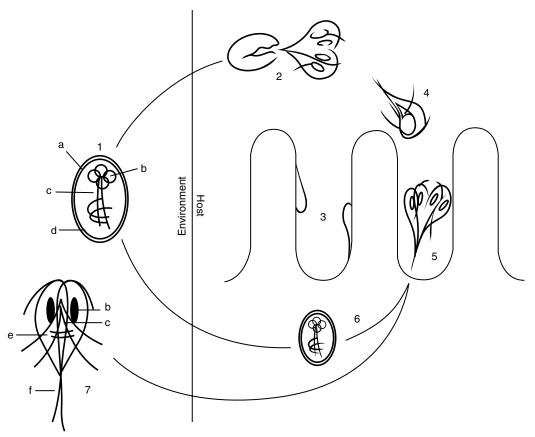

Figure 12-3 Schematic representation of *Giardia* life cycle and structural features of *Giardia* cysts and trophozoites visible by light microscopy. Infection begins when a cyst (1) is ingested by the host. Excystation (2) in the upper small intestine results in the release of an incompletely divided pair of trophozoites. Trophozoites attach to villous epithelial surfaces (3) or swim freely (4) in the lumen of the small intestine, where asexual division of trophozoites (5) also takes place. Encystment (6) of trophozoites, probably in the lower ileum or in the colon, results in the passage of infective cysts in the feces. Trophozoites (7) may also be passed into the environment, but they die quickly. Key to organelles: *a*, cyst wall; *b*, nuclei; *c*, axonemes; *d*, adhesive-disk fragments; *e*, median bodies; and *f*, flagella. (From Kirkpatrick CE: Giardiasis. *Vet Clin North Am Small Anim Pract* 17: 1377, 1987.)

to the brush border surface of the villous epithelium. The trophozoites obtain their nutrients by way of the host cell membrane. The flagella provide locomotion from one attachment site to another. The trophozoites reproduce by binary fission. After several divisions the trophozoites encyst and are shed in the feces; they are immediately infective.

Conventional fecal floatation techniques make identification of the parasite difficult because concentrated salt floatation media distort the trophozoites. Preferred methods of diagnosis include microscopic examination of saline smears, which readily show the motile trophozoites. Alternatively, a zinc sulfate centrifugal method may be used to concentrate the giardial cysts and improve sensitivity.¹ Improved techniques for evaluation of duodenal aspirates and fecal enzyme-linked immunosorbent assay (ELISA) testing have recently become available.

Treatment

Albendazole

Albendazole is a broad-spectrum benzimidazole commonly used for treatment of nematode and trematode infections in large animals. Early evidence suggested that albendazole is 100% effective in treating giardiasis in dogs.²⁷ The dose given in that study was 25 mg/kg orally twice a day for four doses. Albendazole is available in an oral suspension (Valbazen) containing 113.6 mg/mL.

Albendazole, like other benzimidazoles, is well absorbed (about 50% bioavailable) and converted in the liver to its active metabolites, albendazole sulfoxide and albendazole sulfone. These active metabolites are thought to bind to tubulin molecules, which prohibits the formation of microtubules and disrupts cell division. There is also evidence that benzimidazoles can inhibit fumarate reductase, which blocks mitochondrial function, thus depriving the parasite of energy and resulting in death. The parent drug and its metabolites are excreted primarily in the urine.

Albendazole has been shown to be teratogenic, thus limiting its use in pregnant animals. Dogs treated with 50 mg/kg twice daily may develop anorexia, and cats treated with 100 mg/kg per day for 14 to 21 days showed weight loss, neutropenia, and mental dullness.¹⁰ More recently, the drug was shown to be toxic to dogs and cats in clinical use.^{28,29} Reported toxicities include myelosuppression (anemia, leukopenia, and thrombocytopenia), abortion, teratogenicity, anorexia, depression, ataxia, vomiting, and diarrhea. Veterinarians are advised to use due caution with this product in dogs.

Fenbendazole

Fenbendazole is currently approved by the U.S. Food and Drug Administration (FDA) for removal of gastrointestinal helminthes in dogs. Recently, it has shown excellent activity against *Giardia*.^{28,30,31} The approved dose and the effective dose against *Giardia* is 50 mg/kg orally once daily for 3 days. Treatment of giardiasis is not an approved use for this product.

The drug is well tolerated and has a good safety profile. The only reported adverse effects are vomiting and diarrhea. This time-tested anthelmintic should enjoy more widespread use in the treatment of *Giardia* in dogs. Fenbendazole (50 mg/kg orally once daily for 5 days) was variably effective in treating cats concurrently infected with *Giardia* and *Cryptosporidium parvum*.³² Although the number of oocysts decreased the first week after treatment (compared with controls), no difference was detected the second week (the power of the study was not addressed). Only 50% (4 of 8) of cats treated with fenbendazole were negative 3 weeks after treatment.

Furazolidone

There is a report of successful treatment of giardiasis in cats with furazolidone.³³ As noted previously, furazolidone was once widely available for oral treatment of food animals. Presently, the nitrofurans have been systematically eliminated from the veterinary marketplace in the United States because of concerns regarding carcinogenicity. Furazolidone is still available in a dosage form that is approved for human use (Furoxone). Toxicity includes gastrointestinal disturbance, peripheral neuritis, decreased spermatogenesis, and weight gain.¹⁵ Cats can be treated with a dose of 4 mg/kg twice daily for 7 to 10 days.^{26,34} The product is available in two formulations approved for use by people (Furoxone): 100-mg tablets and an oral liquid containing 3.33 mg/mL.

Metronidazole

The nitroimidazoles represent a very useful class of drugs that have broad-spectrum activity against trichomonads, amebas, *Giardia*, as well as anaerobic cocci and *Bacillus* spp. The prototypical nitroimidazole is metronidazole, which has become the drug of choice for treatment of *Giardia*. Other drugs in the class (ipronidazole, tinidazole, nimorazole, ornidazole, and benznidazole) have been used to control *Giardia*, although none of these is currently available in the United States. None of the nitroimidazole drugs is approved for use in animals. The FDA strongly warns against their use in food-producing animals because this class of drug has been shown to produce tumors in laboratory rodents.

KEY POINT 12-4 Metronidazole has become the drug of choice for treatment of *Giardia*.

Metronidazole (Flagyl) is well absorbed from the gastrointestinal tract. It has very low protein binding and is well

distributed in the body. After entering the target cell, it interacts with the protozoal DNA, where it causes a loss of helical structure and strand breakage.12 The liver extensively metabolizes the drug, and in humans hepatic transformation is responsible for 50% of the elimination. Patients receiving cimetidine or phenobarbital may require adjustment in the dosage because of drug interaction. Metronidazole toxicity may be seen with high doses. Neurologic toxicity includes ataxia, nystagmus, seizures, tremors, and weakness.^{12,35} Numerous studies have demonstrated that metronidazole is an effective treatment for giardiasis,³⁶⁻⁴⁰ although efficacy is rarely 100%. Dogs may be treated orally with 12.5 to 32.5 mg/kg twice daily; therapy should be continued for 8 days. Cats may be treated orally with 17.4 mg/kg once daily for 8 days.¹² The commercially available product (Flagyl) is formulated in 250- and 500-mg tablets. Parenteral formulations are also available, but their usefulness is questionable insofar as the giardial trophozoites remain in the lumen of the gastrointestinal tract. Efficacy of metronidazole benzoate (25 mg/kg orally twice daily) for treatment of giardia was studied prospectively in experimentally infecting cats that had been vaccinated for giardiasis (n = 16) and cats that had not been vaccinated (n = 16). All cats had been shedding giardia for 3 months and were confirmed positive 1 week before treatment. All cats were negative by the 15-day posttreatment period.

Quinacrine

Quinacrine has also been shown to be useful in treating giardiasis in dogs and cats.⁴⁰ Unfortunately, commercial production of the product (Atabrine) was discontinued in 1993.

MISCELLANEOUS DRUGS AND PROTOZOAL INFECTIONS

Drugs

Folate Antagonists

Folate antagonists used to treat protozoal disease are categorized as type 1 or type 2. Type 1 antagonists include the sulfonamides and sulfones, which mimic para-aminobenzoic acid, thus targeting dihydropteroate synthase. Type 2 antifolates include the diaminopyrimidines, such as pyrimethamine, biguanidines, the triazine metabolites (discussed later), and quinazolines. These drugs target dihydrofolate reductase, preventing the formation of tetrahydrofolate, a cofactor necessary for the biosynthesis of thymidylate, purine nucleotides, and selected amino acids.⁴¹ Type 1 folate antagonists are discussed in greater depth in Chapter 7. Pyrimethamine is characterized by an 80- to 90-hour half-life in humans. Although not a firstline antimalarial drug, it, along with a sulfonamide (sulfadiazine), is the first choice for treatment of toxoplasmosis. Other drugs with which it is given include clindamycin and the macrolides; the drug also has been administered with dapsone, but this may increase the risk of agranulocytosis. The drug is relatively well tolerated in humans.

Dapsone also is a folate antagonist, (similar to paraaminobenzoic acid, it should be considered a type 1 folate antagonist) shown to be useful against *Pneumocystis carinii*.⁴² Synergy has been demonstrated toward some organisms when dapsone is combined with pyrimethamine and trimethoprim; efficacy was greater compared with sulfonamide combinations toward selected organisms.

Atovaquone

Atovaquone is a hydroxymapthoquinone used for the treatment and prevention of selected protozoal disease in humans, including malaria. It is available as either the sole drug, or in combination with proguanil. Proguanil is a biguanide prodrug that must be converted to the triazine metabolite, cycloguanil. The combined drug minimizes the risk of resistance. Synergy also has been demonstrated with the combination toward some organisms. The mechanism of action of atovaquone includes, but probably is not limited to, impaired mitochondrial function in the protozoal organism, probably at the level of electron transport. Dihydroorotate dehydrogenase has been the suggested mitochondrial enzyme targeted by atovaquone.⁴¹ Resistance to atovaquone, reflecting single point mutations, occurs rapidly when atovaqone is used alone.⁴¹ The pharmacokinetics have been cited as a contributing factor to resistance: slow uptake and high lipophilicity may result in prolonged exposure of the protozoa to subtheraeputic concentrations.

Triazines

Toltrazuril is a triazine coccidiostat used in poultry; ponazuril is the major metabolite. Toltrazuril targets the mitochondrial respiratory chain of the susceptible protozoal organism; at higher concentrations, it also blocks pyrimidine formation.⁴³ Ponazuril has been shown to be active against Sarcocystis neurona both in vitro and in vivo and has been approved for use in horses to treat protozoal encephalitis caused by Sarocystis. Efficacy also has been demonstrated in vivo against Neospora caninum.44 In vitro studies with toxoplasmosis indicates that ponazuril interferes with tachyzoite division. Disease regressed in mice treated with 100 mg/kg of toltrazuril and ponazuril, but recrudescence occurred with the ponazuriltreated mice but not those treated with toltrazuril.43 At 10 or 20 mg/kg, ponazuril treatment 1 day before or 3 days after infection followed by 10 days of therapy completely protected mice against acute toxoplasmosis. Treatment with 20 mg/kg but not 10 mg/kg once before and daily for 6 days after infection, followed by 10 days of therapy, also protected against fatal toxoplasmosis.45

Using a murine model of neosporosis, either toltrazuril or ponazuril administered at 20 mg/kg in drinking water completely prevented the formation of cerebral lesions and decreased polymerase chain reaction (PCR) detection by 90%.⁴⁶ Ponazuril is being used at 20 mg/kg once weekly for 2 weeks for coccidia in dogs (see other doses).

Other Nitroimidazoles

Tinidazole and ronidazole are newer nitromidazoles that have been used with variable success for treatment of protozoal disease. Of the two, the kinetics have been described for tinadazole in dogs and cats after single intravenous (15 mg/kg) and oral doses (15 mg/kg or 30 mg/kg). Oral bioavailability was described as completed, with peak plasma concentrations after oral administration of 15 mg/kg being 17.8 and 22.5 μ g/ mL in dogs and cats, respectively, and after 30 mg/kg, 37.9 μ g/mL in dogs, and 33.6 μ g/mL in cats. The apparent volume of distribution in dogs and cats was 0.67 and 0.54 L/kg, respectively. The elimination half-life in dogs was 4.4 hours, compared with 8.4 hours in cats, suggesting 8- to 12-hour dosing intervals in both species. However, plasma drug concentrations were above the minimum inhibitory concentration of tinidazole-susceptible bacteria for 24 hours in cats and 12 hours in dogs after a single oral dose of 15 mg/kg. No adverse events were reported.

Other Nitrofurans

Numerous nitrofurans have been studied for efficacy against protozoal organisms. Among them, nifurtimox demonstrated significant efficacy against Chagas disease. Although nifurtimox is available in the United States, access can be gained only through the Centers for Disease Control and Prevention (CDC), presumably to allow tracking of human cases of Chagas infections. Trypanocidal effects reflect partial reduction and formation of reactive oxygen radicals; the organisms have low concentrations of glutathione and thus have a limited capacity to scavenge the oxygen radicals. However, like the organisms, host toxicity also reflects oxygen radical formation. The ability of N-acetylcysteine to protect the host apparently has not been studied. Although absorbed well after oral administration, metabolism is sufficiently rapid that concentrations of the parent compound remain low; efficacy of the metabolites is not known. Side effects include gastric upset and weight loss.

Quinolones

The quinolone-containing drugs are classified as two types: Type 1 drugs include the 4-aminoquinolones such as chlorquinolone, whereas the type 2 drugs include the aryl-amino alcohols such as quinine and quinidine. Their use has been principally for the treatment of malaria in humans, but they occasionally are used to treat other parasites. Quinine is the primary alkaloid of cinchona, the bark of a South American tree, and has been used medicinally since the early 1600s. The drug is still derived primarily from natural sources. Quinidine differs from quinine only by the orientation of an alcohol group, resulting in greater potency and toxicity. Chloroquine is characterized by less toxicity and greater efficacy compared with quinine.47 However, widespread resistance to chloroquinine has markedly reduced its use. The mechanism of action of these drugs is not well known, with a number being proposed. These include inhibition of protein sythnthesis, inhibition of FV lipase or aspartic proteinases and inhibition of DNA or RNA synthesis.⁴¹ Quinine and similar drugs increase the refractory period of muscle, antagonizing the action of physostigmine on skeletal muscle.47 Respiratory distress and dysphagia occur in humans with myasthenia gravis. Quinine is well absorbed after oral administration. The drug is extensively metabolized and is characterized by an elimination half-life of about 11 hours, but this can increase (owing to decreased clearance) to close to 20 hours with repetitive dosing.⁴⁷ Side effects also include hypoglycelmia (which can be life-threatening), hypotension, and central nervous system side effects.

Diaminidines

The diaminidines include diminazene aceturate and pentamidine isethionate (approved in the United States to treat *Pneumocystis* pneumonia), and a carbanilide member, imidocarb diproprionate. The latter is approved for use in the United States to treat canine babesiosis. The mechanism of action of these drugs is not clear and may vary for the individual parasite. Proposed mechanisms include cationic interactions with DNA or nucleotides or interference with polyamine uptake or function. Efficacy within a genus of protozoa may vary with the species. Efficacy of pentamide is particularly good against *Pneumocystis*, hence its importance in human medicine. As a class, the diamidines are fungicidal toward some organisms, although their usefulness was largely replaced by amphotericin B.⁴⁷

In humans pentamidine has a half-life of about 6 hours but is very slowly eliminated in the urine. The drug is extensively accumulated in tissues, which may explain its apparently prophylactic efficacy against for some organisms. Side effects can be life threatening and may reflect anticholinergic- or histaminergiclike responses (perhaps reflecting mast cell degranulation and histamine release). Clinical signs include tachycardia, dyspnea, vomiting, and (in humans) fainting or dizziness. Sterile abscesses have been reported in humans after intramuscular injection. Pancreatitis and either hyperglycemia or hypoglycemia (the latter potentially life-threatening) also have been reported.⁴⁷

Sodium Stibogluconate

Sodium stibolugonate (SSG) is a pentavalent antimonial compound used for the treatment of leishmaniasis. As with several other antiprotoazoal drugs, SSG is available only through the CDC. Its mechanism of action is not known, but bioenergetics, including glycolysis and fatty acid metabolism and generation of ATP and GTP of amastigotes is impaired. The drugs may be prodrugs with generation of Sb³⁺ being the toxic compound. The preservative chlorocresol may contribute to the activity of the compound. The drug is eliminated in humans in two phases: a short 2-hour phase followed by a longer 30- to 75-hour phase. Accumulation of the drug in macrophages may facilitate efficacy. Resistance is limiting efficacy of the drugs for treatment of leishmaniasis; increasingly higher doses are required. Currently, when given (20 mg in humans) daily for 10 days, the drug yields an 85% to 90% cure rate.⁴⁷ The drug is relatively well tolerated, with pain at the injection site, chemical pancreatitis (high incidence), hepatitis, bone marrow suppression, myalgia, and malaise being reported side effects in humans.⁴⁷

Miscellaneous Protozoal Infections

Leishmaniasis

Leishmaniasis is caused by protozoa of the Trypanosomatidae family. In mammals the organisms reside in macrophages as amastigotes. Two major forms occur. The cutaneous form is caused by a number of species, including *Leishmania major*, *Leishmania tropica*, and *Leishmania mexicana*. The visceral form is caused by *Leishmania* of the *donovani* complex. The dog is the major reservoir for human visceral leishmaniasis in Mediterranean countries.⁴⁸ Whereas the cutaneous form has been reported in the United States and other countries, the visceral form has largely been limited to Asia and the Middle East, with afflicted dogs generally having traveled to endemic countries.⁴⁹ Recently, the visceral form has been described in a kennel of Foxhounds in Oklahoma; additional multiple dog outbreaks have since been reported.

Two reviews have addressed treatment of leishmaniasis.^{50,51} The latter is a systemic review of the literature. The goal of treatment ranges from resolution of clinical signs to eradication of organisms. Because experimental infections are difficult to establish, clinical trials tend to focus on spontaneous disease. Therapeutic response is based on decreased *Leishmania*-specific antibody concentrations and return of parasite-specific cell mediated immunity.⁵⁰ Improvement persists unless organisms have not been cleared.

A number of studies have focused on the role of altered immune response in refractory infections caused by intracellular protozoal infections.48 Resistance to leishmaniasis may reflect Th-1-mediated immunity. Among the cytokines important for an effective Th-1 response, IL-1 is among the most potent inducers. Depending on the immune response, infection in dogs can cause manifestations that range from asymptomatic subclinical disease to complete manifestation.⁵² In one study dogs experimentally infected with Leishmania infantum failed to express IL-4 compared with control dogs. Further, in infected but asymptomatic dogs, although both Th-1 and Th-2 cytokines were produced, cell-mediated immunity reflected preferential expression of Th-1 cytokines.⁵² IL-12 augmented interferon-gamma production by peripheral blood mononuclear cells in dogs either experimentally or naturally infected with canine visceral leishmaniasis, suggesting that IL-12 may be a feasible cytokine therapy in infected dogs refractory to therapy.48

Treatment with antiprotozoal drugs traditionally has included pentavalent antimony compounds, including SSG (obtainable through the CDC) and meglumine antimoniate. Baneth and Shaw⁵⁰ reviewed the efficacy of antimony for treatment and cure of leishmaniasis in dogs. Cure rate is considered low, although clinical signs often improve. Use has been limited more recently by the emergence of *L. infantum*, which is resistant to therapy.

KEY POINT 12-5 Successful therapy of leishmaniasis ultimately may require appropriate immunomodulation.

The use of a liposomal antimony preparation for treatment of leishmaniasis was studied in experimentally infected Beagles (n = 6). Dogs first received an intravenous injection of a commercial product (Glucantime; Rhône–Mérieux, France; 9.9 μ g/kg antimony), and 1 week later the same dose of antimony was given as a liposomal preparation intravenously for 2 days, then subcutaneously for 8 days. The cycle was repeated 10 days later. The disposition of antimony was characterized for both antimony preparations. Regarding the disposition, for the liposomal and nonliposomal preparations, the results were, respectively: C_{max} at steady state (µg/mL) 51, 114; volume of distribution at steady state (L/kg), 0.4 ± 0.16 and 0.2 ± 0.06 ; clearance (1 + hr/kg) 0.009 ± 0.005 and 0.17 ± 0.05 ; area under the curve (µg/hr/mL) 1494 ± 1038 and 61.2 ± 14; and elimination half-life + hr) 33.1 ± 13.8 and 6.1 ± 0.7. Response to therapy was addressed only in terms of total protein and gamma globulin concentrations treatment and at long-term follow-up. These increased 3 months after treatment with the free form of antimony but not the liposomal form.⁵³

Allopurinol is metabolized by Leishmania to an inactive analog of inosine, which is then incorporated into the RNA of the parasite, causing faulty protein translation. It can be used alone or in combination with other drugs. Although clinical signs are likely to improve, clinical cure is unlikely. Survival (78% for more than 4 years in one study) is more likely if renal insufficiency is not present when therapy is begun; the proportion of survivors is similar to that in dogs treated with antimony. Among the clinical sequelae of leishmaniasis is progressive renal disease. The efficacy of allopurinol (10 mg/kg twice daily for 6 months) in slowing the progression of renal disease associated with proteinuria was prospectively studied in dogs (n = 12; 5 no treatment controls) without proteinuria or renal insufficiency, asymptomatic dogs with proteinuria (n = 10; 5 no treatment controls), and symptomatic (azotemic) dogs (n = 8) with proteinuria and renal insufficiency.⁵⁴ Compared with untreated controls, proteinuria was decreased in dogs that already had proteinuria and the progression slowed of tubular but not glomerular disease in all asymptomatic dogs. Finally, azotemia resolved in the symptomatic dogs. Cure of visceral leishmaniasis with the combined use of fluconazole and allopurinol for 4 months has also been reported.55

A number of other drugs have been studied for their potential efficacy. Among the drugs used to treat leishmaniasis is the antifungal agent, amphotericin B (see Chapter 9). Baneth and Shaw⁵⁰ reviewed use of amphotericin B for treatment of leishmaniasis. In general, efficacy is limited by emerging renal disease after total cumulative doses ranging from 8 to 26 mg/kg. This study reported that 27 of 28 naturally infected dogs that responded to amphotericin B (out of a total of 30 infected dogs) remained in clinical remission for 12 months after treatment of 0.5 to 0.8 mg/kg intravenously 2 to 3 times a week for a total cumulative dose of 15 mg/kg (as reviewed by Baneth and Shaw⁵⁰). In another study 100% of 16 dogs diagnosed with leishmaniaisis were clinically cured (no organisms in the bone marrow and 87% negative on PCR) at the end of 4 to 5 weeks of amphotericin B prepared as the desoxycholate salt in soybean oil (0.8 to 2.5 mg/kg). However, 6 dogs (including 2 dogs that never became negative) subsequently became PCR positive for infection at some point in the posttreatment follow-up. Of these 6 dogs, 3 became clinically ill again. The authors concluded that a single negative PCR result should not be interpreted as clinical cure.56 Oliva and coworkers⁵⁷ reported the failure of liposomal amphotericin B (3 to 3.3 mg/kg for 3 to 5 treatments) to cure dogs (n = 13) with cutaneous leishmaniasis. Although animals responded clinically very rapidly, recrudescence of clinical signs returned 4 months later and lymph node aspirates remained positive. Of 17 dogs treated with amphotericin B prepared in a lipid, 14 were treated successfully, as indicated by negative bone marrow PCR results at 1 to 3 months after therapy; however, the timing of recheck may have been inappropriately short.

Pentamidine (4 mg/kg intramuscularly every 3 days for 8 treatments) has also been used successfully in resolving clinical signs in a small number of dogs naturally (n = 3) or experimentally (n = 5) infected with *L. infantum*. Two of the experimental animals were cured. Other drugs that have been used with variable efficacy include metronidazole, itraconazole, ketoconazole, and terbinafine.

Noli and Auxilia⁵¹ systematically reviewed the literature for evidence of effective therapy for treatment of *L. infantum*. Clinical trials that addressed prevention or treatment (n = 47) were reviewed from 1980 to 2004. Good evidence was found to support the use of meglumine antimony (at least 100 mg/kg for 3 to 4 weeks). Fair evidence existed for pentamidine (4 mg/ kg twice weekly) and aminosidine (5 mg/kg twice daily) for 3 to 4 weeks. Aminosidine is an aminoglycoside antimicrobial whose efficacy is similar to that of antimony, but its use is limited by emergent nephrotoxicity. Insufficient evidence existed for allopurinol alone, amphotericin B, ketoconazole, enrofloxaxcin, metronidazole, or combinations thereof.

Trypanosomosis

Trypanosomiasis is caused by protozoa of the genus Trypanosoma spp. Two major diseases occur: that associated with T. brucei in subsahara Africa and that associated with T. cruzi, occurring largely in Latin America. Infection with T. bruceia is transmitted by the tsetse fly and occurs either in small vessels or connective tissue. The disease is of major regional economic importance, impacting food producing and companion animals as well as humans. Resistance has emerged toward the three primary chemotherapeutic agents, with underdosing and delay in treatment being major mitigating factors.^{51a} Treatment of experimentally induced T. brucei brucei in dogs has been studied. The use of diaminazene aceturate (7 mg/kg) as a single dose, or pentamidine esethionate (4 mg/kg, IM, at either every other day for 6 treatments [Group 2] or at 3, 2, 14, 16 days [Group 3]), was studied in dogs (n = 4 per group and 3 untreated controls) 14 days after experimental infection with T. brucei brucei. All dogs were parasitemic by day 7 of infection. By day 7 posttreatment, parasitemia had cleared in all dogs but not the control animals (these died by day 28 postinfection). However, one dog in the diaminazene group relapsed at day 42 (dog died at day 70); the remaining dogs remained free of parasites through the 77 day study period. Two dogs treated with pentamidine (group 3) also died, without evidence of parasitemia. Serum liver enzymes increased more significantly in the diaminazine group. The authors concluded that pentamidine at 4 mg/kg every other day for 2 weeks was a reasonable choice for treatment of trypanosomosis in dogs. Chagas disease is caused by T. cruzi which is transmitted by the kissing (reduviid) bug. Infection occurs after rubbing feces from the bug into the bitewound made by the bug; infection also can be acquired by eating the bug. The acute stage occurs within weeks after initial infection and is followed by a latent and then chronic stage. The chronic stage in humans impacts the nervous (neuritis and other neuropathies), digestive (e.g., megaesophagus or megacolon; reflecting in part neurologic damage) and cardiovascular systems (cardiomyopathy). Cardiovascular disease in dogs is generally associated with right-sided cardiac dysfunction, and its sequelae, including arrhythmias, pleural effusion, ascites, and hepatomegaly. Treatment focuses on parasiticides and supportive care. Intracellular amastigotes destroy intramural neurons; inflammation, fibrosis, and cell death result in organ damage and clinical signs. Antiparasiticides include azoles (benznidazole) or nitros (nifurtimox). The latter may be associated with gastrointestinal signs, peripheral neuropathy, and hemolytica anemia.

Cryptosporidiosis

Cryptosporidiosis is a ubiquitous protozoal disease spread by the fecal-oral route and associated with immunosuppressive diseases in dogs or cats. C. parvum is the strain that most commonly infects mammals. Clinical manifestations reflect malabsorption or secretory diarrhea through unknown mechanisms. Signs are similar to those associated with giardiasis, although mucus is more common with infections by the latter. The syndrome may be self-limiting. Like giardia, cryptosporidiosis is a zoonotic concern. In humans nutritional approaches (including probiotics, low-fat diets, high-fiber diets, simple carbohydrates) to treatment are generally effective, with antimicrobial therapy reserved for nonresponders. Antiprotozoal therapy has largely been ineffective. Tylosin (11 mg/kg by mouth twice daily for 28 days) may help reduce diarrhea. Clindamycin was ineffective in single cases for treatment of cryptosporidiosis in cats. The aminoglycoside paramycin may be effective following oral (not parenteral) administration. When paramycin is used in cats (150 mg/kg every 12 to 24 hours orally for 5 days), fecal oocysts were cleared from infected cats,58 but when it was used to treat feline trichomoniasis, 25% of the cats developed acute renal failure. Azithromycin has been used with some success in the treatment of cattle and might be considered as an alternative therapy in dogs or cats. Nitazoxanide, approved for use in humans to treat Giardia, is a derivative of nitrothiazole found to be effective against a wide range of parasites and bacteria. The use of this drug in dogs and cats has not yet been reported.

Fenbendazole (50 mg/kg orally once daily for 5 days) was variably effective in treating cats concurrently infected with *Giardia* and *C. parvum.*³² Although the number of oocysts decreased the first week after treatment compared with controls, no difference was detected the second week (the power of the study was not addressed). Only 50% (four of eight) of cats treated with fenbendazole were negative 3 weeks after treatment.

Trichomoniasis

Tritrichomonas foetus, the cause of trichomoniasis in cattle, is an emerging protozoal enteric pathogen of domestic cats. Infection occurs in the lumen of the colon, where inflammatory

colitis and explosive, chronic, foul-smelling diarrhea result.⁵⁹ The disease may be prevalent in high-density cat populations such as catteries or show environments and therefore may be more prevalent in purebred cats. A number of treatments have been tried without consistent therapeutic success, including metronidazole, fenbendazole, albendazole, pyrantel pamoate, sulfadimethoxine, trimethoprim–sulfadiazine, furazolidone, tylosin, enrofloxacin, amoxicillin, clindamycin, paromomycin, and erythromycin.⁵⁹

Trichomonads generate pyruvate through glycolysis and reductive fermentation. The latter pathway is targeted by 5-nitroimidazole antibiotics such as metronidazole. Reduction of the nitroimidazoles in hydrogenosomes generates anion radicals, which accumulate to toxic concentrations in the protozoal cell. Metronidazole as sole therapy generally has been ineffective against T. foetus infection in cats: Transient improvement is generally followed by recrudescence of clinical signs.⁶⁰ Gookin and coworkers⁶⁰ found that, based on in vitro comparison of metronidazole, ronidazole, and tinidazole, ronidazole was the most potent toward T. foetus isolated from a cat with spontaneous disease. Ronidazole was then prospectively studied for its efficacy in a cat naturally infected, and 10 specific pathogen-free (SPF) kittens experimentally infected with T. foetus. Ronidazole at 30 to 50 mg/kg every 12 hours for 14 days resolved clinical signs and cured (based on PCR results) all 11 cats. Relapses occurred at 10 mg/kg. Kather and coworkers⁶¹ reported in vitro susceptibility for T. foetus collected from four Bengal cats with spontaneous disease. Omeprazole and paromomycin were ineffective, and metronidazole, ronidazole, and furazolidone were equally effective at 0.625 to 2.5 µg/mL. However, ronidazole was characterized by greater lethality.

In SPF kittens experimentally infected with *T. foetus*, ronidazole (10 mg/kg every 12 hours for 2 weeks) initially was effective but relapse occurred in 5 of 5 cats 2 to 20 weeks after treatment. However, at 30 to 50 mg/kg, 10 of 10 cats remained negative for 21 to 30 weeks after treatment. Likewise, treatment with 10 mg/kg ronidazole for 2 weeks resolved clinical signs of infection in a spontaneously diseased cat, with clinical signs returning at 85 days.⁶⁰

Cytauxzoonosis

Cytauxzoonosis is a generally fatal tick-borne protozoal disease that afflicts cats. The bobcat appears to be the reservoir host. Cytauxzoon has an erythrocytic phase, which morphologically cannot be distinguished from babesiosis, as well as a tissue phase. Schizonts develop in monocytes, which then marginate into the vascular endothelium, often occluding the vessel. Schizonts then develop into merozoites, which, on release into the blood and tissue, invade other cells, including erythrocytes. Clinical signs rapidly progress, with the course of the disease generally being less than 1 week. Clinical signs generally include pale mucous membranes, dehydration, dyspnea, icterus, anorexia, and severe lethargy. Treatment with either diminazene aceturate (2 mg/kg subcutaneously, repeated in 2 to 4 weeks) or imidocarb dipropionate (5 mg/kg, subcutaneously, repeated in 2 weeks) should be considered.⁶² In one report, 6 of 7 cats diagnosed with cytauxzoonosis responded to 2 intramuscular injections (2 to 4 weeks apart) of either diminazene aceturate or imidocarb dipropionate (2 mg/kg). However, the seventh cat died after the first injection of diminazine.⁶³ Drugs generally shown to be ineffective include paravaquone (20 or 30 mg/kg intramuscularly daily), buparaquone (5 or 10 mg/kg intramuscularly daily), sodium thiacetarsamide, and tetracyclines.^{62,64}

Babesiosis

Babesiosis is a tick-borne hematozoan disease afflicting dogs and cats. Dogs are known to host Babesia canis (large and more important form) and Babesia gibsoni (small form), both of which cause hemolytic anemia, whereas cats are infected with Babesia felis, among others. However, other body systems may also be involved. In dogs the disease can present as hyperacute, acute, chronic, and subclinical. Greyhounds appear to have a higher prevalence compared with other breeds of dogs. Treatment with imidocarb dipropionate (approved by the FDA for this use) is generally successful. A number of protocols for treatment have been described. Imidocarb at 7.5 mg/kg can be followed with diminazene (3.5 mg/kg) or given in two doses (5 to 6.6 mg/kg 14 days apart). Imidocarb is the preferred drug with concurrent infection with Erhlichia. A single dose of imidocarb should be protective. Phenamidine (15 mg/kg once a day, for two doses), pentamidine (16.5 mg/kg, two doses 24 hours apart), or trypan blue (10 mg/kg of a 1% solution intravenously, once) also have been suggested for severe infections when the anticholinergic properties of the diamidine derivatives are a concern. Clindamycin at 25 to 50 mg/kg daily for 7 to 10 days also may be useful. For cats the antimalarial drug primaquine, (0.5 mg/kg orally or intramuscularly) has been recommended. However, because the lethal dose is 1 mg/kg, extreme caution should accompany use of this drug in cats. Another drug that may be useful is atovaquone.

The mechanism of action of atovaquone against other protozoa is believed to involve the inhibition of cytochrome *b* and electron transport. The antiprotozoal drug atovaquone has proved effective for treatment of at least two *Babesia* species, *Babesia microti* and *Babesia divergens*, when combined with azithromycin.⁶⁵ The combined use of atovaquone (13 mg/kg orally every 8 hours) and azithromycin (10 mg/kg orally once daily) was successful in the treatment of babesiosis in dogs.⁶⁵ Of 11 dogs remaining infected with *B. gibsoni* (Asian genotype) despite therapy with either imidocarb. diproprionate alone (dose: 6 to 6.6 mg/kg intramuscularly) for two doses 1 to 2 weeks apart, diminazene aceturate (3.5 mg/kg intramuscularly) for two doses 2 weeks apart, or a combination of the two, 8 became PCR negative compared to 11 of 11 controls that remained positive.⁶⁵

Evidence (PCR) of infection was absent in 80% of treated dogs, whereas it was present in all dogs in a placebo group of similar size. No adverse events were reported in treated animals. Treatment was limited to animals that did not require hospitalization, indicating a need to study acutely ill animals. However, the lack of any other known effective therapy warrants consideration of this combination for treatment in acutely ill animals as well. Of the two preparations (atovaquone or atovaquone combined with proguanil) currently available in the United States, the single product is probably less likely to cause gastrointesintal side effects.⁶⁵

Hepatozoonosis

Hepatozoonosis is a tick-transmitted hemosporazoon disease infecting dogs. The organism is similar to Babesia. The clinical syndrome is characterized by a stiff gait and myalgia, inactivity, and weight loss and profound leukocytosis (mature neutrophilia: 70,000 to 200,000 cells/µL). Periosteal proliferation and increased alkaline phosphatase may be present. Severe hyperesthesia may be manifested as stiffness. Analgesic therapy, probably with nonsteroidal antiinflammatory drugs, is indicated. Tepoxalin (Zubrin) might be considered for its ability to target leukotrienes (prevalent in white blood cells) as well as prostaglandins. Definitive diagnosis appears to have been facilitated using an ELISA-based test. Treatment with triple combination therapy (TCP) may resolve clinical signs and has dramatically improved the prognosis in dogs. Therapy includes trimethoprime sulfadiazine (15 mg/kg orally, twice daily), clindamycin (10 mg/kg orally, three times daily), and pyrimethamine (0.25 mg/kg orally, once daily), each administered for at least 14 days. Efficacy with imidocarb dipropionate (5 mg/kg subcutaneously, given once) alone or combined (at 6 mg/kg subcutaneously, every 14 days) with tetracycline (22 mg/kg orally, thrice daily) for 14 days) is less effective. Treatment with the coccidiostat toltrazuril (5 to 10 mg/kg subcutaneously or orally, once daily for 3 to 5 days, or 5 mg/kg orally, twice daily for 4 days) may resolve clinical signs, but the risk of relapse may be great. Decoquinate (10 to 20 mg/kg orally, twice daily; continuous therapy) may be indicated to prevent relapses after TCP.

Neospora Caninum

N. caninum is a Toxoplasma gondii-like protozoan for which canids are the only known definitive host. The life cycle involves cysts containing bradyzoites in the intermediate host and rapidly dividing tachyzoites in multiple tissues of the definitive host. The intestinal phase in the definitive host is similar to that of coccidiosis and leads to passage of nonsporulated oocysts in feces. Clinical disease, which is most severe in puppies, presents as hind limb paresis that rapidly progresses to rear limb paralysis and occasionally rigid hyperextension of limbs. Other signs include dysphagia, jaw muscle paralysis, muscle atrophy, and heart failure. Neosporosis in adult dogs generally includes neurologic disease but also may manifest as encephalomyelitis, polymyositis, myocarditis, or dermatitis. Puppies can be infected transplacentally. A canine kidney cell model, recombinant canine interferon alpha (IFN-alpha), beta (IFN-beta), and gamma (IFN-gamma) inhibited the growth of N. caninum tachyzoites. However, the effect was associated with the suppression of the host cell viability.⁶⁶ Treatment is similar to that for toxoplasmosis.

Protothecosis

Prototheca are achlorophyllous algae, related to green algae and ubiquitous in the environment. Their importance as a cause of infection in immunocompromised infections is increasing in human medicine.⁶⁷ Infections are either subcutaneous to cutaneous, synovial or systemic. Infection is generally preceded by skin or wound infections. Therapy with amphotericin B requires high concentrations, which may include local as well as systemic therapy. Duration of treatment in humans ranges from several days to months. Tetracyclines (doxycycline) may act synergistically. Imidazoles and flucytosine have been used systemically successfully, and a number of local therapies have been successful (gentian violet, polymyxin B, clotrimazole, neomycin, hydrogen peroxide, and potassium iodide). Protothecosis in cats usually is cutaneous, whereas dogs may present with a variety of clinical manifestations. The most common presenting sign in dogs is protracted hemorrhagic diarrhea, with the colon the most common site.⁶⁸ Treatment in dogs has included amphotericin B rectally in an enema form (3% cream), itraconazole, and ketoconazole.

SUMMARY

Therapy of protozoal infections in small animals may range from simple to complex therapeutic dilemmas. The best treatment of each case must be determined by considering the life cycle of the pathogen, the general physical condition of each animal, and the animal's environment. Therapy must include adequate attention to supportive therapy to control clinical signs and support normal body function. Therapy also should include adequate hygiene to limit reinfection and disease transmission. The selection and administration of the specific antiprotozoal agent are only parts of the overall therapeutic picture.

Drugs for the Treatment of Helminth Infections: Anthelmintics

Tad B. Coles and Randy C. Lynn

Chapter Outline

NTHELMINTICS
Macrolides
Benzimidazoles
Tetrahydropyrimidines
Cyclic Depsipeptides
Piperazines
Isoquinolones
Arsenicals
Miscellaneous

Practicing veterinarians commonly use drugs to treat and prevent helminth infections in small animals. The life cycle and biology of the most important parasites are well understood by graduate veterinarians and are not discussed here; however, current textbooks of parasitology may be consulted for review.¹⁻⁴ Gastrointestinal parasites are among the most common infectious agents that veterinarians in small animal practice face. A landmark parasite prevalence study evaluated more than 6000 canine fecal specimens from all 50 states and the District of Columbia.5 The results indicate that parasites are common in American dogs. Nationwide, 36% of the samples tested were positive for roundworm (Toxocara canis), hookworm (Ancylostoma caninum), or whipworm (Trichuris vulpis). Even more surprising, 52% of the samples from the southeastern United States were positive for at least one nematode. In a recent study of the results of heartworm and fecal testing in the western United States, the importance of annual testing and routine use of preventives was highlighted.⁶ Clinics in 11 states were surveyed, and local dogs with no history of travel were diagnosed with heartworms in every state but Idaho and Wyoming. The prevalence of intestinal parasites in companion animals in Ontario and Quebec, Canada, during the winter was recently evaluated.7 The fact that 30% of feline and 39% of canine fecal samples were positive for gastrointestinal parasites prompted the authors to recommend that all veterinarians follow the Companion Animal Parasite Council (CAPC) guidelines8 regarding use of year-round broad-spectrum deworming protocols. Another reason for following CAPC guidelines, in this instance regarding routine heartworm testing and prophylaxis, is concern about animals moving from heartworm-endemic areas to those with limited heartworm exposure. These concerns were realized when Hurricane Katrina resulted in thousands of dogs and cats being shipped from Louisiana, where heartworm prevalence is quite high, to shelters across the United States.⁹

Emodepside Plus Praziquantel Pyrantel Plus Praziquantel Pyrantel Plus Praziquantel Plus Febantel Ivermectin Plus Pyrantel Ivermectin Plus Pyrantel Plus Praziquantel Milbemycin Oxime Plus Lufenuron Imidacloprid Plus Moxidectin

KEY POINT 13-1 Helminth infections are common in pets.

KEY POINT 13-2 Testing, treatment, and prevention of helminth infections in pets have profound zoonotic implications.

Although these parasites are important to the health of dogs, several are also important zoonotic pathogens. Ascarid larvae migrate through human tissues, causing a variety of signs correlated to the location of the migration. These are primarily *Toxocara* species ascarids, but the raccoon ascarid, *Baylisascaris procyonis*, is being increasingly implicated as a cause of human disease in the United States.¹⁰ The Centers for Disease Control and Prevention (CDC) have published *Guidelines for Veterinarians: Prevention of Zoonotic Transmission of Ascarids and Hookworms of Dogs and Cats*, which is an excellent resource and is available online as a PDF download.¹¹

KEY POINT 13-3 The raccoon ascarid is an emerging zoonotic threat.

Worldwide, helminth infections are a major animal and human health concern,¹² with hookworms infecting large numbers of people worldwide, especially those of low economic status.¹³ More than 30% of the human population, in vast areas of South America and Asia, is infected with hookworms. More than half of the population is infected with hookworms in many southern areas of the African continent. Experts estimate that a billion people, more than a fifth of the planet's human inhabitants, harbor hookworms.¹⁴ One study showed that nearly all dogs in a remote community of northeastern India were infested with one or more zoonotic gastrointestinal parasites.¹⁵ This study demonstrated that dogs played a major zoonotic role both in transmitting parasites that use dogs as their definitive and paratenic host and in mechanically transmitting and spreading the dissemination range of an array of human-specific parasites. A recent feline study in metropolitan Rio de Janeiro revealed an 89.6% prevalence of overall gastrointestinal helminth parasites in cats.¹⁶

KEY POINT 13-4 The practicing veterinarian who judiciously uses anthelmintics is in a unique position to have a dramatic impact on the health of pets and people.

Through the prudent use of anthelmintics in companion animals, the practicing veterinarian is in a unique position to positively affect not only the patient's health but also public health.

ANTHELMINTICS

In this chapter anthelmintics that are approved by the U.S. Food and Drug Administration (FDA) and commercially available in the United States are grouped together by class according to their generic names. The literature on antiparasitic drugs is enormous. In the interest of both economy and readability, only a few references are listed for each drug. These will guide the veterinarian who needs more specific information about the subject. Table 13-1 provides a general overview of anthelmintic drug spectrum against the common canine and feline helminths.

Since the last edition of this text was published, there have been considerable changes, most notably the more widespread use of ivermectin and the emergence of other macrocyclic lactones. New information on avermectin toxicity is covered in the ivermectin section. Drug manufacturers have discontinued production of many tried-and-true anthelmintics such as dichlorvos (Task Capsules) and diethylcarbamazine citrate (Filaribits). In addition, some drugs, such as N-butyl chloride, have simply been superseded. For simplicity's sake, discontinued products and drugs that are not widely available do not appear in the current edition; however, an earlier edition of this text can certainly be consulted for information about them. The latest information about diethylcarbamazine citrate can be obtained from the American Heartworm Society 2005 guidelines for the diagnosis, prevention, and management of heartworm infection in dogs.¹⁷ This organization produced similar guidelines for cats in 2007¹⁸ and updated the guidelines for dogs in 2010.18a

New anthelmintic products are continuously researched and frequently launched. The Compendium of Veterinary Products provides a comprehensive list of commercially available products approved by the FDA.¹⁹ An exhaustive review of the pharmacology, mechanism of action, pharmacokinetics, and efficacy of anthelmintics is beyond the scope of this chapter. There are excellent texts available for those interested in more exhaustive information on anthelmintics.²⁰⁻²² Pharmacologic activity against nonhelminths, such as flukes, fleas, and ticks, by some anthelmintics and anthelmintic drug combinations may be mentioned, but such activity is not the focus of this chapter.

Macrolides

Macrolides, which include both avermectins and milbemycins, have revolutionized the control of parasites in both humans and animals. Ivermectin is the best known agent in this class. The dual activity of some macrolides, such as ivermectin and selamectin, against endoparasites, such as helminths, and ectoparasites, such as fleas, gave rise to the term *endectocide*. These products are similar in that they are large complex macrocyclic structures produced by soil microorganisms in the *Streptomyces* genus. They are generally regarded as the most effective and least toxic parasiticides yet developed. Commercially, they have crushed the competition. Many conventional drugs that were direct competitors of this class were retired from common use and eventually discontinued by the manufacturer.

KEY POINT 13-5 Macrolides are large complex macrocyclic products of soil microorganisms. This class includes the most effective, least toxic parasiticides.

Macrolides are excreted in the feces as active drug. Drugs in this class, especially the avermectins, are toxic to dung-feeding insects, but not birds, plants, and earthworms. Elimination of coprophagous insects appears to delay processing of nutrients, but the overall environmental impact of this finding is unclear.²³

Although originally believed to act by disturbing gammaaminobutyric acid (GABA)–mediated neurotransmission, it now appears that they act with high affinity to a nematodespecific glutamate-gated chloride channel.^{24,25} Macrolides trigger chloride ion influx, which hyperpolarizes the parasite neuron and prevents initiation or propagation of normal action potentials. The selectivity of macrolides is due to different glutamate function in invertebrates compared with that of vertebrates. Glutamate acts as an inhibitory neurotransmitter in invertebrates and an excitatory neurotransmitter in mammals.² The net effect is paralysis and death of the target parasite.

Despite their beneficial activities, macrocyclic lactones have several flaws. They are ineffective against cestodes and trematodes, and they are sometimes expensive. That said, the U.S. patent on ivermectin has now expired, allowing generic competitors to enter the market and reduce the cost of ivermectin treatment, but to date the cost savings have not been realized on products for dogs and cats to the same degree as those for horses and food animals. Although macrolides are generally regarded as the most effective and least toxic parasiticides yet developed, toxicity may occur with overdosage, especially in Collies, many of which are unusually sensitive to macrolide endectocides. An excellent summarized overview of the pharmacology, indications, dosing, precautions, and side effects of commercially available macrocyclic lactones is available online as a PDF download from the United States Pharmacopeial Convention, Inc.23

KEY POINT 13-6 Macrolides are ineffective against trematodes and cestodes.

Ivermectin

Ivermectin was the first commercially available macrolide, released for use in animals in 1981.²⁴ The avermectins were isolated from the fermentation broth of *Streptomyces avermitilis*. The discovery of its anthelmintic activity was made after administration of the actinomycetic broth to mice infected with the nematode *Nematospiroides dubius*. Ivermectin is effective against many nematodes and arthropods. In particular, ivermectin is very effective against immature *Dirofilaria immitis*.

KEY POINT 13-7 Ivermectin, the first macrolide used commercially, revolutionized the control of parasites in humans and other animals.

Administration of ivermectin to pregnant rats, mice, and rabbits produced teratism only at or near doses that were maternally toxic. There was no teratogenesis in cattle, sheep, and dogs when ivermectin was administered to pregnant animals at four times the recommended dose. Although toxicity for aquatic animals is high, the binding of ivermectin in soil reduces its concentration to levels that have minimal effect on the environment, as previously discussed. The acute oral LD_{50} in mice varied from 11.6 to 87.2 mg/kg; and the LD_{50} for rats was 42.8 to 52.8 mg/kg. In a 14-week study with rats, the "no-effect" level was 0.4 mg/kg.

Ivermectin is well absorbed (95%) after oral administration and well distributed to most tissues except the central nervous system. It is largely eliminated unchanged in the feces and is metabolized to a small degree in the liver by oxidation. In dogs the terminal half-life is approximately 48 hours. No teratism was observed in fetuses when pregnant bitches received repeated oral doses of ivermectin of 0.5 mg/kg. A single oral dose of 2 mg/kg and repeated oral doses of 0.5 mg/kg per day for 14 weeks were well tolerated by dogs.²⁶

Avermectin Toxicity. It is important not to administer avermectins concurrently with drugs that could increase avermectin blood-brain barrier penetration, such as ketoconazole, itraconazole, cyclosporine, and calcium-channel blockers.²⁷ Selamectin toxicity information is addressed in detail later, in the selamectin section. According to a popular veterinary pharmaceutical clinical text, signs of ivermectin toxicity in dogs, in order of frequency, are ataxia, blindness, mydriasis, tremors, and vomiting.²⁸ Other signs include dehydration, depression, diarrhea, hyperthermia, bradycardia, sinus arrhythmia, coma, seizures, and death.^{26,29,30} A recent retrospective study of ivermectin toxicosis cases evaluated at a poison control center revealed clinical signs in the following order of frequency: ataxia, lethargy, tremors, mydriasis, and blindness.^{30a}

The apparent LD_{50} for Beagles is 80 mg/kg.²⁶ The primary clinicopathologic sign in dogs is decreased serum iron values.²² A common reference used by clinical veterinarians states that death could occur with doses above 40 mg/kg, tremors at 5 mg/kg, and mydriasis at 2.5 mg/kg and that signs of toxicity rarely occur at doses below 1 mg/kg.²⁸ But a recent retrospective poison control center study revealed that clinical signs may develop between 0.2 to 2.5 mg/kg.^{30a} A wide variety of signs were noted, including more severe signs like coma and seizure, at doses below 1 mg/kg. In fact, death was noted in dogs that received 1 to 2.5 mg/kg doses of ivermectin.

A common presenting history is that of a dog that was in close proximity to horses during deworming and later started showing signs of disease. Dogs that develop clinical signs within 4 to 6 hours of ivermectin ingestion typically develop severe clinical signs, whereas dogs with signs developing 10 to 12 hours after exposure tend to have much milder clinical signs.²⁹ It is not uncommon for dogs with ivermectin toxicity to have seizures. When seizures are severe and uncontrolled for a considerable period of time, hemolytic anemia and muscle damage may occur. Some severe cases present with seizures and miosis, which warrants a poor prognosis. It is possible that severe seizures and miosis on presentation may be associated with severe brain damage.³¹

Clinical signs of ivermectin toxicity in cats, in order of frequency, are ataxia, mydriasis, tremors, hyperesthesia, and hypothermia.²⁸ Dogs are about 10 times as likely as cats to have ivermectin toxicity.²⁸

Some Collies are unusually sensitive to the toxic effects of ivermectin, although it is safe for all breeds at the approved dose of 0.006 mg/kg (6 mcg/kg). Early studies indicated that some genetic lines of Collies developed severe adverse reactions when ivermectin was given at a dose of 100 to 200 mcg/kg (16 to 32 times the label dose), producing mydriasis, ataxia, tremors, drooling, paresis, recumbency, excitability, stupor, and coma. At that time Australian Shepherds, Border Collies, Shetland Sheepdogs, and Old English Sheepdogs were also reported to be sensitive to ivermectin. The lethal dose for some Collies was reported to be 1/200th that of Beagles.³²

After Collies were also found to be more sensitive to loperamide,³³ the canine multidrug resistance (MDR1) gene was identified and found to be mutated in ivermectin-sensitive Collies.³⁴ MDR1 codes for a glycoprotein that is an integral part of the blood-brain barrier. There are many excellent sources of information about the MDR1 gene mutation and mechanisms of ivermectin toxicity associated with increased GABA activity.^{29,30,35} The mutant MDR1 allele was found in 35% of the 40 Collies that were tested in one study, about the same percentage of Collies that are sensitive to ivermectin.³⁶ A survey of DNA from 4000 purebred dogs revealed that the MDR1 mutation was present in seven breeds of Collie lineage and two sighthound breeds, although the mutation was not identified in all breeds known to have ivermectin sensitivity.³⁷

It was found that the potential for ivermectin sensitivity could be estimated by genotypic or polymerase chain reaction (PCR)-based testing for the MDR1 mutation.³⁸ In this study the mutant MDR1 allele was found in Australian Shepherds, Miniature Australian Shepherds, English Shepherds, German Shepherd Dogs (white), Longhaired Whippets, McNab Shepherds, Old English Sheepdogs, Shetland Sheepdogs, Silken Windhounds, and Longhaired Whippet.^{23,37} Sensitivity to ivermectin was also noted in Australian Cattle Dogs, Bearded Collies, and Border Collies, but the mutant MDR1 allele was not found in these breeds.³⁷ More recently, the relationship with P-glycoprotein, the product of the ABCB1 (formerly MDR1) gene, was studied in depth by looking for the ABCB1- 1Δ allele in a DNA study of 5368 dogs.³⁹ The ABCB1- 1Δ allele was found in Collies, Longhaired Whippets, Standard and Miniature Australian Shepherds, Shetland Sheepdogs, Old English Sheepdogs, Border Collies, Silken Windhounds, and German Shepherd Dogs.

The fact is, until a particular dog is tested, its susceptibility to ivermectin toxicity is unknown. Washington State University, College of Veterinary Medicine, Veterinary Clinical Pharmacology Lab, provides genetic testing to determine the presence of the MDR1 mutant gene. Table 13-2 was adapted from information available at the aforementioned institution's website.⁴⁰ The general practitioner can also use this table when presented with a dog that has had a known exposure to ivermectin to determine prognosis and the appropriate level of treatment. As noted previously, a common finding when taking history on ivermectin and moxidectin exposure cases is that the dog was present while the owner was deworming a horse. It is not unusual for horses to spit out a small amount of dewormer, which is ingested by the dog. If the amount ingested can be quantified, then this table can help the veterinarian estimate prognosis and determine how aggressive to get with treatment. Obviously, the risk of a severe toxicity is much greater with a Collie than with another breed.

Another presentation to consider is dogs with the habit of eating horse feces. Dogs that are not ivermectin sensitive are probably not at risk, but an ivermectin-sensitive dog that eats the feces of a horse that has been treated with ivermectin within the last few days may have a severe, even fatal reaction. Ivermectin reaches maximum fecal concentration 2 to 3 days after the horse is treated.⁴¹ By 4 days posttreatment, 90% of the drug has been excreted in the feces. Owners of ivermectin-sensitive coprophagic dogs should treat feces from

Table 13-2Breeds Affected by MDR-1 Mutation

Border Collie	< 5%				

(Data from Washington State University, College of Veterinary Medicine, Veterinary Clinical Pharmacology Lab. (2010). Affected breeds Retrieved Jan 26, 2010, from http://www.vetmed.wsu.edu/depts-VCPL/breeds.aspx.)

ivermectin-treated horses as toxic waste and dispose of it in a manner that will prevent the dog from eating it.

Regarding treatment of ivermectin toxicity, although there is some evidence that intravenous administration of physostigmine may be of some benefit for dogs⁴² and neostigmine may help treat cats⁴³ suffering from severe ivermectin intoxication, adverse events associated with these treatments typically outweigh benefit, thus the mainstay of care given by most veterinarians is supportive and symptomatic.²⁶ Inducing emesis, giving activated charcoal, providing fluid therapy, supplying parenteral alimentation, and maintaining respiratory support and normal body temperature are essential. This supportive care may be needed for an extended period of time because the half-life of ivermectin is 2 days and the half-life of moxidectin is 19 days.³⁰

There is no antidote for ivermectin and moxidectin toxicity, but veterinarians should consider lipid rescue, a promising therapy adapted from human medicine. Dr. Guy Weinberg initially described the use of an intravenous lipid emulsion (Intralipid) to treat local anesthetic toxicity (bupivacaine) in humans. He coined the term "lipid rescue." One of the studies to support human use of lipid rescue was an experiment on dogs that were overdosed with bupivacaine and rescued from certain toxicity with intravenous lipid emulsion.⁴⁴ Dr. Weinberg established a noncommercial website (www.lipidrescue.com) to disseminate information and foster discussion of cases. Since then, lipid rescue has been used to treat nonbupivacaine toxicities in other species. Although support is certainly anecdotal, in 2008 a veterinary online contributor to the lipid rescue website described an ivermectin-overdosed dog that had clinical signs of toxicity and recovered nicely after activated charcoal, supportive care, and an intravenous lipid emulsion were administered. More recently, a case report of a puppy with moxidectin toxicosis was published describing the use of an intravenous lipid emulsion given as a bolus of 2 mL/kg, followed by 4 mL/kg/hr for 4 hours beginning 10 hours after exposure and repeated at 0.5 mL/kg/min for 30 minutes beginning 25.5 hours after exposure.⁴⁵ The 16-week-old dog presented with acute onset seizures, paralysis, and coma soon after exposure to moxidectin. Diazepam, glycopyrrolate, and intravenous fluids were given along with respiratory ventilation and other supportive care. The puppy improved dramatically within 30 minutes of the second dose of Intralipid. Although ideal dosages have not been established, the typical recommendation is for bolus administration of 1.5 mL/kg of intravenous lipid emulsion, followed by 0.25 mL/kg/min for 30 to 60 minutes.⁴⁶ Other brands of intravenous lipid emulsion, such as Liposyn, can also be considered. It is best to have the product available ahead of time rather than try to acquire it in the midst of an emergency. Dr. Weinberg's lipid rescue website (mentioned previously) describes preparation of a kit to have on hand.

Dogs. Ivermectin (Heartgard) tablets are administered orally at a dose level of 0.006 mg/kg (6 mcg/kg) at monthly intervals to prevent the establishment of the *D. immitis.* The initial dose should be given within 1 month of the first exposure to mosquitoes and throughout the period of the year when mosquitoes are active. The last treatment must be given

to dogs within 1 month after the last exposure to mosquitoes. Ivermectin alone has minimal activity against the adult heartworm in the short term. It is active on the third- and fourthstage larvae and the circulating microfilariae. A single oral dose of ivermectin administered within 2 months of infection prevents the establishment of adult worms in the heart. A single oral dose of 0.05 mg/kg is adequate to clear the circulating microfilariae when given to dogs 4 weeks after the administration of an adulticide, although ivermectin is not approved as a microfilaricide.⁴⁷ Review of the original reference is suggested for more complete information. When ivermectin (0.006 mg/ kg) is given to heartworm-positive dogs over several months, the circulating microfilariae are eliminated, resulting in an occult infection. Thus dogs receiving monthly ivermectin should be tested annually with an occult heartworm test.^{17,48,49}

Knight provides an excellent review of heartworm testing and suggested chemoprophylaxis timing for various regions in the United States.⁵⁰ The American Heartworm Society guidelines for diagnosis, prevention, and management of heartworm infection in dogs should also be consulted.¹⁷ Although there is no FDA-approved microfilaricide, macrocyclic lactones are the safest and most effective microfilaricidal drugs available for use in heartworm-positive dogs.¹⁷ Compared with ivermectin, milbemycin is a more potent microfilaricide and causes quicker clearance of microfilariae.¹⁷

Short-term use of ivermectin alone has minimal effect on adult heartworms, but when given continuously over a prolonged period, for 1 to 2 years, or when combined with doxycycline, it may have some utility for treating dogs with adult heartworm infection. The older the adult heartworms are when first exposed to ivermectin, the longer it takes them to die; because they continue to cause damage during this time, long-term ivermectin therapy generally is not a substitute for melarsomine (Immiticide) therapy.¹⁷ In addition, a mild hypersensitivity reaction has been observed in dogs with circulating microfilariae that are treated with ivermectin. Many products that contain ivermectin have precautions suggesting removal of adult heartworms and microfilariae before initiating ivermectin heartworm prophylaxis.

Regarding the combination of ivermectin and doxycycline as a heartworm adulticide; it has been found that *Wolbachia* spp. bacteria are filarial species endosymbionts—that is, their presence is necessary for filial worm survival—and that eliminating this bacteria from heartworm-positive dogs and cats will decrease host antigenic response.^{51,52} In fact, one study of heartworm-positive dogs comparing groups that were treated with three drugs (i.e., melarsomine, doxycycline, and ivermectin), two drugs (i.e., doxycycline and ivermectin), doxycycline alone, ivermectin alone, and melarsomine alone, led the authors to conclude that the combination of doxycycline and ivermectin was synergistic and could eliminate adult heartworms with less potential for severe thromboembolism than melarsomine alone.⁵² This is discussed in greater depth in the melarsomine section.

Ivermectin given as a single subcutaneous injection or orally administered at 0.2 mg/kg demonstrated high efficacy against the immature and adult *T. canis, A. caninum,* Ancylostoma braziliense, Uncinaria stenocephala, Strongyloides stercoralis, Capillaria spp., and Filaroides hirthi.⁵³ At that dose its activity against *Toxascaris leonina* and *T. vulpis* is erratic.²³ When treating respiratory nematode parasites a higher dose, 0.4 mg/kg by subcutaneous injection or orally every 2 weeks for 2 to 3 doses has been recommended recently for Oslerus (Filaroides) osleri, F. hirthi, Aelurostrongylus abstrusus, and Capillaria aerophila infections.⁵⁴

Several combination products containing ivermectin are available. A combination product (Heartgard Plus) containing ivermectin and pyrantel pamoate is available. See the discussion of combination products for more information.

Cats. Ivermectin is FDA approved as a monthly heartworm preventive in cats (Heartgard Chewable for Cats). The approved monthly oral dose of 0.024 mg/kg is effective in preventing the development of *D. immitis* and hookworms (*A. braziliense* and *Ancylostoma tubaeforme*).⁵⁵⁻⁵⁷ Feline roundworm (*Toxocara cati*) infections have been controlled with 0.2 to 0.3 mg/kg of ivermectin and lungworm (*A. abstrusus*) infections with 0.4 mg/kg of ivermectin.⁵⁸⁻⁶⁰ Capillaria species are rarely implicated in feline cystitis, and infestations are thought to be self-limiting usually, but in one case a single dose of ivermectin 0.2 mg/kg, administered subcutaneously, was successfully used to treat the condition in a cat.⁶¹

Milbemycin Oxime

Milbemycin oxime was the second macrocyclic lactone approved by the FDA. It is a fermentation product of *Streptomyces hygroscopicus aureolacrimosis*. It has structural similarities to ivermectin and is believed to work by a similar mechanism of action and have similar pharmacokinetic properties with regard to absorption, metabolism, and excretion. Although an LD_{50} was never determined for dogs, single oral doses of 200 mg/kg were tolerated in laboratory Beagles. Collie dogs tolerated single oral doses of 10 mg/kg without toxicity.

KEY POINT 13-8 Milbemycin, the second macrolide used commercially, is similar to ivermectin.

Dogs. Milbemycin oxime tablets (Interceptor) are formulated to deliver a minimum dose of 0.5 mg/kg of body weight. When given every 30 days it is effective in preventing heartworms (*D. immitis*).⁶²⁻⁶⁴ It also kills *A. caninum*, *T. canis*, and *T. vulpis*.^{65-68,23} One study indicates that milbemycin may help control raccoon roundworm (*B. procyonis*) infections in dogs and thus decrease the zoonotic potential of a parasite that can have devastating effects in humans, including death.⁶⁹

KEY POINT 13-9 Milbemycin is safe for nursing and pregnant animals.

Milbemycin oxime has been extensively tested with regard to safety. It is nontoxic to Collies at up to 20 times the recommended dose and is safe when given to pregnant and nursing animals.^{70,71} Milbemycin oxime, like ivermectin, is known to kill heartworm microfilariae and inhibit the release of new microfilariae. Thus all dogs receiving routine monthly heartworm prophylaxis with milbemycin should be tested with adult antigen tests.^{72-74,49,17}

KEY POINT 13-10 Use of milbemycin may help control the raccoon roundworm, which has human health implications.

Cats. Milbemycin oxime (Interceptor) is approved for use in cats. The product is effective in preventing in heartworm (*D. immitis*) at a monthly dose of 0.5 mg/kg⁷⁵ and removing roundworms (*T. cati*) and hookworms (*A. tubaeforme*) at a monthly dose of 1.5 mg/kg.^{76,23}

Moxidectin

Moxidectin was the third macrolide to enter the parasite market. It is a chemically altered product of *Streptomyces aureolacrimosus noncyanogenus* and has a similar range of activity and safety margin as ivermectin and milbemycin oxime. Moxidectin is currently approved in the United States for injectable use as a heartworm (*D. immitis*) preventive and hookworm (*A. caninum* and *U. stenocephala*) treatment in dogs (ProHeart 6) and for topical use in combination with imidacloprid to prevent heartworms, treat fleas, and control and treat ear mites and intestinal parasites in dogs and cats (Advantage Multi). The combination product is reviewed later in this chapter. The oral use of moxidectin in dogs is covered in the previous edition of this text. Moxidectin toxicity was discussed previously in the Avermectin Toxicity section.

KEY POINT 13-11 Moxidectin, the third macrolide used commercially, is also similar to ivermectin and milbemycin.

KEY POINT 13-12 Moxidectin is available as a sustainedrelease injectable heartworm preventive and hookworm treatment.

KEY POINT 13-13 Moxidectin combined with imidacloprid is available as a topical heartworm preventive and flea treatment that controls ear mites and internal parasites.

Dog. Moxidectin injection (ProHeart 6) was launched in the United States in 2001 with an indication to prevent heartworms and treat hookworms in dogs. The label for the sustained-release injectable product instructed that it was to be given no more often than once every 6 months. The FDA had concerns about safety as a result of adverse event reports that it received, and the manufacturer voluntarily recalled the product from the U.S market in 2004 to address those safety concerns.⁷⁷ During that time the product remained on the market in Australia, Japan, and parts of Europe. In 2008 the product was reintroduced to the U.S. market with a new label under a postmarketing surveillance initiative based on human drug programs and known as a Risk Minimization Action Plan (RiskMAP), which includes veterinarian training and use of a pet-owner consent form. This is the first veterinary drug to be marketed under RiskMAP, a strengthened risk minimization and restricted distribution program.⁷⁸ The new label advises not to administer the drug to sick, debilitated, or underweight dogs or those with a history of weight loss and states that the product should be used with caution in dogs with preexisting allergic disease, including food allergy, atopy, and flea allergy dermatitis. The label also warns not to administer moxidectin injection within 1 month of vaccinations.⁷⁹

Injectable moxidectin is indicated for use in dogs 6 months of age and older for the prevention of heartworm disease. It should be given at 0.17 mg/kg by subcutaneous injection within 1 month of the dog's first exposure to mosquitoes or within 1 month of the dog's last dose of monthly heartworm preventive. The sustained-release injection provides a 6-month window of protection from heartworms.⁷⁹ However, it does not clear microfilariae or remove adult heartworms.²³ A challenge study comparing efficacy and adverse reactions among four groups of dogs given placebo or moxidectin at 0.06, 0.17, or 0.5mg/kg and inoculated with 50 D. immitis third-stage larvae 180 days later revealed 100% efficacy at the label dose (0.17 mg/kg).⁸⁰ However, one of eight dogs given the lower dose (0.06 mg/kg) was infected. The authors speculated that the failure of protection was a result of individual pharmacokinetic variation because the moxidectin serum concentration in the unprotected dog was at the limit of quantitation (lowest detectable quantity) 8 days after treatment and undetectable thereafter compared with others in that group that had detectable concentrations until at least day 14 and for as long as 55 days for most of the other dogs.⁸⁰ Both the frequency and size of injection-site granulomas correlated positively with the moxidectin dose.80

Moxidectin sustained-release injection is also indicated for the treatment of hookworms *A. caninum* and *U. stenocephala*; although it will eliminate larval and adult stages of those parasites, reinfection may occur in less than 6 months, making its use less than ideal when attempting to control recurrent hookworm disease.

Selamectin

Prepared by semisynthetic modification of doramectin,⁸¹ selamectin (Revolution) is the latest macrolide to enter the U.S. marketplace. This product is unique among other macrolides used in small animals in that it is formulated for convenient topical administration. It is simply "spotted" onto the skin of the pet. It was the first macrocyclic lactone approved for use in dogs and cats to provide activity against both internal and external parasites. However, the discussion here focuses on the activity of selamectin against internal parasites.

KEY POINT 13-14 Selamectin is the latest macrolide to be used commercially in the United States.

KEY POINT 13-15 Selamectin is unique among macrolides in its topical formulation and extreme broad spectrum against internal and external parasites.

It is produced as a fermentation product of *S. avermitilis*, which is then chemically modified.⁸² The pharmacokinetics after topical administration has been studied extensively. The topical bioavailability varies greatly among species. In dogs the bioavailability is only 4%, but it is much greater in cats (74%). The terminal half-life was much longer in both species after topical administration than after intravenous administration, suggesting sustained release from an extravascular depot. The half-life after topical administration was 11 days for dogs and 8 days for cats.²³ The product is absorbed in sufficient quantities and persists for sufficient time to control the target parasites. The approved topical dose is a minimum of 6 mg/kg for dogs and cats.

Selamectin is approved for the prevention of heartworm (D. immitis) in both dogs and cats when applied topically every month.8 Extensive studies proved that the drug's efficacy against heartworms remained^{84,85} even when bathing followed application. The bathing study demonstrated that after topical application efficacy is not likely to be decreased by inadvertent swimming or exposure to rainstorms. The drug is not effective in clearing microfilariae. In cats selamectin is also effective in removing hookworm (A. tubaeforme) and roundworm (T. cati). This effect is undoubtedly due to the greater topical bioavailability observed in cats.⁸² Selamectin is effective against roundworms in dogs²³ and lungworms (A. abstrusus) in cats,⁸⁶ but these are not label-approved indications. The drug has labeled indications in dogs for activity against ear mites, sarcoptic mange mites, and ticks and in cats for activity against ear mites, but these indications are not the focus of this chapter.

KEY POINT 13-16 Selamectin has much greater bioavailability after topical administration on cats compared with dogs.

The safety of selamectin has been established in both dogs and cats and even for use in puppies and kittens over 6 weeks of age. It is also safe to use in ivermectin-sensitive Collies and in breeding dogs and cats.84 Selamectin did not cause any abnormalities when applied topically to ivermectin-sensitive Collies at 40 mg/kg.²² However, avermectin-sensitive Collies given a topical overdose of 10 times the label dose had hypersalivation.²⁸ Clinical signs of dogs reported to the ASPCA Animal Poison Control Center are, in order of frequency, hypersalivation, agitation, diarrhea, facial edema, and hyperactivity.²⁸ In cats the signs in decreasing frequency are vomiting, anorexia, hyperesthesia, hyperthermia, and mydriasis.²⁸ If cats are exposed orally to selamectin they invariably have hypersalivation and sometimes vomit, but topical overdoses at 10 times the label dose in cats did not cause any abnormality.²⁸ Although the insert recommends that dogs should be tested for existing heartworm infections before selamectin administration, it also notes that hypersensitivity reactions were not observed when heartworm-infected dogs were treated with selamectin at 3 times the label dose.⁸⁷ Clinical studies have confirmed the wide safety margin demonstrated in the laboratory studies.

Benzimidazoles

The benzimidazoles represent a large family of broadspectrum agents that have been in widespread use for many years in a vast array of animal species. Several excellent review articles⁸⁸⁻⁹⁰ discuss the history, mode of action, and spectrum of activity of this useful class of anthelmintics.

Thiabendazole, the first benzimidazole discovered, represented a major step forward when it became available in the early 1960s.⁹¹ At the time of its introduction, thiabendazole was a true broad-spectrum product that was very safe to the host animal. Since that time, parasite resistance to the benzimidazoles has been discovered in several species.

KEY POINT 13-17 Introduced to the market in the early 1960s, thiabendazole was the first benzimidazole used commercially and was a major advancement in anthelmintics. It is not commercially available as an anthelmintic for small animals.

Considerable effort has been devoted to determining benzimidazole mechanism of action. Conventional wisdom holds that benzimidazoles bind to tubulin molecules, which inhibit the formation of microtubules and disrupt cell division.^{92,93} It has a much higher affinity for nematode tubulin versus mammalian tubulin, thus providing selective activity against parasites. Evidence also indicates that the benzimidazoles can inhibit fumarate reductase, which blocks mitochondrial function and kills the parasite by depriving it of energy.

The benzimidazoles are poorly soluble and thus are generally given by mouth. They are more effective in horses and ruminants because of their slow transit through the cecum and rumen. Proper use in small animals requires that the benzimidazoles be given for a minimum of 3 days in a row. The dose is usually more effective when divided into two doses per day, thus prolonging the contact time with the parasite.

KEY POINT 13-18 Benzimidazoles are not very soluble.

Because both albendazole and oxfendazole were found to be teratogenic, their use is limited to nonpregnant animals. For simplicity, febantel, a nonbenzimidazole drug that is metabolized to a benzimidazole, thus sharing efficacy and mechanism of action, is included in this section with the other benzimidazoles.

Albendazole

Albendazole is the newest benzimidazole. It has potent broadspectrum anthelmintic activity, but is not approved for use in dogs and cats. Albendazole has demonstrated a broad spectrum of anthelmintic activity against gastrointestinal nematodes; lung nematodes, including inhibited larval forms; cestodes; and lung and liver trematodes in farm animals, companion animals, and humans. Albendazole (Albenza or Zentel) is used overseas to treat humans with intestinal helminth infections, hydatid disease, or cysticercosis. It is commonly used for treatment of nematode and trematode infections in large animals (Valbazen).

KEY POINT 13-19 Albendazole is the latest benzimidazole to be used commercially, but it is not approved for use in dogs or cats.

Albendazole, like other benzimidazoles, is well absorbed (about 50% bioavailable) and converted in the liver to the active metabolites albendazole sulfoxide and albendazole sulfone. These active metabolites are thought to bind to tubulin and inhibit fumarate reductase. The parent drug and its metabolites are excreted primarily in the urine.

Because albendazole was shown to be teratogenic, its use is limited to nonpregnant animals. Dogs treated with 50 mg/ kg twice daily may develop anorexia. Cats may exhibit lethargy, depression, and anorexia when treated.²⁸ When cats were given 100 mg/kg/day for 14 to 21 days, they displayed weight loss, neutropenia, and mental dullness.²⁸ When used clinically, albendazole may be associated with significant toxicity, including myelosuppression (leukopenia, anemia, and thrombocytopenia), abortion, teratism, anorexia, depression, ataxia, vomiting, and diarrhea.^{94,95} Recent evidence suggests that it may cause aplastic anemia in dogs and cats.²⁸ Veterinarians are advised to use due caution with this product.

Albendazole is available as an oral suspension (Valbazen) containing 113.6 mg/mL. Dogs can be treated for lungworms *(F. hirthi)* at a dose of 25 to 50 mg/kg twice daily for 5 days, with the treatment repeated in 2 to 3 weeks, and for bladder worms *(Capillaria plica)* at a dose of 50 mg/kg twice daily for 10 to 14 days.²⁸ Both dogs and cats can be treated for the lung fluke *(Paragonimus kellicotti)* at a dose of 25 mg/kg twice daily for 14 days or 50 mg/kg orally once daily for 21 days.²⁸ Although albendazole is effective against these uncommon parasites, ivermectin and praziquantel are more convenient therapies and likely to be just as effective.

Febantel

Febantel is a prodrug that is metabolized to fenbendazole and oxfendazole, which are undoubtedly the active parasiticides.⁹⁰ The oral acute toxic dose in mice, rats, and dogs is more than 10 g/kg (10,000 mg/kg). At oral doses above 150 mg/kg per day for 6 days, transient salivation, diarrhea, vomiting, and anorexia may be seen in dogs and cats. Febantel is not available in a single-entity formulation but only in combination with praziquantel and pyrantel, which are discussed in the section on combination products.

Fenbendazole

Fenbendazole (Panacur) is a commercially successful benzimidazole that is widely used in dogs. The oral LD_{50} for rats and mice is more than 10 g/kg (10,000 mg/kg).²⁸ Fenbendazole does not have embryotoxic or teratogenic effects in rats, sheep, or cattle. In the rabbit fenbendazole was fetotoxic but not teratogenic, and no carcinogenesis was observed in lifetime studies of rats and mice. In a 6-month toxicity study in dogs, no effect was observed at 4 mg/kg or less.

KEY POINT 13-20 Febantel is metabolized to fenbendazole and oxfendazole, which are probably the active molecules.

KEY POINT 13-21 Fenbendazole is used in a wide variety of species, including dogs, cats, livestock, horses, and zoo animals.

Fenbendazole is a broad-spectrum anthelmintic with activity against a wide variety of nematodes and cestodes in dogs, cats, cattle, sheep, goats, horses, and many zoo animals. Absorbed fenbendazole is metabolized to at least two active metabolites, oxfendazole sulfoxide and oxfendazole sulfone. It undergoes enterohepatic cycling in ruminants, which prolongs effective blood levels.⁹⁶ In the United States fenbendazole is approved for control of helminth parasites of horses, cattle, and dogs.

KEY POINT 13-22 Fenbendazole has a broad spectrum of activity against many nematodes and cestodes.

Dogs. Fenbendazole is approved only for use in dogs 6 weeks of age and older. Fenbendazole granules (Panacur) are mixed in the feed at a dose level of 50 mg/kg and given to dogs for 3 consecutive days for the removal of *T. canis, T. leonina, A. caninum, U. stenocephala, T. vulpis,* and *Taenia pisiformis.*⁹⁷ It has shown excellent activity against *Giardia* spp. in dogs at the approved dose.^{95,98} At longer-than-approved duration of therapy (i.e., 50 mg/kg daily for 10 to 14 days), it has been used to treat the lung fluke, *P. kellicotti,* in dogs.²⁸ Fenbendazole is relatively safe, and there are no known contraindications to its use in dogs.

Cats. Fenbendazole is not currently approved for use in cats. When given at a dose of 50 mg/kg for 5 days, it is effective against ascarids, hookworms, *Strongyloides*, and *Taenia* spp. tapeworms.²⁸ Treatment of *A. abstrusus*, *P. kellicotti*, and *C. aerophila* may require 14 days of therapy.²⁸

Tetrahydropyrimidines

The tetrahydropyrimidines include the numerous salts of pyrantel, morantel, and the investigational compound oxantel, which is available outside the United States. They all act as nicotinic agonists, which disturb the neuromuscular system, causing contraction and subsequent tonic paralysis.⁹⁹⁻¹⁰² In vitro experiments indicate that pyrantel is 100 times more powerful than acetylcholine. It seems that the nicotinic acetylcholine receptors of invertebrate parasites are essential for neurologic function but differ in physiology and distribution in mammals.¹⁰³ In ruminants these products are rapidly metabolized to inactive metabolites; therefore higher doses are required to treat ruminants compared with monogastric animals.²⁰

KEY POINT 13-23 Tetrahydropyrimidines are nicotinic agonists. They cause contraction and subsequent tonic paralysis of parasites.

KEY POINT 13-24 Pyrantel is 100 times more powerful than acetylcholine.

Pyrantel

Pyrantel was introduced in the United States as a broadspectrum anthelmintic for sheep in 1966²² and is now available under a wide variety of trade names in the form of tablet, paste, oral suspension, and medicated feed.¹⁰⁴ The tartrate salt of pyrantel is a white powder, soluble in water, that is used in horses and swine. Pyrantel tartrate is well absorbed after oral administration in the rat, dog, and pig. Plasma levels peak within 3 to 6 hours.²² Pyrantel tartrate is rapidly metabolized and in dogs is primarily eliminated by way of the urinary tract, but pyrantel pamoate is poorly absorbed from the gastrointestinal tract and is primarily eliminated through the feces with less than 15% excretion through the urinary tract.¹⁰⁴

KEY POINT 13-25 Pyrantel pamoate is poorly absorbed, which contributes to its safety in young animals.

The pamoate salt of pyrantel is a yellow powder, insoluble in water. It is available as a ready-to-use suspension and as tablets for dogs and horses. The fact that pyrantel pamoate is poorly absorbed from the intestine adds to its safety in very young or weak animals. Pyrantel salts are stable in solid form but photodegrade when dissolved or suspended in water, resulting in reduction of potency.

Dogs. Pyrantel pamoate is available as a tablet, chewable tablet, and palatable suspension (Nemex and many other trade names) and is indicated for the removal of T. canis, T. leonina, A. caninum, and U. stenocephala from dogs and puppies.¹⁰⁵⁻¹⁰⁸ The drug has also been used to treat Physaloptera stomach worms in dogs, although such use is not approved.^{104,109} Pyrantel may have some effect on tapeworms as well, but other drugs are commonly used to treat tapeworm infections in small animals. The recommended dose of 5 mg/kg of pyrantel pamoate suspension is administered orally or mixed with a small amount of feed.¹⁰⁴ For animals weighing 2.25 kg or less, the dose is increased to 10 mg/kg. Tablets may be administered directly or placed in a small portion of food. Pyrantel pamoate is safe for nursing and weanling pups, pregnant bitches, males used for breeding, and dogs infected with D. *immitis.* The oral LD_{50} is greater than 690 mg/kg in dogs.²² In chronic toxicity studies dogs had no adverse effects when given 20 mg/kg daily for 3 months but did have ill effects at 50 mg/kg or above daily.²² Pyrantel pamoate is compatible with organophosphates and other antiparasitic and antimicrobial agents.

Cats. Pyrantel pamoate products used in dogs are not labeled for cats but are considered very safe and effective against some common feline parasites, the ones that are similar to those afflicting dogs and are listed as indications on the canine label. The oral dose range of 5 to 20 mg/kg is reportedly efficacious against ascarids, hookworms, and *Physaloptera* spp., with the dose repeated in 2 to 3 weeks in some cases.^{22,27,28,104} Pyrantel

pamoate is labeled for cats as a combination product with praziquantel (Drontal), which is described later, in the combination product section.

Cyclic Depsipeptides

The cyclodepsipeptide PF1022A, isolated from *Mycelia sterilia*, was found to have low toxicity and strong anthelmintic properties when tested against *Ascaridia galli* in chickens, making it one of the most promising deworming prospects to emerge since the discovery of avermeetins and milbemycin.

Emodepside

Emodepside is the first cyclic depsipeptide to be approved for use against animal parasites in the United States. It is a semisynthetic derivative of PF1022A, mentioned previously. The product binds to a presynaptic latrophilin receptor in parasitic nematodes, which results in flaccid paralysis and death.¹¹⁰ It has low to moderate acute toxicity in mammalian species. The oral LD_{50} in rats is greater than 500 mg/kg and is more than 2000 mg/kg when applied to the skin. Studies in rats and rabbits suggest that emodepside may interfere with fetal development.¹¹¹ Women who are pregnant or may become pregnant should avoid direct contact with emodepside and wear disposable gloves if product handling is necessary. Emodepside is only available commercially as a combination product, combined with praziquantel, and as such is discussed in detail later, in the section on broad-spectrum combinations.

KEY POINT 13-26 Emodepside is the first cyclic depsipeptide approved in the United States.

KEY POINT 13-27 Pregnant women should use care if they must handle this drug.

Piperazines

Piperazine was used to treat human gout in the early 1900s because it acts as an excellent uric acid solvent. Its anthelmintic activity was discovered in the 1950s.²² Since then, a wide variety of piperazine salts have been derived. The various salts of piperazine (adipate, hydrochloride, sulfate, monohydrate, citrate, and dihydrochloride) are used as anthelmintics in swine, poultry, horses, dogs, and cats. Piperazine is quite safe to use in these species but has a narrow spectrum of action, limited primarily to roundworms.^{93,27} Anthelmintic activity depends on the salt freeing its piperazine base in the gastro-intestinal tract. The amount of piperazine (base) in each salt varies widely. The citrate salt contains 35% piperazine; adipate salts, 37%; phosphate salts, 42%; and dihydrochloride salts, 50% piperazine base.⁹⁶

Piperazine paralyzes worms by blocking the action of acetylcholine and GABA at the neuromuscular junctions, and the worms are eliminated by intestinal peristalsis.^{20,112} It acts by hyperpolarizing nerve membranes at the neuromuscular junction, leading to flaccid paralysis of the parasite.²² Piperazine is also one of the active ingredients in a number of combination anthelmintic products. Piperazine should not be used in combination with pyrantel pamoate because the modes of action are antagonistic.

KEY POINT 13-28 Piperazine paralyzes worms by blocking acetylcholine and GABA, and the worms are eliminated by intestinal peristalsis; thus it may not work well in the face of gastrointestinal hypomotility.

Piperazine is rapidly absorbed from the gastrointestinal tract and rapidly cleared by urinary excretion. Elimination is virtually complete within 24 hours.⁹⁶ It may not be effective in animals with intestinal hypomotility because the paralyzed worms may recover from the drug effect before they are passed in the stool. Piperazine should be used with caution in animals with hepatic or renal dysfunction. Occasional adverse reactions observed in dogs include ataxia, diarrhea, and vomiting.

Piperazine is available as tablets, solution, and soluble powder under many proprietary names (Pipatabs, Puppy Paste, Happy Jack KittyKat Paste, Tasty Paste). It is practically nontoxic. The oral LD_{50} for rats is 4.9 g/kg and for mice is 11.4 g/ kg. Treatment for intoxication is symptomatic and supportive. Piperazine can be administered to animals of all ages.

Dogs and Cats

Piperazine is usually administered orally at 45 to 65 mg of base per kilogram,⁹⁶ although higher doses (100 to 250 mg/kg) have been reported in the literature.^{107,113-115} Piperazine is effective against adult roundworms *T. canis, T. cati,* and *T. leonina.*

Isoquinolones

The cesticidal isoquinolones are represented by two closely related drugs: praziquantel and epsiprantel. This cesticidal class is the safest and most effective yet approved in the United States. They attack the parasite neuromuscular junction and the tegument. These drugs cause increased cell membrane permeability to calcium and resulting loss of intracellular calcium. This effect produces an instantaneous contraction and paralysis of the parasite.¹¹⁶ The second effect is a devastating vacuolization and destruction of the protective tegument.^{92, 117} The combined effects of paralysis and tegmental destruction provide excellent activity against cestodes.

KEY POINT 13-29 Isoquinolones are the safest and most effective cesticidal drugs approved in the United States.

Praziquantel

Praziquantel was the first cesticidal isoquinolone approved in the United States. It has marked anthelmintic activity against a wide range of adult and larval cestodes and trematodes of the genus *Schistosoma*. Oral administration results in nearly complete absorption and rapid distribution throughout the body and across the blood–brain barrier. Although 80% of the drug is eliminated in the urine, the main site of inactivation is the liver, with only trace amounts of the unchanged drug excreted primarily in the urine.^{22,91} Praziquantel has high oral bioavailability, high protein binding, and a marked first-pass effect. The oral half-life in dogs is reported to be 30 to 90 minutes²² to 3 hours.²⁸

KEY POINT 13-30 Praziquantel, the first approved cesticidal isoquinolone in the United States, has marked anthelmintic activity against cestodes and trematodes.

Praziquantel is a very safe anthelmintic. Rats tolerated daily administration of up to 1000 mg/kg for 4 weeks, and dogs tolerated up to 180 mg/kg per day for 13 weeks. Vomiting is typically observed at high dosage rates. Injected doses of 200 mg/kg were lethal in cats.²⁸ Praziquantel did not induce embryotoxicity, teratogenesis, mutagenesis, or carcinogenesis, nor did it affect the reproductive performance of test animals. Occasional adverse experiences in clinical use include pain on injection, anorexia, diarrhea, salivation, vomiting, sleepiness, staggering, and weakness. Overdoses have been reported to cause diarrhea, depression, incoordination, tremors, salivation, and vomiting.

KEY POINT 13-31 Praziquantel has a wide margin of safety.

Dogs and cats. Praziquantel (AmTech, Droncit) is administered orally or injected subcutaneously at 2.5 to 7.5 mg/kg for the removal of *Dipylidium caninum*, *Taenia taeniaeformis*, *T. pisiformis*, *T. hydatigena*, *T. ovis*, *Mesocestoides corti*, *Echinococcus granulosus*, *Echinococcus multilocularis*, *Spirometra* spp., *Diphyllobothrium latum*, *D. erinacei*, and *Joyeuxiella pasquali*.^{118-124,96} The product insert has extensive information about using this drug to help control *E. multilocularis*, including the life cycle of the parasite, difficulty of diagnosis, and other public health considerations.¹²⁵ Praziquantel injection is not intended for use in puppies or kittens younger than 4 weeks of age. Several combination products contain praziquantel; see the section on combination products for more information.

Epsiprantel

Epsiprantel (Cestex) was the second cesticidal isoquinolone to be approved in the United States. Unlike its cousin praziquantel, epsiprantel is poorly absorbed after oral administration. Less than 0.1% is recovered from the urine; there are no known metabolites.²⁸ It is eliminated in the feces unchanged.²² Because of the low bioavailability, systemic toxicity and teratogenic effects are very unlikely, but the safety of epsiprantel in pregnant dogs and cats has not been proved. In acute toxicity studies in mice and rats, the oral minimum lethal dose of epsiprantel was shown to be more than 5000 mg/kg. Doses as high as 36 times the label dose were well tolerated in dogs and caused vomiting in some kittens.²⁸ Cats given the drug at 40 times the label dose for 4 days had minimal signs. Dogs given 90 times the label dose for 14 days had no significant adverse events.¹²⁶

KEY POINT 13-32 Like praziquantel, epsiprantel, the second cesticidal isoquinolone approved in the United States, has a wide margin of safety, but unlike praziquantel, it is poorly absorbed orally.

Epsiprantel treatment as an oral film-coated tablet, at 2.75 mg/kg for cats or 5.5 mg/kg for dogs, effectively removes *D. caninum, T. taeniaeformis, T. pisiformis,* and *T. hydatigena* after a single dose.^{127,128} Evidence suggests that the drug is effective against *E. granulosa* and *E.multilocularis,* but the data are insufficient to recommend a dosage that will completely clear the infection from those treated.¹²⁹ Epsiprantel was given concurrently with diethylcarbamazine (in dogs), antiinflammatory drugs, insecticides, and nematocides with no incompatibilities observed.¹²⁶ It should not be used in puppies and kittens younger than 7 weeks of age.

Arsenicals

Heavy metals like arsenic and antimony are well represented in the history of anthelmintics. To date, safer and more effective drugs for the most common parasites have largely replaced arsenicals. Their use is now limited to removal of adult *D. immitis*. Thiacetarsemide (Caparsolate) is no longer available commercially in the United States¹³⁰ and thus will not be covered in this chapter. The therapeutic effect of arsenicals depends on a reaction between the arsenic salt and sulfhydryl-containing enzymes.¹³¹ Inactivation of parasite enzyme systems causes death. Because arsenic is widely known as a toxin in man and animal, caution is required when using these products.

KEY POINT 13-33 Arsenicals typically have a narrow margin of safety.

Melarsomine

Although contraindicated in cats, melarsomine dihydrochloride (Immiticide), the only arsenical anthelmintic commercially available in the U.S. veterinary market, has 92% to 98% efficacy against adult D. immitis in dogs.¹³²⁻¹³⁶ The arsenic content of the product is less than that of thiacetarsemide, making melarsomine less toxic to the patient. Melarsomine is labeled to be administered intramuscularly at a dose of 2.5 mg/ kg for two injections given 24 hours apart to dogs at low risk of thromboembolic complications.¹⁷ Dogs that have moderate risk of thromboembolism may be treated with an alternative three-injection regimen of a single injection followed by a rest period of 1 to 2 months, after which two standard injections are given.¹⁷ This later three-injection regimen is reportedly less hazardous for the patient and more efficacious and therefore is the preferred regimen recommended by the American Heartworm Society, regardless of the stage of disease (unless melarsomine is otherwise contraindicated).^{17, 18a} Melarsomine is contraindicated in dogs with severe heartworm disease associated with caval syndrome.²⁸ Injections should only be made deep into the lumbar epaxial muscles along L3 to L5. Peak blood level is achieved in about 11 minutes after injection, and the half-life is 3 hours.²⁸

KEY POINT 13-34 Melarsomine is the only commercially available arsenical anthelmintic.

About one third of dogs treated will have injection site reactions, most of which resolve within a week, but firm nodules at the injection site can persist indefinitely.²⁸ Additional adverse reactions include elevated hepatic enzymes, coughing, gagging, depression, lethargy, anorexia, fever, pulmonary congestion, and vomiting.²⁷ This drug exemplifies the problem of parasite removal by poisoning the patient just enough to kill the parasite, hopefully without damaging the patient too much. It has a narrow therapeutic range. The toxic dose is only 2.5 to 3 times the recommended dose and can result in panting, pulmonary inflammation, salivation, vomiting, edema, and death. Safety has not been determined in breeding, pregnant, or lactating dogs. That said, clinical studies indicate that the treatment is well tolerated even in dogs that have clinical signs of heartworm disease.^{135,137,138}

As previously mentioned in the ivermectin section of this chapter, the American Heartworm Society guidelines for diagnosis, prevention, and management of heartworm infection in dogs should be consulted before treating a heartworm-infected dog with melarsomine.^{18a} Treatment with a macrocytic lactone before administration of melarsomine should be considered along with other methods to reduce the potential for melarsomine adverse reactions. For example, as previously mentioned in the ivermectin section, one study of heartworm-positive dogs comparing groups that were treated with three drugs (i.e., melarsomine, doxycycline and ivermectin), two drugs (i.e., doxycycline and ivermectin), doxycycline alone, ivermectin alone, or melarsomine alone led the authors to conclude that the combination of doxycycline and ivermectin was synergistic.⁵² All dogs treated with ivermectin plus doxycycline (with or without melarsomine) were free of microfilariae in 9 weeks. This may be related to the elimination of Wolbachia sp. bacteria, which are filarial endosymbionts. The authors found that the administration of doxycycline plus ivermectin for several months before (or without) melarsomine resulted in elimination of adult heartworms with less severe thromboembolism than did treatment with melarsomine alone.52

KEY POINT 13-35 The prudent practitioner will consult American Heartworm Society guidelines before using melarsomine.

Miscellaneous

Dichlorophen

Dichlorophen (Happy Jack Tapeworm Tablets) is a chlorinated analog of diphenylmethane. It has low toxicity for mammals. The oral LD_{50} is 2690 mg/kg for rats, and the acute oral LD_{50} in dogs is 1000 mg/kg. Dichlorophen has bacteriostatic, fungicidal, and cesticidal properties. It causes electron transport–linked phosphorylation to uncouple in the parasite mitochondria and is relatively safe in the host because of low gastrointestinal absorption.⁹¹ Dichlorophen may be given orally as an "aid in the removal" of *D. caninum* and *T. pisiformis* tapeworms from dogs.¹³⁹ The drug may be administered orally in tablet or capsule form at 220 mg/kg after an overnight fast. The tapeworms are killed, digested, and eliminated in an unrecognizable form. Animals occasionally vomit or develop diarrhea after treatment with dichlorophen.

KEY POINT 13-36 Dichlorophen is not absorbed well from the gastrointestinal tract, which improves its safety profile.

KEY POINT 13-37 Dichlorophen aids in the removal of tapeworms from dogs.

BROAD-SPECTRUM COMBINATIONS

The veterinary practitioner is always looking for anthelmintic products that cover an ever-increasing spectrum of parasites. Broad-spectrum products provide two important advantages. First, they obviate dosing with several different products at once when a patient has a mixed parasite infection, making administration easier. Second, they provide peace of mind that a treated animal will be cleared of possibly undiagnosed parasites. For instance, a puppy from the animal shelter will be better served by use of a product that is effective in removing both roundworms and hookworms than a product that is effective against only roundworms. There are two ways to increase the spectrum of anthelmintics: either by tackling the arduous task of discovering a single broad-spectrum chemical or by combining several compatible active ingredients to build the desired spectrum of activity.

KEY POINT 13-38 Broad-spectrum anthelmintic combinations make treating mixed parasitic infections easier and may treat common undiagnosed parasites; therefore they are associated with increased veterinary and owner confidence.

Combination anthelmintic products are briefly reviewed in this section, but not combinations that are formulated to treat or prevent fleas or other nonhelminth parasites. In many cases combination-product formulation and dosing regimens are different from those of the single-entity drug ingredients. The toxicity and mechanism of action of the individual ingredients are covered earlier in this chapter.

Emodepside Plus Praziquantel

This product is formulated for use in cats (Profender) as a topical spot-on that contains 1.98% emodepside and 7.94% praziquantel. The prefilled applicators deliver a minimum dose of 3 mg/kg emodepside and 12 mg/kg praziquantel when applied to the skin. The active ingredients are readily absorbed through the skin, enter systemic circulation, and act on target parasites in the gastrointestinal tract. It is labeled for use in cats and kittens that are at least 8 weeks of age and is considered safe to use in heartworm-positive cats.¹¹¹ The product is safe and effective in removing roundworms, *T. cati* (adults and fourth-stage larvae); hookworms, *A. tubaeforme* (adults, immature adults, and fourth-stage larvae); and tapeworms,

D. caninum and *T. taeniaeformis*.¹⁴⁰⁻¹⁴² The topical emodepside– praziquantel product was very effective and safe when used in a large-scale clinical study comparing it with topical selamectin– oral epsiprantel.¹⁴³

Pyrantel Plus Praziquantel

Two-way combination products containing pyrantel and praziquantel are approved for use in the United States in both dogs (Virbantel) and in cats (Drontal).

Dogs

The canine product is formulated to deliver 5 mg of praziquantel and 5 mg of pyrantel pamoate per kilogram. A single dose is given to dogs to remove tapeworms (*D. caninum* and *T. pisiformis*), hookworms (*A. caninum*, *A. braziliense*, and *U. stenocephala*), and roundworms (*T. canis* and *T. leonina*).

Cats

The feline product is formulated to deliver at least 5 mg of praziquantel and 20 mg of pyrantel pamoate per kilogram. A single dose is given to cats and kittens to remove tapeworms *(D. caninum* and *T. taeniaeformis)*, hookworms *(A. tubaeforme)*, and roundworms *(T. cati)*. The product is 98% effective and well tolerated. Cats maintained in conditions of heavy or constant parasite exposure should be reevaluated in 2 to 4 weeks. This combination product should not be used in kittens weighing less than 1.5 pounds or those younger than 4 weeks of age.

Pyrantel Plus Praziquantel Plus Febantel

A three-way combination of pyrantel, praziquantel, and febantel (Drontal Plus) is available in the United States and many other parts of the world. This product is formulated to deliver at least 25 mg febantel, 5 mg praziquantel, and 5 mg pyrantel pamoate per kilogram. A single dose is given to dogs to remove tapeworms (*D. caninum*, *T. pisiformis*, *E. granulosus*, *E. multilocularis*), hookworms (*A. caninum*, *U. stenocephala*), roundworms (*T. canis*, *T. leonina*), and whipworms (*Trichuris vulpis*).^{144,145} It is interesting to note that a single dose of this combination is effective against nematodes, especially whipworms, but that febantel alone requires three daily doses to effectively remove nematodes. This combination of ingredients may be synergistic. This product should not be used in pregnant dogs, dogs weighing less than 2 pounds, or puppies younger than 3 weeks of age.

Ivermectin Plus Pyrantel

Ivermectin combined with pyrantel pamoate is available in flavored chunks or tablets (Heartgard-30 Plus, Iverhart Plus, Tri-Heart Plus) for dogs. Pyrantel pamoate is added to provide action against gastrointestinal parasites because the heartworm-preventive dose of ivermectin, which is safe for Collies, is not effective against these important parasites. The product is formulated to deliver a target dose of 0.006 mg (6 mcg) of ivermectin and 5 mg of pyrantel pamoate per kilogram of body weight. Given orally to dogs every 30 days, it treats and controls roundworms (*T. canis, T. leonina*) and hookworms (A. caninum, A. braziliense, and U. stenocephala) and prevents heartworms (D. immitis).¹⁴⁶ At a minimum, the product should be given at monthly intervals during the heartworm season. Adult heartworms do not produce detectable levels of microfilariae when exposed to ivermectin, so an antigen test should be used to reveal the presence of adult heartworms.¹⁷ Safety tests have revealed that the ivermectin–pyrantel combination is well tolerated.¹⁴⁷ This medication should not be given to dogs younger than 6 weeks of age. (See the ivermectin section of this chapter for a discussion of administration of ivermectin to dogs harboring adult heartworms, a procedure that carries some risk and is not a labeled indication for use.)

Ivermectin Plus Pyrantel Plus Praziquantel

Ivermectin combined with pyrantel pamoate and praziguantel is available in flavored tablets (Iverhart Max) for dogs. Adding praziquantel to the two-way combination product previously mentioned extends the parasite spectrum to include tapeworms. This product is formulated to deliver a target dose of 0.006 mg (6 mcg) of ivermectin, 5 mg of pyrantel pamoate, and 5 mg of praziquantel per kilogram. Given orally to dogs every 30 days, it treats and controls roundworms (T. canis, T. leonina), hookworms (A. caninum, A. braziliense, and U. stenocephala), and tapeworms (D. caninum, T. pisiformis) and prevents heartworms (D. immitis). At a minimum, the product should be given at monthly intervals during the heartworm season. Adult heartworms do not produce detectable levels of microfilariae when exposed to ivermectin, so an antigen test should be used to reveal the presence of adult heartworms.¹⁷ This medication should not be given to dogs younger than 8 weeks of age or those with existing heartworm infections. (See the ivermectin section of this chapter for a discussion of administration of ivermectin to dogs harboring adult heartworms, a procedure that carries some risk and is not a labeled indication for use.)

Milbemycin Oxime Plus Lufenuron

A two-way combination of milbemycin oxime and lufenuron (Sentinel) is approved for use in dogs. It is formulated to deliver a minimum dose of 0.5 mg of milbemycin oxime and 10 mg of lufenuron per kilogram of body weight. When given every 30 days, it is effective in preventing heartworms (*D. immitis*). The product also kills hookworms (*A. caninum*), removes and controls roundworms (*T. canis* and *T. leonina*) and whipworms (*T. vulpis*), and controls fleas. This medication should not be used in puppies younger than 4 weeks of age or those that weigh less than 2 pounds. This product is approved for concurrent administration with nitenpyram (Capstar) for quick knockdown of existing flea populations.

Imidacloprid Plus Moxidectin

A new combination product (Advantage Multi) contains imidacloprid for external parasites and moxidectin for internal parasites. The canine product provides a minimum of 10 mg/kg of imidacloprid and 2.5 mg/kg moxidectin, whereas the feline product provides the same dose of imidacloprid and 1 mg/kg moxidectin. It is important not to use the canine product on cats because cats are more sensitive to moxidectin than dogs.

Dogs

The canine product is approved for the prevention of heartworms (*D. immitis*), for the treatment and control of adult and larval hookworms (*A. caninum, U. stenocephala*), adult and larval roundworms (*T. canis, T. leonina*), and whipworms (*T. vulpis*).¹⁴⁸ The canine product has not been tested in dogs that weigh less than 1.36 kg (3 lb) or are younger than 7 weeks of age. Nor has it been tested in breeding, pregnant, or lactating dogs. Dogs should be tested for the presence of heartworm before administration. The canine product is not effective against adult heartworm or for clearing microfilariae. It was well tolerated at 5 times the label dose. Oral ingestion of the product by dogs may cause serious reactions, including depression, salivation, dilated pupils, incoordination, panting, and generalized tremors. Thus it is important to prevent dogs from licking the product from the application site.

Cats

The feline product is approved for the prevention of heartworm, *D. immitis;* for the treatment and control of adult and larval hookworm, *A. tubaeforme;* and adult and larval roundworm, *T. cati.* It should not be used on cats that weigh less than 0.9 kg (2 lb) or on cats younger than 9 weeks of age. This product was well tolerated when given at 5 times the label dose in 9-week-old kittens. Cats dosed with a single dose at 10 times the label dose exhibited mild transient hypersalivation. Oral ingestion of the product may cause hypersalivation, tremors, vomiting, and decreased appetite.

This combination is also effective in treating fleas in dogs and cats and ear mites in cats.

CARDIOVASCULAR PHYSIOLOGY AS IT PERTAINS TO CARDIOVASCULAR DRUGS

Membrane Ion Movements and the Action Potential

Predicting the nuances of pharmacodynamic responses to cardiac drugs depends, in part, on understanding the electrophysiology of myocardial cells. Selected mechanisms of ion movement into the cell are demonstrated in Figure 14-1. The action potential duration (APD) of myocardial cells is long compared with that of nerves, reflecting the well-orchestrated coordination of multiple ion channels and associated transport proteins.¹ The magnitude and direction of the ion flow, and thus current, depends on both transmembrane voltage and ion concentration gradients. Two types of myocardial cells will be discussed: those capable of automaticity (i.e., spontaneous

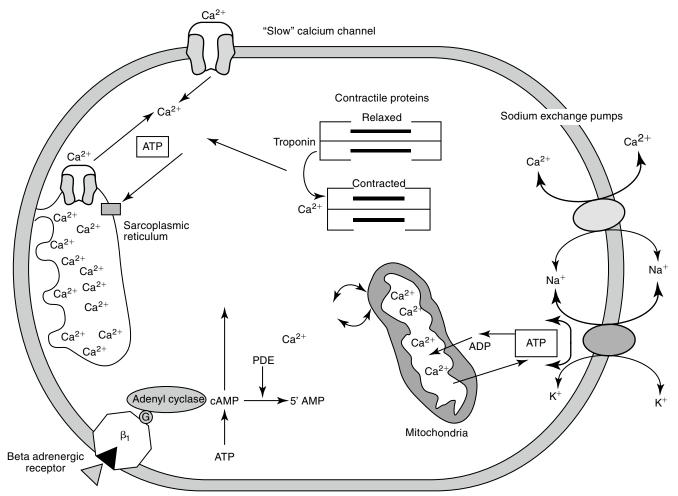

Figure 14-1 Calcium can enter the myocardial cell through several mechanisms, including the slow calcium channel, the sodiumcalcium exchange ATPase pump, and beta 1 adrenergic receptor stimulation. Increased intracellular concentrations of calcium lead to the release of sarcolemmal calcium. Calcium leads to the interaction between actin and myosin, causing myocardial contractility. Sequestration of calcium in the sarcoplasmic reticulum causes myocardial relaxation. Sodium and potassium channels are not shown in this diagram. *ATP*, Adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *PDE*, phosphodiesterase.

depolarization), exemplified by cells that normally serve as pacemakers (e.g., sinoatrial [SA] node) and those cells not normally capable of automaticity (e.g., atrial and ventricular myocardial cells). Although overlap exists, the electrophysiology of each differs from one another (Figure 14-2).

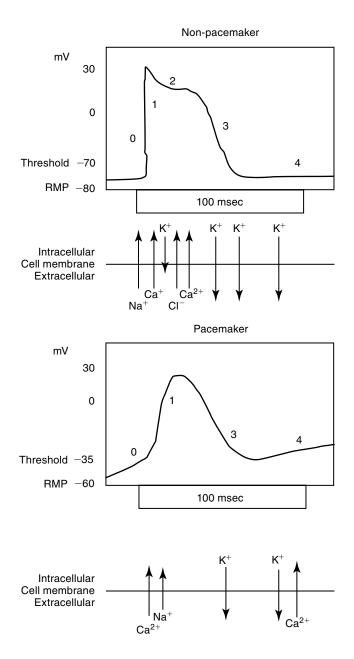

Nondepolarizing cells

In nondepolarizing cells, the resting membrane potential (RMP) of -80 to -90 (inside compared with outside) reflects the relative distribution of sodium, potassium, and chloride across the cell membrane. The external and internal concentration of sodium approximates 145 and 15 mmol/L, respectively (ratio of 9.7), whereas that of potassium approximates 4 (range 3 to 6) and 145 mmol/L respectively (ratio of 0.027). Chloride ions contribute to the RMP only by virtue of their influence on cellular electrical responses to incoming signals. At rest the distribution of ions is not at equilibrium but is in a dynamic state, constantly subject to internal and external influences. The major driving force for the negative RMP is ion movements through channels (molecular pores) that span the myocardial cell membrane. These channels generally exist in either an

open (conducting) or closed (resting) state, with a third state of "inactivation" reflecting a period in which the nonconducting channel cannot be activated. The state of channels targeted by cardiac drugs markedly influences their impact on the action potential. Drugs with greater affinity for inactivated channels generally are more influential than those that target other states.

KEY POINT 14-1 Differences in response of pacemaker versus nonpacemaker cells to cardioactive drugs reflects, in part, differences in membrane electrophysiology and ion flow.

Movement of ions through the channels follows both concentration and electrical (i.e., electrochemical) gradients. Ion flow is also influenced by energy-dependent pumps that actively and selectively direct ion movement against the electrochemical gradients. A "leak current" allows a constant, albeit smaller, ion flux. At rest the status of all channels influencing the membrane potential is static, save for a specific ("inward rectifier") channel that is permeable only to potassium, allowing it to efflux down an electrochemical gradient. This efflux is countered by a Na+,K+-ATPase pump, which

exchanges 3Na+ for 2K+, thus maintaining the intracellular concentration necessary for the gradient. Accordingly, potassium has the greatest influence on the RMP, and very slight changes in extracellular potassium can influence potassium flux, the RMP, and the cardiac cell cycle.

KEY POINT 14-2 Potassium has the greatest influence on the resting membrane potential. As such, even slight changes in extracellular potassium can influence potassium flux, the resting membrane potential, and the cardiac cell cycle.

Myocardial sodium channels are the primary gatekeepers of the action potential in nonpacemaker cells (see Figure 14-1). They are voltage gated and closed at rest. Membrane depolarization in nonpacemaker cells (see Figure 14-2) increases selective permeability in sodium channels. The concentration gradient causes an initial sodium influx, stimulating more voltage-gated sodium channels to open, thus perpetuating a Figure 14-2 The action potential (AP) occurs in four phases. The ions responsible for and the configuration of each phase differ between cells capable of automaticity (i.e., pacemaker) and non-pacemaker (i.e., nondepoloarizing) cells. Phase 0 occurs when the resting membrane potential (RMP) reaches threshold, resulting in the generation of the AP. The rapid upswing in the membrane potential reflects sodium (non-pacemaker) and, to a lesser degree, calcium influx. In cells capable of automaticity (bottom), calcium is the primary ion moving inward during phase 0. This calcium influx stimulates release of calcium from the sarcoplasmic reticulum. The small influx of calcium in non-depolarizing cells is important to intracellular calcium fluxes. Phase 1 represents the early phase of repolarization. An influx of chloride and decreased efflux of potassium lead to reestablishment of the membrane potential. During phase 2 electrogenic movement of calcium through "slow" channels prolongs repolarization, causing a plateau phase. With phase 3, the membrane potential reaches the diastolic resting level. In cells capable of automaticity, this phase is characterized by a gradual depolarization, probably because of calcium influx, until threshold is reached. The heart rate is determined by the slope of phase 4; tissues with the steepest phase 4 slope will serve as the cardiac pacemaker.

self-regenerating action potential (phase 0, depolarization). Sodium channels inactivate when depolarization is complete and must go through a resting (recovery) period before they can be reactivated. Membrane permeability reestablishes itself largely in response to potassium ion efflux, and the membrane potential begins to decline back toward the RMP (phase 1, early repolarization). As the membrane potential continues to repolarize (phase 3), the ability of sodium channels to reactivate increases, until the RMP is once again reached (phase 4). Because sodium influx and sodium channel recovery is rapid, sodium channels are referred to as "fast," in contrast to "slow" calcium channels, which take longer to recover. Drugs with greater affinity for inactivated sodium channels generally are more able to affect the refractory period and the APD compared with those that target either resting or open channels. Sodium influx during phase 0 depolarization influences other ion channels and their ion movements.

Among the ions most influenced by sodium flux in nonpacemaker cells are potassium channels, of which multiple types, exist, varying in tissue and intracellular location, and control (Table 14-1). Inward rectifier potassium channels are among the channels that determine the RMP. Depolarization causes conformational changes in transient potassium channels, which rapidly inactivate, and delayed rectifier potassium channels, which include both slow and rapid inactivators (each voltage gated). Efflux of potassium through these channels causes the membrane to begin to repolarize. Initially, the outward potassium current is balanced by an inward depolarizing current of calcium through L-type channels, causing the plateau, or phase 2, of repolarization in nonpacemaker (but not pacemaker) cells. Increased activity of delayed rectifier channels increases potassium efflux, which, when coupled with closing calcium channels, results in late repolarization (phase 3; see Figure 14-2). Slower delayed rectifier potassium

Channel	Designation	Regulation	Role
	*K _{2p} 1-7,9-12,13,15-18	Oxygen, pH, mechanical stretch, G	Leak K ⁺
1. Tandem (or two) pore domain	**KCNK	proteins	Establish RMP
2. Inward rectifier	K _{ir} 1-7 or IRK; KCNJ	ATP (K _{ir} 6); G-proteins	Inward K flow (some "weak" channels allow efflux) Establish RMP
3. Calcium activated	K _c a BK (also Maxi-K or slo1; K _c a-1 KCNMA) SK (K _c a 2-4; KCNN, KCNT) IK; K _c a-5, KCNU	Calcium; or other signals (sodium, chloride) (BK also responds to voltage; SK responds to sodium)	BK: large ion flow SK: small ion flow
4. Voltage gated	K _v a	Transmembrane potential	Contribute to AP repolarization; limits frequency of AP
Delayed rectifier	K _v a 1,2,3,7,10		Repolarization
Outward rectifying	K _v a 10 (KCNH)		
Inward rectifying	K _v a 11 (KCNH)		
Transient			
А-Туре	K _v a 1,3,4 (KCNA, KCNC, KCND)		Repolarization (efflux)
Slowly activating	K _v a12 (KCNH)		

channels remain open to ensure net outward potassium efflux such that the membrane potential becomes more negative, causing rapid delayed rectifier and inwardly rectifying potassium channels to open. The delayed rectifier K⁺ channels close when the membrane potential is restored to about -80 to -85 mV, but the inwardly rectifying potassium channels remain open throughout phase 4, thus maintaining the RMP. Because potassium channels generally remain open as long as the membrane is not at its resting potential (i.e., is in some state of depolarization), potassium channels also influence the duration of the action potential. Thus the influence of potassium channels in nondepolarizing cells includes the RMP and the rate of repolarization. In pacemaker cells (discussed in greater depth later in this chapter), potassium channels influence the RMP, the rate of repolarization, and the initial rate of phase 4. Consequently, potassium and drugs that target potassium channels potentially influence all cardiac (e.g., depolarizing and nondepolarizing) tissues.

KEY POINT 14-3 Inward flux of sodium is the primary ion responsible for phase 0 of nondepolarizing cells, whereas calcium influx is the primary ion in pacemaker cells.

Calcium also plays a major role in both nondepolarizing and depolarizing myocardial cells. The extracellular to intracellular calcium ratio of myocardial cells approximates 10, generating a calcium ion flow down both a concentration and electrical gradient. In contrast to the vasculature, in which channel movement is predominantly receptor mediated, calcium flux in the myocardium is predominantly voltage dependent. At least three types of voltage-gated calcium channels exist in the cardiovascular system, with differences reflecting conductance and sensitivity to voltage: T, N, and L types.² The N-type (neuronal) calcium channels are located predominantly in neural tissues and markedly differ in responsiveness compared with L and T calcium channels. The best characterized of the calcium channels are of the L-type (long-lasting, large), and they are the predominant influencing channel during the states of the cardiac action in which the membrane potential is positive. Despite being voltage gated, calcium L-channels contain receptors (similar to those in the vasculature) that influence calcium channel flow and are subject to drug-induced blockade. In contrast to L-type channels, T-type (transient, tiny) channels are more active at negative potentials and are the predominant channel of influence at rest. As such, whereas L- channels are activated at high voltages, T-channels are activated at low voltages.

In nonpacemaker cells, in response to sodium influx, extracellular calcium enters the cell through L-type channels as repolarization begins. The influx is sufficient to stimulate release of intracellular calcium from the sarcoplasmic reticulum and other Ca²⁺ stores (e.g., mitochondria). This (initial sodium and subsequent) calcium ion flow links the action potential to excitation-contraction coupling in nondepolarizing cells.³ The duration of contraction is determined by the rate of intracellular calcium removal from actin and myosin sites in the cytosol by either resequestration into the sarcolemma (or other stores) or efflux from the cell. Efflux is accomplished by at least two pumps, both of which exchange sodium for calcium. The Na⁺/Ca2⁺ ATP-ase pump exchanges 1 Na⁺ for 3 Ca2+ but has only a minor influence on phase 2 of repolarization. The plateau of phase 2 repolarization in nondepolarizing cells is primarily influenced (sustained) by a balance between inward movement of calcium through L-type channels and outward movement of K⁺ through the slow delayed rectifier potassium channels.4

As with sodium channels, calcium channels exist in resting (closed, but responsive), open, or inactivated (unresponsive)

states, and recovery must occur before the resting (responsive) state is achieved. Because both current movement and recovery of calcium channels are slower compared with those of sodium channels, the term *slow channels* is used to refer to ion movement through calcium channels. Hormones, neurotransmitters, and inorganic ions influence calcium channels. As with sodium channels, those drugs with a greater affinity for inactivated calcium channels are more effective.

Pacemaker Cells

Ion flow in cells capable of automaticity inherently is different from that of nondepolarizing cells to allow for spontaneity. Spontaneous depolarization occurs in response to ion fluxes across the cell membrane. The spontaneity of pacemaker cells reflects several electrophysiologic differences between pacemaker and nonpacemaker cells. In contrast to nonpacemaker cells, pacemaker cells have only a few sodium channels. They tend to be in an inactivated state, rendering the cell less responsive to sodium-induced depolarization. However, sodium can influence depolarization, albeit slightly, because more sodium channels are open in the resting state for pacemaker fibers compared with nonpacemaker cells, allowing sodium ions to continually flow down the concentration gradient into the cell. As a result, the maximum RMP of pacemaker cells is only about -60 mV. Second, calcium channels, rather than sodium channels, are responsible for phase 0 of the action potential in pacemaker cells. Third, depolarization is slow, beginning with calcium influx through T-channels until L-channels are activated to initiate phase 0 (depolarization). Fourth, phase 2 is not apparent in pacemaker cells. Fifth, as with nonpacemaker tissues, repolarization in pacemaker cells is initiated by potassium efflux. However, in contrast to nonpacemaker cells, repolarization continues beyond the RMP (-60 mV), resulting in a hyperpolarized (phase 4) membrane. As such, phase 4 in pacemaker cells is a "prepotential," consisting of an initial reduction in potassium efflux, followed by opening of transient T calcium channels. Calcium influx decreases the membrane potential, causing it to become increasingly positive until the firing level (approximately -40 mV) is reached and L-channels are opened.

Automaticity

The rate (slope) of phase 4 in pacemaker cells is influenced by a number of factors. The slope determines the rate at which the action potential threshold of pacemaker cells is reached. Thus the slope of phase 4 determines the rate of spontaneous depolarization, and the cells that set the pace of the heart, the pacemaker cells, are those tissues with the steepest slope. Under normal circumstances, because it is characterized with the steepest slope, the SA node sets the pace. It is followed by conducting tissues, the Purkinje fibers, and, finally, myocardial tissue. As the default pacemaker, the SA node is innervated by both sympathetic and parasympathetic fibers. Vagal activation associated with acetylcholine (ACh) decreases the slope of phase 4 and thus SA nodal pacemaker rate; these actions reflect increased potassium conductance (efflux) and decreased slow inward Ca²⁺ and Na⁺ movement. Vagal activity also causes the cell to become hyperpolarized, increasing the time needed to

reach threshold. However, in atrial fibers, vagal tone facilitates K⁺ channel-mediated repolarization, thus shortening the APD. Finally, vagal tone inhibits sympathetic activity, but the heart rate will increase only if sympathetic outflow (norepinephrine under normal conditions and epinephrine with pathologic conditions) is sufficient. Sympathetic tone, in turn, inhibits vagal tone. Changes in the serum concentration of ions, particularly potassium, also influence SA pacemaker activity. Hyperkalemia increases K⁺ conductance and thus efflux, resulting in bradycardia, whereas hypokalemia increases the rate of phase 4 depolarization (causing tachycardia), presumably by decreasing potassium conductance during phase 4. The slope of phase 4 can change in diseased myocardial tissue (e.g., hypoxia, acidosis, conditions that alter membrane permeability), and the generation of faster impulses may allow these tissues to take over as pacemakers.

KEY POINT 14-4 The cell with the steepest slope of phase 4 sets the heart rate. Although the sinoatrial node is the normal pacemaker, nonpacemaker cells can emerge as pacemakers if cell permeability is altered by disease, hypoxia, trauma or drugs.

Conduction Velocity

The interrelationship between phase 4 and phase 0 of the action potential (the rate of depolarization) determines the conduction velocity-that is, the speed of impulse propagation through pacemaker and nonpacemaker cardiac fibers. Conduction depends on the magnitude of the depolarizing current and the geometric (physical) relationship between myocardial cells. Conduction velocity is directly proportional to the rate and magnitude of phase 0 depolarization. Thus factors that slow the rate or magnitude of sodium (for nondepolarizing cells) or calcium (for pacemaker cells) flow during phase 0 also influence conduction velocity. Conduction velocity, in turn, influences the ability of the impulse to depolarize surrounding cardiac fibers. The faster and the greater the magnitude of depolarization, the more likely the impulse will depolarize surrounding cardiac fibers. For nonpacemaker cells, sodium is the major determinant of conduction velocity by virtue of its impact on the rate and extent of phase 0 upswing. However, calcium conductance during phase 0, albeit slight, also is able to influence phase 0 of nondepolarizing cells. For pacemaker cells, calcium is the major determinant of conduction velocity, with sodium an influencing factor.

Refractory Periods

Myocardial cells are neither excitable nor responsive to additional stimuli during the early and intermediate phases of the action potential cycle. Further, they are only partially responsive if stimulated before complete repolarization has occurred—that is, as the RMP returns to normal. Refractory periods (RPs) describe the period of time (or proportion of the APD) in which cells are nonresponsive. During the absolute refractory period (ARP), cells are totally nonresponsive. In contrast, cells may be partially (effective; ERP) or relatively (RRP) refractory to stimuli, with the state dependent on the number of open (i.e., recovered from inactivation) sodium channels. The ARP occurs when sodium channels are closed. Tissues will not respond to any stimuli, no matter how strong. The ERP is the shortest interval that can occur before a premature impulse can propagate a response.⁵ It includes the ARP plus a shorter period following the ARP that reflects the opening of some sodium channels but not enough to transmit an impulse. The RRP follows the ERP and represents a state in which a sufficient number of sodium channels are open such that a very strong stimulus might be propagated. The refractory periods are protective in that they limit the rate at which myocardial tissues can respond to impulses, thus ensuring sufficient time for cardiac filling and ejection to occur before the next contraction occurs. Proper direction of impulse propagation is also facilitated. Because sodium channels during these periods are refractory to reopening, unilateral (one direction only) conduction is ensured along a myocardial fiber, precluding the premature regeneration of an action potential and inappropriate coordination between excitation-contraction coupling. Loss of unilateral conduction is a contributing factor to re-entrant or circus rhythms.

Afterload and Preload

Both afterload and preload are variably defined depending on the source. Each is determined by the law of Laplace (T =PR/2, where T is wall tension, P is chamber or vessel pressure, and R is chamber or vessel radius). Preload occurs just before (end-diastolic) and afterload just after contraction. Preload is often referred to as the end-diastolic filling pressure, or the end-diastolic volume. Preload reflects the combined factors that influence passive (i.e., relaxed) ventricular wall stress at the end of diastole. Among the most important factors is the volume of blood that fills the ventricles. Increased filling volume enlarges the ventricular chamber, causing either tension or pressure or both to increase. A greater force is necessary for contraction to overcome the tension. Preload pressure occurs in the heart, is highest at the end of filling, or the end of diastole, and is virtually the same in the ventricle and its atria. Other measures of preload have included end-diastolic fiber length or stretch. Afterload is presented outside the heart (aorta) and is the pressure against which the heart must pump to effectively empty the ventricular chamber. At the point that ejection begins (beginning of systole), the aortic valves open and aortic pressure = peripheral resistance = arterial pressure = ventricular pressure. Afterload is also referred to as myocardial wall tension, or the force that must be generated by the heart for myocardial fiber shortening (contraction) to occur such that blood is ejected from the ventricle. Among the most important factors influencing afterload is peripheral resistance.

KEY POINT 14-5 The primary determinant of preload, or ventricular filling, is blood volume. The primary determinant of afterload is peripheral (arterial) resistance.

Myocardial Contractility

Contraction of both cardiac and smooth muscle depends on Ca^{2+} . The inotropic state of the muscle reflects the relationship between resting fiber length and peak isometric tension.

The myocardium develops force for contraction and thus the strength to pump blood by forming cross-bridges between actin and (tropo) myosin myofilaments in cardiac muscle. The amount of force that the muscle can generate depends on the number of cross-bridges that form when myosin engages actin. Energy in the form of adenosine triphosphate (ATP) causes a sliding motion between the proteins of the myofilaments and cardiac muscle to shorten and develop force. The interaction between proteins in the myofilament is regulated by troponin, which is found at regular intervals on the tropomyosin fibers. Troponin is formed from three subunit proteins: T binds to tropomysin, I inhibits the actin-binding site on tropomyosin, and C binds to calcium.⁴ Calcium binding of troponin C forces a conformational change in the troponin complex, causing troponin I to move away from tropomyosin, thus allowing cross-bridging between actin and myosin. The force that develops as actin and myosin interact depends on both the affinity and amount of calcium binding to troponin. The amount is regulated by the concentration of intracellular calcium. It is only as intracellular calcium is removed that troponin I moves back into position; thus contraction will continue until all intracellular calcium is removed.

Multiple mechanisms influence myocardial intracellular (cytosolic) calcium (see Figure 14-1). Extracellular calcium can enter through two sources: movement through (slow) electrogenic or voltage-gated calcium L channels embedded in T-tubules, which ensures that calcium is delivered in close proximity to the sacroplasmic reticulum, and movement though Na⁺-Ca²⁺ ATP channels, which is dependent on cell membrane ATPase.^{3,6} Cytosolic calcium flow is modulated primarily by β-adrenergic receptors; increased cyclic adenosine monophosphate (cAMP) activates protein kinase, which in turn increases calcium movement through the L-channels.⁴ Opening of slow calcium channels in response to depolarization causes intracellular calcium to rise rapidly, stimulating subsequent release from intracellular storage sites (sarcoplasmic reticulum and, to a lesser degree, mitochondria). The contracted myocardial muscle relaxes as intracellular calcium concentration falls as a result of resequestration into the sarcoplasmic reticulum and efflux from the cell, both of which are energy (ATP) dependent. Disorders of lusitropy (i.e., disorders of diastolic relaxation) occur if intracellular calcium does not decrease. The velocity and extent of cardiac muscular contraction are regulated by sarcomere length.⁴ Length (stretch) reflects preload, or the transmural filling pressure. An optimal stretch maximizes the relationship between actin and myosin filaments, allowing more Ca2+-activated cross-bridges and more forceful contractions. In the normal cat and dog, the upper limit of filling pressure in the left ventricle stretches the sarcomere to the length that generates peak tension during contraction. With sustained systolic overloading of the heart, however, the ideal sarcomere stretch is exceeded, cross-bridging decreases and myocardial contractility declines. Abnormalities of the excitation-contraction coupling mechanism contribute to the pathogenesis of cardiomyopathies and chronic hemodynamic overloading.

KEY POINT 14-6 Both cardiac contraction—mediated by intracellular release of calcium—and cardiac relaxation—mediated by reuptake of intracellular calcium—increase myocardial energy and thus oxygen demands.

The most important factor regulating myocardial contractility is stimulation of cardiac sympathetic nerves; cAMP serves as the secondary messenger, altering intracellular calcium flux and myocardial contractility. Myocardial cAMP is produced by adenylyl cyclase, which in turn is regulated by either stimulation or inhibition of adenine or guanine nucleotide proteins. Many cell surface receptors interact with proteins that regulate adenylyl cyclase. An increase in intracellular cAMP causes phosphorylation of proteins that increase calcium influx through the "slow" calcium channels, and the release, reaccumulation, and storage of calcium in the sarcoplasmic reticulum. Cyclic AMP is degraded by several phosphodiesterases (PDEs) isoenzymes, each of which has been associated with specific pharmacodynamic actions. At least 11 isoforms have been named. Inhibition of these enzymes causes the same effect as an increase in either adenylyl or guanylyl cyclase and thus cAMP or cGMP, respectively (see Figure 14-1). The pharmacodynamic response varies with tissue site: PDE II is located in smooth muscle of the urinary bladder detrusor muscle; PDE III in the heart, systemic vascular smooth muscle, and platelets (cAMP); PDE IV in bronchial smooth muscle and pulmonary circulation (cAMP); PDE V in the smooth muscle of the corpus cavernosum, visceral smooth muscle, skeletal muscle, platelets, kidney, lung, cerebellum, and pancreas (cGMP); and PDE VI in the retina (responsible for transduction).

KEY POINT 14-7 The most important factor regulating myocardial contractility is stimulation of cardiac sympathetic nerves.

Adrenergic Receptors

The adrenergic nervous system has a major physiologic role in modulating normal myocardial inotropic and chronotropic states and the time-variable tension that develops as ventricles contract. Both the myocardium and peripheral vasculature are innervated with sympathetic nerve terminals. Under normal conditions norepinephrine released from nerve endings in the heart acts as the primary regulator. Circulating catecholamines released from the adrenal gland play a less important role in normal conditions, but their influence increases as myocardial failure progresses. Molecular cloning techniques have identified nine subclasses of receptors: alpha (α) 1 (three subclasses); α 2 (three subclasses); and β 1, 2, and 3.⁷ Adrenergic receptors are linked to different G protein-coupled receptors, which differentially influence secondary messenger systems (sometimes the same one). Beta receptors are linked to adenylyl cyclase through Gs proteins. Beta agonists regulate cell processes by increasing cAMP, thus influencing downstream effects through cAMP-dependent protein kinases (see the discussion of smooth muscle). In contrast, α receptors are linked to Gi proteins, which oppose the actions of Gs proteins, thus decreasing cAMP.

KEY POINT 14-8 Norepinephrine from local nerve endings is the primary regulator of the heart under normal circumstances, but circulating catecholamines (e.g., epinephrine) predominate with myocardial failure.

In the normal heart, stimulation of the sympathoadrenal system is the primary method by which the heart adjusts to transient changes in workload. The myocardium possesses predominantly ß receptors whereas vascular smooth muscle is rich in α receptors. Both β receptors and α receptors are subdivided into two types. Beta-1 receptors predominate in the myocardium, increasing inotropy (strength of contraction) and chronotropy (rate of impulse generation) (see Figure 14-1). Myocardial effects of adrenergic receptors are achieved through increased magnitude of the calcium current, slowed channel inactivation, and increased magnitude of K⁺ and Cl⁻ repolarizing currents. Pacemaker current and thus sinus rate increase.⁵ Beta-2 receptors (and recently described β-3 receptors) are also located in the heart, but their function is not clear. Disease affects the state of receptors. Continued stimulation of adrenergic receptors, such as that which accompanies diseases states (e.g., congestive heart failure) or long-term adrenergic therapy, results in a dampening or desensitization of response to receptor stimulation. Desensitization reflects internalization and destruction of cell surface receptors. For example, β -1 receptors decrease up to 75% (β -2 receptors are spared) in human patients with congestive heart failure, leading to a compensatory increase in sympathetic signal outflow, which likely contributes to the pathophysiology (see the discussion of myocardial remodeling).7 The function of myocardial β -3 receptors is not clear, but they may provide feedback inhibition of contractility; an imbalance in myocardial disease may contribute to the pathophysiology of myocardial disease.⁸

In vascular smooth muscle, α -2 receptors mediate vasodilation (Figure 14-3). Most α activity in the cardiovascular system is mediated by way of α -1 receptors. Effects include contraction of vascular (and nonvascular) smooth muscle. A-2 receptors inhibit neurotransmitter release but also mediate vascular contraction (as do α -1 receptors). Subtypes 1 and 2 of either α or β receptors can be selectively pharmacologically stimulated (agonists) or inhibited (antagonists) to manage cardiovascular disease.

Smooth Muscle of the Vasculature

Myocardial oxygen demand is directly related to heart rate, myocardial wall tension, and the inotropic state of the myocardium.^{3,9} Myocardial wall tension is determined by the size (diameter) of the ventricle and intraventricular pressure. Thus tension is affected by preload (end-diastolic volume and stretch) and afterload (aortic blood pressure). Drugs that decrease systemic arterial pressure through dilation of arterioles decrease left ventricular afterload. Following the path of least resistance, a larger volume of blood will be ejected from the ventricular chamber into systemic circulation, thus

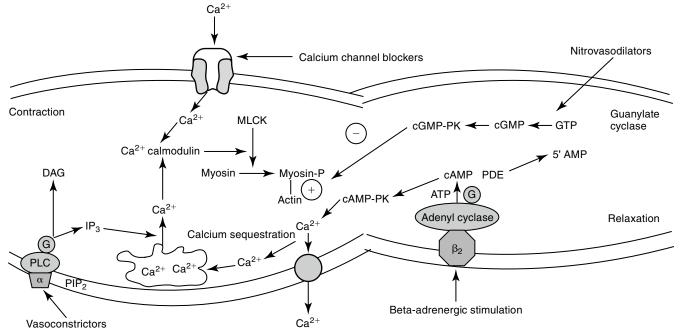

Figure 14–3 Contraction of vascular smooth muscle (vasoconstriction) reflects an influx of calcium, although mechanisms may differ from those in the myocardial cell. Calcium influx occurs through receptor-mediated channels or, less commonly, voltage-gated channels. Intracellular calcium combines with calmodulin. Myosin light-chain kinase (MLCK) is activated, and myosin light chain is phosphorylated (Myosin-P), promoting the interaction between myosin and actin. Cyclic adenosine monophosphate (cAMP) appears to stimulate sequestration and efflux of intracellular calcium and through cAMP protein kinase (cAMP-PK) decreases MLCK, causing vascular smooth muscle to relax (an action opposite to that in the myocardial muscle cell). Cyclic guanosine monophosphate (cGMP) also causes relaxation, probably through nitric oxide–mediated mechanisms. Intracellular calcium also can be released from the sarcoplasmic reticulum after hydrolysis of membrane phosphate; *DAG*, diacylglycerol; *GTP*, guanosine triphosphate; *PDE*, phosphodiesterase; *PLC*, phospholipase C.

diverting blood from the pulmonary vasculature. Left ventricular filling (preload) and thus myocardial wall size and tension will decrease, as will myocardial oxygen demand. An advantage of preload or afterload is that the decrease in cardiac work occurs without affecting myocardial contraction.

KEY POINT 14-9 A number of mediators act to cause arterial constriction and thus increase peripheral resistance.

The excitation-contraction coupling in vascular smooth muscle depends on calcium influx, which enters the cell through either voltage-sensitive (electrogenic) signals associated with depolarization or, more commonly, through receptor-operated Ca2+ channels. Intracellular calcium also is released from the sarcoplasmic reticulum in response to membrane phosphatidylinositol hydrolysis and formation of the secondary messenger inositol triphosphate.² Intracellular calcium interacts with calmodulin, activating myosin lightchain kinase (MLCK) to phosphorylate myosin light chain. Cross-bridging between myosin and actin causes smooth muscle to contract. Cyclic AMP decreases both MLCK and intracellular calcium, causing relaxation of vascular smooth muscle. As with cAMP, the secondary intracellular messenger cGMP causes vascular smooth muscle relaxation, although the mechanism is different (see Figures 14-1 and

14-3). Endothelium-derived relaxing factor (EDRF; chemically related to nitric oxide) and endothelium-derived constricting factor (EDCF) are among the vasoactive substances released by the endothelial cell that control the hemodynamics of the cardiovascular system. Intracellular response to EDRF (or nitric oxide) is probably signaled by cGMP. Other mediators of vascular smooth muscle response include, but are not limited to, prostacyclin, histamine, and acetylcholine. Mediators released from the endothelial cell generally act locally on vascular smooth muscle (Figure 14-4); an exception might include mediators released from the pulmonary vasculature, which may be sufficient to modulate a systemic response.

Systolic and diastolic pressures are, respectively, the upper and lower limits of the oscillations around mean arterial pressure. The mean arterial pressure is the arterial pressure over time and is defined as the diastolic pressure plus one third of the pulse pressure. Arterial blood pressure is the product of cardiac output (determined by stroke volume and heart rate) and total peripheral resistance. Total peripheral resistance is the sum of resistance in all vascular beds. It is also affected by aortic impedance (resistance to flow) and diastolic arterial pressure, which in turn is determined by the sympathetic nervous system, the renin–angiotensin–aldosterone system and arginine vasopressin system, vascular (extracellular fluid) volume, and aldosterone or other volume active hormones.⁴³

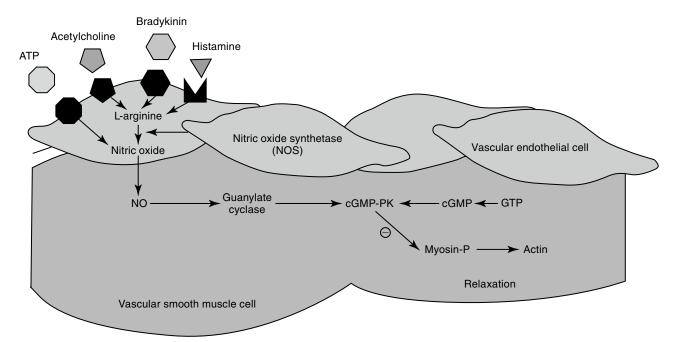

Figure 14-4 Vasoactive mediators responsible for vasodilation (e.g., prostacyclin, histamine, acetylcholine) stimulate nitric oxide synthetase to convert L-arginine to nitric oxide (NO) in the endothelial cells. Nitric oxide enters the smooth muscle cell and stimulates guanylate cyclase such that cyclic guanosine monophosphate (cGMP) is released. *ATP*, Adenosine triphosphate; *cGMP-PK*, cGMP-dependent protein kinase; *GTP*, guanosine triphosphate; *Myosin-P*, phosphorylated myosin.

The Renin–Angiotensin–Aldosterone System

The renin–angiotensin–aldosterone system (RAAS) plays an important role in regulating blood volume, arterial pressure, and cardiac and vascular function (Figure 14-5).¹⁰ An additional but critically important role in cardiac repair and remodeling has recently emerged. RAAS regulation of arterial pressure is accomplished through constriction of resistance vessels, mediated by several mechanisms. Included are direct stimulation of AGII receptors and indirect stimulation through facilitation of norepinephrine. Vasopressin also is a potent mediator of peripheral vasoconstriction by way of V-1 receptors. Its increase reflects either increased release from sympathetic nerve terminal endings or decreased reuptake.¹¹

Other neurohumoral-endocrine mediators of RAAS are produced by a number of organs, resulting in both local and systemic responses. Contributing organs include the kidney, brain, heart, vasculature, adipose tissue, gonads, placenta, and pancreas. In the kidney, renin is produced in the juxtaglomerular cells, and angiotensinogen in the proximal tubular cells. The majority of the effects of RAAS reflect its most potent mediator, angiotensin II (AGII), which in turn is dependent on renin. Renal renin release is stimulated by hypotension, decreased sodium delivery to the distal tubules, or direct stimulation of β-1 adrenergic receptors. Renin catalyzes proteolytic cleavage of circulating angiotensinogen to the decapeptide, angiotensin I. Angiotensin I is then converted to AGII by angiotensin-converting enzyme (ACE), located in vascular endothelium with the majority of systemic release coming from the lungs. AGII is further degraded by angiotensinoginases located in red blood cells AG III and IV.

ACE is a kinase II metallopeptidase enzyme bound to the membrane of a variety of cells, but particularly endothelium, epithelium, neuroepithelium, and brain cells.¹² Organs respond to both systemic and local renin, with local response influenced by local concentrations of ACE and angiotensin receptors. Concentrations of ACE differ among tissues, with that in the renal tubular brush border the greatest (300- and 10-fold higher than the left ventricle and lung, respectively). Thus, although the kidney is the most important site of renin release, it also is a target of the RAAS, responding to both systemic and urinary renin. Renal AGII concentrations exceed circulating AGII more than 1000-fold, causing renal vasoconstriction and sodium retention. Degradation of AGII yields angiotensin III (AgIII), which has 40% of the pressor and 100% of the aldosterone effects of AGII.

Through AGII, RAAS modulates responses to low sodium intake and provides for long-term control of renal function, body fluid volumes, and arterial pressure. In the healthy canine kidney, response to AGII results in increase in both preglomerular and postglomerular vascular resistance, although the predominant effect is on the efferent rather than afferent arteriole. Renal blood flow consequently decreases, but glomerular capillary pressure increases.¹² AGII regulates body fluid content by directly stimulating thirst centers in the brain; adrenal release of aldosterone, which mediates increased renal sodium and fluid retention; and posterior pituitary release of vasopressin (antidiuretic hormone, ADH), a component of the arginine vasopressin system (AVP). Vasopressin increases renal fluid retention through V2 receptors in renal tubular cells. In addition to its vascular effects, AGII released from endothelial cells also facilitates cardiac hypertrophy and vascular

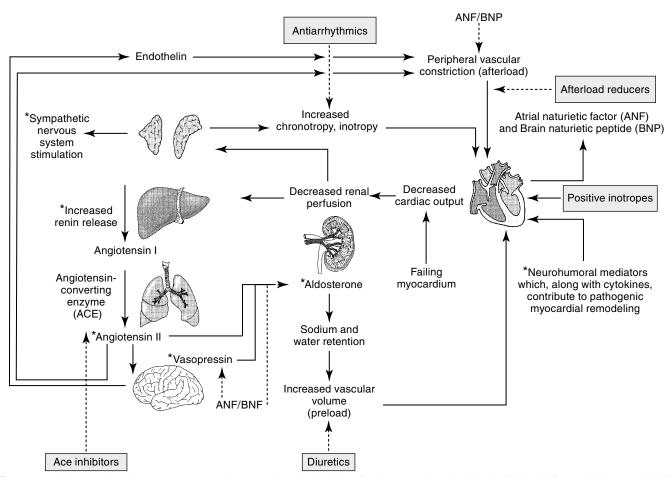

Figure 14-5 Neuroendocrine responses to decreased peripheral perfusion associated with the failing left ventricle may initially result in increased contractility, increased cardiac output, and increased tissue perfusion. Systems activated include the sympathetic adrenergic system, the renin–angiotensin–aldosterone system, and the arginine vasopressin system. Compensatory mechanisms, however, lead to increased afterload (adrenergic stimulation, angiotensin release) and increased preload (aldosterone, release of vasopressin), both of which may detrimentally increase the workload on the failing heart. Mediators signaling these responses contribute to myocardial remodeling (indicated by asterisk*), leading to progressive myocardial failure. Therapeutic approaches that target these mediators (shaded boxes) are intended to not only alter the negative sequlae of increase preload, afterload and cardiac response, but also remodeling. *ACE*, Angiotensin-converting enzyme; *dashed line*, inhibited.

hypertrophy. Notably, production of inflammatory cytokines is increased from both normal and abnormal (damaged) myocardial tissue, contributing to the negative sequelae of cardiac remodeling.¹³ AGII is prothrombotic and may induce cardiac muscle hypertrophy.

KEY POINT 14-10 The effect of the renin–angiotensin– aldosterone system is complex. It comprises both systemic as well as local systems, multiple receptors and mediators, and complex receptor–mediator interactions.

KEY POINT 14-11 Ultimately, the negative sequelae of compensation contribute to the progression of myocardial disease and failure

Renal vascular response to AGII is mediated by AGII receptors (ARs), a transmembrane G-coupled protein receptor consisting of several subtypes that vary in location, numbers,

affinity for AGII, and secondary messenger systems. The most well known of the subtypes, AR-1, preferentially binds AGII and AGIII, mediating the classic angiotensin RAAS responses on blood pressure and water and electrolyte balance. Included are water, sodium intake, renal sodium retention, secretion of vasopressin and aldosterone, and cell growth/proliferation. In addition to AR-1, AR-2 receptors also bind AII and AIII.¹⁴⁻ ¹⁶ However, AR-2 receptor density is greatest in the brain, including areas involved with fluid and electrolyte regulation and balance, arterial pressure, cognition, behavior, and locomotion. Concentrations of AR-2 also are high in steroidproducing glands, including the adrenal glands and ovaries.¹⁶ Because of the central location of AR-2, AGII and AGIII can modulate many body functions and responses. Expression of AR-2 is particularly high during fetal development, but it persists in the adult brain, supporting a role in neuronal function. In the brain, AR-2 appears to oppose the traditional RAAS effects of AR-1 on drinking behavior and vasopressin secretion. Other effects mediated by AR-2 receptors are regulation of cell proliferation, apoptosis, and cellular differentiation.¹⁶ Again, AR-2 appears to attenuate AR-1 mediated apoptosis, pressor, and chronotropic effects. Like AR-1 receptors, several secondary systems appear to signal AR-2 effects, including the mitogen-activated protein kinase (MAPK) and nitric oxide/ cGMP pathways.¹⁶

Regulation of RAAS effects through angiotensin receptors is complex, possibly involving feedback inhibition pathways, responses that vary with duration of exposure, and systems that may oppose one another. Likewise, pharmacologic management of heart disease through manipulation of AR receptors may be complex.¹⁵ Disease is likely to contribute to variability in response to AGII and its modulating drugs. For example, in the failing heart the expression of AR-1 decreases, whereas that of AR-2 does not change or increases. Both receptors are associated with effects that initially, in moderation, might benefit the patient, but with progression become detrimental. Not surprisingly, a link has been described between AR and β -adrenergic receptors. Both AR-1 and β receptors interact with G proteins, with AR-1 through activation of phospholipase C and β -receptors through activation of adenylyl cyclase. Diamerization of the two receptors has been described in vitro and occurs in vivo.¹⁷ This integration will further complicate pharmacologic manipulation.

Among the mediators stimulated by AGII are vascular endothelial production of nitric oxide and endothelin (ET-1), both of which contribute to regulation of renin release. Nitric oxide appears to oppose, whereas endothelin appears to reinforce, the vascular effects of AGII. Endothelins are peptide vasoconstrictors released from endothelial cells; three have thus far been identified: ETs 1 through 3. Endothelins exert their effects through a number of endothelin receptors (ET) including ET-A, associated with vasoconstriction and vascular smooth muscle proliferation, and ET-B, which promotes both constriction and dilation, clearance of endothelin, and production of endothelial cell prostacyclin and nitric oxide. Endothelin receptor antagonists have facilitated understanding of the role of endothelins in vascular regulation and ultimately may offer a mechanism of pharmacologic manipulation. Endothelin is the most potent vasoconstrictor known. In addition to direct vascular effects, endothelin modulates plasma concentrations of both atrial natriuretic factor (ANF), arginine vasopressin (AVP), and aldosterone. Additionally, endothelin contributes to vascular remodeling.

Mechanisms other than ACE modulate formation of AGII. Opposing effects of ACE are regulated in part by AR, but other body systems also modulate the influence of ACE. For example, ACE also inhibits breakdown of bradykinin. Bradykinin consequently increases, resulting in vasodilation and naturiesis.¹⁸ The vasodilatory effects of bradykinin are mediated in the vascular endothelium through arachidonic acid derivatives, nitric oxide, and endothelium-derived hyperpolarizing factor in the vascular endothelium. The mechanism of natriuresis is not clear.¹² Bradykinin also has beneficial effects on cardiac remodeling, which helps oppose the negative sequelae of AGII.

The Role of Nitric Oxide

For decades, researchers have attempted to identify a factor released from endothelial cells, referred to as EDRF, which is responsible for mediating a number of stimuli causing vasodilation. Ultimately, nitric oxide (NO) was recognized to be the smallest and most basic mediator of vascular response.¹⁹ Released as a gas (and thus often mistaken for nitrous oxide $[N_2O]$, or "laughing gas"), it is synthesized in response to NO synthetase (NOS) enzymes from L-arginine and oxygen or by sequential reduction of inorganic nitrate (see Figure 14-4). However, as a free radical, NO is very reactive and unstable and interacts with oxygen on exposure to air to form the pollutant nitrogen dioxide (NO₂). Two major classes and three isoforms of NOS have been identified.¹⁹⁻²¹ Constitutive NOS (cNOS or NOS-1) is continuously produced and includes two isoforms synthesized either by vascular endothelial cells (eNOS) or neurons (nNOS). Constitutive NOS, which is calcium dependent, tends to mediate cell responses through cellular receptors. Responses of cNOS include that mediated by vascular mediators such as acetylcholine, norepinephrine, histamine, and substance P. Not surprisingly, response is rapid. Inducible NOS (iNOS or NOS-2) is produced as needed by inflammatory cells (e.g., macrophages, neutrophils, and Kuppfer cells), generally after exposure to cytokines (e.g., tumor necrosis factor or interleukins) or bacterial lipopolysaccharides. Production of NO from iNOS requires new protein synthesis and is characterized by a delay of several (2 to 4) hours.

Regardless of origin, NO causes its effect by diffusing across cellular membranes to intracellular targets. Cytosolic cGMP is the major intracellular messenger (see Figure 14-4) causing physiologic response to NO. Responses include dilation of blood vessels, inhibition of thrombogenesis, cytotoxic responses, and neuronal signaling. However, because NO contains an unpaired electron in its outer orbit, it is a free radical. As such, it can contribute to the formation of other radicals while simultaneously scavenging oxygen radicals. The half-life of NO is so short that studies involving NO generally are based on its oxidation end products nitrates and nitrites.²⁰ However, despite its very short half-life, NO has many important and complex actions in the body. Under basal conditions, peripheral vasoconstriction is locally relieved by intermittent cNOS-induced NO in response to sheer stress and endothelial cell receptor stimulation. Inflammation and immune signals also induce NO release by way of iNOS. NO inhibits platelet aggregation and adhesion, contributing to antithrombogenic mechanisms in the vascular endothelium. NO may ameliorate the detrimental effects of norepinephrine on the growth of cardiac myocytes and fibroblasts, suggesting that increased NO bioavailability may prevent or reverse remodeling in patients that have experienced heart failure.²² Modulation of inflammation varies, however, with cell type and the source of NO production (i.e., iNOS versus cNOS). Although targeting NO production through drug therapy may appear to be a reasonable approach to the treatment of a variety of cardiovascular disorders, the complex nature of its release and the events

leading to its release currently preclude predictable and safe modulation. It is likely, however, that selective modulation of NO ultimately will provide a therapeutic approach to many disorders.

PATHOPHYSIOLOGY OF CARDIAC DISEASE AS IT RELATES TO DRUG THERAPY: CONGESTIVE HEART FAILURE

Neural–Humoral–Endocrine Compensatory Mechanisms in the Myocardium and Vasculature

Congestive heart failure (CHF) refers to the inability of the heart to deliver blood necessary to meet the metabolic demands of body tissues. Backward failure is the most common form, reflecting increased end diastolic pressure and atrial pressures. Venous and capillary pressures increase to the point that fluid transudates into interstitial tissues, resulting in the clinical manifestations that result from heart failure, including (left sided) pulmonary and circulatory edema or (right-sided) ascites. Patients generally are hypervolemic and thus are referred to as "wet." Less commonly, forward failure reflects decreased cardiac output and poor periperhal perfusion ("cold") resulting in exercise intolerance or cool extremities. Backward failure ultimately may lead to forward failure.

Mechanisms that compensate for loss of contractility or abnormal loading on the heart initially maintain cardiac output in the normal range either at rest or with limited exercise. Clinical signs of disease may not be evident (preclinical stage). However, the negative sequelae of compensation ultimately contribute to the progression of myocardial disease and failure. Decompensation occurs when cardiac output is no longer sufficient to support circulation despite compensatory mechanisms

Regardless of the cause of cardiac failure, decreased blood pressure and compromised organ perfusion initiate complex interactive compensatory responses of the neural, hormonal, and endocrine systems.^{11,23} Neuroendocrine changes reflect "fight or flight" stimuli, affecting blood pressure and fluid volume (see Figure 14-5). Baroreceptors and the vasomotor center interact with the sympathetic and parasympathetic systems to increase heart rate, myocardial contractility, and blood pressure and to activate the RAAS. Although cardiac output may increase, the responses contribute to fluid accumulation and myocardial remodeling, which ultimately lead to irreversible myocardial failure.

The kidney directs responses designed to increase arterial blood volume in response to poor renal perfusion accompanying the failing heart. Renal compensatory mechanisms are mediated by RAAS in the juxtaglomerular apparatus. Renal glomerular arterioles are exquisitely sensitive to catecholamines; their reflex vasoconstriction exacerbates diversion of blood flow from the glomerulus. However, renal arteriolar underperfusion coupled with adrenergic stimulation causes the release of renin in pressure-volume–sensitive receptors of the afferent arterioles. In response to decreased renal plasma flow and glomerular filtration rate (GFR), the filtration fraction increases, normalizing renal excretory function. Proximal tubular function is maintained (and possibly enhanced) such that a greater percentage of sodium and water is reabsorbed from the filtrate. Decreased sodium in the filtrate causes further renin release. Fluid retention initiated by these changes increases ventricular filling. Actin and myosin interaction are optimized with myocardial cell stretching (sarcomere length– active tension relationship or Frank–Starling phenomenon), leading to improved contractility. Stroke volume and cardiac output increase, as does cardiac work. Effective restoration of blood volume and ventricular filling will improve renal perfusion but at a new equilibrium characterized by increased ventricular filling pressures and intravascular and interstitial fluid volumes.

Myocardial disease is accompanied by changes in concentrations of components of the RAAS. For example, AGII increases twofold to threefold in the left ventricle and kidneys and tenfold in plasma. Because AGII is produced by mechanisms other than ACE (e.g., chymase), the impact of ACE inhibitors on resolution of increased AGII is variable among tissues. Inhibitors of ACE may vary in their relative impact on efferent or afferent arterioles; the impact may also vary within renal zones.

Other systems influenced by RAAS also change in the diseased heart. ANF and atrial natriuretic peptide (ANP, or atriopeptin) production by atrial myocytes is stimulated by atrial stretch in the heart and a number of other signals (adrenergic stimulation, AGII, endothelin, increased sodium) associated with congestive heart failure. Brain natriuretic factor, although originally identified in brain tissue, is secreted by ventricular myocytes and interacts with ANF receptors, causing similar effects. The effects of ANF are mediated by at least three receptors (NPRA1-3 or A-C), two (NPRA 1 and 2) of which are linked to cGMP and the third to G-protein. ANF inhibits AVP activated by RAAS. Renal response to ANF includes dilation of the afferent glomerular arteriole, renal sodium wasting, and decreased renin secretion; aldosterone secretion from the adrenal gland also decreases. Vascular smooth muscle is relaxed. As such, normally, ANF induces natriuresis, diuresis, and vasodilation, inhibits renin and aldosterone secretion, and appears to attenuate vasoconstriction. . Interestingly, ANF also influences adipose tissue, causing, among other things, release of amino acids. Although plasma concentrations of ANF are increased in heart failure, response is blunted for reasons that are not clear. Diagnostically, detection of ANF has been used to differentially diagnose acute dyspnea. e.g., that associated with pulmonary edema.

Circulating ET-1 increases in both plasma and the left ventricle in response to a number of signals, including norepinephrine, AVP, and interleukin-1. Increases parallel the progression of myocardial injury and correlate with increased pulmonary arterial pressures. ET-1 may play a role in the pathophysiology of pulmonary hypertension of heart failure in humans.²⁴

Heart failure not only is the result of dysfunction of the RAAS but also reflects several abnormalities of the second major compensatory system, the adrenergic nervous system.^{17,25,26} Indeed, the two systems appear to influence each other, affecting both the heart and peripheral vasculature. Loss of myocardial contractile support is partially compensated for by increases in plasma catecholamines released from the adrenal gland; autonomic imbalance occurs as the parasympathetic system fails to "check" adrenergic response. This may reflect the reduced sensitivity of baroreceptors.²⁶ The failing heart becomes increasingly dependent on circulating, rather than local catecholamines. In the failing heart, maximum contractile and heart rate response are decreased for several reasons. In the later stages of failure, myocardial response to sympathetic nerve stimulation is blunted as a result of decreased synthesis, storage, and release of myocardial norepinephrine. Beta-1 receptors decrease and inhibitory guanine nucleotidebinding proteins (G_i) increase.²⁷ Sustained adrenergic signaling associated with myocardial injury causes downregulation of β -1 receptors and uncoupling of both β -1 and β -2 receptors from G proteins. Because β receptors are diamerized with AR, AR-1 decreases in concert with β receptors.¹⁷

KEY POINT 14-12 Heart failure is the result of integrated altered functions of the renin–angiotensin–aldosterone system; the adrenergic nervous system; and their integrated influences on afterload, preload, heart rate, and myocardial remodeling.

As the heart fails, α -adrenergic-mediated vasoconstriction in response to circulating catecholamines causes regional peripheral vasoconstriction, ensuring preservation of arterial blood pressure. Differential vasoconstriction among the vascular beds causes blood flow to be redistributed to organs with the highest metabolic requirements (i.e., brain, heart, and active skeletal muscles). Accordingly, renal blood flow is restricted, resulting in activation of the RAAS. Autoregulation of intrarenal blood flow (e.g., efferent renal arteriolar constriction) helps maintain glomerular filtration despite systemic redistribution. Venoconstriction and fluid retention increase preload, providing some compensation for decreased cardiac output.

Although the goal of compensatory mechanisms is to increase cardiac output, eventually the secondary sequelae prove detrimental and both diastolic and systolic cardiac dysfunctions emerge. In the peripheral vasculature, vasoconstriction mediated by AGII, circulating catecholamines, AVP, and ET-1 results in persistent and significant increased systemic vascular resistance. Mechanical vascular stiffness, reflecting intramural sodium and water content, worsens resistance. The vasculature, particularly in skeletal muscle, can no longer autoregulate. Increased resistance tends to raise (maintain) blood pressure and organ perfusion, but at a cost: the marked increase in cardiac afterload causes a proportionate decrease in stroke volume. The heart must work harder, using more oxygen to affect the same cardiac output. Because stroke volume is less, the end-diastolic volume (preload) in the heart is greater, increasing myocardial wall tension. Myocardial diastolic relaxation, necessary for myocardial perfusion, is impaired. Increasing myocardial oxygen and energy needs cannot be met as myocardial perfusion decreases. Thus increased peripheral resistance represents a vicious cycle as it worsens the failing heart. Abnormal relaxation during diastole also has been associated with direct changes in the myocardial cell. These include abnormal sarcoplasmic reticulum regulation of intracellular Ca²⁺ and decreased density of Ca²⁺-ATPase.²⁷ Drugs that increase cAMP thus may influence either contractility (inotropy) or diastolic relaxation (lusitropy).

Negative Sequelae of Myocardial Remodeling

In the last decade, as more data regarding the role of RAAS and related systems in the progression of myocardial failure have emerged, therapies have been designed to minimize the negative sequelae of compensatory mechanisms. Accordingly, the traditional goals of therapy have been to lower venous pressure (diuretics), decrease afterload on the failing heart (vasodilators), decrease heart rate (e.g., β blockers, calcium channel blockers [CCBs], or digoxin), and increase myocardial contractility (positive inotropes).²⁸ However, the traditional view of CHF as a hemodynamic syndrome characterized by fluid retention, high venous pressure, and low cardiac output has been modified over the last decade. This change reflects a response to a number of unanticipated findings in reviews of clinical trials testing traditional therapies targeting neurohumoral responses in humans. Notably, clinical trials failed to demonstrate long-term survival with traditional therapies. Further, drugs that initially caused a favorable response often shortened, rather than lengthened, survival time. For example, vasodilators such as α -adrenergic blockers, short-acting L-type CCBs, inoxidil, prostacyclin, and phosphodiesterase inhibitors failed to prolong survival despite effective afterload reduction. Inotropic agents increased contractility by increasing cAMP but shortened long-term survival as cardiac energy needs and arrhythmias increased. Increased calcium flux associated with their use may also have contributed to diastolic dysfunction.²⁸ In concert with these findings, selected drugs that initially worsened clinical signs (e.g., β-adrenergic drugs) were associated with improved long-term survival. Finally, several classes of drugs were associated with improved survival through mechanisms other than that expected on the basis of their known pharmacologic effects. For example, selected diuretics (e.g., spironolactone) and drugs active in the RAAS, including ACE inhibitors and angiotensin II-receptor blockers, appeared to slow myocardial deterioration and remodeling.28-30

The findings of the clinical trials reoriented investigators to the potential impact of disease and drug therapies on myocardial deterioration, progressive remodeling, and maladaptive hypertrophy. For example, worsening of disease despite effective afterload reduction appears to have reflected, in part, increased release of neurohumoral mediators (norepinephrine, AGII, and endothelin), stimulating further proliferation and remodeling. Inhibition of inappropriate mediators through drugs such as β blockers may decrease maladaptive myocardial proliferation, and progressive dilation of the heart was proposed as a mechanism.²⁸ The impact of remodeling and its prevention on the progression of CHF is now a well-recognized target of therapy. The extent of progressive remodeling is associated with clinical outcome, and the key to improved survival for CHF that has emerged as a result of these findings is the blunting of the progressive deterioration, remodeling, and proliferation associated with disease.²⁸

Remodeling reflects a number of cellular and biochemical activities that lead to myocardial hypertrophy, fibrosis, altered excitation-contraction coupling, apoptosis, altered cellular metabolism, and discordant electrophysiologic responses. The negative sequelae of remodeling include altered ventricular myocardial wall and chamber dimensions and altered geometry. Although myocyte hypertrophy does not appear to be associated with negative sequelae in the failing heart,³¹ the responses also include maladaptive proliferation and chronic dilation, leading to eccentric hypertrophy. Myocardial cell life span is shortened, initiating a vicious cycle of myocardial cell death, increased load on surviving myocytes, and compensatory proliferation. Consequently, myocardial cell death and remodeling and dilation increase. Elongation of cardiac myocytes increases cardiac chamber size but also increases individual myocyte tension, further stimulating hypertrophy.²⁴ Several mediators recognized for their neurohumoral compensatory responses contribute to cardiac remodeling, offering a target of therapy. In particular, AG II contributes to several aspects of cardiac remodeling through AG II type 1 (AT1) receptors.³² Fibroblast gene expression increases, leading to increased density and proliferation, and myocyte hypertrophy.³¹ Aldosterone activates several genes responsible for synthesis of myocardial extracellular matrix.³³ The myocardium appears to include a local RAAS regulated in part by AG II that supports cardiac fibrosis; the more severe the failure, the more aldosterone is activated, with local activation occurring independently of systemic effects.³⁴ Underlying proliferation and remodeling is inflammation; both are associated with increased gene expressions of proinflammatory cytokines.³⁵ Inflammatory cytokines, NO, and reactive oxygen species act as negative inotropes, contributing to cardiac remodeling.³⁵ NO also impairs mechanical myocardial function by increasing intracellular cGMP, reducing calcium current and desensitizing myofilaments. NO has both negative inotropic and chronotropic effects on the heart and has been associated with myocardial necrosis.²⁴ Free radicals also decrease calcium sensitivity and calcium accumulation in the sarcoplasmic reticulum.³⁶ Calcium sensitization is further reduced by pathologic conditions such as acidosis or hypoxia. These changes determine the long-term prognosis in patients with heart failure.²⁸ In the heart damaged by myocardial infarction, proinflammatory cytokines (e.g., tumor necrosis factor [TNF]-a, IL-1b, and others) stimulate cardiac fibroblasts to alter the extracellular matrix (ECM), primarily through AGII and AR-1 receptors. Plasma TNF- α has been positively correlated with the severity of CHF in humans and is increased in dogs and cats with heart failure.²⁴ Eventually, damaged and normal tissue is replaced with scar tissue that maintains structural integrity but limits chamber size. Remodeling involves production of structural proteins, including

fibronectin, collagens (Col) I and III, tissue inhibitors of matrix metalloproteinases (TMPs) and "secondary" growth factors. Apoptosis may contribute to progressive left ventricular dysfunction, as is supported by increased plasma apoptosis–signaling surface receptors that trigger programmed cell death in patients with heart failure.²⁴ Angiotensin receptor density also increases in area macrophages.³⁷

KEY POINT 14-13 Several mediators recognized for their neurohumoral compensatory responses contribute to cardiac remodeling, with angiotensin and its subsequent influences playing a major role.

As the understanding of the pathophysiology of CHF has advanced, the tools with which disease and response to therapy can be monitored also will advance. Preferred biomarkers have been circulating molecules associated with neurohumoral responses to the failing heart, such as endothelin, natriuretic peptides, AGII, and endothelin or markers of myocardial damage (e.g., creatine kinase isoenzymes and troponins). Increased cardiac troponin (I or T) has emerged as the preferred gold-standard marker for acute events involving the myocardium, whereas increased B-type natriuretic peptide may be preferred for identification of cardiac diseases as a cause of dyspnea. Boswood³⁸ has addressed the status of biomarkers in feline and canine cardiac disease.

Management should attempt to correct maladaptive responses in cardiovascular function and inflammatory and proliferative responses (Tables 14-2 and 14-3). Functional changes reflect short-term hemodynamic neurohumoral responses initiated by the endocrine system that are intended to improve cardiac performance, vascular tone, and salt and water excretion. As such, traditional approaches to treatment of congestive heart failure have included drugs that decrease preload (e.g., diuretics), afterload (e.g, ACE inhibitors), and heart rate (e.g., beta-blockers). However, drugs that slow the progression of myocardial disease by virtue of their effects on myocardial inflammation, remodeling, necrosis, or apoptosis represent the newest group of drugs used to treat the failing heart. Selected drugs (including those in current use) that improve hemodynamic effects by blocking neurohumoral stimuli may prove most beneficial because of their simultaneous inhibition of proliferative stimuli. Accordingly, attempts should be made to select those drugs in each category with demonstrable muting of myocardial remodeling.

VASODILATOR THERAPY

Vasodilator drugs can be categorized according to the type of vessels that they dilate: arterioles (i.e., resistance vessels: arterial dilators), veins (i.e., capacitance vessels: venodilators), or both. All three types of vasodilators can be useful in the patient with CHF. Arterial vasodilators target resistance vessels, relieving vasoconstriction that accompanies CHF or primary hypertension. Normally, vasoconstriction maintains systemic pressure in the normal range of 100 to 110 mm Hg. However, the critical organs (i.e., the brain, kidneys, and

Stage	Drug or Drug Class	Target Effect	Asymptomatic			SYMPTOMATIC		
				Mild	Moderate	S	evere	
						No arrhythmias	Arrhythn	nias
							Ventricular	Atrial
II B ₂	ACE Inhibitor	Peripheral vasoconstriction (Increased afterload)	+	+	+	+	+	+

IV	Amiodarone	Arrhythmias					+	+
		Diastolic failure						
IV D ₁	Nitroprusside	Peripheral vasoconstriction and volume overload				+	+	+
IV	Dobutamine	Decreased contractility						+

Table 14-2 Timing of Cardioactive Drug Use

*Consensus could not be reached regarding the early use of beta-blockers for myocardial protection.

+= indicated for use. The New York Heart Association and International Small Animal Cardiac Health council provides a functional classification of CHF: Class I (asymptomatic); Il (clinical signs with strenouous exercise); Ill (clinical signs with routine daily activities or mild exercise), and IV (severe clinical signs at rest). The American College of Veterinary Internal Medicine has promulgated a complementing classification system for CVMI based on structural changes: Stage A (high risk but no identifiable disorder), B (structural disease without clinical signs, subclassified as 1 [no radiographic or echocardiographic changes] and 2 [significant regurgitation with evidence of left-sided heart enlargement], C (structural disease with current or historical clinical signs), and D (end-stage disease refractory to standard therapies).

heart) are effectively perfused at pressures 20 to 30 mm Hg less than normal. This "reserve" allows arterial dilating agents to decrease systemic blood pressure and cardiac afterload without compromising critical organ blood flow. As peripheral resistance decreases, in the patient with CHF, stroke volume increases. In the presence of mitral insufficiency, the regurgitant fraction that enters the pulmonary circulation and reenters the heart is reduced. Finally, with reduction in volume overload, the end-diastolic volume of the left ventricle is reduced, wall tension is reduced, and myocardial perfusion increases. Venodilators increase the volume of the capacitance vessels, also reducing preload to the right, and subsequently left, ventricle. Preload reducers may also relieve some pulmonary vascular congestion. Potential negative inotropic effects of peripherally acting drugs tend to be masked by baroreceptor-mediated increase in sympathetic tone² in the normal animal.

KEY POINT 14-14 More than any class of drugs, cardioactive drugs are associated with adverse effects, and their use should be implemented only if they are well understood and proper monitoring tools are available.

Arterial Vasodilators

In the 1980s the role of increased resistance in cardiac failure became a focus of therapy. Drugs that decrease peripheral resistance do so by dilating arterial or resistance vessels. The inclusion of peripheral vasodilators in the armament of treatment for CHF, particularly in its early stages, has proved useful in reducing the dependency on digitalis for long-term treatment. However, their efficacy as venodilators increasingly is being challenged. Those drugs whose mechanisms also contribute to the inhibition of neurohumoral endocrine compensatory responses are more likely to address both the *Text continued on p.491*.

Drug	Indication	Dose	Route	Interval (hr)
Acepromazine	Arterial thromboembolism	0.15-0.3 mg/kg	SC	8-12
Amiodarone	Antiarrhythmic	Initial dose: 10-25 mg/kg	PO	12×7 days
Annodatone	7 millar my unine	Followed by: 5-7.5 mg/kg	PO	12×7 days 12×14 days
		Thereafter: 7.5 mg/kg	PO	24
	Doberman cardiomyopathy	Initial dose: 10 mg/kg	PO	12×7 days
	Doberman cardiomyopathy	Thereafter: 8 mg/kg	PO	12 × 7 days 24

hemodynamic and proliferative alterations that accompany the progressively failing heart compared with those drugs whose actions decrease only resistance. For the latter group, although initially beneficial, their use may contribute to a worsening of disease, particularly if the degree of afterload reduction stimulates a hemodynamic response that counters decreased resistance. Thus care should be taken in the timing of therapy and its implementation.

KEY POINT 14-15 Because drugs that decrease peripheral resistance can cause hypotension and reflex tachycardia, care must be taken to avoid overzealous therapy and worsening of the neurohumoral compensatory responses initiated by cardiac failure.

Hydralazine

Hydralazine is a pure arterial vasodilator whose mechanism is not completely understood. Arteriolar smooth muscle is directly relaxed, perhaps by inhibiting calcium fluxes into the cell.9 Conversion to NO and increased cGMP also have been suggested.³⁹ The decrease in peripheral vascular resistance caused by hydralazine is associated with an increase in cardiac performance.⁴⁰ Coronary and venous vasculature is not affected. Hydralazine lowers mean arterial pressure, total systemic resistance, and left ventricular filling pressures, causing an overall increase in cardiac performance in dogs with left ventricular failure.⁴⁰ In addition to its vasodilatory effects, hydralazine has been associated with a number of other effects that might benefit the patient with CHF. A positive inotropic effect has been described, perhaps reflecting stimulation of cAMP through β-receptors.⁴¹ Hydralazine acts as an antioxidant by inhibiting membrane-bound enzymes that form free radicals, including super oxide.⁴² More recently, hydralazine inhibition of prolyl hydroxylase domain (PHD) enzymes has been described, ultimately leading to an increase in vascular endothelial growth factor [VEGF], which has a number of positive effects. Endothelial cell growth is associated with angiogenesis, coronary vessel density, and improved myocardial perfusion;³⁹ VEFG also is antiapoptotic and cardioprotective in animal models.

Hydralazine binds to smooth muscle, resulting in a biological half-life that is longer than its plasma half-life. The drug is well absorbed after oral administration in both dogs and humans. However, in humans it is subject to first-pass metabolism with elimination by acetylation. The extent of first-pass metabolism in the dog, which is deficient in acetylation, is not described. Peak effects occur in the dog at 3 to 5 hours.³ The incidence of adverse reactions may be significant. Hydralazine frequently causes increased heart rate; this effect may prove to be detrimental to the patient with CHF because of increased myocardial oxygen demands. β-blocker therapy (or, historically, in the case of myocardial failure, digitalis therapy) may be indicated to slow the heart rate. Hypotension may occur but is largely prevented by proper dose titration.³ If sufficient, hypotension may activate the RAAS.⁴³ In humans, hydralazine has been associated with a variety of immune-mediated reactions, including a well-described drug-induced lupuslike syndrome.9 A previous indication for hydralazine include afterload reduction in patients with moderately early to late signs of CHF. Hydralazine should be administered in small increments until an effective dose is reached. The advent of the ACE inhibitors has largely replaced the use of hydralazine, which currently is limited to animals that cannot tolerate or respond to ACE inhibitor therapy. In a canine model of chronic left ventricular dysfunction, however, hydralazine combined with nitrate therapy can cause a more marked increase in stroke volume compared with ACE inhibitors alone.44 As the beneficial effects of hydralazine on the failing heart are realized, its use may increase.

Calcium Channel Blockers

Structure-Activity Relationship

Five types of calcium channels have been identified, with the L, N, and T subtypes the best characterized (the other two being P/Q and R subtypes). Each comprises a major subunit, α 1, which is the major pore-forming unit of the channel, and associated subunits α 2, β , γ and δ , which modulate α 1. Calcium channels can be broadly blocked by large divalent (cadmium and manganese). Currently, 10 CCB cations have been approved for use in human medicine, all targeting the α -1 subunit.⁴⁵ Three categories target L-channel blockers, each targeting different domains of the α 1 subunit: phenylalkylamines, represented by verapamil; benzothiazepines, represented by diltiazem (Figure 14-6); and the dihydropyridines, represented by nifedipine (including amlodipine, felodipine, nicardipine, and others). A newer category of CCBs, represented

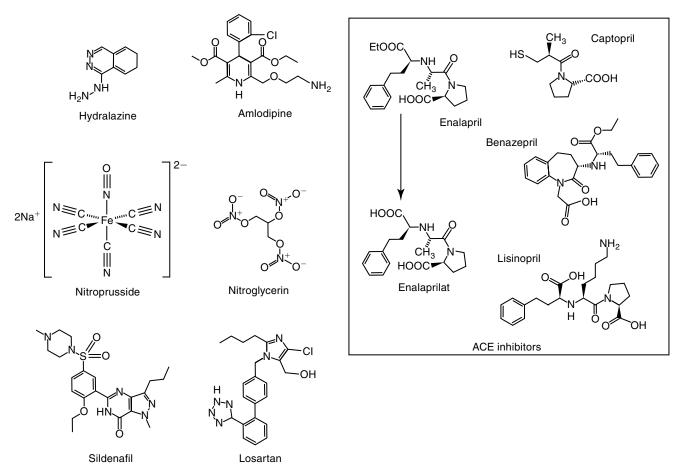

Figure 14-6 Structures of selected vasoactive drugs. *Inset:* Many of the angiotensin–converting enzyme inhibitors (ACE inhibitors) are prodrugs that must be metabolized to the active "prat" form.

by mibefradil, selectively block T-type channels.⁴⁵ The drugs vary among classes in pharmacodynamic effects and adverse events.

Pharmacodynamic Effects

Although calcium channel (or entry) blockers are also referred to as *calcium antagonists*, they do not directly antagonize calcium. Rather, they inhibit the entry of calcium into the cell or inhibit its mobilization from intracellular stores. CCBs inhibit the voltage-dependent channels in vascular smooth muscle at significantly lower concentrations than that necessary to interfere with the release of intracellular calcium or receptor-operated channels.² The pharmacodynamic effects of the CCBs reflect differences in potency at the various tissue receptors (i.e., either cardiac or vascular).

The effects of calcium entering cells by way of L-type channels is better documented than that entering T-type channels. Most clinically used CCBs block exclusively L-type channels, which are the most effective in the vasculature. Vasodilator effects of CCBs are primarily arterial, with little to no venodilator effects. Coronary vasodilation is significant but variable among drugs. The order of vasodilator potency of prototypical drugs from each class is nifedipine > verapamil > diltiazem. This may be balanced by differences in oral bioavailability; as such, the magnitude of the hemodynamic effects of the calcium channel antagonists also reflects the route of administration. Bioavailability is reduced (in humans) as a result of first-pass metabolism for nifedipine > verapamil > diltiazem. The impact of bioavailability on therapy can be complex. For example, whereas oral bioavailability of diltiazem is only 50%, chronic therapy is facilitated by decreased metabolism, which increase bioavailability. Diltiazem (discussed in greater depth as a class IV antiarrhythmic) is metabolized by acetylation, a phase II conjugation system; however, deficiencies in clearance in the dog have not been described.

All three prototypic drugs are available as oral preparations. Both verapamil and diltiazem are available as an intravenous solution for the rapid treatment of supraventricular arrhythmias. Hypotension, bradycardia, and tachycardia (generally reflex) are the predominant clinical indicators. In patients with poor myocardial reserve, exacerbation of CHF may result in peripheral or pulmonary edema. Further clinical pharmacology and side effects may be addressed for specific drugs under the appropriate category.

Amlodipine is a congener of nifedipine. Nifedipine causes vasodilation at concentrations that have little effect on the heart. Like nifedipine, amlodipine affects predominantly smooth rather than cardiac muscle and decreases total peripheral resistance. However, even at doses causing vascular effects, amlodipine has little effect on sinus node function and cardiac conduction. Thus a major advantage to amlodipine compared with other CCBs is that it may not cause reflex cardiac stimulation.

Vasodilator effects of selected CCBs may reflect modulation of NO. For example, amlodipine, but neither nifedipine nor diltiazem, experimentally causes NO release from canine coronary microvessels.⁴⁶ The clinical relevance of this finding is not yet clear but may imply that such CCBs are particularly effective for treatment of heart failure. Calcium channel blockade appears to have no effect on thrombus formation.^{47,48} The effect of amlodipine on myocardial contractility is not clear, but most evidence to date does not support a clinically relevant positive inotropic effect.

At physiologic pH, with a pKa of 8.6, amlodipine is largely ionized, which contributes to a gradual association with the calcium channel receptor. Onset of action is thus a gradual event if therapy is begun with a loading dose. Among its peripheral vasodilatory effects, amlodipine prevents coronary vasospasm in response to a number of vasoconstrictive stimuli. Amlodipine has a protective effect against myocardial injury in an animal model of heart failure; the mechanism may be inhibition of NO induction mediated, in turn, by cytokines. Amlodipine inhibits ouabain-induced production of IL-1a, IL-1b, and IL-6, an action that appears to be calcium dependent in mononuclear cells.³⁵

Clinical Pharmacology

In humans, amlodipine disposition is markedly variable. Peak concentrations following single oral administration do not occur for 6 to 12 hours; bioavailability ranges from 64% to 90% and is not affected by food. Protein binding is approximately 95% in human hypertensive patients. The elimination half-life is long. Approximately 90% of the drug is metabolized to inactive products. Based on limited information, the disposition of amlodipine in dogs appears similar to that in humans. Oral bioavailability in dogs is 88%; at least 50% of the drug is cleared by nonrenal mechanisms, and renal clearance includes that of both parent compound and its metabolites. The elimination half-life of amlodipine in dogs is 30 hours; little of the drug is excreted unchanged in the kidneys.⁴⁹ As with many cardiovascular drugs, amlodipine contains a chiral carbon. In humans each contributes to approximately 50% of the total area under the curve (the balance leaning toward S), but only the S enantiomer is pharmacologically active. The S-isomer is characterized by a longer half-life (49.6 hours) in humans compared with the R-isomer (35 hours); the long half-life allows once-daily dosing.⁵⁰ Enantiomer information is not available for dogs. Steady-state concentrations are not achieved for 5 to 10 days. Although administration of a loading dose may decrease the time to reach steady state, delayed response also reflects drug-receptor binding kinetics. Despite its use in cats, no pharmacokinetic data could be found for amlodipine in cats.

KEY POINT 14-16 The delay in efficacy of amlodipine in cats may be only partially overcome by starting therapy with a loading dose.

Drug Interactions and Side Effects

As a class, CCBs are involved in a number of drug interactions. Drugs that generally inhibit drug-metabolizing enzymes (e.g., cimetidine, chloramphenicol) will prolong the elimination and thus the cardiovascular effects of several CCBs. Selected CCBs can, in turn, prolong the elimination of drugs (e.g., cyclosporine, theophylline, and digoxin). The effects vary with the drug and are more likely with diltiazem and verapamil, but are largely absent for amlodipine. Side effects of CCBs vary with the primary pharmacodynamic effect. The major toxicities associated with CCBs are excessive vasodilation, which may activate the RAAS; negative inotropy; and depression of sinus nodal rate and atrioventricular conduction (negative chronotropy). These latter effects may be of therapeutic benefit (see the discussion of antiarrhythmics). Overzealous therapy associated with activation of the RAAS has been demonstrated in normal dogs receiving 0.57 mg/kg orally twice daily for 6 days.⁵³ A number of oral adverse drug events have been attributed to cardiovascular drugs.⁵¹ Among them is gingival hyperplasia, particularly by nifidipine and its congeners, including amlodipine.⁵² Amlodipine has been associated with gingival hyperplasia in dogs; the risk may be worsened in animals receiving other drugs associated with this adverse drug event (ADE)(e.g., cyclosporine).

Clinical Use

Amlodipine, a congener of nifedipine, is often the drug of choice for treatment of feline hypertension.54 Because its actions are independent of the renin-angiotensin-converting enzyme system, the renal afferent (rather than efferent) article is preferentially dilated with amlodipine. Although renal perfusion and glomerular filtration are preserved in renal stressor states such as hypotension, increased glomerular perfusion may activate the RAAS, which may worsen renal disease in the impaired kidney. Accordingly, amlodipine should not be used as the sole afterload reducer in animals with myocardial failure associated with neural humoral compensatory mechanisms. As such, the use of amlodipine in dogs tends to be limited to hypertension associated with minimal compensatory mechanism. Mathur and coworkers⁵⁵ have demonstrated an antihypertensive effect of amlodipine (0.25 mg/kg orally daily) in cats with surgically induced hypertension associated with renal insufficiency.

Other indications for amlodipine therapy include afterload reduction in dogs whose myocardial failure has not responded or for those that have developed an intolerance to enalapril and diuretics. In human patients a synergistic effect occurs when amlodipine or another peripherally acting CCB is combined with ACE inhibitors. The complementary actions of CCBs and ACE inhibitors may facilitate control of systemic hypertension while minimizing detrimental renal effects. In humans the co-administration of amlodipine and ACE inhibition at low doses has been suggested to provide superior renoprotective benefits compared with those of either drug alone.⁵⁶ When combined with other therapies, a lower dose may be indicated (see Table 14-3). To guide therapy, clinicians should monitor patients with a targeted pressure of less than 150 mm Hg. Response should occur in 24 to 48 hours.

The use of amlodipine in veterinary cardiology has been reviewed.⁵⁷ Using an open, uncontrolled study, Jepson and coworkers⁵⁸ prospectively studied for 7 years (1998-2004) the efficacy of amlodipine (0.625 mg/cat/day) in hypertensive cats (n=141; median 15 years of age), with systolic blood pressure (SBP) 195 mm Hg; (184 and 214 mm Hg, 25th and 75th quartile, respectively). The dose of amlodipine was increased to 1.25 mg/cat if SBP remained above 160 mmHg. Phosphate-restricted diets were offered for azotemic cats, with aluminum hydroxide initiated if hyperphosphatemia became uncontrolled. Predictors of duration of survival in cats that did not survive to study end (n=89) were limited to urine protein: creatinine ratios (UPC), with the decline significant.

Helms⁵⁹ studied transdermal absorption of amlodipine (0.625 mg once daily) using a nonrandomized (oral dosing occurred first), nonblinded design in client-owned cats (n=6) with systolic hypertension (SBP \geq 180 to 220 mm Hg depending on underlying cause). Oral doses were titrated up until SBP < 180 mm Hg was achieved; the final dose was maintained for 7 days, and blood was collected at that point. Cats were then crossed over to transdermal amlodipine at the same oral dose established for each cat. Blood pressure was recorded at 3 and 7 days, and plasma amlodipine was determined 12 hours after the last dose at 7 days for both treatment groups. After oral dosing SBP decreased a median of 73.5 mm Hg below baseline; after 7 days of transdermal dosing, SBP remained 52 mm Hg below baseline. The relative decrease was greater after oral compared with transdermal administration. Plasma amlodipine concentrations ranged from 5.7 to 18.7 ng/mL after oral administration compared with 1.4 to 4.5 ng/ mL after transdermal administration. The lack of a crossover design may be a limitation of the study because a time effect could not be considered. This may be particularly important for a drug with a half-life that is likely to exceed 30 hours (the canine half-life) in cats (resulting in time to steady state of 3 to 6 days) coupled with further delay related to drug receptor interactions. This could result in a substantial hold-over effect from the first treatment simply as a result of drug concentrations. Further, a cumulative effect for the sequential treatment groups would not be identified. Post transdermal SBP was not compared with post oral SBP, so it is not clear if the decline was significant.

Although diltiazem is not recognized for vasodilatory actions, it apparently can improve GFR and enhance urine production in dogs with leptospirosis. The presumed mechanism is renal arterial vasodilation and subsequent reversal of renovasoconstriction. Mathews and Monteith⁶⁰ retrospectively studied the impact of diltiazem on acute renal failure in dogs (n = 11; seven dogs received standard care) associated with leptospirosis. Diltiazem was administered intravenously at 0.1 to 0.5 mg/kg slowly, followed by 1 to 5 μ g/kg/min within 60 hours of admission and was continued until serum creatinine stabilized. Compared with standard therapy, renal recovery defined by reduction in serum creatinine occurred almost twice as fast in the diltiazem-treated group compared with the standard group, without a change in systemic blood pressure.

For cats with hyperthyroidism, the degree of hypertension associated with hyperthyroidism generally is mild, unless accompanied by renal insufficiency. Because hyperthyroidisminduced hypertension associated with hyperthyroidism alone is due to high-adrenergic output (causing increased cardiac inotropy and rate), β blockers are preferred to calcium channel blockers for control of hypertension. However, the addition of amlodipine may be indicated in hyperthyroid hypertensive cats that also exhibit renal insufficiency.

Angiotensin-Converting Enzyme Inhibitors

Structure–Activity Relationship

ACE inhibitors are carboxyalkyl dipeptide or tripeptide drugs whose chemistry yields three classes of drugs (see Figure 14-6): the sulfhydryl-containing drugs, which are structurally related to captopril; dicarboxyl-containing drugs related to enalapril (including lisinopril, benazepril, ramipril, and quinapril); and phosphorous-containing drugs related to fosinopril.¹⁸ At least nine drugs have been approved in the United States for use in humans. Those approved for veterinary use are in the dicarboxyl group, including enalapril (United States), and ramipril and imidapril (Canada and Europe). With exception of lisinopril, each is a prodrug, being metabolized, at least in part, by CYP 3A4, to their respective active form (enalaprilat, benazeprilat, ramiprilat, and imidaprilat, respectively). Although differences exist in potency for ACE, all appear clinically equal in the inhibition of RAAS, and no compelling reason exists to select one ACE inhibitor over another based on pharmacodynamic response.18

Pharmacodynamic Effects

The primary effect of ACE inhibition is prevention of the conversion of AGI, which is relatively inactive, to the active AGII. However, ACE inhibitors also inhibit bradykinin inactivation. Because bradykinin stimulates prostaglandin synthesis, pharmacodynamic actions of ACE inhibitors may reflect bradykinin or prostaglandin activity.¹⁸ However, of the two actions ACE inhibition is a more sensitive and measurable indicator of the complex dose-response relationship that characterizes the primary actions of ACE inhibitors (see the section on clinical pharmacology).⁶¹ Actions of ACE inhibition target the neurohumoral and renal compensatory responses associated with myocardial failure. The detrimental sequelae of neurohumoral compensatory effects involving the RAAS have been previously reviewed. Specific inhibition of ACE decreases circulating levels of AGII and aldosterone. Effects include vasodilation (arterial), decreased systemic blood pressure, increased cardiac output, and reduced heart rate. Aldosterone secretion is reduced (but not obliterated), and natriuresis (loss of sodium in urine) occurs. Mild venodilation reduces some preload. ACE inhibitors also target a variety of mediators associated with myocardial remodeling. In the normal feline kidney, ACE inhibitors mildly increase Na⁺ and Cl⁻ urinary excretion and may increase K⁺ excretion. The ACE inhibitors have a positive inotropic effect on the heart but do not increase heart rate. The mechanism is unclear, but with enalapril it is associated with increased cardiac vasoactive intestinal peptide in rats.⁶² Primary cardiac effects increase their importance in the management of cardiac disease accompanied by CHF. Inhibition of ACE also increases circulating concentrations of the endogenous stem cell regulator Ac SDKP (*N*-acetyl-seryl-aspartyllysyl-proline), which may contribute a cardioprotective effect.¹⁸

KEY POINT 14-17 Because angiotensin and its downstream signals contribute so much to progressive myocardial failure, ACE inhibitors offer much more than simply afterload reduction in the patient with congestive heart failure.

Clinical Pharmacology

Pharmacokinetic-Pharmacodynamic Relationship. The use of ACE inhibitors has been reviewed in dogs and cats.^{12,61,63} The exact relationship among ACE inhibitors, ACE inhibition, impaired AGII production, pharmacodynamic responses (blood pressure and cardiovascular), and pharmacokinetics is complex.⁶¹ Most ACE inhibitors used in animals (e.g., enalapril and benazepril) are prodrugs, which are more easily absorbed than the active metabolite. Those that are not prodrugs include captopril and lisinopril.⁶⁴ In addition to passive oral absorption, prodrugs are actively transported in the jejunum by peptide carrier-mediated transport (PEPT). Substrate specificity has been described for the different transport proteins.⁶¹ The importance of transport on drug absorption is not clear. Food does not appear to affect absorption. Parent compound oral bioavailability is low (20% to 40% in dogs); only a fraction of the low bioavailability appears to reflect first-pass metabolism by hepatic carboxyl esterases to active metabolites. Maximum drug concentrations occur approximately 30 minutes after administration in the dog. A small amount of drug not metabolized on first pass will be metabolized by esterases located in tissues.61

Tissue distribution and subsequent action of ACE inhibitors is among the most complex of drugs, being influenced by lipophilicity; systemic and local binding; receptor numbers and affinity; and, for prodrugs, presence of local metabolizing enzymes. Protein binding and its profound impact on pharmacokinetic-pharmacodynamic relationships are described later in this chapter. Lipophilicity determines distribution, particularly of the prodrug, into sanctuaries such as the brain, where local esterases produce the active compound. Accordingly, lipophilic prodrugs such as fosinopril are more likely to affect the central nervous system compared with less lipophilic drugs such as enalapril.⁶¹ Elimination of ACE inhibitors (i.e., active metabolite) is largely renal. However, the magnitude excreted renally varies with the drug.⁶¹ In dogs enalaprilat is largely (85% to 95%) eliminated by renal clearance, whereas benazeprilat and ramiprilat are cleared through both the kidney (45%) and bile. Fosinopril is also cleared (in humans) by liver and kidneys.

Protein binding of ACE contributes to complex pharmacokinetic-pharmacodynamic responses.⁶¹ Binding to proteins is both nonspecific, to albumin, yielding an inactive state, or specific, to ACE (located in circulation or tissue vascular endothelium), resulting in an active complex. Nonspecific binding is nonsaturable, whereas specific binding is saturable, with the latter resulting in nonlinear pharmacokinetics. Based on

modeling, circulating ACE represents approximately 5%, 10%, and 30% of the total ACE pool in dogs, cats, and humans, respectively, with the balance represented by tissue ACE. Endothelial ACE occurs in many tissues but predominates in the lungs. Tissue endothelial ACE acts locally (paracrine) but also is released such that it can act systemically (hormonally). Bound, endothelial ACE is regularly cleaved to yield circulating ACE, which, is in turn, bound to circulating plasma proteins (in an inactive form) to ensure a steady supply of either ACE or its inhibitors. Endothelial ACE is accessible to ACE inhibitors in the extracellular space, facilitating an immediate response to ACE inhibitors. However, because the drug is bound to ACE, the (active) ACE inhibitor will not be detected (analytically). If drug is detectable, then all available tissue binding sites are saturated. Thus a decline in response that reflects a decline in drug concentrations occurs only after tissue sites are not saturated, which occurs only at drug concentrations that are not detectable. As such, the saturable nature of binding to ACE by the ACE inhibitor results in a nonlinear dose-response curve (detectable concentrations do not correlate well to response). Thus, in contrast to most drugs for which the terminal component of the plasma-concentration versus time is a reasonable guide to duration of effect, for ACE inhibitors the terminal curve reflects what is generally considered distribution for other drugs. The true terminal curve for ACE inhibitors reflects slower elimination at very low, but largely non-detectable concentrations. The slower elimination occurs as receptors become unsaturated, and free drug is eliminated; as such, it must take into account both elimination from the body and the relationship between drug and receptors-that is association-dissociation interactions. Consequently, the true terminal elimination phase of ACE inhibitors is physiologically (rather than pharmacokinetically) based, being influenced by receptor numbers (total binding capacity), the affinity between drug (metabolite) and receptor, and the amount of drug available for binding.61

Because bound, nondetectable drug is active drug, the pharmacodynamic (biologic) half-life of the ACE inhibitor might be anticipated to be much longer than the (detectable) plasma elimination half-life. Indeed, the complex pharmacokineticpharmacodynamic relationship of ACE inhibitors affects the design of a dosing regimen, particularly when adjusting doses for disease. This complexity reflects several characteristics. First, for most drugs, response correlates with the time course of drug concentrations. However, for ACE inhibitors response correlates better with tissue concentrations that are not detectable. Second, saturation of tissue receptors is characterized by a lag time. Therefore the slope of the true terminal phase of the plasma elimination curve is very flat, and maximum response may not be realized for several days.⁶¹ Third, once saturation occurs, further increases in dose are not likely to cause an increase in response. However, a very low dose (e.g., 0.03 mg/ kg) might not be prudent because saturation will take longer and the maximal response may occur more slowly than with higher doses (e.g., 0.125 mg/kg). Simulation studies examining the pharmacokinetic-pharmacodynamic relationship of benzeprilat and ACE inhibition predict ACE inhibitor doses higher than 0.125 mg/kg every 24 hours will increase ACE inhibition very little,⁶⁵ a finding supported by a study of ramilprat in cats.⁶⁶ King and coworkers⁶⁷ also demonstrated that increasing doses of 0.25, 0.5, and 2 mg/kg were well tolerated in cats but did not result in a comparable increase in ACE inhibition.

KEY POINT 14-18 The complex relationship between drug and tissue receptors includes a persistent effect in the absence of detectable drug and a saturable dose–response relationship.

For ACE inhibitors, neither circulating nor tissue concentrations significantly differ after 8 days of therapy. Consequently, the pharmacodynamic response tends to exceed the time course of the metabolite by several orders of magnitude based on measured elimination half-life of the metabolite. For example, the elimination half-life of enaliprat in dogs approximates 61 minutes, compared with a predicted pharmacodynamic half-life of 17 to 19 hours.⁶¹ For benazeprilat ACE inhibitory activity approximates 100% after multiple dosing at 0.25 mg/kg once daily and persists throughout each 24-hour dosing interval,⁶⁸ despite the fact that the plasma elimination half-life of benazepril is 1.4 hours in dogs (39 ± 6 min for benazilprilat). This is consistent with the predicted pharmacokinetic-pharmacodynamic half-life of 17 to 19 hours.^{61,65} In cats receiving benazeprilat, plasma ACE was inhibited at 0.25 mg/kg, with 90% of activity persisting at 24 hours after a single dose.65 The modeled terminal elimination half-life of the active metabolite is approximately 28 hours compared with a measured half-life of approximately 60 minutes. Finally, in Beagles ramipril and ramiprilat elimination half-lives are 0.5 and 0.75 hours, respectively,69 with the pharmacokineticpharmacodynamic half-life predicted to be approximately 23 hours.⁶¹ In cats benazeprilat is excreted predominantly (about 85%) through the bile. Plasma half-life is approximately 1 hour, but the pharmacokinetic-pharmacodynamic half-life is characterized by an elimination half-life of 28 hours following single oral dosing.61

Contributing to the complex pharmacokinetic-pharmacodynamic relationship will be variability among normal animals resulting from differences in disposition, in receptor number and affinity. Further, concentrations accumulate with multiple dosing up to 50% in dogs.^{68,70} It is likely, however, if these differences in plasma disposition will translate to differences in pharmacodynamic response. Indeed, the pharmacokinetic-pharmacodynamic relationship between ACE and ACE inhibition is likely to mitigate differences in response among animals that reflect altered clearance because of disease, unless the disease also affects drug-receptor interaction. For example, a decrease in renal function that prolongs the half-life of an ACE inhibitor twofold is not likely to translate into a duration of effect that is twice as long. As such, benazepril (cleared predominantly by the liver) offers no advantage to enalapril (renally cleared) in the renal-compromised patient. The complex nature between pharmacokinetics and pharmacodynamics must be taken into account in studies that attempt to describe changes in response associated with disease, age, gender, drug interactions, and so forth. Such studies must address not only changes in pharmacokinetics but also the ways in which these changes influence (if at all) the physiologic response. Additionally, such studies must also address the impact of those factors on the interaction between drug and receptor (i.e., ACE), including the impact on the amount of ACE and its affinity for the drug. Finally, none of the discussion thus far has addressed the response of the body to inhibition of ACE. Because mechanisms other than ACE exist for formation of AGII, response to ACE inhibitors may decline within 24 hours after a maximum response has been realized despite maintenance of drug-receptor interactions.⁶¹

Dose modification in the diseased patient. Response to ACE inhibitors can be influenced by several factors. Sodium depletion in the dog shifts the ACE inhibitory mechanism of action from decreased renal AGII to enhanced kinin activity. Decreased circulating ACE associated with ACE inhibitors may correct after several days to weeks, a phenomenon referred to as angiotensin escape. Plasma renin activity may increase as negative feedback is lost. This effect may vary with the drug but is higher in hypertensive than in normotensive dogs.¹² However, response to therapy (perhaps muted) may continue because of inhibition at the tissue level or alternative mechanisms of action. Variability in ACE inhibitory response also may reflect genotype differences in plasma and tissue ACE concentration or receptors. Genetic polymorphism appears to influence response in humans; ACE gene polymorphism has been demonstrated in dogs.¹²

The impact of liver disease on formation of active drug has not been determined for all prodrug ACE inhibitors. However, severe liver disease does not appear to impact metabolism of benazepril to benazeprilat in dogs.⁷¹ Dose modification in response to renal disease-induced altered drug disposition for drugs cleared by the kidney is complicated by the apparent lack of correlation of response to active drug concentration in plasma or vascular tissue.^{12,61} The impact of renal failure on ACE inhibitory pharmacokinetics (drug disposition) and pharmacodynamics (drug-receptor-response interaction) has been summarized by Lefebvre and Toutain.¹² The impact on overall ACE inhibition reflects not only changes in drug concentration associated with altered clearance of drug from plasma but also distribution to tissue endothelial ACE and binding kinetics to ACE. Based on mathematical modeling in dogs with experimentally induced renal disease (GFR decreased by 50%), enapirilat clearance may decrease up to 45%, with changes in the area under the curve markedly varying from 30% to 40%. These changes are offset somewhat by decreased binding (decreased potency), such that enaliprilat inhibitory activity increased by about 65% in the first 24 hours. In contrast, neither benazeprilate nor ramiprilat response appears to be affected by renal disease in dogs.⁷² Dose adjustment for benazepril is not necessary in cats with renal insufficiency.73

In the cat the impact of increasing the dose of ACE inhibitors may vary with the intent (e.g., hypertension versus progressive renal disease). For example, feline hypertension in patients with low or undetectable plasma renin activity and aldosterone responded poorly to enalapril at 0.25 mg/kg once daily, but the response (decreased ACE activity) doubled when a second dose was added.⁷⁴ In contrast, although benazepril was associated with a decrease in blood pressure and an increase in GFR in a surgical model of renal insufficiency, increasing the dose of benazepril (from 0.25 up to 2 mg/kg daily for 6.5 months) did not result in a proportional improvement in response in cats with chronic renal failure.^{12,75} Indeed, overzealous increase in dosing may put patients at risk for initiation of neurohumoral responses that may contribute to renal dysfunction. These studies highlight the complex nature of dose–response relationship of ACE inhibitors and underscore the need for monitoring response when changing doses regardless of species or disease state.

KEY POINT 14-19 Overzealous therapy with angiotensinconverting enzyme inhibitors may activate or potentiate the very neurohumoral endocrine responses targeted with therapy.

Ramipril and ramilprilat kinetics have been studied in both dogs⁷² and cats.⁶⁶ In Beagles (n=10) the elimination half-life of free drug is 11.5 ± 6.0 minutes; this increased to 14.9 ± 7.2 minutes when renal impairment was surgically induced.⁷² After renal impairment, GFR was decreased by 58%. Although clearance of the free fraction of drug and metabolite was reduced, no pharmacodynamic changes occurred in renally impaired dogs, leading the authors to conclude that dose adjustment was not necessary in renal disease. In cats ramipril and its active metabolite ramiliprat have been reported after single and multiple oral dosing (0.125 to 1 mg/kg daily).⁶⁶ Peak concentrations of ramiprilat occur in 1.5 hours, and the mean elimination half-life ranged from approximately 20 to 30 hours, depending on the route. Steady-state concentrations of metabolite were present after 2 days of dosing, and food did not affect oral absorption. Although a dose-dependent effect on ACE activity was present with single dosing, after multiple dosing the maximum inhibition of ACE was the same for all doses. Detectable drug was still present 72 hours after the last dose. Inhibition was still present 24 hours after the last dose. Based on their study, the authors concluded that the elimination of the active metabolite would not be altered in patients with renal disease; a dose of 0.125 mg/kg daily was suggested as a basis for further studies.

Adverse Events

Potential adverse drug events associated with ACE inhibitors have been reviewed¹² and are largely limited, in dogs and cats, to the sequalae of hypotension (previously discussed) and to nephropathies induced by pharmacodynamic response to the drugs. In general, the risk is more likely in patients also receiving diuretics or in the face of impaired renal function. However, acute hypotension is a risk as therapy is begun, particularly in renin-dependent (sodium-depleted) patients. Clinical signs indicative of hypotension may include fatigue and apathy. Increased dietary salt or decreased diuretic therapy may be indicated initially as ACE inhibitor therapy is begun. Acute renal failure may occur as a result of altered renal perfusion. The RAAS, and particularly AGII, is the principal autoregulatory mechanism that maintains renal perfusion in the presence of low arterial pressures. In the kidney, angiotensin regulates both renal blood flow and GFR by modulating constriction of the postglomerular efferent arteriole in the presence of reduced GFR. In addition, tubular sodium is reabsorbed, and renin release is inhibited. Inhibition of ACE and AGII precludes constriction of the postglomerular efferent arteriole (Figure 14-7).⁷⁶ As ACE inhibitor therapy is begun, total peripheral vascular resistance, renal vasoconstriction, and renal perfusion pressure decrease. Net glomerular filtration decreases in concert with decreased glomerular hydrostatic pressure. Decreased glomerular filtration after ACE inhibitor therapy is more likely to occur in the presence of excessive vasodilation, moderate to severe volume depletion, or minimal myocardial reserve. In patients with mild to moderate cardiac dysfunction, renal filtration generally is maintained despite initiation of ACE inhibitor therapy as long as afterload is decreased such that cardiac output (and thus GFR) can increase. As heart failure progresses, the risk of acute renal decompensation increases because reflex efferent arteriolar tone becomes increasingly important to the maintenance of glomerular filtration in these patients. All ACE inhibitors are equally likely to have a negative impact on renal function in patients at risk. This includes benazepril, for which clearance depends on liver metabolism.

KEY POINT 14-20 Renal adverse events associated with angiotensin-converting enzyme inhibitors are more likely if renal autoregulation is impaired by drug or disease.

Initial acute ACE inhibitor treatment of at-risk patients can decrease both creatinine clearance and GFR. Assuming that renal damage is not irreversible, however, chronic treatment generally causes GFR to return to baseline levels. An initial increase in serum urea nitrogen and creatinine associated with initiation of therapy may actually indicate a positive renal response; in human patients an increase from baseline of up to 30% in serum creatinine is acceptable as long as the GFR remains above the minimum of 20 mL/min. However, GFR is not routinely measured in animals and an "acceptable" increase in GFR has not been established. Accordingly, an increase in either serum urea nitrogen or creatinine concentrations may indicate the need to decrease or temporarily discontinue therapy in dogs and cats. Although deterioration of renal function associated with ACE inhibitor therapy is generally reversible if therapy is discontinued, damage may become irreversible if decreased GFR persists. Therapy is contraindicated with preexisting hypotension, hypovolemia, hyponatremia, and acute renal failure. ACE inhibition may potentiate hypotensive episodes in surgical patients. However, withdrawal of therapy to prevent hypotension should be reconsidered in patients receiving ACE inhibitors for treatment of hypertension. Should it occur, hypotension can respond to fluid therapy, and as such, ACE inhibition probably should be continued up to the surgical procedure. Sodium depletion can

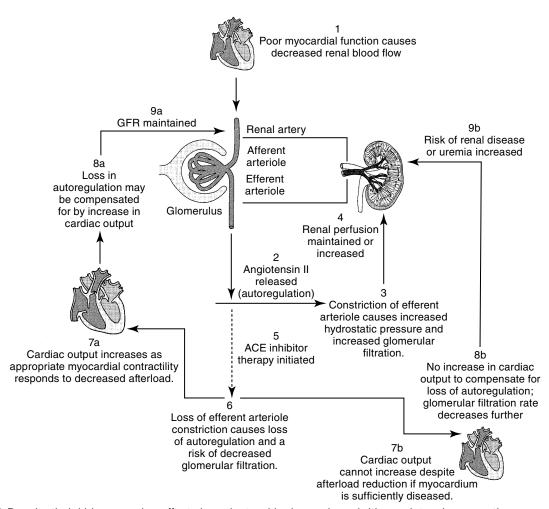

Figure 14-7 Despite their kidney-sparing effects in patients with glomerulonephritis, angiotensin-converting enzyme (ACE) inhibitors may contribute to renal disease in patients whose renal blood flow is threatened. In such patients maintenance of glomerular filtration may depend on increased efferent arteriolar tone (vasoconstriction). Use of ACE inhibitors reduces this tone. In patients whose cardiac function is sufficient (including those that respond to decreased afterload), increased cardiac output can compensate for decreased efferent arteriolar tone, thus maintaining glomerular filtration rate. In patients that are sodium depleted or have severe myocardial dysfunction, glomerular filtration rate may decline. *Dashed line,* inhibited.

activate the RAAS in normal dogs and cats. Experimentally, the use of ACE inhibitors and the subsequent loss of renal autoregulation in the presence of sodium restriction is accompanied by a decrease in renal blood flow, GFR, and filtration fraction. Accordingly, the use of ACE inhibitors in the presence of a low-sodium diet should be accompanied by frequent monitoring of renal function, particularly in patients predisposed to renal dysfunction.

The BENCH (BENazepril in Canine Heart Disease) study group reported the long-term tolerability of benazepril in dogs with CHF.⁷⁷ Although the authors found plasma creatinine concentrations to be lower in the benazepril group than in the placebo group, a significant difference could not be demonstrated. However, serum creatinine levels tended to be higher than normal more often in the placebo group, leading the investigators to suggest that improved renal function was associated with benazepril. No abnormalities in electrolytes were associated with benazepril. Although aldosterone production is impaired in the presence of ACE inhibitor therapy, hyperkalemia is unlikely even in the presence of high-potassium diets, unless the patient is otherwise predisposed to potassium retention. Potassium monitoring might be indicated in the presence of dietary sodium restriction⁷⁸ or when combined with potassium-sparing diuretics such as spironolactone. Because the impact of aldosterone on sodium retention and potassium excretion is muted, the combination of ACE inhibitors with potassium-wasting diuretics decreases the risk of hypokalemia.⁷⁸ The impact of ACE inhibitor therapy on erythropoiesis associated with renal disease is unclear, but studies suggest renal erythropoietin production probably will not normalize in response to ACE inhibitor therapy. As such, supplementation may be indicated.

The ACE inhibitors reportedly cause a dry cough in up to 20% of human, particularly female, patients. Onset ranges from 1 to 26 weeks of therapy, with clinical signs resolving within the first week of discontinuing therapy. The mechanism

may reflect accumulation of pulmonary bradykinin or prostaglandins; interestingly, treatment with aspirin has reduced cough, suggesting a possible role for prostaglandins.¹⁸

Despite their ability to decrease proteinuria (discussed at more length later in this chapter), ACE inhibitors have been associated with the advent of proteinuria in human patients. Therapy need not be discontinued if it develops. Therapy also has been associated with skin rashes and angioedema. The latter is not dose related and generally occurs soon after dosing, within the first week of therapy.¹⁸ Neutropenia, glycosuria, and hepatotoxicity are rare side effects reported in humans.

The ACE inhibitors should not be used in pregnant animals. In human women therapy in the first trimester appears to be safe but results in multiple fetopathologies (potentially related to fetal hypotension) when administered in the second and third trimester.

Drug Interactions

Lefebvre and Toutain¹² reviewed the literature addressing clinically relevant adverse reactions that might reflect interactions between ACE inhibitors and simultaneously administered drugs. Because AGII and aldosterone synthesis can occur in the absence of ACE, drugs that contribute to hypotension, sodium loss, or alteration of renal autoregulation should be avoided or used cautiously in patients receiving ACE inhibitors. The risks of combining ACE inhibitors and diuretics on renal dysfunction have been documented in humans and dogs. AGII and aldosterone may increase, despite the administration of furosemide in patients receiving ACE inhibitors. Further, the diuretic effect can decrease proportionately with GFR when combined with ACE inhibitors. However, the combined use of ACE inhibitors and sodium-wasting diuretics, and specifically furosemide, decreases the risk of hypokalemia.⁷⁸ The impact of combined use of nonsteroidal antiinflammatory drugs (NSAIDs) and ACE inhibitors is less clear. Although presumably, NSAIDs that minimize cyclooxygenase-(COX-) 1 inhibition are less likely to be associated with nephropathy, in human patients the risk is equivalent when either traditional or newer NSAIDs are used. A number of studies have investigated the sequelae of combined NSAID and ACE inhibitor therapy in normal dogs and dogs with experimentally induced decreased renal function. In general, no significant detrimental impact on renal function has been reported. However, this should not be interpreted as proof of no effect, and the combined use should be avoided or undertaken cautiously, with additional attention to monitoring of renal function. Note that NSAIDs may attenuate antihypertensive actions of ACE inhibitors, although the impact may be less with those drugs that target principally COX-2. ACE inhibitors may increase the risk of nephrotoxocitiy induced by other agents, including contrast dye.79

The combination of ACE inhibitors with angiotensin receptor blockers (ARBs) might be considered for a beneficial therapeutic effect. However, a meta-analysis that studied the combined use of ACE inhibitors and ARBs found the addition of an ARB to ACE inhibitor therapy was not associated with a reduced mortality rate compared with ACE inhibitor treatment alone. The addition of an ARB did not affect exercise capacity, functional capacity, and quality of life. Of the outcome measures studied, only the rate of hospitalization was reduced with the combination of therapy.⁸⁰

Beta blockers normalize β-receptor signaling and antagonize cytotoxic effects of circulating catecholamines, which increased with heart failure.⁸⁰ Additionally, β blockers may also directly block AGII-mediated pathways. As such, ß blocker therapy combined with ARBs and ACE inhibitors theoretically might completely remove the effects of angiotensin in cardiac patients. However, results of clinical trials regarding use of the combination in humans are controversial. A meta-analysis found that, compared with ACE inhibitors alone, the combination did not improve survival rates, although hospital stays did shorten.⁸⁰ Further, subgroup analysis suggested that the addition of ARBs is redundant and combined use of ARBs with ACE inhibitors and β blockers potentially puts the patient at an increased risk of adverse drug events. A subsequent study using the ARB candesartan demonstrated that when it was combined with β blockers in patients also taking ACE inhibitors, it does tend to increase the risk of adverse events.81

Hypotension has been reported with the combined use of the β blocker atenolol, the ACE inhibitor quinapril, and an overdose of the selective serotonin reuptake inhibitor fluvox-amine, treatment with aminophylline was successful.⁸²

Other reported drug interactions include decreased drug absorption when combined with antacids, although the clinical relevance of this finding in light of the relationship between plasma drug concentrations and responses is questionable.

Clinical Use in Canine Patients with Myocardial Disease

The role of ACE inhibitors in general for treatment of CHF associated with myocardial failure in dogs has been well established, with use emerging as part of cornerstone therapy. However, the timing of administration in the progression of diseases remains to be fully defined. The most extensively studied of the ACE inhibitors is enalapril, although captopril, benazepril, and lisinopril have also been studied. More recently, ramipril is being studied in dogs and cats. Captopril, the efficacy of which was demonstrated in an experimental model of canine mitral regurgitation (see BENCH study group)83 was the first generally accepted ACE inhibitor to be used in dogs and cats. Captopril can induce positive hemodynamic effects within 1 hour of therapy, although the effects are short lived (4 hours).⁸⁴ Its short half-life led to dosing at 8-hour intervals. Subsequently, the safety and efficacy of quinipril were demonstrated when administered once daily (0.5 mg/kg) compared with captopril (0.5 mg/kg every 8 hours or 24 hours, respectively) in dogs (n=92) with CHF.85

Enalapril administered at 12-hour dosing intervals was also demonstrated to be of benefit in dogs with experimentally induced heart failure. The first placebo-controlled study demonstrating efficacy of ACE inhibitors in dogs with spontaneous myocardial disease (dilated cardiomyopathy [DCM] or mitral regurgitation) was the Cooperative Veterinary Enalapril (COVE) Study.⁸⁶ This multicenter study involving 211

dogs demonstrated that enalapril therapy (for 28 days) was associated with improved longevity and quality of life.86 The IMPROVE⁸⁷ study group reported in the same issue that enalapril (0.5 mg/kg twice daily) was associated with lower heart rate and mean systemic and pulmonary arterial pressures in dogs (35 with DCM, 22 with mitral regurgitation) compared with dogs in the placebo group. Dogs continued to receive traditional therapies (i.e., digoxin or diuretic). Ettinger and coworkers⁸⁸ subsequently established the beneficial effects of enalapril for dogs (n=110; 15 locations throughout the United States) with either DCM or other chronic acquired heart disease (primarily mitral insufficiency). Although the study was not well controlled for stage of disease or differences in conventional therapy, results supported the importance of ACE inhibition in improving the quality of life and, particularly in dogs with DCM, prolonging life. The mean time to treatment failure (including treatment with traditional cardiovascular drugs) increased from 77 days in the placebo group to 156 days in the enalapril-treated group. Although more dogs died suddenly in the enalapril treatment group, all but one had preexisting ventricular arrhythmias for which they were receiving antiarrhythmic therapy. The BENCH study group⁸³ focused on long-term survival afforded by the addition of benazepril to dogs (n=162) with class (International Small Animal Cardiac Health Council [ISACHC]) II or III heart failure associated with chronic valvular disease (n=125) or DCM (n=37). This prospective, randomized, placebo-controlled, doubleblinded European study was multicenter (n=16) and multicountry (n=4). It studied benazepril (0.25 mg/kg once daily) as either sole therapy or as an add-to traditional therapy for up to 34 months. Mean survival significantly improved from 158 days in the placebo group to 428 days in the treatment group. Survival rates at 1 year were 20% and 49%, respectively, for the two groups. High-risk dogs had not been removed from the study group, suggesting that survival would improve in less severely afflicted animals. The risk of progression to a worsening class of heart failure was also reduced, whereas quality of life measures were improved in the benazepril group. Benefits could also be demonstrated in subgroup analysis for those dogs with cardiovascular disease, but not the smaller sample of dogs afflicted with DCM. Adverse events to benazepril were slightly less (not statistically so) than to placebo.

KEY POINT 14-21 Evidence of clinical efficacy of angiotensinconverting enzyme inhibitors is provided among clinical trials based on improved quality of life, improved survival, and objective measures of cardiac function.

Pouchelon and coworkers⁸⁹ retrospectively addressed the efficacy of benazpril in dogs with Class II and III CHF (n=141). Dog were classified as untreated if they did not receive benazepril before the appearance of clinical signs of CHF; these dogs served as controls. For the treated dogs, the mean dose was 0.3 ± 0.13 mg/kg. Median survival times were greater (3.3 years) in the treatment group (n=34) compared with untreated dogs (1.9 years, n=59 dogs) for all breeds except Cavalier King Charles Spaniels.

Controversy still exists regarding when ACE inhibitor therapy should be initiated in the patient with CHF, if and when it is the preferred vasodilator, and its position in the sequence of drugs. For humans, ACE inhibitors are indicated for any patient with left ventricular systolic dysfunction even in the absence of clinical signs of overt cardiac failure.⁶⁴ Studies in humans suggest that inhibition of ACE in patients with systolic dysfunction can prevent or delay the progression of heart failure, decrease the incidence of sudden death, and improve the quality of life.⁶⁴ Although treatment plans have been offered for enalapril, based on severity of disease,⁸⁸ the importance that ACE inhibitors may have in attenuating myocardial remodeling and the need for early intervention may supersede treatment plans based on severity.

KEY POINT 14-22 The timing of initiation of angiotensinconverting enzyme inhibitor therapy in relation to other drugs remains controversial.

To minimize negative sequelae of afterload reduction, particularly that leading to activation of the RAAS, treatment with enalapril or other ACE inhibitors might be initiated at a lower dose⁹⁰ (see Table 14-3) with increased increments at weekly intervals until clinical signs indicate improvement or further increases cannot be tolerated. Renal function should be monitored weekly for the first month of therapy in patients predisposed to adverse renal effects.

The role of ACE inhibitors in cats with hypertrophic cardiomyopathy (HCM) is not clear. However, using an experimental feline banding model of pressure-overload left ventricular hypertrophy, 4 weeks of enalapril (0.5 mg/kg orally once daily) was associated with less intraventricular septum and free-wall diastolic thickness as well as decreased arterial (systolic and mean) pressure compared with placebo. Renal function and other physiologic parameters did not differ between placebo and treatment groups.⁹¹

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND TREATMENT OF PROGRESSIVE RENAL DISEASE

The use of ACE inhibitors for the treatment and attenuation of progressive renal disease in humans and animals has been well reviewed.¹² The evidence of efficacy is not clear, but therapy is generally accepted as beneficial. It is likely that a combination of therapies will be most beneficial.⁹² ACE inhibitors have repeatedly been demonstrated to provide superior renoprotective effects in patients with renal disease compared with other vasoactive drugs.⁹³ The potential application of ACE inhibitors for this indication emerged as early as 1985, following a demonstrable beneficial effect on proteinuria and accompanying renal damage in a rat model of renal failure. Potential application to a variety of human renal diseases was demonstrated over the next decades, with use in animals lagging not far behind. A meta-analysis⁹⁴ of clinical trials in humans with hypertension found a small benefit, probably reflecting reduction in blood pressure.

This study was met with controversy, indicating that the role of ACE inhibitors in progressive renal disease has yet to be clearly defined. Benefits demonstrated in dogs and cats have resulted in the approval of benazepril in Europe and Australia for treatment of chronic progressive renal diseases in animals.

ACE inhibitors have three potential positive effects in the patient with renal disease: control of systemic and glomerular capillary hypertension, delayed progression of glomerulosclerosis and tubulointerstitial disease, and decreased proteinuria.¹² In humans control of the progression of renal disease depends on control of systemic hypertension but this is not necessarily the mechanism whereby ACE inhibitors impart renoprotection. Systemic hypertension may accompany chronic renal disease in 50% to 93% of dogs and cats, and a similar dependency might be expected in animals. Hyperperfusion and hypertension accompanying renal diseases initially enhances the filtration capacity of remaining nephrons. However, this compensation for nephron loss occurs at a cost. AGII-mediated hypertension leads to distention of the glomerular capillary and mechanical strain on the glomerular mesangial cell. Podocyte coverage becomes inadequate, changing the size exclusion of the glomerulus such that permeability is increased. The exposed mesangial cells stimulate extracellular matrix proliferation and release of proinflammatory cytokines. Inflammatory and other proteins are increasingly filtered through the damaged glomerulus. The protein is toxic to tubular epithelials cells and stimulates further cytokine release. Included is transforming growth factor- β , which stimulates excessive renal deposition of extracellular matrix in both the glomerulus and tubulointerstitium. Persistent inflammation mediated by AGII leads to glomerular and tubulointerstitial fibrosis, a characteristic of end-state renal disease.12

In humans and experimental models, ACE inhibitors have demonstrated renoprotection in selected states of nephrotoxicosis associated with renal vascular hypertension. Examples include experimentally induced cyclosporine nephrotoxicity,⁹⁵ in which ACE inhibitors decrease renal vascular resistance, increase GFR, and promote diuresis in experimentally induced doxorubicin nephprotoxicity.⁹⁶ Beneficial effects of ACE inhibitors include decreased deposition of extracellular matrix. The effects of ACE inhibitors have been demonstrated in humans to be greater if therapy is begun early in a variety of renal diseases, with polycystic renal disease being the sole disease thus far that has not responded to therapy.¹²

KEY POINT 14-23 Efficacy of angiotensin-converting enzyme inhibitor therapy for progressive renal disease in dogs or cats depends on use early in disease.

In dogs a variety of studies have attempted to demonstrate renoprotective effects of ACE inhibitors. Studies in dogs have predominantly involved enalapril, whereas benazepril has been the drug of choice for cats for reasons that are not clear other than approval status of the drugs in the country of origin of each study. Results varied with the disease, the model (including experimental versus spontaneous nephropathies), and doses studied (enalapril at 0.5 mg/kg every 24 hours to 2 mg/kg every 12 hours). Outcome measures generally include objective measures such as azotemia, renal plasma flow, GFR, survival rates, weight gain or loss, and histopathology or more subjective measures such as appetite. In a canine experimental model, differences were limited to fewer histologic lesions after 6 months of treatment (1 mg/kg every 12 hours for 2 weeks followed by 0.5 mg/kg every 12 hours) compared with untreated controls. A controlled study in X-linked hereditary nephritis in Samoyeds demonstrated increased survival time in treated dogs (enalapril at 2 mg/kg every 12 hours from 4 weeks of age); therapy was begun before proteinuria could be detected. In the treatment group increased serum creatinine was delayed in onset and progression was slowed, although the magnitude of azotemia did not change. The life span of afflicted dogs increased 36%,97 an outcome measure that must be considered in the context of studies that found up to 53% increased survival time in dogs receiving a modified diet.98 In a third study, a difference in serum creatinine level could not be detected in untreated dogs versus enalapril-treated (0.5 mg/kg every 12 to 24 hours) dogs with spontaneous idiopathic renal disease. However, this lack of a difference probably reflected the small number of animals studied because serum creatitine levels had not increased more than 0.2 mg/dL in 13 of 16 treated dogs compared with 1 of 14 untreated dogs by the end of the 6-month study period.99

In cats benazepril has proved effective for treatment of hypertension associated with experimental feline renal disease⁷⁵ and cats with HCM.^{100,100a} Cats with experimentally induced chronic renal failure responded to benazepril (0.5 to 2 mg/kg once daily), although serum creatinine levels did not differ from those of the control group.⁷⁵ In cats with polycystic renal disease, enalapril-treated (0.5 mg/kg once daily) cats had less azotemia compared with untreated cats, although GFR did not differ.¹⁰¹ Although the potential efficacy of ACE inhibition for treatment of progressive renal disease may be less clear in cats than in dogs, sufficient evidence exists to warrant its consideration as early in the disease as possible.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND TREATMENT OF PROTEINURIA

Among the specific renal indications of ACE inhibitors is proteinuria. Proteinuria appears to be correlated with renal disease, so much so that it is a marker of the progression of disease. Decreased proteinuria can be correlated with improved renal function, perhaps by preventing the inflammatory effects of protein in the tubule. Proteinuria is a demonstrated risk factor for the progression of chronic renal failure in cats.¹⁰²

In humans, ACE inhibitors are considered superior to other vasoactive drugs in decreasing proteinuria, although the mechanism still is not understood and may depend on the cause of proteinuria. Use as part of combination therapy is likely to be the key.¹⁰³ The mechanism may reflect maintenance of podocyte function in the face of glomerular hypertension; ACE inhibitors decrease podocyte hypertrophy. Reduced filtration pressure has been demonstrated in cats with experimental chronic renal disease.¹⁰² Whether control of systemic hypertension is sufficient to control podocyte function has yet to be demonstrated; additional direct effects on podocytes or mesangial cells may occur. Regardless of the mechanism, renal function improves in concert with reduction of proteinuria in human patients. Reduction of proteinuria appears to be dose dependent, occurs rapidly, and remains drug dependent in that proteinuria will recur once the drug is discontinued.

Response of canine proteinuria to ACE inhibitors is variable, but again this may reflect limitations in study design. Finco and coworkers¹⁰⁴ were not able to demonstrate a renoprotective effect caused by decreased proteinuria in experimental renal disease in dogs.¹⁰⁴ However, in another experimental model of renal failure, the urine protein to creatinine ratio was lowered in dogs receiving enalapril (0.5 mg/kg every 12 hours) for 6 months.¹⁰⁵ In a prospective, blinded study of dogs with spontaneous glomerulonephritis, enalapril (0.5 mg/kg) twice daily (but not once daily) reduced the urinary protein to creatinine ratio to less than 50% of baseline, although response required 1 to 3 months. The ratio decreased by 4.2 in treated dogs, compared with a 1.9 increase in placebo-treated dogs.⁹⁹ In cats benazepril also has proved effective for treatment of proteinuria associated with spontaneous renal diseases.¹⁰⁶

Mizutani and coworkers¹⁰⁷ prospectively studied the effect of benazepril (0.5 to 1 mg/kg) in cats (n=61) with chronic renal disease using a randomized, placebo, double-blinded parallel design. Cats were studied for up to 6 months. The urine protein to creatinine ratio was reduced in benazapriltreated cats; further, fewer cats progressed to stage 4 renal disease in the treatment group compared with the placebo group. Using a randomized, double-blinded parallel design, King and coworkers¹⁰² also prospectively studied the impact of benazepril (0.5-1 mg/kg daily) in cats (n=192; 96 treatment and placebo control each) with chronic renal disease (creatinine \geq 2 mg/dL; urine specific gravity \leq 1.025). Cats were treated for up to 1119 days. Proteinuria was significantly reduced based on the urine protein to creatinine ratio. Response was present at the first posttreatment sampling time (7 days) and was greatest in those with the highest ratios, although response was significant also in cats with low ratios ($p \le 0.02$). Survival time (which was inversely related to initial urine protein to creatinine ratio in the placebo group) did not differ between placebo and treatment groups (637 \pm 480 for benazepril; 520 \pm 323 placebo), although variability was marked for both treatment groups, limiting the power to detect a significant difference. Quality of life also did not differ between groups, although appetite improved more in treated cats with initial urine protein to creatinine ratio of 1 or higher. Therapy was well tolerated. Adverse events did not differ between treatment groups; creatinine concentrations did not differ between the groups, including as therapy began.

Angiotensin II Receptor Antagonists

The development of losartan, the first approved AGII receptor antagonist (ARA), represents a concerted pharmaceutical development endeavor to design a drug based on the core structure of the pharmacologic target. Currently, seven ARA

drugs have been approved in the United States. Although each is devoid of agonistic activity, only very minor molecular changes can render the drugs as potent agonists.¹⁸ Generally, ARA receptors have a 10,000-fold greater affinity for AR-1 compared with AR-2 receptors. Potency varies among drugs, with candesartan being most and losartan being least potent for AR-1 blockade. However, losartan is metabolized to an active, more potent compound. Blockade of AR-1 is competitive, but inhibition of AGII response is described as insurmountable, perhaps because of the slow release of drug from the receptor.¹⁸ Regardless of the mechanism, maximal response to AGII is attenuated; blockade is effective despite increased concentrations of AGII or missed doses. Blockade generally attenuates most biologic effects of AGII. This includes peripheral vasoconstriction, pressor response (rapid and slow), the release of vasopressin, adrenal catecholamines or aldosterone, the advent of thirst, altered renal function, cellular hypertrophy, and hyperplasia.¹⁸

In humans oral bioavailability of the various ARA products is generally less than 50%, and protein binding is greater than 90%. Hepatic metabolism varies among the drugs: candesartan and olmesartan are prodrugs, losartan (14%) is metabolized (CYP2C9 and 3A4) to a metabolite more potent than the parent compound, and several others are metabolized to inactive metabolites. The half-life is variable among drugs, ranging from 2.5 hours for losartan (6-9 hours for its active metabolite) to 24 hours for telmisartan. Losartan is excreted both renally and by hepatic metabolism, with liver, but not renal, disease affecting disposition. Losartan is a competitive antagonist of thromboxane A2 and impairs platelet aggregations.¹⁸

The pharmacokinetics of ARAs have not been well established in dogs and cats. Several studies in dogs reflect preclinical studies for human products. Limited pharmacokinetic and pharmacodynamic data of losartan potassium were reported in dogs after oral administration of 5 to 20 mg/kg.^{107a} Oral bioavailability ranged from 22% to 33%. The elimination halflife approximated 2 to 2.5 hours after oral administration but only 40 minutes after intravenous administration. The volume of distribution of 0.3 L/kg suggested limited tissue distribution; the drug is very highly (>95%) bound to plasma proteins. Clearance approximated hepatic blood flow; the proportion of drug converted to the active metabolite was not measured. Maximum drug concentration was dose dependent, with a low of 0.8 \pm 4 µg/mL at 5 mg/kg to 2.9 \pm 1.6 at 20 mg/kg. Pharmacodynamically, an unbound plasma drug concentration of 3 ng/mL (total drug of 96 ng/mL) was determined to the 50th percentile concentration needed to block a pressor response. This concentration was almost achieved at the lowest oral dose of 5 mg/kg, suggesting a dose between 5 and 10 mg/kg. Irbesartan has been studied in dogs alone or in combination with hydrochlorthiazide.^{107b} Dogs were treated with 30 mg/kg once daily for 8 days. Maximum drug concentrations at day 8 were $4.3\pm1.0 \ \mu\text{g/mL}$, with an elimination half-life of 21 ± 3.7 hours. Although pharmacodynamic response did not relate well with plasma drug concentrations, the effective concentration (EC_{50}) associated with decreasing systemic or diastolic blood pressure was $3.3 \pm 0.4 \,\mu\text{g/mL}$, potentially supporting a dose of 30 mg/kg once daily. A lag time to efficacy of several days would be expected.

Indications for ARA treatment in humans include hypertension, diabetic nephropathy, stroke prophylaxis, and heart failure in patients intolerant to ACE inhibition. It is not clear whether antagonism of AGII receptors is more efficacious than therapy with ACE inhibitors. Compared with ACE inhibitors, ARAs differ in their impact on the RAAS in several aspects. Because non-ACE alternative pathways exist for generation of AGII, ACE inhibitors cannot completely attenuate its effects. In contrast, ARAs will effectively block all AGII effects. However, AGII receptors can still be activated. Because ARAs will result in a several-fold increase in renin, AGII concentrations will increase. Finally, inhibition of ACE also results in the inhibition of other pathways; this effect will not occur with ARAs, resulting in persistence of substrates (e.g., bradykinin, Ac-SDKP). Losartan has proved comparable in efficacy to enalapril, but efficacy compared with captopril was variable among studies. In human medicine, ACE inhibitors remain the first-line drugs of choice, with ARAs reserved for nonresponders. The combined use of ACE inhibitors and ARAs is controversial and requires further study.¹⁸ The ARAs have also been used alone or in combination with ACE inhibitors or amlodipine to treat proteinuria.

Arterial and Venous Dilators

Organic Nitrates

Organic nitrates activate cGMP, which ultimately decreases actin and myosin interaction, leading to relaxation of vascular smooth muscle and arterial and venous dilation (see Figure 14-4). At low concentrations venodilation predominates, and net systemic vascular resistance is usually not affected. Coronary vessels are directly dilated. Pharmacologic effects occur rapidly. First-pass metabolism precludes oral administration of nitrates; therapeutic routes include intravenous, sublingual, and topical (transdermal ointment).

Nitroglycerin is a member of the organic nitrate group. Although all vascular smooth muscle might be relaxed, the dose of nitroglycerin administered causes predominantly venous dilation and preload reduction. Pulmonary and systemic congestion and myocardial workload are reduced.¹⁰⁸ Nitroglycerin is available for intravenous and sublingual use and as an ointment. The 2% ointment form has been the most commonly used preparation in veterinary medicine. It can be applied to the hairless portion of an animal's skin (abdomen or ear). Gloves should be used by the caregiver to avoid percutaneous absorption of drug. The clinical indication for use is limited to acute (emergency) treatment of CHF.

Sodium Nitroprusside

Nitroprusside (see Figure 14-6)⁹ contains cyanide, which oxidizes intracellular sulfhydryl groups to produce methemoglobin; NO is simultaneously released. Activation of cGMP causes vasodilation (see Figure 14-3). The NO system that activates nitroglycerin is different from that activating nitroprusside, accounting for differences in vascular beds targeted by each drug.⁹ Both arterioles and venules are dilated by nitroprusside;

systemic and pulmonary vasculatures are targeted. Nitroprusside is one of the most potent vasodilators available. The advantages of nitroprusside over other vasodilator drugs include its potency, its effect in both preload and afterload reduction, immediate hemodynamic effects, extremely short half-life, and low cost. Nitroprusside must be administered by constant intravenous (IV) infusion using an infusion pump; the potential for hypotension necessitates close monitoring. Free cyanide released during intracellular metabolism is cleared in part by transulfation of thiosulfate yielding thiocyanate, which itself is potentially toxic. Overdosing of nitroprusside may yield excessive cyanide, causing severe lactic acidosis; the risk is increased in patients with liver disease or those receiving diuretics (decreased thiosulfate stores). Co-administration of sodium thiosulfate may be indicated in at-risk patients. Clearance of the toxic end product, thiocyanate, may be decreased in patients with renal disease, particularly if infusion continues beyond 24 to 48 hours. Monitoring of thiocyanate should be considered in at-risk patients; concentrations should not exceed 0.1 mg/mL.9 Feline hemoglobin may be predisposed to oxidation and methemoglobin formation. The primary indication of sodium nitroprusside is treatment of severe (catastrophic) CHF. Nitroprusside is administered as a constantrate infusion using a dedicated line and an infusion pump (1-10 µg/kg/min, starting at 1 µg/kg/min in dogs and 0.5 µg/ kg/min in cats; increasing 0.5-1 µg/kg/min every 5 minutes to maintain systolic pressure at 90-1000 mm Hg). Nitroprusside is inherently unstable and will decompose under alkaline conditions and with exposure to light.

Prazosin

Prazosin is an α -adrenergic receptor blocker. However, it also is a venous dilator (perhaps owing to inhibition of cAMP) and thus might be considered as both a preload and an afterload reducer. Despite significant first-pass metabolism in humans, prazosin is effective after oral administration. Prazosin is an effective antihypertensive agent. However, tolerance develops rapidly. It is more effective when used in combination with other drugs. Clinical use of prazosin is limited because hydralazine affords a much better reduction in peripheral resistance and increase in cardiac output.

Phosphodiesterase Inhibitors

Several selective inhibitors of phosphodiesterase (PDE) V have been approved for treatment of penile erectile dysfunction in humans. These include sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra). In contrast to most other PDE inhibitors, PDE V inhibits breakdown of cGMP. Subsequent release of NO in nerve terminals of endothelial cells causes smooth muscle relaxation and increased blood flow. PDE V is located in corpus cavernosum smooth muscle, vascular and visceral smooth muscle, skeletal muscle, platelets, kidney, lung, cerebellum, and pancreas. Potency of tadalafil with PDE V is more than 9000-fold compared with that of other PDE isoforms except for PDE VI (retina) and PDE XI (in skeletal muscle), for which potency is 700- or 14-fold greater, respectively, indicating a relative selectivity for PDE V. Disposition

of tadalafil in humans is characterized by oral absorption that is not impaired by food (bioavailability not reported on package insert), greater than 90% binding to plasma proteins, and a volume of distribution approximating 1 L/kg. In humans tadalafil is metabolized by CYP 3A4 to inactive catechols. In humans the elimination half-life is 17 hours. Drug interactions caused by inhibition or induction of CYP 3A4 may result in clinically relevant adverse drug events. For example, the dosing interval is prolonged from 12 hours to 72 hours in humans concomitantly receiving imidazole antifungals or other inhibitors of CYP 3A4. Despite hepatic metabolism, renal insufficiency may increase area under the curve and C_{max} twofold to fourfold, whereas moderate hepatic disease does not appear to affect disposition. Although systemic hypotension is not a common side effect of tadalafil, PDE V inhibitors in general potentiate nitrate-induced hypotension and co-administration is contraindicated. Care is indicated when combined with α -blocker therapy. Visual disturbances in humans reflect temporary impairment of color vision, reflecting inhibition of PDE VI in the retina. The PDE V inhibitors have been used with variable success to treat pulmonary hypertension in dogs.

KEY POINT 14-24 Selectivity of phosphodiesterase inhibitors reflects specificity for different enzymes and the presence of specific enzymes in different tissues.

ANTIARRHYTHMIC DRUGS

Cardiac Arrhythmias

Underlying molecular causes of arrhythmias have been reviewed in humans.¹ Arrhythmias result from a combination of factors, including genetic predisposition, external stressors and subsequent myocardial remodeling, as well as iatrogenic contributions. Ischemia, electrolyte imbalances, activation of the RAAS and other systems, and pharmacologic therapy are among the triggers for arrhythmias.¹ Inherited causes of arrhythmias are rare, but generally pathophysiology is straightforward, particularly if associated with mutations in ion channel genes. In contrast, arrhythmias associated with acquired heart disease are complex. Structural and electrical remodeling, hemodynamic changes, and neuroendocrine signals each influence ion channel function, intracellular calcium response, and intercellular communication and matrix composition.

Regardless of the source, all cardiac arrhythmias arise from two primary abnormalities: impulse initiation, which includes spontaneous automaticity and triggered activity, and impulse propagation—that is, conduction (generally manifested as reentrant arrhythmias). Impulse initiation establishes heart rate and is determined primarily by the rate of diastolic depolarization—that is, the slope of phase 4. In the normal heart the slope (heart rate) is autonomically controlled, being decreased by acetylcholine released from parasympathetic nerves and increased by norepinephrine released from the adrenal cortex. Stroke volume decrementally decreases as heart rate increases; accordingly, cardiac output may ultimately decrease with faster rates. The slope of phase 4 can be affected by a number of abnormal conditions. Enhanced automaticity occurs when the rate of spontaneous diastolic depolarization increases sufficiently to allow emergence of pathologically slowed or increased rates (e.g., sinus tachycardia). Ectopic foci (pacemakers that normally are latent) may emerge and may cause tachycardia if the frequency exceeds that of the sinoatrial node. Arrhythmias of initiation may also be triggered by an abnormal depolarization (phase 0), resulting in secondary upstrokes in the action potential. Two types of triggered arrhythmias occur. Delayed after-depolarization (DAD) occurs after a normal action potential and is followed by an overload of intracellular calcium. Examples include arrhythmias associated with myocardial failure, myocardial ischemia, adrenergic stress, and digoxin toxicity. Early after-depolarization (EAD) upstrokes occur during phase 3 repolarization and follow abnormally long cardiac action potentials. They generally result from abnormal inward sodium or calcium channel currents or exchange pumps and are associated with very slow heart rates or low extracellular K⁺ or in association with drugs that cause prolonged action potential duration.

KEY POINT 14-25 Arrhythmias reflect altered impulse initiation (automaticity) or impulse propagation (conduction).

Drugs that decrease automaticity do so through several mechanisms. Some decrease the rate (slope) of phase 4 spontaneous depolarization, suppressing the ectopic focus such that the sinoatrial node is allowed to resume its dominance. Automaticity might also be reduced by lengthening the time needed to attain threshold potential by increasing either the excitation threshold (more positive; e.g., Na⁺ or Ca²⁺ channel blockers) or the diastolic membrane potential (i.e., hyperpolarization, or more negative). Finally, spontaneous discharge might be reduced by prolonging the action potential duration, such as might occur with prolonged effective or absolute refractory periods.⁵ Triggered automaticity can be impaired by inhibiting the development of after-depolarizations or interfering with inward sodium or calcium channels. Shortening (rather than prolongation) of the action potential duration will inhibit EADs. Although the mechanism is not well known, magnesium will also inhibit EADs.5

KEY POINT 14-26 Automaticy can be reduced by prolonging the effective refractory period or increasing the time it takes for the membrane potential to reach threshold (phase 4).

Arrhythmias associated with conduction abnormalities are exemplified by reentrant arrhythmias. Reentrant arrhythmias may be either anatomic or functional. Functional reentrant arrhythmias are exemplified by pathologies such as ischemia that markedly slow conduction. Anatomic arrhythmias involve two or more pathways that travel to the same region of the heart but differ in electrophysiology (e.g., refractory period or conduction speed). Emergence of reentrant arrhythmias reflects the unique histologic make up of myocardial muscle. The geometric connection of myocardial cells to one another facilitates rapid movement of impulses throughout the myocardium such that the heart acts as a single large cell (Figure 14-8). One region might receive signals from several different pathways. Coordination of impulse conduction ensures that myocardial fibers are excited in a sequence that maximizes pump efficiency. Normally, retransmission of an impulse received in a specific region from an alternative (i.e., second) direction is prevented because either the signals arrive simultaneously, thus canceling one another, or the fiber remains refractory from the first impulse and cannot respond to the second. However, if the refractory period is abnormally short, or conduction of the reentering, alternative impulse is markedly slowed, the fiber will no longer be refractory from the first impulse. The impulse can be reinitiated and travels in the opposite direction, until it returns to the region again, generating a (circus) reentrant arrhythmia (see Figure 14-8). Altered membrane channel and ion movements with injured cardiac tissue channels slow movement through fast Na⁺ channels (phase 0) and slow Ca²⁺ channels. Conduction is accordingly slowed, potentially generating reentrant arrhythmias.

Clinically relevant antiarrhythmics act to prevent reentrant arrhythmias by blocking specific ion channels or by targeting autonomic function, thus altering initiation, or conduction or action potential duration (thus refractory periods)

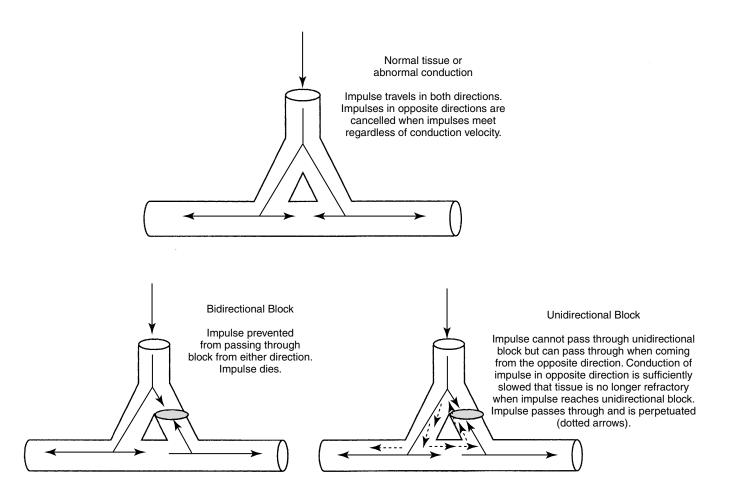

Figure 14-8 In the normal myocardium, electrical impulses travel down one or more paths of a bifurcated myocardial cell. Bifurcations allow coordination of contractions in all directions such that myocardial emptying is efficient and complete. Several mechanisms exist to ensure that impulses travel only in the proper direction. Those impulses that travel in opposite directions will be canceled by one another, precluding their transmission in the wrong direction. In the presence of a unidirectional block (i.e., resulting from damaged myocardium), transmission of one of the impulses will be prevented. However, although the impulse that normally would be canceled is now able to pass through the damaged tissue in the other direction, it will meet tissue that remains refractory from the first impulse. Consequently, it will not be transmitted any further. However, if conduction of the second unimpeded impulse is slowed, the myocardium will no longer be refractory when the impulse passes through the unidirectional block. Therefore the myocardium is receptive to the electrical impulse of this misdirected impulse, and the signal will be transmitted. Because of the combined effects of the unidirectional block and slowed conduction, the impulse may be perpetuated, resulting in a circus or reentrant arrhythmia. Drugs can reduce the arrhythmia by causing a bidirectional block, which prevents the second impulse from traveling through the damaged site, or by increasing the rate of conduction of the second impulse such that it reaches myocardial tissue while it is still in its refractory state from the first impulse.

of cardiac fibers. Initiation and thus automaticity can be suppressed through blockade of ion channels or drugs that facilitate adenosine or acetylcholine (thus increasing the maximum diastolic or resting potential) or antagonize adrenergic receptors (thus decreasing the slope of phase 4). Acceleration of conduction or prolongation of the ERP or APD causes the second impulse to reach tissue still refractory from the first impulse. Examples include Ca^{2+} channel blockers, β -adrenergic receptor antagonists, and digitalis glycosides. Slowed conduction caused by these drugs may increase the risk of functional reentrant arrhythmias. However, because reentrant arrhythmias respond best to drugs that prolong the refractory period, such drugs nonetheless remain effective for treatment of reentrant arrhythmias if the effective refractory period is prolonged. Examples of drugs that prolong ERP or APD might include drugs that delay recovery of sodium channels (particularly those that target inactivated channels) or potassium channel blockade (the delayed rectifier channels is particularly amenable to drug blockade), or drugs that prolong the APD. However, potassium channel blockade is also particularly conducive to causing arrhythmias, perhaps in part because of the importance of potassium channels in multiple phases of the action potential cycle.

KEY POINT 14-27 Reentrant arrhythmias can be decreased by increasing the rate of conduction or prolonging the effective refractory period.

In general, the complex action of antiarrhythmic drugs renders antiarrhythmic therapy generally inefficient and risky. All antiarrhythmic drugs are proarrhythmogenic. A major contributing factor to both inefficiency and risk is lack of knowledge regarding the particular electrophysiologic mechanism that underlies each arrhythmia or the drug. For example, the number of potassium channels, their differences in location, control, and role in the action potential complicate understanding, let alone predicting the impact of potassium channel blockade on cardiac function or rhythm. Increasingly, the arrhythmogenicity of drugs is likely to be understood as the differences in potassium channel impact by these drugs are understood. For example, blockade of delayed rectifier potassium current (I_{k5}) in the presence of high (β) adrenergic output predictably causes torsades de pointes in dogs.^{110a}

Differences in clinical actions of antiarrhythmic drugs reflect in part different affinities of ion channel–blocking drugs for target receptors on the ion channel proteins, with some drugs targeting specific receptor subtypes. Affinity may change with conformation of the protein channel. As such, affinities are often state dependent (i.e., occurring only in the open, conducting state; in the closed, resting state; or during the inactivated, recovering state). Further, cardiac drugs often target more than one channel, and changes induced by a drug in one current generally influences the other currents. Direct and indirect (through the autonomic system) effects on cardiac contractility contribute to adverse effects.⁵ Finally, most antiarrhythmic drug target channels in both normal and abnormal tissues. Electrolyte abnormalities and hypokalemia in particular often predispose arrhythmogenicity and may increase adverse effects to antiarrhythmics.^{109,110} Indeed, a randomized human clinical trial that focused on the use of antiarrhythmic drugs for prevention of sudden death found that sudden death actually increased, primarily because of the proarrhythmic effects of drugs that target ion channels.¹¹¹ Accordingly, antiarrhythmics should be considered dangerous,^{109,111} and their use should be pursued, whenever possible, under the guidance of clinicians with appropriate expertise (i.e., cardiologists).

Antiarrhythmic cardiac drugs fall into four main classes according to their dominant electrophysiologic effect on myocardial cells^{5,112} (Figure 14-9). Although this classification serves to couple electrophysiologic actions with antiarrhythmic effects, increasing emergence of the complex mechanisms of actions of these drugs complicates the classification, and care should be taken not to assume that drugs within classes behave the same way; indeed, most drugs have multiple effects that cross into multiple classes.

KEY POINT 14-28 All antiarrhythmics are proarrhythmic, and their use should be initiated cautiously and only if proper monitoring tools are available.

Class I Antiarrhythmic Drugs

Class I agents comprise the standard membrane-stabilizing drugs such as lidocaine, quinidine, and procainamide. These agents work by selectively blocking the fast Na⁺ channels and depressing phase 0 of the action potential through the direct membrane-stabilizing or "local anesthetic" effect. Accordingly, class I drugs increase the threshold of excitability and decrease the rate of spontaneous phase 4 depolarization, thus reducing the emergence of ectopic foci (decreased automaticity). Although decreased phase 0 depolarization also decreases conduction velocity (thus prolonging conduction and increasing the risk of re-entrant arrhythmias), effects on automaticity and generation of ectopic foci appear to predominate over effects on conduction velocity. Some class I drugs also prolong action potential duration, especially the effective refractory period, and as such are particularly useful in treating reentrant arrhythmias.¹¹³ Class I agents can be further subdivided according to their effects on the refractory period and the rate of repolarization. Class 1A are intermediate blockers, including quinidine and procainamide. Class 1 B are rapid blockers, including lidocaine and mexiletine. Class 1C blockers are characterized by slow blocking kinetics and include flecainide, propafenone, and moricizine.

The risk of proarrhythmogenicity of antiarrhythmics is increased in dogs and cats by virtue of the dearth of scientifically based data supporting their use. However, regarding the data that do exist, when comparisons are made between dogs and humans, the concentrations at which antiarrhythmic effects of class I drugs are realized generally are similar. However, marked differences in pharmacokinetics exist; indeed, an exception to the generalization occurs for procainamide because of differences in its metabolism between dogs and humans.¹¹⁴

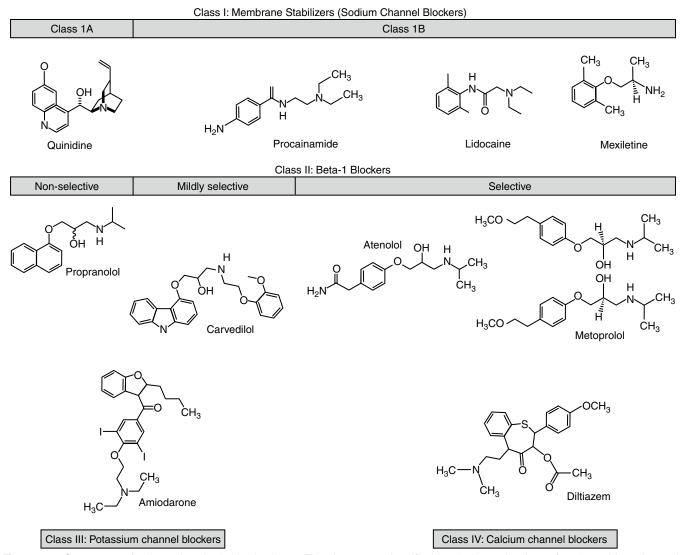

Figure 14-9 Structures of selected antiarrhythmic drugs. The drugs are classified by their mechanism of action, although much overlap occurs, particularly with potassium channel effects. Metoprolol exemplifies the chiral carbon present on most β blockers (some have two). Rotation of the four groups around the carbon yields enantiomers (stereoisomers that are non-superimposablemirror images). Although similar in structure, the enantiomers are likely to be different in both pharmacokinetic and pharmacodynamic properties. Most products are sold as racemic mixtures of both isomers, although only one may be active. The body is likely to handle the isomers differently. Class 1C drugs are not shown.

KEY POINT 14-29 Although antiarrythmics are classified according to the major ion targeted, newer data indicate that this scheme is simplistic and much overlap occurs among the classes.

Class IA Drugs

Class 1 A drugs increase the threshold for excitability and decrease automaticity, reduce the rate of phase 0 depolarization and thus slow conduction, prolong both the effective refractory period and the action potential duration, and delay repolarization. A shared arrythmogenic effect of sodium channel blockers with atrial flutter reflects slowed conduction. Subsequent slowing of atrial flutter may allow more signals to be transmitted through the atrioventricular node, causing the heart rate to increase.

Quinidine

Quinidine, derived from the bark of the cinchona plant, is a diastereomer of the antimalarial drug quinine. Quindine affects most types of cardiac muscles.^{5,112} Its efficacy against supraventricular and ventricular arrhythmias facilitates its classification as a broad-spectrum antiarrhythmic. Quinidine has both direct and indirect effects. For direct effects, quinidine blocks open Na⁺ channels, increasing the threshold for excitability and decreasing automaticity, thus suppressing ectopic pacemakers. Blockade of multiple K⁺ currents prolongs action potentials, particularly at slow heart rates. Electrophysiologically, quinidine increases the QRS complex; the QT interval may also be prolonged, causing *torsades de pointes* at therapeutic or subtherapeutic concentrations in some patients.⁵ Because it also prolongs the effective refractory period, especially in the atria, quinidine is particularly useful for treatment of reentrant arrhythmias such as atrial fibrillation.^{112, 113,2,115} In the atria quinidine also has an indirect effect through antivagal ("atropine-like") actions, contributing to undesirable side effects, and specifically, tachycardia.

KEY POINT 14-30 Blockade of sodium channels might be expected to affect nondepolarizing cells more than depolarizing cells.

KEY POINT 14-31 The anticholinergic effects of quinidine – which initially result in an increased heart rate –contribute to its efficacy in the treatment of atrial fibrillation.

Although given intravenously (which markedly increases the risk of cardiotoxicity) and intramuscularly, quinidine is most practically administered orally. Intramuscular injection is painful. Quninidine has been prepared as different salts to manipulate (prolong) oral absorption. Quinidine sulfate is absorbed rapidly after oral administration,^{5,112} whereas the gluconate form is absorbed more slowly. Despite marked (90%) binding to α glycoproteins, quinidine distributes rapidly to most tissues, resulting in a large volume of distribution. In states of high stress, it may be necessary to increase doses of quinidine to overcome increased binding associated with increased inflammatory and other α glycoproteins, although this may be an issue more commonly encountered in humans with myocardial infarction. Quinidine binds to tissue, including cardiac proteins. Hepatic metabolism is mediated by CYP3A and is extensive, with excretion of parent compound or metabolites in the urine. Variability in metabolism is marked among patients and can be influenced by other drugs, necessitating individualized therapy. The duration of action of quinidine may be shortened or lengthened by drugs that target CYP3A4. The half-life is about 6 hours, but the dosing interval may be prolonged with slow-release preparations.

Quindine disposition has been studied in Beagle dogs (n=4). An intravenous dose of 1 mg/kg distributed to a volume of 1.17 ± 0.40 L/kg and was cleared at a rate of 5.90 ± 0.40 mL/min/kg, yielding an elimination half-life of 3.46 ± 1.44 h and mean residence time (MRT) of 3.34 ± 1.25 h. After oral administration of the sulfate salt (100 mg orally), C_{max} was 2162 ± 598 ng/mL and oral bioavailability was 73%.¹¹⁶

Quindine can cause or be affected by drug interactions, particularly by drugs that affect CYP 2D6 and 3A. It is a potent inhibitor of CYP 2D6, prolonging the elimination of selected drugs or preventing the formation of active drug (e.g., morphine from codeine).⁵ Its clearance is affected by other drugs that impair (e.g., cimetidine, verapamil) or induce (e.g., phenobarbital, phenytoin, rifampin) CYP 2D6. Clearance of quinidine was decreased in normal Beagles (n=4) by 50% after treatment with the CYP3A substrate inhibitor ketoconazole. The elimination half-life (hr) increased from 3.46 ± 1.44 to 6.78 ± 1.98 ; C_{max} increased from 2162 ± 598 to 3295 ± 636 ng/mL.¹¹⁶ Quindine clearance also is prolonged by drugs that alkalinize the urine (e.g., carbonic anhydrase inhibitors, thiazide diuretics). Quindine decreases digoxin clearance and may compete with it for P-glycoprotein–mediated efflux.

Competition at cardiac binding sites also may displace digoxin, further increasing plasma digoxin concentrations, which may exacerbate digoxin-induced cardiac arrhythmias.¹¹⁷

Quinidine is associated with cardiotoxicity-induced arrhythmias such as atrioventricular blockade or ventricular arrhythmias. Sudden death caused by syncope has been reported. The atropine-like (antivagal) effects of quinidine probably account for some potentially serious side effects. Loss of vagal tone, important to the control of conduction in the atrioventricular node, may increase impulse conduction to the ventricles, resulting in paradoxical acceleration, an undesirable increase in heart rate in the patient with supraventricular tachycardias (including atrial fibrillation). This loss of vagal tone also impacts drugs whose cardiac effect is based on enhanced vagal tone. In humans, digitalization prior to therapy is indicated. Quinidine is also an α -adrenergic blocking agent and can cause vasodilation and potential hypotension. Gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea) may occur, particularly with the sulfate form.

As a broad-spectrum drug, quinidine may be effective for acute or chronic management of supraventricular and ventricular arrhythmias. However, its efficacy particularly targets atrial arrhythmias. Quinidine is contraindicated in the presence of complete A-V heart block. Daily doses range from 5 to 15 mg/kg; therapeutic concentrations are 2 to 6 μ g/mL. The drug can be given intravenously, but only with extreme caution.

Procainamide

Procainamide differs from the local anesthetic procaine only by replacement of an ester with an amide (see Figure 14-9). Like quinidine, procainamide blocks open Na⁺ channels and outward K⁺ channels. Thus it decreases automaticity, increases refractory periods, and slows conduction as well as prolongs the action potential duration. Its N-acetyl metabolite (in which the dog is deficient) is active and accounts for a major proportion of activity in humans. Although the metabolite does not block Na+ channels, it does prolong the action potential duration (a K+-blocking effect).⁵ The metabolite is equal in efficacy but less potent than the parent compound in the control of ventricular arrhythmias.¹¹⁸ The effects of procainamide on automaticity, excitability, responsiveness, and conduction are similar to those produced by quinidine. Indirect effects (those affecting the autonomic nervous system) are significantly weaker, with no α -adrenergic blockade or paradoxical acceleration.5

KEY POINT 14-32 Because the acetyl metabolite of procainamide targets potassium channels, decreased efficacy can be anticipated in dogs compared to humans.

Procainamide is rapidly and almost completely absorbed after oral administration, although the rate varies with the preparation. Peak concentrations occur within 45 to 75 minutes with a capsule but take longer with tablets. Bioavailability in the dog approximates 85%.¹¹⁹ Only about 20% of the drug is protein bound to glycoproteins in humans.⁵ Distribution

occurs to most tissues except the brain,⁵ yielding a large (1.44 L/kg in dogs) volume of distribution.¹¹⁹ Procainamide is extensively biotransformed by the liver to metabolites. In humans, *N*-acetylprocainamide is a major active metabolite, contributing significantly to antiarrhythmic effects. In dogs acetylation is deficient and therapeutic concentrations reflect principally the parent drug whereas for humans, it reflects both parent and metabolite. In dogs the mean concentration necessary to control arrhythmias in ouabain (a cardiac glycoside)-intoxicated dogs was 33.8 µg/mL, with a range of 25 to 48.5 µg/mL.¹²⁰ This compares with a therapeutic range of concentration of 5 to 30 µg/mL for the combined parent and metabolite in humans. The elimination half-life of procainamide in the normal dog is 2.5 to 2.8 hours.

The fluoroquinolones decrease clearance of procainamide or its *N*-acetyl metabolite in humans. The extent and target (parent versus metabolite) varies with the fluoroquionlone drug. In humans ciprofloxacin decreases clearance of both by nearly 20%; competition appears to be occurring for renal tubular transport proteins.¹²¹ Toxicities of procainamide include cardiotoxicity, similar to that induced by quinidine; hypotension with rapid intravenous administration (bolus); and gastrointestinal signs (anorexia, nausea, vomiting, diarrhea). Cardiac toxicity is indicated by a 50% widening of the QRS complex or by bradyarrhythmias or tachyarrhythmias.

Procainamide is available as oral capsules, tablets, and sustained-release tablets. Intravenous preparations are available for acute or unstable situations. Intravenous infusion is a reasonable approach for the treatment of the acute patient and may be preferred to rapid bolus, which may be associated with hypotension. Procainamide also can be administered intramuscularly (15 to 20 mg every 2 hours [dog] or 8 to 16 mg every 3 to 6 hours [cat]). An advantage to procainamide over other antiarrhythmics is ease of converting from an intravenous to an oral preparation. The transition is best accomplished by stopping an infusion, and, at one elimination half-life, administering the first oral dose (125 to 500 mg every 6 to 8 hours, for a total of 33 mg/kg per day).

Procainamide is a broad-spectrum antiarrhythmic drug. In general, its effectiveness as a ventricular antiarrhythmic drug parallels or exceeds that of quinidine, and it is useful for patients who have failed quinidine therapy. Arrhythmias for which procainamide have proved useful include ventricular¹²² and, to a lesser degree, supraventricular types. Procainamide can suppress digitalis-induced toxicity but fatalities may occur.

Disopyramide

The pharmacologic effects and spectrum of disopyramide are similar to those of procainamide and quinidine. Although it is effective in controlling supraventricular arrhythmias, its primary use is for ventricular tachyarrhythmias. Disopyramide has been studied in the dog.¹²³ It is quickly absorbed after oral administration, but it undergoes rapid metabolism and clearance. Its half-life is less than 2 hours in the dog, necessitating multiple daily administrations. Like quinidine, disopyramide has potent antivagal effects and can therefore increase the ventricular rate dramatically in patients with supraventricular tachycardias. More important, disopyramide also has a negative inotropic effect on the heart and can be lethal for patients with preexisting myocardial disease. Clinical indications for disopyramide are probably limited by its potential adverse affects on the heart.¹²⁴

Class IB Drugs

Class IB drugs include agents such as lidocaine and its congeners and phenytoin. Lidocaine (see Figure 14-9), widely used as a local anesthetic, is the prototypic class IB drug. Increasingly, it is being used for a variety of conditions (discussed later). Lidocaine preferentially binds to open (phase 0) and inactivated (phases 1 through 3) channels. Therefore cardiac tissues with long action potential duration or tissues that are rapidly firing (because more time is spent in the inactivated state), such as ischemic tissues, are more affected by lidocaine. Because atrial tissues have a very short action potential compared with ventricles, lidocaine preferentially targets arrhythmias in the abnormal Purkinje system and ventricles. In contrast, it minimally affects the sinoatrial node, atria, or atrioventricular node, although it has been used to successfully treat supraventricular arrhythmias in a limited number of dogs.¹²⁵ Additionally, abnormal ventricular tissues are preferentially affected compared to normal myocardial tissues. Lidocaine also minimally affects the autonomic system.

Lidocaine suppresses automaticity, increases the threshold, and hyperpolarizes (increases the resting membrane potential) of Purkinje fibers. Increased conduction velocity may facilitate inhibition of reentrant arrhythmias. The action potential duration is either unaffected or shortened. Lidocaine efficacy is dependent on potassium; hypokalemia will minimize its efficacy.

KEY POINT 14-33 Lidocaine targets inactive sodium channels, which are more prevalent in diseased, rapidly beating tissues, thus minimizing binding to normal or atrial myocardial tissues.

Lidocaine is well absorbed orally, but it is subject to firstpass metabolism, with only one third of the drug reaching systemic circulation. Rectal bioavailability ranges from 32% to 56%, depending on the preparation.¹²⁶ Peak concentrations in dogs after intravenous administration of 6 mg/kg approximate 10 µg/mL, declining to 0.1 µg/mL by 3 hours, with the elimination half-life approximating 50 minutes.¹²⁷ After intramuscular administration, absorption is complete, with peak concentrations at the same dose approximating 1.8 µg/mL at 30 minutes. Distribution is rapid to a volume of approximately 1.4 L/kg.^{127,128} About 70% of the drug is bound to protein (glycoprotein). Lidocaine is cleared by hepatic metabolism to active and inactive metabolites. Clearance in female dogs (n=4; dose of 2 mg/kg infused over 5 minutes) was 27.5 \pm 6.0 mL/min/kg. As a flow-limited drug, systemic clearance of lidocaine should decrease in proportion with hepatic blood flow. Portosystemic shunting will increase oral bioavailability; experimentally induced portosystemic shunting in dogs increases it from 15% to 80%.129 Lidocaine is prepared for intravenous administration. Lidocaine can be administered intravenously as a rapid bolus or as a continuous intravenous infusion. It can also be given intramuscularly in emergency situations. Topical creams, salves, or gels and patches are intended for local anesthetic use only and will not provide antiarrhythmic efficacy.

As an antiarrhythmic, lidocaine is indicated for emergency treatment of ventricular arrhythmias. Pharmacologic effects occur rapidly. Lidocaine has several undesirable effects. Although lidocaine may decrease the risk of acute death associated with ventricular fibrillation, one study demonstrated decreased hospital survival, mitigating its routine use. The primary toxicity in the dog occurs in the central nervous system, with symptoms that range from drowsiness or agitation to muscle twitching and convulsions at higher plasma concentrations. Therapeutic and toxic lidocaine concentrations have been established experimentally. In an study of canine myocardial infarction, inhibition of electrically stimulated ventricular tachycardia responded to mean concentrations of 3.5 µg/mL (1 mg/kg intravenously followed by 80 µg/kg/min).¹³⁰ Wilcke and coworkers¹³¹ compared effective and toxic concentrations in six dogs. Minimum effective concentrations for experimentally induced ouabain toxicity (outcome measure was eradication of ventricular tachycardia) ranged from 3.8 to 7.65 µg/mL (mean $6.25 \,\mu\text{g/mL}$). The time necessary to eradicate the arrhythmia ranged from 0.3 to 1 hour after infusion of 1480 mg/hr. However, neurologic manifestations of toxicity appeared at 6.3 to $10.4 \,\mu\text{g/mL}$ (mean 8.21 $\mu\text{g/mL}$) (tonic extension) and became more exaggerated (cortical seizures) at 7.3 to 11.2 µg/mL (mean 9.58 µg/mL). Other neurologic manifestations of lidocaine toxicity include anxiety, sedation, and disorientation. The risk of toxicity with intravenous administration is greater in the cat compared with the dog; however, the cat s prone to cardiac toxicity. Cardiac suppression will occur at higher doses; exacerbation of heart failure has been reported in human patients with poor left ventricular function.⁵ Lidocaine can worsen first-degree or second-degree atrioventricular block and is contraindicated for patients with third-degree heart block because of suppression of ventricular automaticity. A large intravenous bolus may cause sinus arrest; cats are more prone to this adversity.

Drug interactions involving lidocaine are limited. Care should be taken when mixing lidocaine solution with other drugs to avoid pharmaceutic direct drug-drug interactions. Selected drug interactions reflect competition with other basic drugs for binding sites on glycoproteins, although their clinical relevance is not clear. Lidocaine increases hepatic blood flow: a 12-hour infusion of 76 µg/kg/min increased hepatic arterial blood flow 1.6- to 9.2-fold.¹²⁸ Despite its flow-limited behavior, lidocaine appears to decrease its own clearance, with the impact being demonstrable following longer infusions compared with bolus administration.128,132 Changes were more profound in one study following a 24-hour compared with a 90-minute infusion period.¹³² Another study found that multiple administration of lidocaine (once daily) was associated with a decrease in hepatic intrinsic clearance from 1224 ± 859 to 285 ± 104 mL/min/kg.¹²⁸ Lidocaine metabolism is inhibited by a number of drugs, including midazolam and thiamylal.¹³³

Tocainide (no longer marketed in the United States) and mexiletine are class IB antiarrhythmic drugs that are similar in chemistry and mechanism of action to lidocaine but modified to reduce first-pass metabolism, thus allowing oral administration. For example, tocainide is 100% orally bioavailable. Using a model of canine myocardial infarction, tocainide prolonged conduction intervals and the effective refractory period by 26% to 31% in damaged tissue compared with 6% to 8% in the noninfarcted zone.134 Tocainamide has been used for long-term management of ventricular arrhythmias, particularly those that respond to lidocaine or fail to respond to procainamide. Arrhythmias that are refractory to lidocaine are not likely to respond to tocainide. Tocainide is prepared as a racemic mixture. Both the R and S enantiomers appear to have greater antiarrhythmic activity alone compared with the racemic mixture, whereas the racemic mixture appears more toxic than either enantiomer alone. Consequently, safety and efficacy might be improved if single enantiomer preparations become available.¹³⁵ Tocainaide may be more likely than lidocaine to cause CNS and gastrointestinal adverse reactions. Bone marrow dyscrasias and pulmonary fibrosis have limited use of tocainide. Blood dyscrasias have occurred in dogs.¹¹⁰ Contraindications to lidocaine should be followed for tocainide.

After intravenous administration of tocainide, spontaneous premature ventricular complexes were reduced in dogs with experimentally induced myocardial infarction.¹³⁶ In Doberman Pinschers (n=23) with cardiomyopathy, tocainide at 15 to 25 mg/kg every 8 hours reduced the number of ventricular premature complexes short term by at least 70% in 80% of treated dogs; ventricular tachycardia was corrected in 90% of affected dogs. Serum concentrations at 2 hours and 8 hours were 6.2 to 19.1 mg/L and 2.3 to 11.1 mg/L, respectively. Long-term control was more difficult in animals whose left ventricular shortening fraction was less than 17%. Although efficacious, tocainide therapy may be limited by side effects. Anorexia and gastrointestinal disturbances occurred in 35% of dogs, with peak concentrations being higher in afflicted dogs (14 µg/mL) compared with dogs not exhibiting toxicity (11 μ g/mL). Serious adverse effects occurred in 58% of dogs treated longer than 4 consecutive months and included progressive corneal endothelial dystrophy; renal dysfunction occurred in 25% of the dogs.137

Mexiletine, like tocainide, is a structural analog of lidocaine, indicated for oral management of life-threatening ventricular arrhythmias. Like lidocaine, it decreases the the APD more than the ERP such that the ratio of ERP/APD increases (package insert). Normal cardiac tissue is minimally impacted. In humans and dogs, mexiletine is characterized by high oral bioavailability, low first pass metabolism, 50-60% bound to plasma protein, and a volume of distribution of 5-7 liters/kg. Clearance in humans is primarily hepatic via CYP2D6 metabolism (hence, major differences in metabolizer phenotypes may occur), with some CYP1A2; metabolites are largely inactive. extensive metabolizer phenotypes. In dogs, most of the drug may be renally excreted, although its plasma elimination half-life approximates 10-12 hours; liver disease may prolong clearance. Mexiletine exists as a racemic mixture; in humans, the S isomer is characterized by a higher area under the curve (mean R/S ration = 0.8). ^{137a} In dogs, mexiletine has demonstrated stereoselective effects, with *R*-(-)-mexiletine being more potent in the prevention of ventricular tachycardia than *S*-(+)- mexiletine. ^{137b}

In human clinical trials involving mexiletine, approximately 40% of study participants withdrew from studies because of adverse effects; this rate was similar to treatment groups receiving quinidine or procainamide. Rarely, mexiletine has been associated with liver disease, warranting monitoring in patients with abnormal tests indicative of liver disease. Although mexiletine does not cause heart block in normal animals, it occasionally exacerbates pre-existing conduction disturbances; its use is contraindicated in the presence of 2nd or 3rd degree heart block. Mexiletine is arrhythmogenic: sustained ventricular arrhythmias worsened in approximately 10% of human patients receiving mexiletine. Minimum therapeutic plasma concentrations appear to approximate 0.5 mcg/ ml in humans (range 0.05 to 2 mcg/ml). Dosing intervals are designed to minimize fluctuation.

Studies of mexiletine in dogs are largely experimental in nature, supporting use in humans. Experimentally, including studies using canine models, it suppresses induced ventricular arrhythmias. Mexiletine (5 mg/kg) (or esmolol at 1.25 mg/kg or verapamil at 0.4 mg/kg) was limited in its success in preventing torsades de pointes in a canine model involving blockade of delayed rectifying current and β-adrenergic stimulation. ^{110a} However, mexiletine (4.5 mg/kg load followed by 1.5 mg/kg/ hr infusion) was able to partially prevent the proarrhythmic effects of β-adrenergic A-V blockade (sotalol 4.5 mg/kg load followed by 1.5 mg/kg/hr infusion) in diuretic (furosemide and hydrochlorthiazide)-induced hyopkalemic dogs. Mexiletine prevented sotalol-associated torsades de pointes that was electrically induced in the dogs. ^{110b} Pharmacodynamic effects of melixetine were determined in three canine models of arrhythmias. The minimum effective plasma concentrations (µg/ml) of mexiletine necessary to suppress arrhythmias were 1.8 ± 0.6 when induced by digitalis, 3.7+0.9 for adrenaline, and 2.2 ± 0.4 for coronary ligation $\mu g/mL^{.110c}$ The plasma elimination half-life in dogs is 3 to 4 hr. Mexiletine may be more effective when used in combination with other drugs. For example, it was more effective at in preventing experimentally induced ventricular arrhythmias in dog myocardium when combined with quinidine. ^{110d}

Like tocainide, mexiletine is more likely than lidocaine to cause central nervous system and gastrointestinal toxicity. Mexiletine induces seizures in dogs at 25 mg/kg; vomiting occurs at 15 to 30 mg/kg. However, the drug was well tolerated at 15 mg/kg for 13 weeks in normal dogs. ^{138b} Contraindications to lidocaine should be followed for mexiletine.

Phenytoin is an anticonvulsant with a limited spectrum of cardiac antiarrhythmic activity. Its mechanism and impact are similar to those of lidocaine. Its primary use in veterinary medicine has historically been management of digitalis-induced arrhythmias; phenytoin will shorten atrioventricular nodal and Purkinje refractory period in digitalized patients.

Class IC Drugs

Class IC drugs cause effects similar to those of the class IB drugs except that they do not prolong the refractory period. Examples include encainide, flecainide, lorcainide, and propafenone. Conduction velocity is depressed. In addition to sodium channel blockade, flecainide also blocks (in vitro) delayed rectifier potassium channels and calcium channels. Action potential duration is shortened in Purkinje cells (as a result of blockade of late-opening sodium channels) but prolonged in ventricular tissues (because of potassium channel blockade). In contrast to most class 1B drugs, flecainamide affects atrial tissues, prolonging the action potentials proportionately with rates, rendering it effective for atrial arrhythmias. However, it affects normal as well as abnormal tissues. Flecainide studies in dogs have been largely experimental. In one study concentrations of 610 ± 111 ng/mL increased the electrically induced defibrillation threshold in dogs.¹³⁸ The arrhythmogenicity of flecainamide can be lethal. Reentrant ventricular tachycardia may emerge when treating atrial arrhythmias, heart block may occur in conduction disturbances, and congestive heart failure can be exacerbated if ventricular performance is poor.5

Propafenone is a Na⁺ channel blocker that is similar to flecainide, including K⁺ channel blockade. It is prepared as a racemic mixture with the S-(+) isomer also exhibiting β -adrenergic antagonism in some (human) patients at concentrations at or above 1 µg/mL. Its efficacy is greater with atrial than with ventricular arrhythmias. It is eliminated through CYP2D6 metabolism as well as renal excretion, generally undergoing first-pass metabolism to an equipotent active metabolite. At least one other metabolite is active. Metabolism can be saturated with only small dose increases, resulting in disproportionately high plasma drug concentrations. Inhibitors of CYPD26 will contribute to high drug concentrations. It is available in slow-release preparations. Dosing is modified in human patients with liver disease.

Class II Antiarrhythmic Drugs

Class II antiarrhythmic drugs are β -adrenergic receptor blocking agents. Although discussed here because they affect cardiac arrhythmias, β -blockers have a number of potentially positive effects, particularly on the failing heart. Abbott²⁶ has reviewed β blockade in the management of systolic dysfunction. β -adrenergic stimulation causes the following effects, which are antagonized by β blockers: decreased magnitude and inactivation of calcium current, increased magnitude of potassium and chloride repolarizing currents, increased pacemaker activity, and increased DAD- and EAD-mediated arrhythmias.^{5,9} Adrenergic signals stimulate atrial chronotropic β receptors more so than ventricular receptors. As such, β -blocking drugs (propranolol, alprenolol, and metoprolol) are most effective in slowing atrial compared with ventricular rates and are more effective during states of adrenergic stress.¹³⁹ Beta blockers decrease pacemaker current and thus sinus rate.⁵ Because β blockers increase atrioventricular nodal conduction and prolong atrioventricular nodal refractoriness, they are useful for reentrant arrhythmias associated with the atrioventricula node.⁵ In acutely ischemic myocardial tissue, β blockers increase the energy necessary to fibrillate the heart and thus may decrease mortality (in humans) if used in the first couple of weeks after myocardial infarct.⁵

A number of clinical trials have revealed the efficacy of β -blockade in the treatment of heart failure, reflecting a major effect on remodeling associated with the failing heart.¹⁴⁰ The effects of β blockade in chronic heart failure have been described as protective. Effects considered protective include decreased heart rate, decreased energy consumption, and antifibrillatory effects. Prevention of adrenergic overactivation decreases myocardial cell necrosis. Beta blockers that induce an upregulation of β receptors improve contractility. These benefits tend to outweigh negative inotropic effects that might lead to deterioration of hemodynamics and decompensation, although care must be taken in patients experiencing acute failure. The success of the "paradoxical intervention" may not be obvious until 2 to 3 months after initiation of additional β blocker therapy.

KEY POINT 14-34 In addition to slowing the heart rate — particularly in the presence of high sympathetic tone — β blockers also provide cardioprotection and slowing of progressive myocardial failure.

Drug therapy with β blockers presents pharmacokinetic and pharmacodynamic challenges generally not encountered by many other drugs. Among the challenges are the potential sequelae of interactions between drugs and receptors. Pharmacodynamically, chronic exposure of receptors to agonists or antagonists may cause receptors to be internalized and destroyed, resulting in decreased response or desensitization. Desensitization of β receptors may accompany long-term β blockade therapy. However, initiation of therapy at low doses may attenuate desensitization, an approach that is recommended in human patients with CHF.7 Patients are monitored closely for acute adversities, and the dose is gradually increased only as low doses are tolerated. Low-dose metoprolol therapy simultaneously reduces vascular resistance and avoids reflex tachycardia, an advantage previously recognized only for carvedilol.141 Use of low doses may also decrease the rebound effect that has been documented in humans once β blockade is discontinued. Rebound is associated with worsening heart failure and arrhythmias. Down-titration (decreasing the dose as the drug is discontinued over a 2-week period) reduces the rebound effects.¹⁴² Use of β blockers in states of excessive adrenergic stimulation may allow unopposed a-adrenergic stimulation-mediated hypertension. Beta-blockers should be tapered rather than suddenly decreased to avoid the negative sequelae of receptor up regulation.

Beta blockers are not equal in efficacy. Protective effects of carvedilol and metoprolol were compared in progressive CHF in humans.¹⁴³ Carvedilol performed better in preventing cardiovascular-related illness in a clinical trial (COMET) involving human patients with heart failure associated with ischemia or idiopathic cardiomyopathy (see later discussion). Pharmacokinetically, distribution into the central nervous system-which may be important for maximal response-varies with lipophilicity, with effects of water-soluble drugs (atenolol, nadolol) potentially muted compared with those of more lipophilic drugs (e.g., metoprolol). Distribution is complicated by binding to both albumin and α -glycoproteins, the latter a protein whose concentration increases with inflammation; this may be more relevant to acute myocardial infarction. Binding decreases concentration of active drug; however, because clearance of flow-limited drugs generally is not affected by protein binding, a compensatory increase in drug clearance should not be anticipated and the risk of drug interactions at the level of protein binding increases. Lipophilic β-adrenergic drugs generally are characterized by hepatic clearance that is flowlimited (exceptions are the water-soluble atenolol and nadolol, which are predominantly renally excreted). For flow-limited drugs, the rate of substrate delivery (hepatic blood flow) determines clearance. As such, oral administration is characterized by significant (if not total) hepatic extraction and first-pass metabolism. Beta blockers interact with P-glycoprotein, with carvedilol being an example; its impact is sufficient to warrant its therapeutic use for inhibition of drug transport, which otherwise would result in multidrug resistance. 143a The impact of disease and its successful treatment may impact response. Progressive cardiac disease or improvement thereof might profoundly alter clearance; disposition will be markedly altered in patients with liver disease associated with portosystemic shunting. Pharmacokinetics are further complicated by production of metabolites that are variably active. For example, for carvedilol, M4 and M5 are equipotent to the parent drug; M14 appears to be responsible for greater antioxidant effects compared with the parent. The hydroxymetabolite of metoprolol has 20% of the parent compound in dogs.144

Finally, most β -adrenergic blockers contain at least one chiral carbon, and thus are present as two isomers, each differing both kinetically and dynamically from the other.¹⁴¹ The stereometric character of β-blockers markedly complicates their use. Complicating interpretation, the isomers can be described according to their spatial orientation (S versus R) or the direction in which they rotate light (+ or -); the two are not necessarily related. Blockade of β-1 receptors is achieved predominantly by the S isomer for most drugs. An exception occurs for sotalol, for which the R isomer exhibits more β blocker activity. In the dog the (-) isomer (based on rotation of polarized light; not related to R or S terminology is almost twofold more potent than the (+) isomer of metoprolol.¹⁴⁵ In contrast, non- β -1-blockade effects (e.g., blockade of α receptors, antiarrhythmic activity) generally are not stereoselective. All β blockers are marketed as a racemic mixture; exceptions include imolol (marketed as the S isomer), labetolol (which contains two chiral carbons), and nadolol (which contains three chiral carbons); all these are marketed as a mixture of four isomers. Absorption of β blockers does not appear to be stereoselective, although timolol may be stereoselectively metabolized by intestinal epithelial cells.141 Binding to proteins may be steroselective, with selectivity varying with the binding protein. Distribution to tissues does not appear to be stereoselective beyond that determined by differences in protein binding. However, β blockers appear to be stored at terminal nerve endings in a stereoselective manner, with preferential storage of the (–) isomer, particularly for water-soluble drugs such as atenolol. Metabolism of ß blockers is very complicated. Each isomer may be stereoselectively metabolized to active metabolites, which maintain the chiral carbon; as such, metabolites may be stereoselectively active or further metabolized. For metoprolol and carvedilol (but not significantly for other lipid-soluble drugs), metabolism is stereoselective, resulting in stereoselective plasma drug concentrations. In humans concentrations of the (+) carvedilol isomer (the less active isomer) are approximately twice that of the (-) isomer with regard to C_{max} and area under the curve; for metoprolol the concentrations of the isomers are almost equivalent, with the (-) isomer up to 30% higher than the (+) isomer. Renal clearance of water-soluble drugs (atenolol, nadolol) does not appear to be stereoselective. Drug interactions also may be stereoselective. In humans CCBs (verapamil and diltiazem) decrease first-pass metabolism. However, the inhibition is stereoselective for verapamil (but not diltiazem) toward the (+) R-isomer of propranolol. Cimetidine and quinidine also have exhibited stereoselective inhibition of β blockers. Finally, genetic polymorphism has been demonstrated for enzymes responsible for CYP-mediated drug metabolism in humans (and should be anticipated in dogs), although differences do not appear to be stereoselective.141

KEY POINT 14-35 Like many cardioactive drugs, enantiomers and active metabolites contribute to variability in disposition among patients.

Nonselective B Blockers

Propranolol is the prototype β blocker. It is a competitive, nonselective β blocker of both β -1 and β -2 receptors. Like all β blockers, propranolol is most effective in the presence of elevated sympathetic tone. Its negative chronotropic effect is less likely in conditions not associated with elevated levels of catecholamines (e.g., less effective if associated with hypokalemia, fever, some heart diseases). It will slow ventricular rates in patients suffering from supraventricular arrhythmias, including those induced by digitalis toxicity, but is rarely able to convert a supraventricular arrhythmia to a normal sinus rhythm. As a β -1 blocker, propranolol is also a negative inotrope. This pharmacologic effect might be detrimental in the patient with small cardiac reserve (e.g., the patient with decompensated CHF) during acute treatment. Propranolol has been studied in euthryoid and hyperthyroid cats.¹⁴⁶ Changes in disposition induced by hyperthyroidism suggest that a lower dose is indicated for oral administration because of increased bioavailability. Clinical indications of propranolol (β blockers) as an antiarrhythmic include reduction of ventricular rate in cases of supraventricular tachycardias, hypertrophic and other forms of obstructive

heart disease, and hyperthyroidism. The effects of propranolol are dose, time, duration and route dependent; although oral administration may be associated with decreased bioavailability of the parent drug, formation of a more effective metabolite may cause better response with oral administration.^{146b}

The toxic effects of propranolol are the result of nonselective β blockade and include bradyarrhythmias, hypotension, heart failure, bronchospasm, and hypoglycemia, particularly in diabetics. In an intact experimental canine model, insulin (4 IU/min intravenously with glucose) was shown to be superior to epinephrine for treatment of acute propranolol toxicity.¹⁴⁷

Nadolol (5 to 10 mg orally every 6 to 12 hours [cat]; 40 to 60 mg orally every 6 to 12 hours [dog]) also is a nonspecific β blocker that is renally excreted. Side effects and contraindications typical of propranolol occur for nadolol.¹¹⁰ Sotalol is another non-specific β -blocker that also prolongs the APD and ERP of atrial and ventricular fibers (Class III).

Selective Beta Blockers

Metoprolol is a relatively selective, lipophilic β -1 blocker. It is marketed as a racemic mixture, although the (–) isomer provides the predominant β blockade effect. The clinical pharmacology of metoprolol exemplifies the complexities associated with therapeutic use. Metoprolol undergoes hepatic clearance to several metabolites, of which the α -hydroxyl metabolite, the product of metabolism steroselective for the S(–) isomer is active. However, the proportion of this metabolite formed from the parent compound may not be clinically significant. O-Demethylation and N-dealkylation appear to be the major metabolites formed in dogs.¹⁴⁸

The β -blocking effect of α -hydroxymetoprolol has been compared with that of metoprolol after intravenous administration in the dog. The dose-response relationship was linear for both compounds, but the metabolite required 10 times the plasma concentration of the metoprolol (5 times the dose) for therapeutic equivalence. The volume of distribution for the metabolite was 2 liters/kg compared with 3.5 liters/kg for metoprolol, whereas clearance was 3.5 mL/kg/min for the metabolite compared with 20 mL/kg/min for metoprolol. The net effect of these differences resulted in an elimination halflife for the α -hydroxy metabolite of 7 hours compared with 2 hours for the parent compound. Approximately 5% of an intravenous dose of metoprolol was metabolized to the active metabolite.¹⁴⁴ In Beagles (n=4, 8 years old, all female) receiving 1.37 mg/kg metoprolol orally, the area under the curve (0-48 hours; $\mu g/mL/hr$) was 2 for α -hydroxymetoprolol, compared with 4.39 for metoprolol acid and 1.89 for metoprolol. Peak plasma concentrations (estimated from concentration versus time curve) of metoprolol and its metabolites were 400 ng/mL at 0.5 hour for metoprolol, compared with 100 ng/mL at 3 hours for α -hydroxymetoprolol. An intravenous dose of 2 mg/kg resulted in a decrease in heart rate in normal dogs by 35% at a concentration of 379 ± 24 ng/mL; the concentration of the α -hydroxyl metabolite was approximately 38 ng/mL. A similar intravenous dose of the metabolite (2 mg/kg) resulted in a 25% reduction in heart rate. These studies suggest that the active metabolite of metoprolol may not play a major

role in cardiac response, although the impact on other effects (i.e., antiarrhythmic, cardioprotective) is not clear.

Stereoselective pharmacodynamic effects of metoprolol also have been described in dogs. The concentration (µg/mL) necessary to achieve 50% of the inhibitory effect for each isomer were as follows: for $V_{max} 250 \pm 80$ (R) versus 70 ± 30 (S), dP/dtmax: 450 \pm 210 (R) versus 70 \pm 40 (S) and heart rate, 520 \pm 210 (R) versus 82 \pm 27 (S). As such, the (S) isomer was more potent than the (R) isomer at a ratio of 3.7, 6.8, and 6.3 for V_{max}, dp/dt_{max}, and heart rate, respectively.¹⁴⁵ Stereoselectivity has also been reported for the disposition of metoprolol in anesthetized dogs, (although applicability to awake dogs is not clear). The peak times to maximum inhibitory effect of either metoprolol isomer occurred at 90 to 120 minutes-Because the isomers were not given intravenously, volume of distribution(Vd) and CLs could not be corrected for bioavailability (F); however, differences occurred in Vd/F, CLs/F, and area under the curve between the isomers;.145 Another investigator¹⁴⁹ documented that hepatic clearance of metoprolol in dogs is slightly selective for the (S) isomer.

Metoprolol is prepared as an oral tartrate (Lopressor^{*}), and slow-release succinate salt (Toprol XI^{*}); the latter allows oncedaily dosing in humans. The slow-release preparation does not appear to have been studied in dogs or cats. Indications of the slow-release preparation in humans include hypertension as well as treatment of stable CHF.

Verapamil (3 mg/kg) inhibited clearance of metoprolol in dogs approximately 50% to 70%. The effect is profound after oral administration, abolishing first-pass metabolism, with inhibition selective toward O-demethylation of the (S) isomer.¹⁴⁹

A large multicenter clinical trial studied the use of metoprolol for treatment of acquired heart disease and particularly DCM compared with a placebo in dog.^{149a} The drug did not appear to decrease mortality rates but did improve ventricular function as well as quality of life.

Carvedilol represents one of the more recently (third) generation of β blockers associated with potential antiarrhythmic, antihypertensive, and antiremodeling effects.¹⁵⁰⁻¹⁵² Carvedilol is specifically approved to reduce cardiovascular mortality in human patients. Although it is characterized by β_1 and β_2 as well as α -adrenergic blockade, it is relatively (mildly) β_1 selective in human patients. Vascular endothelium contains β 1 and β 2 receptors as well as α -1 receptors, each targeted by carvedilol. As such, it decreases total peripheral resistance and preload without compromise of cardiac output or causing reflex tachycardia. This advantage however, might be minimized by low-dose therapy of other (i.e., not carvedilol) β blockers.¹⁵³Advantages compared with traditional selective β blockers such as metoprolol include reduced mortality in human patients with left ventricular failure, perhaps resulting from a more complete antagonism of sympathetic activation.140,142,154,155 Carvedilol benefits do not reflect a reduction in heart rate as much as improvement in left ventricular function. Additional advantages may include antioxidant and antiproliferative properties and inhibition of apoptosis in the heart.^{150-152,156} Finally, carvedilol may inhibit the synthesis of endothelin in coronary arteries.¹⁵⁷ Carvedilol appears to protect against doxorubicin-induced cardiomyopathy.¹⁵⁸ In a rabbit model of ischemia, carvedilol provided superior cardioprotection, probably because of antioxidant and antineutrophil effects.¹⁵⁹ Similar effects were reported in a human patient receiving doxorubicin.¹⁶⁰

KEY POINT 14-36 An advantage of carvedilol compared with other selective β blockers is α -adrenergic blockade, which may decrease afterload.

Carvedilol has been relatively well studied in dogs, It is well absorbed and undergoes extensive hepatic metabolism, including glucuronidation and subsequent biliary excretion.¹⁶¹ The kinetics and selected pharmacodynamics have been studied in anesthetized¹⁶² and awake^{163,164} dogs. In anesthetized dogs the elimination half-life was 54 minutes (compared with 2.4 hours in humans), and the volume of distribution was 2 L/kg. When studied at doses ranging from 10 µg to 630 µg/kg, heart rate did not decrease, although reports in awake dogs indicate otherwise. Pulmonary and systemic pressures decreased in treated animals but increased in control animals, consistent with the β blockade effect of the drug. The authors recommend an optimal plasma drug concentration of 100 ng/mL, achieved after intravenous infusion of 150 to 310 µg/mL. Disposition was characterized by marked variability. The median peak concentration (extrapolated) of carvedilol after intravenous administration of 1.75 µg/mL was 476 ng/mL (range 203 to 1920 ng/ mL), elimination half-life $(t_{1/2})$ was 282 minutes (range 19 to 1021 minutes), and MRT was 360 minutes (range 19 to 819 minutes). Volume of distribution at steady state was 2 L/kg (range 0.7 to 4.3 L/kg). After oral administration of 1.5 mg/ kg, the median peak concentration was 24 μ g/mL (range 9 to $173 \,\mu\text{g/mL}$), time to maximum concentration was 90 minutes (range 60 to 180 minutes), $t_{1/2}$ was 82 minutes (range 64 to 138 minutes), and MRT was 182 minutes (range 112 to 254 minutes). Median bioavailability after oral administration of carvedilol was 2.1% (range 0.4% to 54%). However, the bioavailability of active metabolites (M4 and M5, which are equipotent to parent drug in humans) was not determined, and it is not clear whether these metabolites are produced in dogs. On the basis of these data, monitoring should be considered to adjust dose. The half-life of 3 hours suggests 8-hour dosing. However, pharmacodynamic studies were also performed.¹⁶⁴ Normal dogs were studied at baseline and after multipledose (>5 days) oral administration of carvedilol (1.5 mg/kg of body weight orally every 12 hours). Dogs were challenged with isoproterenol. Carvedilol had no effect on heart rate or blood pressure in six of eight dogs at baseline or study end, but heart rate reduced after multiple dosing in two of eight dogs. Carvedilol attenuated isoproterenol-induced changes in heart rate by 54% to 76% through 12 hours and by 30% at 24 hours. The effects of isoproterenol on blood pressure was attenuated by 80% to 100% through 12 hours. Based on normal dogs, an oral dose of 1.5 mg/kg was recommended every 12 hours. The magnitude of β -blockade response correlated strongly to peak plasma carvedilol concentration, suggesting that therapeutic drug monitoring may be clinically useful. Carvedilol also has been compared to bisopropol (see later discussion).

The efficacy of carvedilol and metoprolol for the treatment of chronic heart failure has been compared in humans. The efficacy of these drugs has also been compared with that of standard therapy in humans.^{154,165} No difference could be demonstrated in most outcome measures between carvedilol versus metoprolol treatment, although blood pressures were lower in carvedilol compared with metoprolol patients. Patients receiving either carvedilol or metoprolol significantly improved compared with those receiving standard therapy.¹⁵⁴ More recently, the results of the COMET study, which compared carvedilol with metoprolol, have been reported. The COMET study was a randomized, double-blind, parallel comparison of carvedilol at approximately 0.3 mg/kg twice a day and metoprolol tartrate at approximately 0.7 mg/kg twice a day. Patients (n=3000) were studied for 58 weeks and had stable chronic heart failure, New York Heart Association (NYHA) functional class II to IV, with left ventricular dysfunction. Patients continued ACE inhibition and diuretics. Patients were randomly assigned to receive either carvedilol or metoprolol and followed for 58 months. Endpoints were cardiovascular events (which may be less relevant in dogs or cats), and the proportion of such events in each group (584 for carvedilol versus 667 for metoprolol), although statistically significant, may not be as clinically relevant.

In a study of myocardial perfusion in dogs receiving either carvedilol (2 mg/kg) or metoprolol (4 mg/kg) orally, carvedilol was associated with greater increase in myocardial perfusion and decrease in blood pressure, whereas metoprolol was associated with greater decrease in heart rate.¹⁶⁶ Carvedilol appears to be an inhibitor of P-glycoprotein, at least as was demonstrated in vitro in cancer cells: the LD₅₀ of doxorubicin in breast cancer cells increased by twentyfold (200 to 10 ng/ mL)¹⁶⁷ despite doxorubicin cardioprotection.¹⁶⁰

Oyama and coworkers¹⁶⁸ prospectively failed to find a significant impact of carvedilol (0.3 mg/kg twice daily) in dogs with DCM (n=16; n=7 placebo) using a placebo-controlled, double-blinded randomized design. Endpoints for which significant differences were not documented included changes in ventricular function, activation of neurohumoral compensatory responses, or owner-perceived quality of life. However, animal death reduced sample size and the power of the study to detect a significant difference was not reported. Marcondes-Santos and coworkers¹⁶⁹ found some beneficial effect of carvedilol when added to traditional therapy (digoxin, benazepril, codeine) in dogs (n=13) with chronic mitral valvular disease; 12 control dogs with disease did not receive carvedilol. Dogs were studied using a prospective blinded parallel study. A tendency for improvement occurred for quality of life and a reduction in SBP, and improved disease classification during the 3-month study period.

Atenolol (see Figure 14-9) is a selective β_2 blocker. In humans its use is associated with greater mortality compared to nonatenolol β blockers. The difference presumably reflects a risk of ventricular fibrillation that is greater with atenolol compared to others. Compared to most other clinically used selective β blockers, atenolol is much less lipid soluble and thus less likely to penetrate the central nervous system; increased mortality may be related to the lack of centrally mediated vagal tone, which would otherwise counteract the risk of fibrillation.¹⁷⁰ The implications of this difference among β blockers is not clear for dogs or cats. Little information is available regarding active metabolites or stereoisomers.

Atenolol is 90% bioavailable after oral administration in normal adult cats.¹⁷¹ Elimination half-life in normal adult cats is 3.44 ± 0.5 and 3.65 ± 0.39 hours after intravenous and oral administration, respectively. A dose of 3 mg/kg orally generates a peak plasma concentration of 0.48 \pm 0.16 µg/mL and will block cardioresponsiveness to isoproterenol for 12, but not 24, hours, suggesting a 12-hour dosing interval. Using a prospective, randomized, crossover, blinded study, atenolol (6.25 mg every 12 hours) was studied in healthy cats as either an oral or transdermal preparation.¹⁷² Peak (2-hour) and trough (12-hour) concentrations were measured after 1 week of administration. Therapeutic concentrations (250 ng/ mL) were reached in six of seven cats (579 \pm 212 ng/mL) 2 hours after oral administration, but in only two of seven cats (177 ± 123 ng/mL) following transdermal administration. Trough plasma atenolol concentrations were 258 ± 142 ng/mL following oral administration and 62.4 ± 17 ng/mL following transdermal administration. The authors concluded Monitoring might be considered in animals that must receive atenolol transdermally. Atenolol is indicated for cats with HCM associated with outflow obstruction and respiratory distress. Henik and coworkers¹⁷³ reported the efficacy of atenolol (1 to 2 mg/ kg PO every 12 hours) for control of hypertension in hyperthyroid cats (n=20). Although heart rate was decreased, SPB was not well controlled, indicating the need for an additional vasodilator. Crandell and Ware174 described the successful use of atenolol for treatment of cardiac toxicity associated with phenylpropanolamine overdose in a dog.

KEY POINT 14-37 Transdermal delivery of atenolol in cats is not predictable and should be implemented only if monitoring is available.

Esmolol is a β_1 -selective blocker (S enantiomer) characterized by a very (ultra) short half-life owing to metabolism by erythrocyte esterases. Methanol is a metabolite of esmolol in humans, but its formation does not appear to be clinically relevant. Duration of effect is about 10 minutes; therefore its effects will rapidly dissipate once the drug is discontinued.⁵ It is administered intravenously and has proved useful in dogs for acute ventricular arrhythmias associated with inhalation anesthesia and surgical removal of hyperactive thyroid glands.¹¹⁰ In anesthetized dogs receiving a constant-rate infusion, steady-state concentrations occurred in 10 minutes, with duration of β blockade paralleling drug concentrations.¹⁷⁵ Peak β blockade occurred within 15 seconds after loading with a 500 µg/kg constant-rate infusion and at 30 to 45 seconds after switching to a maintenance dose of 12.5, 25, or 50 μ g/kg/min. Duration of β blockade was less than 15 minutes once drug was discontinued. Esmolol has been proved to be effective for treatment of cats with HCM and left ventricular outflow tract obstruction.¹⁷⁶

Bisoprolol is among the β -1 selective blockers that have prolonged the life span of humans with cardiac disease. Among its distinguishing characteristics is less lipophilicity than other drugs; consequently, the parent drug is eliminated by both hepatic metabolism and renal excretion (approximately 50% each) in dogs.¹⁷⁷ Bisoprolol is less lipophilic than other β blockers, including carvedilol; the implication is not clear, but pharmacodynamic data for bisoprolol apparently are not yet available in dogs. However, Beddies and coworkers¹⁷⁷ compared the pharmacokinetics of carvedilol and bisoprolol (1 mg/kg either drug) after both intravenous and oral administration in 12 Beagles using a parallel nonrandomized study design (six dogs per group; oral drug was followed by intravenous drug). Intravenous administration of bisoprolol resulted in a C_{max} (presumed to be extrapolated) of 408 ± 75 (presumed to be ng/mL) with a 3.9 ± 0.3 hour half-life. Volume of distribution was 2.4 \pm 0.6 L/Kg, and clearance 0.42 \pm 0.08 L/h/kg). After oral administration of bisoprolol, the $C_{\rm max}$ was 322 \pm 261 at 1.1 ± 0.7 hr. Oral bioavailability of bisoprolol was 91.4%compared with 14.3% for carvedilol. For carvedilol, after intravenous administration, $\mathrm{C}_{\mathrm{max}}$ (presumed to be extrapolated) for carvedilol was 788 \pm 348 (presumed to be ng/mL) and half-life 1 ± 0.2 hour. Volume of distribution was 2.9 ± 0.6 , and clearance 2.1 ± 0.5 L/hr/kg. After oral administration the C_{max} of carvediolol was 51 ± 42 at 1.1 ± 07 hours.

Class III Antiarrhythmic Drugs

Class III drugs prolong the cardiac action potential and refractory period by selective potassium channel blockade. As such, they have no effect on the fast Na⁺ conductance and prolong APD without slowing conduction velocity. They generally do not cause β -blockade; sotalol is an example exception. There are two members of this class: bretylium and amiodarone. Bretylium is used as an antifibrillatory drug in humans. It accumulates in sympathetic nerve terminals, where it blocks norepinephrine release, but only after an initial release of stored neurotransmitter. Bretylium is minimally effective in dogs, in part because it affects primarily the Purkinje fibers and ventricles, limiting its spectrum of activity. It is not used clinically in veterinary medicine but is used in human medicine for ventricular arrhythmias. It reportedly can cause defibrillation in cases of ventricular fibrillation in humans and has been investigated for similar effects in dogs.¹⁷⁸ Because it causes the release of norepinephrine from adrenergic neurons, it may be associated with untenable, undesirable side effects.

Amiodarone is a structural analog of thyroid hormone; its mechanism may involve interaction with nuclear thyroid hormone receptors.⁵ It blocks activated sodium channels, calcium channels, and multiple potassium channels. Conduction velocity is slowed, the action potential duration is prolonged, and repolarization is delayed. Further, it noncompetitively blocks adrenergic receptors. It also inhibits cell-to-cell coupling, which may be important to its effects in diseased tissues. It is a powerful antiarrhythmic drug useful for both atrial and ventricular arrhythmias.¹⁷⁹ In the normal canine heart, however, amiodarone causes negative inotropic effects.¹⁸⁰ It also causes both α -blocking and nonselective β -blocking effects. Proarrhythmogenic effects are more likely in the presence of hypokalemia. Amiodarone is metabolized via CYP 3A4 to an active metabolite in dogs. Amiodarone, however, shows only moderate efficacy for the treatment of arrhythmias (supraventricular or ventricular) in dogs and cats,¹¹⁰ although it was more effective than bretylium in preventing sustained ventricular tachycardia or fibrillation in a canine model of reperfusion arrhythmia.¹⁷⁸ Therapeutic concentrations of 0.5 to 2 µg/mL (1 to 2.5 µg/mL)¹⁸¹ have been recommended.⁵ Because it is very lipophilic, with lipid to plasma ratios may be as high as 300:1, amiodarone accumulates in cells (myocardial concentrations exceed plasma by 15 fold), and is slowly released, resulting in a lag time to onset and long duration of maximum effect. Generally, a loading dose is administered for several weeks, followed by a maintenance dose. Adverse effects tend to persist as the drug is eliminated over a period of weeks to months; one half- the peak effect is reached only after 21 days following drug discontinuation. Lipophilicity also limits oral absorption (bioavailability in humans is 30%). Adverse effects require long-term therapy, with the most serious being pulmonary fibrosis, which can be rapidly fatal. Other side effects include corneal deposits, hepatic dysfunction, neurologic dysfunctions (up to 40% in humans), including peripheral neuropathy, muscular weakness, and altered thyroid function (hyperthyroidism and hypothyroidism). Photosensitivity and blue discoloration of the skin have been reported. Amiodarone is associated with drug interactions.

Saunders and coworkers¹⁸² retrospectively studied the effect of amiodarone (median loading and following maintenance doses of 16.5 and 9 mg/kg/day) for treatment of atrial fibrillation in dogs (n=17). A variety of cardiac diseases were studied. Cardioconversion to normal sinus rhythm occurred in six dogs, and heart rate was decreased by at least 20% in 13 dogs. The drug was discontinued in five dogs because of adversities, including bradycardia and increased liver enzymes. Kraus and coworkers¹⁸¹ retrospectively studied amiodarone toxicity in Doberman Pinschers (n=22) with occult DCM. All dogs were simultaneously receiving either tocainamide or mexiletine; some dogs also were receiving other antiarrhythmics. All dogs had been dosed with a loading dose (9.0-12.1 mg/kg) followed by a maintenance dose (range 4.3 to 6.3 mg/kg). Serum amiodarone concentrations ranged within and between animals, in part because of dose changes, but roughly ranged from 1.5 to 3.7 µg/mL at doses that ranged from 200 to 400 mg/ kg once (for higher concentrations) to (for lower concentrations) twice daily. Adverse events that emerged during loading or maintenance included anorexia and vomiting associated with increased liver enzymes in up to 45% of dogs. Dogs often responded to temporary discontinuation of the drug, but persistent hepatic involvement necessitated discontinuation of therapy for some dogs.

Hepatopathy associated with amiodarone therapy has been reported in a series of 4 cases (3 of which were Doberman Pinchers).^{182a} Doses ranged from 8 to 10 mg/kg per day with duration as short as 6 weeks and as long as 8 months. Patients

were receiving other drugs, including melixetine. Concentrations of amiodarone approximated 1.7 mcg/ml at the time of toxicity. Hepatopathy included increased serum liver enzymes in all dogs, and hyperbilirubinerma in 2 of the dogs. No risk factors were identified other than left ventricular dysfunction. Because the drug had been used by the authors in only 10 dogs, the incidence of hepatopathy was described as 40% in this small population of dogs. Hepatopathy resolved in 3 cases after amiodarone was discontinued despite continuation of other cardiac drugs (including melixetine); one dog died suddently.

Sotalol is a class III potassium blocking antiarrhythmic drug with nonselective β -blocking properties. Studies in dogs appear to be limited to experimental studies supporting its use in humans. For example, sotalol disposition was described in dogs (n=3). Oral absorption was rapid and oral bioavaiability 75 to 90%; elimination half-life was $4.5 \pm 1 \text{ h.}^{177a}$ the volume of distribution is larger (by 4 fold) than total body water. ^{177b} Excretion appears to be renal. Plasma concentrations necessary to achieve 50% and 100% of β -blockade after isoproterenol administration were 1-2 and 2.3 to 3.4 µg/ml, respectively.^{177b} In an early canine model, the relative efficacy of β -blockade following isoproterenol stimulation was l-propranolol > propranolol >>sotalol >bunolol. 146b Sotalol is largely cleared in dogs by renal excretion; volume of distribution ranges from 1.1 to 1.6 L/kg. The half-life is shorter in dogs at 4 to 5 hrs compared to 7 to 18 hrs in humans. Experimentally, sotalol has been used to induce torsades de pointes in hyokalemic dogs (2.5 meg/L).

Class IV Antiarrhythmic Drugs

Class IV antiarrhythmic drugs are the CCBs. Those blockers particularly effective on the vasculature are discussed with the vasodilator drugs. Diltiazem and verapamil have been used in both dogs and cats for their effects on heart rate. Both drugs are also, however, characterized by negative inotropic effects, with verapamil being a more effective but less safe negative inotrope.

Because calcium entry into myocardial cells is regulated primarily by slow channels, the CCBs also affect the heart. Specialized tissues capable of automaticity and atrioventricular conduction tissues are particularly affected by CCBs. The differences in pharmacologic effects induced by these drugs often reflect their impact on recovery of slow calcium channel.² CCBs that do not alter the rate of recovery (e.g., nifedipine and its congener amlodipine) will have little effect on conducting tissues. Drugs that do delay recovery of the channels can also delay conduction. For example, verapamil and diltiazem decrease the rate of recovery of calcium channels and thus not only decrease the magnitude of the cardiac action potential but also slow conduction through the atrioventricular node. The faster that atrioventricular nodal stimulation occurs, the more effective the atrioventricular nodal blockade is. Both drugs are useful for supraventricular arrhythmias. However, verapamil also has been shown to be useful in the treatment of experimentally induced ventricular tachycardias in dogs.¹⁸³ Because of their effect on slow calcium channels, CCBs also decrease myocardial contractility.² Verapamil also appears to provide cardioprotective effects in dogs with acute Chagas disease, which is characterized by destruction of sympathetic nerve terminals and alterations of β-receptor density.¹⁸⁴ A proposed mechanism is increased adrenergic adenylyl cyclase activity.

KEY POINT 14-38 Calcium channel blockers active in the heart target cells normally capable of automaticity and thus are more useful for supraventricular arrhythmias.

Hypotension, bradycardia, and tachycardia (generally reflex) are the predominant clinical indicators of CCB overdose. In patients with poor myocardial reserve, exacerbation of CHF may result in peripheral or pulmonary edema

Diltiazem

Diltiazem (see Figure 14-9) is the most commonly used CCB in veterinary medicine, in part because it has been studied in both dogs and cats. It exerts its greatest effects in the sinoatrial and atrioventricular nodes, tissues in which slow Ca²⁺ influx is largely responsible for phase 0 depolarization. Diltiazem slows sinus rate and atrioventricular conduction. The ventricular rate is reduced in patients with atrial fibrillation or flutter, but primary ventricular arrhythmias are generally unresponsive to diltiazem. Myocardial oxygen demand decreases in response to the effects of diltiazem. Cardiac side effects include hypotension, bradycardia, and various degrees of heart block. In human patients a therapeutic range of 50 to 300 ng/mL has been identified and can be used as a target for clinical response in animals.

The magnitude of the hemodynamic affects of the CCB reflects the route of administration. Bioavailability is reduced as a result of first-pass metabolism for nifedipine > verapamil > diltiazem, with bioavailability of diltiazem only 50% after oral administration. However, the extent of metabolism decreases with chronic administration, facilitating chronic oral therapy. Diltiazem is metabolized by acetylation, which is deficient in the dog but not in the cat; the impact of acetylation deficiencies in the dog on diltiazem disposition has not been studied.

In an attempt to identify a product that allows convenient (once to twice daily) dosing intervals, the disposition of several diltiazem products has been studied in cats. Comparison of intravenous, standard, and slow-release (CD) diltiazem preparations reveals a disappearance half-life of 120 minutes for the intravenous and oral preparations, but 460 minutes (7 hours) for the CD preparation. The bioavailabilities of the oral preparations are 71% (standard) and 36% (CD). The higher bioavailability of the standard preparation for cats compared with humans (30%) may reflect less first-pass metabolism, despite the fact that cats are efficient acetylators. Peak plasma concentrations for the standard preparation occurred at 45 minutes; peak steady-state concentrations of CD should occur at 1 to 2 days. Diltiazem is approximately 55% to 65% bound to serum proteins in cats. Maximum prolongation of the PR interval is less than 20% for either preparation, occurring at approximately 18 hours, when plasma diltiazem concentrations are between 50 and 100 ng/mL. The pharmacodynamic effects have not been studied in cats with HCM. However, on the basis of the pharmacokinetic data, the standard diltiazem

product is administered at 1 mg/kg every 8 hours, but the CD product (prepared in gelatin as either 60-mg or 90-mg capsules) can be administered at 10 mg/kg every 24 hours. An extended-release diltiazem (Dilacor XR) also was studied in cats (n=13; 10 normal and 3 with HCM) after oral administration of either 30 or 60 mg (9.3 to 14.8 mg/kg, obtained as 60-mg tablets in 120-mg capsules; tablets were halved [with difficulty] to yield 30 mg fractions). Peak serum concentrations following 60 mg (8 cats; concentrations not measured until 6 hours) were markedly variable, ranging from approximately 71 to 1500 ng/mL (mean 787 ± 488 ng/mL); by 24 hours, concentrations were 196 ± 232 (range 5 to 920) ng/mL. At 30 mg (5 cats), peak concentrations were 448 ± 370 (20 to 800) at 6 hours and 43 ± 24 (20 to 88 ng/mL) at 24 hours. Variability in absorption indicates that monitoring, if available, would be a useful tool for targeting effective concentrations.¹⁸⁵ The recommended dose is one half of one of the pellets given once or twice daily.

Diltiazem appears to be relatively safe in cats. A retrospective study of client-owned cats (n=25) with HCM treated with 60 mg diltiazem once daily, reported side effects evident at 60 mg per cat included lethargy, gastrointestinal disturbances (vomiting, diarrhea), and weight loss (36%). Clinical signs appeared in 1 to 7 days.¹⁸⁵ Diltiazem has been studied in cats after single-dose transdermal administration. Therapeutic concentrations (50 to 200 ng/mL) were not acheived in any cat (n = 6).^{185a} Administration as a transdermal gel is not recommended until multiple dosing has been documented to predictably achieve therapeutic concentrations.

Diltiazem has been studied in dogs.^{186,187} The PR interval is prolonged approximately 20% at plasma concentrations of 60 ng/mL. In dogs suffering from atrial fibrillation or CHF, diltiazem (0.5 to 1 mg/kg every 8 hours) can be used for its negative chronotropic effects to reduce heart rate in the presence of sustained supraventricular arrhythmias. Diltiazem can be used either alone or in combination with digoxin. Because of its negative inotropic effects, however, it must be used cautiously in patients with myocardial failure, and digitalization may be indicated before diltiazem therapy is begun. The drug can be used intravenously (0.2 to 0.4 mg/kg, followed by infusion of 4 to 8 μ g/kg per minute), although extreme caution is recommended.

A single case of diltiazem toxicity has been reported in a dog that accidentally ingested between 95 and 109 mg/ kg of a slow-release product.¹⁸⁸ Clinical signs included cardiac arrhythmias, bradycardia, hypotension, mental depression, and gastrointestinal upset. The patient was treated with a temporary pacemaker. Costello and Syring¹⁸⁹ reviewed the toxicity associated with CCBs in general. Therapeutic strategies discussed for treatment included calcium as the initial therapy to increase availability to cells. Response should be monitored by electrocardiogram and heart rate. Glucagon may improve or reverse bradycardia and hypotension through unclear mechanisms that increase cAMP. Experimental doses used in dogs were 0.2 to 0.25 mg/kg bolus followed by 150 μ g/kg/min constant-rate infusion. Because calcium blockade may cause hypoinsulinemia (and hyperglycemia) at the level of insulin release from pancreatic β cells, insulin and dextrose may be indicated (4 U/min in 20% dextrose and potassium supplementation as needed), as is a pacemaker. Finally, drugs that act as direct agonists at calcium channels may be beneficial, although no drug is clinically available or described with this effect. Among the drugs studied is 4-aminopyridine.

Verapamil

Verapamil is similar to diltiazem in its actions. It undergoes first-pass metabolism after oral administration in humans. Although it is available in both intravenous and oral preparations, caution is recommended with intravenous use. It has been studied for the treatment of acute supraventricular tachycardia in the dog at a dose of 0.05 to 0.15 mg/kg up to 0.2 to 5 mg/kg.^{110,190} Supraventricular arrhythmias that do not respond to class IA drugs often respond to oral verapamil therapy.¹¹⁰ Among the CCBs used in small animals, verapamil is associated with the greatest negative inotropic effects and as such should be used cautiously in animals with ventricular myocardial dysfunction. Further, verapamil may be associated with more drug interactions than diltiazem.

Miscellaneous Antiarrhythmic Drugs

Digoxin, a cardiac glycoside traditionally recognized as a positive inotrope used to improve cardiac muscle contractility in the failing heart, is also a negative chronotrope as a result of both its direct (inhibition of Na⁺,K⁺-ATPase pump) and indirect (cholinergic-like) effects. In fact, its most common use in the treatment of canine CHF is probably as a negative chronotrope rather than a positive inotrope. Vagomimetic effects inhibit atrioventricular nodal calcium currents and activate acetylcholine-mediated atrial potassium channels. Cardiac glycosides increase the slope of phase 4, particularly in the presence of low extracellular potassium. Indirectly, glycosides hyperpolarize the RMP and shorten atrial action potential durations but increase atrioventricular nodal refractory periods, thus enhancing activity against atrial reentrant arrhythmias.⁶ Although digoxin is less effective in slowing the heart rate in the presence of high catecholamine output compared with nonadrenergic stress conditions, only moderate decreases in heart rate are necessary to improve cardiac function. Use of digoxin as a negative chronotrope is discussed in greater depth along with its positive inotropic effects.

Dofetilide is a pure delayed rectifier K⁺ channel blocker. As such, it has no extracardiac adverse events. Its efficacy is in the maintenance of normal sinus rhythm in the patient with atrial fibrillation. It is renally excreted, with dose modification necessary with renal disease. The drug is available only through limited distribution. Ibutilide also is a pure delayed rectifier K⁺ channel blocker whose use is limited to intravenous administration because of extensive first-pass metabolism. It is metabolized by the liver, with a duration in humans ranging from 2 to 12 hours. Among the more common side effects is torsades de pointes.

Moricizine is a phenothiazine analog that blocks Na⁺ channels. It has been used to chronically treat ventricular

arrhythmias but has been associated with increased mortality when used acutely to treat myocardial infection. Characterized by first-pass metabolism, its long duration of action in humans (many hours) probably reflects active metabolites.

Atropine is considered an antiarrhythmic by virtue of its blockade of vagally mediated cardiac slowing in some bradyarrhythmias. It is useful, however, only for short-term management. Longer-acting orally administered anticholinergics (e.g., propantheline) are indicated only rarely for bradyarrhythmias, with pacemaker placement being the preferred treatment.

Adenosine is an endogenous nucleoside. It must be administered as a rapid intravenous bolus. Adenosine can acutely block reentrant supraventricular arrhythmias and (rare) ventricular tachycardia associated with DAD events. Transient asystole is a not-uncommon adverse event that lasts less than 5 seconds because of rapid intracranial domination. Atrial fibrillation and bronchospasm are rare events. The effects of adenosine are ameliorated by methylxanthine derivatives.

Magnesium is an antiarrhythmic indicated in patients with torsades de pointes, probably by inhibition of ion flow responsible for EAD. When given intravenously, it has also been used for treating arrhythmias associated with digoxin toxicity. Chronic oral magnesium therapy has not been demonstrated to decrease arrhythmias.

POSITIVE INOTROPES

A positive inotrope increases and a negative inotrope decreases myocardial contractility. Although intuitively, the use of a drug that increases cardiac contractility is reasonable in the patient with a failing myocardium, proof of clinical efficacy of positive inotropes has largely been lacking, and their use is controversial.¹⁹¹ The advent of newer positive inotropes, such as pimobendan (an inodilator), may provide more clear direction.

Positive inotropic agents increase cardiac force by mechanisms involving increased intracellular Ca2+-concentration. Most mechanisms increase the quantity of calcium available for binding, which in turn augments contractile protein interaction in the myocardial cell (see Figure 14-1). Mechanisms include increasing cAMP production by stimulating adenylyl cyclase; sensitizing myocardial cells (proteins) to calcium, decreasing cAMP degradation by inhibiting PDEs; altering the Na⁺,Ca²⁺-ATPase exchange pump; and, finally, directly stimulating the proteins in the cell membrane that control calcium channels (see Figure 14-1). However, increased intracellular calcium is also associated with adverse effects. It increases the risk of calcium overload in myocardial cells, which will decrease lusitropy (diastolic relaxation). Additional negative sequaelae include apoptosis, necrosis, and the development of tachycardia and arrhythmia. Further, the increase in contractility increases energy/ATP and oxygen consumption.¹⁹²

KEY POINT 14-39 Inherent in the increased contractility associated with many positive inotropes is increased myocardial oxygen demand.

Digitalis and Other Cardiac Glycosides

Digitalis was used as a cardiac drug as early as the 1200s,^{3,6,193} with its beneficial effects in the failing heart recognized by 1785. That its efficacy reflected increased myocardial contractility was described in 1958. In addition to improved hemodynamics, digoxin slows atrioventricular conduction and thus heart rate, a critical benefit in patients with atrial fibrillation. The popularity of digoxin reflected, in part, its use for treatment of tachycardia associated with rheumatic heart disease, a common cardiac malady of the mid twentieth century. Cardiac glycosides currently are used to increase circulation in patients with CHF and to slow the ventricular rate in the presence of supraventricular tachycardia (e.g., atrial fibrillation and flutter), with the latter negative chronotropic effect probably of more benefit. The therapeutic margin of the cardiac glycosides is narrow, but to date they have not been effectively replaced with an alternative safer drug. This is apt to change in the next decade with safer and more effective drugs that are in various stages of development (e.g., selective PDE inhibitors and calcium sensitizers) being identified and developed.

Structure–Activity Relationship

Digitalis refers to both digoxin and digitoxin. Digitalis is obtained from the dried leaf of the foxglove plant (*Digitalis purpurea*). The active component of cardiac glycosides is an aglycone, which is released from attached sugars by hydrolysis (Figure 14-10).^{3,6} Cardiac glycosides contain a steroidal nucleus containing a lactone ring (at C17) and one or more glycosidic residues (C3). Although the term *digitalis* has been used interchangeably with the term *cardiac glycosides*, current use is largely limited to digoxin in humans.

Mechanism of Action and Pharmacodynamic Responses

Cardiac glycosides are potent but reversible inhibitors of the α subunit of cell membrane-bound Na⁺,K⁺-activated adenosine triphosphate (Na+,K+-ATPase) "pump" (see Figures 14-1 and 14-11). The enzymatic activity is impaired, leading to like impairment of active transport, or exchange of sodium for potassium and a gradual increase in intracellular sodium. Cardiac fibers (both cell membrane and sarcoplasmic membrane) possess a second ATPase pump that exchanges Na⁺ for Ca²⁺; this pump is one of two ATP-ase pumps that extrude intracellular calcium after contraction (the second being a Ca²⁺-ATPase pump). As sodium increases in the cell in response to glycoside inhibition of the Na⁺,K⁺-ATPase pump, exchange of Na⁺ for Ca²⁺ is augmented, increasing calcium influx. Only a small increase in intracellular calcium occurs, but it is sufficient to cause a marked increased in Ca²⁺ release from the sarcoplasmic reticulum during systole (see Figures 14-1 and 14-2). Myocardial contractility improves, resulting in an increase in left ventricular function in both the normal and failing myocardium.⁶ In humans the increased contractility occurs at serum concentrations of 1.4 ng/mL.6

At 1 to 2 ng/mL, digoxin also indirectly increases efferent vagal (cholinergic) tone and decreases sympathetic nervous activity. Increased vagal tone is associated with inhibiting Ca²⁺

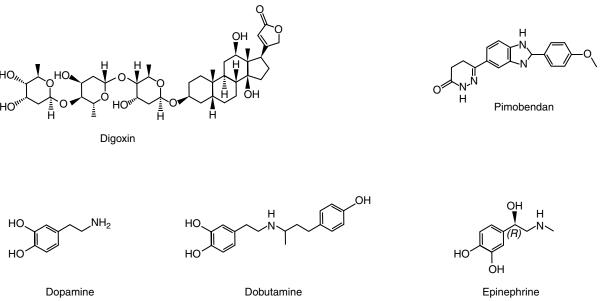

Figure 14-10 Chemical structure of selected drugs with positive inotropic effects.

currents; decreasing automaticity; increasing the diastolic RMP; increasing the ERP, and decreasing conduction velocity, particularly in atrial and atrioventricular nodal tissues. Paradoxically, in nonconducting atrial fibers, acetylcholinemediated potassium currents are increased, which shortens atrial action potentials. Therefore digoxin may contribute to or cause atrial tachycardias, including reentrant arrhythmias such as atrial fibrillation. The risk is greater in the diseased heart. However, although more impulses are transmitted to the AV node by fluttering or fibrillating atrial tissues, the vagal effects of digitalis decrease the number of atrial impulses that are transmitted by the atrioventricular node to the ventricles. Consequently, digoxin is indicated for slowing of ventricular rates in patients with supraventricular tachycardias such as atrial fibrillation. Electrocardiographically, digoxin prolongs the PR interval and depresses the ST segment (the latter mechanism is not understood).6

KEY POINT 14-40 The direct effects of digoxin alter potassium, calcium and sodium flux across the myocardial cell membrane. The indirect effects increase vagal tone. Therefore digoxin is associated with a variety of cardiac arrhythmias .

In addition to increased vagal tone, the indirect effects of digoxin on heart rate also reflect decreased sympathetic nervous system activity.⁶ Digoxin decreases neurohumoral activation associated with heart failure.⁶ Inhibition of the sodium pump in neuronal cells, particularly in the baroreceptor, results in stimulation of parasympathetic and inhibition of sympathetic nerves. Digoxin appears to directly alter carotid baroreflex responsiveness to changes in carotid sinus pressure in animals with heart failure.⁶ Digoxin is less effective as a negative chronotrope for tachycardias associated with marked sympathetic drive such as occurs with CHF. However, even minor reductions in heart rate may markedly improve

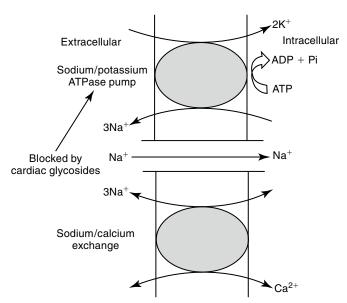

Figure 14-11 Direct effects of digoxin reflect blockade of the sodium/potassium ATPase pump. The resulting increase in intracellular sodium initiates the sodium/calcium ATPase pump. Increased intracellular calcium is sufficient to stimulate intracellular release of calcium, increasing contractility. Myocardial arrhythmias caused by digoxin reflect, in part, disruption in cell membrane fluxes of sodium, potassium, and calcium. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate.

myocardial function. Heart rate will be slowed, particularly in patients with a rapid heart rate, with effects generally occurring at serum digoxin concentrations of 1.3 ng/mL.⁶ Digitalis has only minor indirect effects in ventricular tissue.

The effects of cardiac glycosides on myocardial oxygen demand depend on the net effect on cardiac function. Mechanistically, energy utilization shifts from one ATPase pump to another, which might minimize the increase in oxygen needs. **KEY POINT 14-41** The efficacy of digoxin probably reflects its negative chronotropic effects more than its positive inotropic effects.

Cardiac glycosides can cause peripheral arterial and venous vasoconstriction, but these effects are more likely in the normal animal.⁶ Pulmonary vasoconstriction is induced by all cardiac glycosides except digoxin. Effects in the vasculature are more common after intravenous administration and occur in less than 15 minutes; indeed, with oral administration vaso-dilation predominates. Thus oral digitalization with digoxin will minimize the risk of adverse effects caused by cardiac glycoside–induced vasoconstriction.¹⁹¹

Detrimental effects on myocardial remodeling are a potentially important deterrent to cardiac glycoside therapy. Ouabain (a largely experimental cardiac glycoside) induces mRNA and subsequent production of IL-1b, IL-6, and TNF- α in human peripheral blood mononuclear cells. In an experimental model of myocardial failure, high doses of digoxin increased myocardial necrosis, cellular infiltration, intracardiac IL-1b, TNF- α , and mortality. However, no death occurred among control animals treated with 10 mg/kg.³⁵

Clinical Pharmacology

Digoxin and digitoxin are the two most widely used cardiac glycoside preparations. The disposition of both drugs have been studied in dogs194-197 and is variable among animals and preparations. Oral bioavailability of digoxin varies from 40% to 90%, depending on the preparation. Up to 90% of the alcohol (i.e., elixir) is absorbed, with peak concentrations occurring in 45 to 60 minutes.³ Variation in bioavailability of tablets is affected by differences in dissolution between products. Absorption is retarded by food. Compared with digoxin, oral absorption of the more lipid-soluble glycoside, digitoxin, is much more complete and thus predictable. Interestingly, in humans Eubacterium lentum, a normal microbial inhabitant, metabolizes digoxin to inactive metabolites in a small percentage of the population, leading to unexpected decreased bioavailability. Both digoxin and digitoxin are distributed slowly, in part because of a large volume of distribution that includes most body tissues but also reflects concentration in cardiac tissues. Although the volume of distribution of digoxin is large, it is distributed primarily to cardiac and skeletal muscle, indicating that dosing should be based on lean body weight.⁶ Only 25% of digoxin is protein bound, whereas most of digitoxin (90%) is protein bound. Accordingly, response to digoxin should be faster and the dose of digitoxin should be higher (to compensate for high protein binding). Digoxin is primarily eliminated unchanged in the kidneys. The half-life varies from 21 to 60

hours,³ with a working average of 1.7 days. Half-life is variable in the same animal, ranging from 46 to 154 hours in one study.³ Elimination half-life is strongly influenced by renal function. Because variability increases as renal function changes with the progression of cardiac disease or response to therapy, monitoring of both a peak and a trough is strongly recommended. For example, our laboratory has demonstrated an elimination half-life for digoxin to be as short as 9 hours in animals concurrently receiving an ACE inhibitor and diuretic therapy but longer than 48 hours in animals with presumed renal dysfunction.

KEY POINT 14-42 The half-life of digoxin is markedly variable, and monitoring of both peak and trough samples may be prudent, particularly in patients that have responded to therapy.

In contrast to digoxin, digitoxin is metabolized by the liver to digoxin and other metabolites. Its metabolism is affected by factors that alter the microsomal system but generally not hepatic disease. Despite binding to serum proteins and hepatic metabolism, a half-life of 8 to 12 hours in dogs (parent compound) is shorter than that of digoxin, which may necessitate more frequent dosing. Digitoxin undergoes a small enterohepatic cycle.

Population kinetic analysis has been used to describe the disposition of digoxin in a population (n=161; 32 studied prospectively) of dogs with naturally occurring heart disease.¹⁹⁸ Covariable data collected included serum creatitine and potassium, body weight and body surface area, and formulation of digoxin administered. Dosing regimens (dose, intervals), formulation of digoxin, type and state of cardiac disease, and adjuvant medications and method of monitoring (time of sample collection, analytic technique) varied among animals. The rate of oral absorption was markedly variable. The slowest absorbers (n=19) were prospectively studied and as such had been admitted 2 hours before dosing, compared with the remaining 142 cases, in which dosing occurred at home. Based on the reported rate constant, the absorption half-life in the slow absorbers approximated 6.1 hours compared with 1 hour for the fast absorbers. The type of formulation (Lanoxin tablets versus elixir) did not statistically influence the absorption rate constant. These data suggest that the stress of admission may profoundly affect the rate of absorption and perhaps the peak plasma drug concentration of digoxin, indicating that patients ideally be dosed at home before monitoring. Elimination rate constants (and thus half-life) were not reported. Potassium was negatively correlated to volume of distribution corrected for oral bioavailability (Vd/F), potentially reflecting displacement of digoxin from its tissue binding sites (Na⁺/K⁺ ATPase) by potassium, resulting in a smaller volume of distribution. Creatinine was a poor predictor of changes in digoxin clearance even when corrected for bioavailability (Cl/F).

Preparations and Dosing Information

Digoxin is available for intravenous or oral administration. Intravenous administration results in pharmacologic effects in 5 to 30 minutes, with a maximal effect in 2 hours. Intravenous

administration might (very cautiously) substitute for oral dosing in animals intolerant to the latter. Digoxin should not be given intramuscularly because it is erratically absorbed and causes pain and tissue necrosis. Oral administration results in pharmacologic effects in 1 to 2 hours, although peak effects will not occur until steady state is reached. Digoxin elixir is more orally bioavailable, and it may be necessary to decrease doses by 15%. If deemed necessary, oral digitalization is best accomplished with digoxin tablets. In the absence of a loading dose, steady-state concentrations can be achieved within 48 hours of oral dosing in most patients. If necessary, a prudent intravenous loading dose is administration of the oral daily maintenance dose over a 12-hour period.¹⁹¹ Doses should be calculated on lean body weight; toxicosis is likely to be minimized if dosing is based on body surface area (0.44 mg/m^2) . Daily doses should be divided if warranted on the basis of drug elimination half-life (as calculated from therapeutic drug monitoring) to minimize fluctuation in plasma drug concentrations.

KEY POINT 14-43 The therapeutic window of digoxin is narrow, but the risk of adversities might be minimized if attention is paid to the risk factors presented by disease-and drug-related factors.

Drug Interactions

The concurrent administration of quinidine increases plasma concentrations of digoxin; the mechanism may reflect displacement from tissue binding sites, although this mechanism is controversial.^{117,199} Quinidine also appears to decrease renal digoxin clearance by decreasing renal blood flow.²⁰⁰ Verapamil also increases concentrations of digoxin.¹⁹¹ Interactions between digitalis and diuretics have been reported and stem primarily from the effects on potassium (hypokalemia). Diuretics do not seem to alter the disposition of digoxin.²⁰¹ Phenobarbital has been reported to increase (rather than decrease) digoxin concentrations; the clinical relevance of this report is not clear.^{201,202} Administration of β -adrenergic agonists increases the likelihood of arrhythmias. Amphotericin B may also cause hypokalemia and thus potentiate digitalis intoxication.

Clinical Efficacy

Inotropic response to digoxin is greatest in the initially depressed state of the failing heart. Stroke volume increases as ventricular emptying improves, with a reduction in enddiastolic volume.¹⁹¹ This positive effect is less likely if intrinsic compensatory mechanisms are maintaining cardiac output. The inotropic response to digoxin occurs before evidence of electrophysiologic changes. As a positive inotrope, withdrawal of digoxin in human patients with mild to moderate CHF and a normal sinus rhythm resulted in a significant (compared to placebo) worsening of clinical signs. In patients with severe CHF, fewer patients receiving digoxin died or were hospitalized as a result of CHF during the study period. Retrospectively, digoxin effects were best when concentrations were below 1 ng/mL. However, it is not clear if this effect is due to decreased heart rate or a positive inotropic effect: clinically, animals may have the greatest improvement immediately before accumulated glycoside toxicosis.¹⁹¹ Digoxin may also decrease myocardial remodeling: ouabain increased mediators associated with ventricular remodeling after myocardial infarction.³⁵ Digoxin modulates neurohumoral and autonomic states.³⁵ Currently, in humans digoxin therapy generally is reserved for patients with heart failure accompanied by atrial fibrillation or for patients with a sinus rhythm but who have not yet sufficiently responded to ACE inhibitors and adrenergic receptor antagonists.

Proof of efficacy of digoxin in the treatment of CHF in dogs has been difficult to establish, in part because of poorly designed clinical trials.¹⁹¹ Studies are complicated by failure to control variables and, most notably, adjunct therapy. Subclinical measures based on hemodynamic response often have not been included, making it more difficult to identify efficacy. Different levels of disease also influence outcome; response to digoxin may be less obvious in the terminal stages of congestive cardiomyopathy (shortening fraction of 20%).¹⁹¹ Clinical trials based on survival analysis similarly have been fraught with poor methodologies. Controversy also exists regarding the relative efficacy of digoxin versus digitoxin in the treatment of CHF in dogs.¹⁹¹ Early studies with dogs receiving either drug revealed greater clinical improvement in dogs with CHF treated with digoxin (85%) than digitoxin (55%) but a greater risk of toxicity (based on electrophysiologic changes in the PR interval.^{203,204} It is likely, however, that digitoxin was underdosed in these studies.¹⁹¹ Current consensus among cardiologists is that digoxin is the preferred drug on the basis of both pharmacodynamics and pharmacokinetics.

Knight¹⁹¹ offered a description of the canine patient most likely to respond to digoxin therapy. Such a patient is asymptomatic, with CHF characterized primarily by systolic ventricular dysfunction accompanied by supraventricular tachycardia, including sinus tachycardia, atrial flutter, and fibrillation. Chronic mitral regurgitation is included in the indications, although timing of the use of digoxin as treatment in this syndrome may be less clear unless myocardial failure is evident. Digoxin is not indicated for the compensated patient that is asymptomatic (including normal sinus rhythm; plus or minus diuretics). Aggressive treatment may be necessary to control heart rate. Whereas vagally mediated effects occur at subtoxic concentrations (50% of the toxic dose), the direct effects on a trioventricular nodal conduction occur only at full digitalizationthat is, as toxic concentrations are approached.¹⁹¹ Such concentrations may be more necessary in patients with atrial flutter or fibrillation for which response might be dependent on atrioventricular nodal effects. The negative chronotropic effects are decreased in the presence of concurrent sympathetic stimulation, which is more likely as the severity and chronicity of heart failure increases. Thus sinus tachycardia is most likely to normalize if cardiac function improves sufficiently to minimize sympathetic stimulation. β -adrenergic blockers or CCBs may be useful adjunct therapies if heart rate remains unacceptably high in patients receiving digoxin.¹⁹¹

Controversy exists regarding whether digoxin should precede, accompany, or follow vasodilator therapy and, more specifically, ACE inhibitor therapy. Preference generally favors the latter. Digoxin is, however, indicated for symptomatic patients that cannot tolerate ACE inhibitors and for patients that presented with moderate to severe clinical manifestations of decompensation, particularly if the patient is no longer responsive to diuretic or vasodilator therapy.¹⁹¹

Monitoring

Monitoring recommendations for digoxin are extrapolated from human medicine. The traditional recommended therapeutic range of 0.8 to 2.0 ng/mL is intended to prevent toxic concentrations but not necessarily identify efficacy. Maximal contractile activity in humans generally occurs at concentrations between 0.5 and 1.5 ng/mL.²⁰⁵ Neurohormonal benefits may occur at concentrations of 0.5 to 1 ng/mL.⁶ Although inotropic effects will continue to increase as drug concentrations increase, peak effects are likely to be limited by toxicity. Because the risk of death increases at higher concentrations associated with maximal contractility, concentrations below 1 ng/mL are recommended for humans.

Therapeutic concentrations of digitoxin and digoxin differ. For digitoxin recommended concentrations are 1.4 to 2.6 ng/ mL.³ The recommended range for digoxin is likely to vary with the laboratory but generally is 1 to 2 ng/mL or 1.5 to 2.5 ng/ mL.195 Because the time needed for C_{max} to decline to C_{min} is one half-life, the dosing interval should not exceed patient half-life. The targeted concentration for either cardiac glycoside in the individual animal should be based on clinical signs, including response to therapy. Traditionally, single samples (generally mid trough) have been collected at mid interval for monitoring. However, based on 2 hr peak and 12 hr trough samples, the author has documented a shortening of digoxin half-life in a patient treated with ACE inhibitors (presumably due to increased glomerular filtration rate and thus renal digoxin clearance) or other therapy. In such patients plasma drug concentrations can fluctuate twofold during a dosing interval, causing the patient to become both toxic or subtherapeutic. For such patients design of a dosing regimen might best be based on both peak and trough concentrations (at 2 and 11.5 hours after oral administration at home). If only a single sample is possible, selection of the time of collection depends on the intent of monitoring. If toxicity is of concern, a peak sample should be collected 1 to 2 hours after administration at home; if efficacy is of concern, then a trough sample should be collected just before the next dose. However, neither situation will provide guidance regarding drug concentrations throughout the dosing interval.

Toxicity and Side Effects

Digitalis intoxication is not uncommon, although improper use plays a large role in the incidence of adversity. In addition, signs of toxicity are more easily recognized than are signs of efficacy, contributing to the perceived narrow therapeutic margin. It is likely that with proper use the risk-benefit ratio is not as narrow as perceived. Serious toxic effects of digitalis are due to altered electrical activity, which reflects changes in intracellular calcium, sodium, and potassium changes and thus the electric potential formed across the cell membrane. Digitalis causes an increase in automaticity and ectopic beats. As concentrations surpass 2 ng/mL, the risk of sinus bradycardia or arrest, prolongation of atrioventricular conduction, heart block, or increased sympathetic nervous activity with increased automaticity increases. The negative chronotropic effects of digitalis can be ameliorated with atropine.

KEY POINT 14-44 The risk of hypokalemia, which increases the risk of digoxin toxicity, is increased in the anorectic patient receiving potassium-wasting diuretics. Potassium supplementation may be indicated.

Digoxin binds preferentially to the phosphorylated form of Na⁺,K⁺-ATPase, whose concentration is decreased by extracellular potassium. Thus hypokalemia increases digoxin toxicity by facilitating binding to the target protein.⁶ Increased intracellular calcium also contributes to the arrhythmogenicity of digoxin.⁶ The increased calcium causes the cytoplasmic membrane to become unstable immediately after repolarization and cell membrane permeability to Na⁺, Ca²⁺, and K⁺ increases. Ion flow of Na⁺ and Ca²⁺ follows the concentration gradient, tending to hypopolarize the membrane (i.e., it moves toward 0 mV); flow of potassium is less important because concentration and electrochemical gradients for potassium tend to balance one another. Dysrhythmias tend to worsen as calcium increases as the risk of after-depolarization–mediated automaticity increases.⁵

Because the mechanism of arrhythmogenicity for digoxin is the same as the mechanism of efficacy (positive inotropic and negative chronotropic effects), it is not surprising that cardiac glycosides are characterized by a narrow safety margin. Any cardiac antiarrhythmia may be induced by digitalis. An electrocardiogram should be useful in diagnosing digitalis toxicity if compared with an electrocardiogram obtained before drug administration. Changes in sodium, calcium, or potassium increase the risk of arrhythmias associated with automaticity. In the atrium digoxin shortens the action potential, predisposing it to atrial fibrillation.⁵ The negative chronotropic effects of digoxin also can directly slow sinus nodal activity, leading to heart blockade. Arrhythmias include sinus bradycardia; disturbances of atrial rhythm; atrioventricular conduction, including complete atrioventricular block (thirddegree heart block); and disturbances of ventricular rhythm, especially premature beats. Ventricular tachycardia and flutter may also occur. The likelihood and severity of toxicity are related to the severity of cardiac disease. Toxic effects with digitalis are frequent and can be lethal if allowed to persist. Dogs with severe cardiomegaly and CHF are probably at greater risk of developing ectopic ventricular arrhythmias. Other factors predisposing to digoxin toxicity include but are not limited to hypokalemia, hypercalcemia, hypomagnesemia, hypothyroidism, acid-base imbalances, and abnormal renal function.⁶ Combination therapy with selected drugs also predisposes the patient to toxicity. The cat is more sensitive to digoxin than the dog.

Digoxin also causes noncardiac toxicities as a result of impaired Na⁺-K⁺ pump activity on neuronal and secretory organs. Frequently, the earliest indications of digoxin toxicity are gastrointestinal adversities including anorexia; nausea; vomiting; and, less frequently, diarrhea. Vomiting also results from direct stimulation of the chemoreceptor trigger zone. Neurologic effects include malaise and drowsiness.

The most frequent cause of digoxin toxicity is probably overdosing, which includes failure to individualize dosing regimens. The potential for toxicity is increased with hypokalemia because binding to the Na⁺-ATPase pump is facilitated. This may occur, for example, if the patient is also receiving diuretic therapy that causes potassium loss (furosemide, thiazides, and other "nonsparing" diuretics). Digitalis toxicity can be diagnosed and the risk minimized by plasma drug concentration monitoring. Therapeutic concentrations of digitoxin and digoxin differ. For digitoxin concentrations greater than 3.4 ng/mL are considered toxic.³ For digoxin the risk of toxicosis is greater if concentrations exceed 2 to 2.5 ng/mL.¹⁹⁵ Because of overlap between toxicity and efficacy, concentrations should be considered in the context of clinical signs.

The treatment of cardiac glycoside intoxication includes (1) discontinuation of digitalis therapy for at least one drug elimination half-life; (2) discontinuation of potassium-depleting diuretics; and (3) administration (as needed) of phenytoin, which blocks atrioventricular nodal effects of digitalis (bradyarrhythmias), lidocaine (for ventricular arrhythmias)²⁰⁶ (1-3 mg/kg intravenously), and oral potassium supplementation (e.g., potassium chloride), but only if hypokalemia exists.³ Atropine may be useful to treat sinus bradycardia and second- or third-degree heart block induced by cholinergic augmentation. Procainamide also has been shown experimentally to be useful for treatment of digoxin-induced ventricular arrhythmias in the canine heart when plasma drug concentrations approximate 8 to 12 ng/mL.^{207,208} Cholestyramine can be used as a binding agent to decrease absorption from the gastrointestinal tract (including drug undergoing enterohepatic circulation).

The large volume of distribution of digoxin prevents the use of techniques for increasing clearance as an approach to decreasing the risk of toxicity in the case of overdose. Purified ovine antibody fractions (Fab) to digoxin (DIGIBIND® or DIGIFAB®) have proved to be an effective antidote to life threatening digoxin toxicity (e.g, ventricular arrhythmias) following massive overdose in humans. Although they have been successfully used by the author to treat an accidental overdose of digoxin, their cost is likely to be prohibitive. The drug costs \$700-800 per vial; an adequate dose may result in a cost of thousands of dollars. Dosing is complicated, being based on the total amount of digoxin in the body. This can be estimated on the basis of the amount ingested and the average bioavailability or on serum digoxin concentrations and the average volume of distribution.⁶ Toxicity can recur once the Fab has been eliminated 1 to 2 days after therapy, particularly in patients with impaired renal function.

Clinical Use

The recent approval of pimobendan for use in dogs should result in a decline in the use of cardiac glycosides as positive inotropes. Clinical uses of digitalis have included restoration of adequate circulation in patients with CHF and reduction of the ventricular rate as a treatment of atrial fibrillation or flutter. Both syndromes require long-term treatment. If there is no urgency in treatment, the drug can be administered orally. Maximal effect is achieved in four half-lives. Digoxin is the cardiac glycoside drug of choice except for the patient with renal disease; digitoxin should then be administered. Calculation of digoxin doses should be based on lean body weight, and dosages should be reduced in the obese patient or in the presence of ascites. Electrolyte disorders should be corrected before dosage.

Calcium Sensitizers

A disadvantage of drugs that increase intracellular calcium are the deleterious effects of intracellular Ca2+ overload, including cardiac arrhythmias, and cell injury that could ultimately lead to myocardial cell death.²⁰⁹ Additionally, positive inotropic effects generally are associated with increased myocardial oxygen consumption. Calcium sensitizers are positive inotropic drugs that increase cardiac contractility by direct effects on cardiac myofilaments or the cross-bridge interaction, without altering intracellular Ca2+-concentration.¹⁹² Calcium sensitizers target "downstream" calcium sites, particularly the cardiac excitation-contraction coupling process. Examples of targeted sites include Ca²⁺ binding to troponin C, thin filament regulatory sites and/or directly on the cross-bridge cycling. Because efficacy is not dependent on an increase in intracellular calcium, they do not induce the negative sequelae generally associated with increased intracellular calcium (arrhythmias, cell injury, and death) or does energy activation increase. Further, calcium sensitizers can potentially reverse myocardial contraction dysfunction that accompanies pathologic conditions such as acidosis. Three classes of calcium sensitizers have been described according to the type of interaction between calcium and cellular sites. Class I sensitizers target the interaction between troponin C and calcium, thus increasing the calcium sensitivity of troponin C (e.g., pimobendan and levosimendan). Class II sensitizers directly interact with the thin filaments, facilitating actin-myosin interaction such as might occur if the troponin C/Ca2+-complex is stabilized without altering the Ca²⁺-affinity of troponin C. Class III sensitizers directly interfere with activation steps of the cross-bridgecycle.¹⁹² Although their efficacy is not certain, Ca²⁺ sensitizers are clinically more effective than the agents that are purely downstream regulators of calcium.209

Disadvantages of calcium-sensitizing agents may include the prolongation of myocardial relaxation and possible exacerbation of impaired diastolic function (decreased lusitropy). The risk is greatest if calcium sensitivity of myofilaments increases at low (diastolic) calcium concentrations. The risk is reduced by drugs that increase myofilament calcium sensitivity only during high-calcium conditions (i.e., systole), thus enhancing systole without changing diastolic function. Current calcium-sensitizing drugs generally are characterized by marked inhibition of PDE.³⁶ For example, the impact of levosimendan and pimobendan on lusitropy ranges from no impact to improvement.¹⁹² The ideal calcium sensitizer would not inhibit PDE.

Phosphodiesterase Inhibitors

Selective PDE inhibition has yielded therapeutic options for treatment of cardiovascular disorders. At least five PDE isoenzymes have been described; affinity for cyclic nucleotides may account for differences in activity. For example, the affinity of PDE III (located in the heart and systemic smooth muscle vasculature) for cAMP is greater than that for cGMP, whereas PDE V (limited in location to the retina, corpus cavernosum, and cerebral and pulmonary vasculature) has a greater affinity for cGMP.²¹⁰ PDE inhibitors, including amrinone, pimobendan, and vesnarinone, prevent the breakdown of cAMP, increasing intracellular cAMP concentration. In myocardial cells, PDE inhibition results in an increase in myocardial contractility. PDE inhibitors also inhibit nitrite accumulation, with pimobendan being the most and amrinone the least potent inhibitor.³⁵

Methylxanthine Derivatives

Methylxanthine derivatives have been classified as PDE inhibitors, but the mechanism of action is controversial. Their positive inotropic effects may actually reflect altered calcium fluxes or other mechanisms. Of the methylxanthines, theophylline is the most cardiopotent. The positive inotropic effects of these drugs are complex because they have a variety of pharmacologic actions. In addition to their cardiac effects, these drugs have significant central nervous system, renal, and smooth muscle effects. Thus their use for cardiac disease is limited.

Fatal toxicities can and often do occur during chronic oral or rapid intravenous administration of methylxanthines, probably as a result of cardiac effects. Tachycardia and central nervous system signs (restlessness, hyperexcitability, sensory disturbances) can be correlated with increased plasma concentrations. Plasma monitoring may be used to control toxicity. Local gastrointestinal irritation and nausea, vomiting, and diarrhea may occur with oral administration. These can be prevented by administration of the drugs with food. Therapeutic uses for the methylxanthines in cardiac disease are limited. In veterinary medicine theophylline has been used to treat CHF. Currently, these drugs should be used only in cardiac patients with respiratory disease.

Bipyridines

Bipyridines are nonglycosidic, noncatecholamine positive inotropes that have cardiac effects similar to catecholamines. The mechanism of action of these drugs is probably inhibition of PDE and increased intracellular cAMP concentrations. However, unlike catecholamines, myocardial oxygen consumption does not increase and may actually decrease in patients with CHF. Differences in potency and toxicity when compared with theophylline may reflect selective PDE isoenzyme inhibition for each group of drugs. The bipyridines inhibit PDE III only, whereas theophylline may be a nonselective inhibitor of PDE. Amrinone was the first of this class of drugs to be used therapeutically, but side effects limited its use. Milrinone is more potent than amrinone (20 to 30 times) yet characterized by a toxic to therapeutic ratio of 100 in normal dogs. Milrinone is a selective PDE III inhibitor. It lowers pulmonary vascular resistance in patients with CHF and pulmonary hypertension. Peripheral vasodilation is another major therapeutic benefit of PDE III inhibitors. Milrinone increases renin secretion, presumably by increasing cAMP in juxtaglomerular cells.²¹¹ Side effects at higher doses limit long term use. Intravenous milrinone lowers pulmonary vascular resistance in human patients with CHF and pulmonary hypertension.²¹⁰

Intravenous or oral administration of milrinone results in marked positive inotropic effects in patients with CHF. Effects are dose dependent. Contractility increases up to 100% at plasma concentrations of 200 mm/L after infusion of 10 µg/kg per minute in anesthetized dogs versus only 60% in patients receiving digitalis. An oral dose of 1 mg/kg increases contractility by 90% and decreases blood pressure by 10%. As with the cardiac glycosides, animals with very poor myocardial function may not be able to respond to the bipyridines. In contrast to cardiac glycosides, heart rate increases 40%. As with drug disposition, individual animal response to milrinone appears to be quite variable.²¹² Pilot studies indicate an elimination half-life of about 1.4 hours for milrinone in dogs, although this is likely to be quite variable.²¹² Oral bioavailability approximates 92%. Milrinone does not appear to be as effective a positive inotrope for people as it is for dogs. In clinical trials in dogs with CHF, approximately 80% of animals reportedly respond to milrinone.²¹³ Survival data were not reported for dogs. Milrinone appears to be substantially safer than digoxin when given at an oral dose of 0.5 to 1 mg/kg twice daily. However, exacerbations of arrhythmias may occur in some animals. Ruptured chordae tendineae (4%) and sudden death (13%) were other complications reported in clinical trials with dogs with CHF.

Pimobendan and levosimendan

Pimobendan is a benzimidazole-pyridazinone derivative that acts as a specific type III PDE inhibitor, causing positive inotropy. However, its efficacy may reflect actions as a calcium sensitizer. Pimobendan enhances calcium-troponin C interaction. Pimobendan increases sensitivity at low concentrations, increasing the risk of diastolic dysfunction resulting from decreased lusitropy (relaxation). However, neither pimobendan nor its congener, levosimendan, affect or improve myocardial lusitropy. In addition to its positive inotropic effects, pimobendan prolongs the action potential duration by enhancing calcium current through L-type calcium channels in the sarcolemma. However, prolonged action potential duration may increase the risk of QT syndrome. In contrast to the other Ca²⁺-sensitizers, both pimobendan and levosimendan cause vasodilation of both the arterial and venous vessels, reflecting activation of the Ca²⁺-dependent K⁺-channels (and ATP-sensitive K⁺-channels for levosimendan); As such,

pimobendan is referred to as an inodilator. Additionally, pimobendan is associated with a reduction of proinflammatory cytokines that initiate or perpetuate myocardial remodeling associated with progressive CHF.35 As such, pimobendan appears to provide some level of cardioprotection. Finally, pimobendan also exerts antithrombotic effects. 192,209 In contrast to pimobendan, an advantage of levosimendan is that it appears to sensitize to calcium without influencing PDIII activity unless higher concentrations are achieved. As such, levosimendan may be the perfect "designer" drug for treatment of systolic dysfunction in patient with CHF. Treatment with levosimendan improved hemodynamics and patient survival in one study, although the study groups were too small to allow mortality assessment. Improvement occurred even in patients treated with beta-adrenoceptor blockers, which currently are associated with the best evidence of improved hemodynamics and survival in patients with chronic heart failure.²⁰⁹

KEY POINT 14-45 The potential efficacy of the inodilator pimobendan reflects not only its positive inotropic effects but also calcium sensitization, vasodilation, and cardioprotection.

Pimobendan is prepared as a mixture of stereoisomers. In humans, although the pharmacokinetics of the enantiomers is the same, the l-isomer is 1.5 times more potent in increasing strength of contraction than the d-isomer. In humans both enantiomers accumulate in red blood cells, with the respective (+)- and (-)-pimobendan ratio (red blood cell: plasma) being 5.8 and 8.4. Similar data could not be found in dogs. Food may slow or impair oral absorption. Oral bioavailability is 60 to 65%, In normal dogs, peak plasma drug concentration (C_{max}) for the parent and metabolite following administration of 0.2 mg/kg orally was 3.09 \pm 0.76 ng/mL and 3.66 \pm 1.21 ng/mL, respectively. Pimobendan is highly (>90%) protein bound in dogs. The apparent volume of distribution at steady state (presumably of unbound drug) is 2.6 L/kg. In dogs pimobendan is demethylated to an active metabolite (UDCG-212) that contributes substantially to its pharmacodynamic effects. The metabolite is a more potent inhibitor of PDIII; however, its mechanism of calcium sensitization may be different from that of the parent compound. Metabolism appears to occur primarily by CYP1A2 (in humans), although its contribution to metabolism is variable, ranging from 18 to 76%; CYP3A4 accounts for less than 10% of elimination. The active metabolite is then excreted by sulfation or glucuronidation and eliminated through feces. Elimination half-life of pimobendan and its metabolite in dogs are 0.5 and 2 hours, respectively (which is similar to both isomers in humans).

A delay occurs between peak pimobendan concentration and peak left ventricular contractility response; further, response persists beyond elimination of drug. In both dogs and humans, effects are still evident at 8 hours, despite a short half-life in either species. In humans pharmacodynamic effects include increased ejection fraction, mean shortening velocity, cardiac index, and stroke volume index (each increased 50% to 60%). Left ventricular end-systolic dimension, SBP, and diastolic blood pressure are decreased 8% to 11% in humans. However, although pimobendan improves morbidity and the physical exercise capacity of human heart failure patients, decreased mortality has not yet been demonstrated.

Pimobendan has been used extensively in dogs with acquired cardiac disease including mitral valve insufficieny and dilated cardiomyopathy; its use should be considered in dogs with systolic dysfunction associated with primary myocardial disease or chronic volume loading. The labeled dose of pimobendan in dogs is 0.5 mg/kg administered every 12 hours and given at least 1 hour before food. Dosing is usually started at the low end of the dose range. Pimobendan can be combined with a variety of cardiac drugs, including diuretics, ACE inhibitors, or digoxin. However, the positive inotropic effects may be reduced when given in conjunction with calcium channel antagonists or β -adrenergic antagonists.

Pimobendan has been compared to levosimendan and milrinone in anesthetized dogs.^{213a} All three drugs increased myocardial contractility, venous and arteriolar vasodilation, left ventricular -arterial coupling and mechanical efficiency; levosimendan increased myocardial efficiency. The clinical use of pimobendan in dogs has been reviewed.^{214-216a}

In normal dogs pimobendan moderately reduced systemic and pulmonary vascular resistance, markedly reduced left ventricular end-diastolic pressure, and moderately increased heart rate and cardiac output. Myocardial blood flow also is increased. A lusitropic effect also has been demonstrated in the left ventricle of normal dogs.⁵⁴ Efficacy in diseased dogs may be superior to that in humans. Summaries of the field (clinical) trial (n=355 dogs) supporting approval of pimobendan found efficacy to be equivalent to that of enalapril in dogs with grades II to IV CHF associated with either valvular disease or DCM. Dogs also received diuretics and, as needed, digoxin for supraventricular arrhythmias. Side effects were similar in both groups.

Kanno and coworkers²¹⁹ described the effects of pimobendan (0.25 mg/kg twice daily) on cardiac, hemodynamic, and neurohumoral factors in dogs with mild mitral regurgitation. Dogs were treated for 4 weeks. Pimobendan was associated with a decrease in SBP and the degree of regurgitation, an increase in renal blood flow and glomerular filtration rate, decreased norepinephrine concentrations, and improved heart size. Using a randomized, placebo controlled, doubleblinded study in dogs (10 English Cocker Spaniels, 10 Doberman Pinschers) with DCM, when added to standard therapies (i.e., furosemide, enalapril, digoxin), pimobendan (0.3 to 0.6 mg/kg/day) was demonstrated to improve heart failure class, and to prolong survival in Doberman Pinschers (mean of 329 days compared with 50 in placebo group).²¹⁶ O'Grady and coworkers²²⁰ also found that the addition of pimobendan (0.25 mg/kg PO every 12 hr) to standard diuretic (furosemide) and afterload reduction (benazepril) therapy was associated with a longer time (130.5 days) to treatment failure in Doberman Pinschers with DCM and CHF compared with the placebo group (63 ± 14 days).

Pimobendan also has proven useful for treatment of degenerative mitral valvular disease. The QUEST study²²¹ compared the impact of pimobendan (n=124) versus benazepril (n=128) on mortality in dogs from Europe, Canada, and Australia afflicted with myxomatous mitral valve disease. Of the dogs reaching an endpoint associated with decline the median time was 267 days for pimobendan compared to 140 for benazepril. Pimobendan (0.2 to 0.3 mg/kg twice daily) did not have a sustained positive effect on echocardiographic values of asymptomatic dogs (some were receiving ACE inhibitors) (n=24) with mitral valve disease using a randomized, blinded design. An initial increase in systolic function at 30 days did not persist to study end (6 months). However, a major limitation of the study was the sample size.²²²

KEY POINT 14-46 Pimobendan can be safely combined with other traditional drug therapies for congestive heart failure.

Other studies have compared pimobendan to ACE inhibitor therapy in an attempt to identify the most effective approach. Using a prospective, randomized, single-blinded parallel design, the clinical efficacy and safety of pimobendan was compared in a 6-month study to ramipril in client-owned dogs (n=43) with mild to moderate heart failure associated with mitral valve disease. Treatment was well tolerated in both groups; pimobendan-treated dogs were only 25% as likely to have an adverse outcome related to heart failure (odds ratio 4.09, 95% confidence interval 1.03 to 16.3, P=0.046). However, despite randomization, dogs receiving ramipril began with a higher overall score, suggesting this group had more severe disease.²¹⁷ The efficacy of pimobendan (n=41) was also compared to benazepril as a positive control (n=35) in dogs with atrioventricular disease using a parallel, randomized, blinded multicenter clinical trial (VetSCOPE). Animals were assessed at 56 days, and long-term survival was determined.²¹⁸ Scores in dogs receiving pimobendan improved compared with those of animals not receiving pimobendan; further, long-term survival was greater at 415 days compared with 128 for dogs not receiving pimobendan.

Timing of pimobendan administration in the progression of myocardial disease may be important. Discontinuation of pimobendan improved mitral regurgitation in two dogs⁵⁷ led to a double blinded parallel clinical trial comparing the effect of either pimobendan or benazepril in dogs (Beagles; n=12; 6 per group) with asymptomatic, naturally occurring mitral valvular disease.²²³ Increased systolic function associated with a longer regurgitant jet characterized by a greater velocity was detected in the pimobendan group within 15 days of initiation of therapy. Histologic mitral valvular lesions were worse (moderate to severe) in three dogs at the end of the 512-day treatment period in the pimobendan group compared with the benazepril group (mild to slight in six dogs).

Evidence exists that pimobendan can be combined with standard cardiovascular drugs with no apparent adverse effects, as has been suggested by clinical trials assessing efficacy. In addition, Fusellier and coworkers²²⁴ failed to detect significant differences in adversities when pimobendan was combined with meloxicam in 10 Beagles using a randomized, crossover design. However, dogs were studied 4 times (placebo, meloxicam, pimobendan, and the combination), and the power to detect a significant difference was not addressed, indicating that an adverse reaction cannot be ruled out.

Pimobendan has been associated with histologic damage to the endocardium, myocardium and valves, particularly at high intravenous disease. 224a A randomized, blinded, controlled clinical trail in Beagles (n=12) with mitral valvular disease comparing the impact of 512 days of therapy with either benazepril and pimobendan found that pimobendan was associated with an increase in the maximum area and peak velocity of the regurgitant jet turbulence. Further, acute focal hemorrhages, endothelial papillary hyperplasia, and infiltration of chordae tendinae with glycosaminoglycans occurred in the pimobendan-treated dogs. These studies support avoiding pimobendan use unless indicated.

Beta-Adrenergic Agonists

The β -adrenergic agonists include the catecholamines (norepinephrine, epinephrine, isoproterenol, dopamine, and dobutamine). Catecholamines increase contractility through β -adrenoceptor–mediated accumulation of cyclic AMP and subsequent phosphorylation of regulatory proteins, by protein kinase A (PKA). Proteins targeted include L-type Ca²⁺ channels, phospholamban (regulates the calcium pump), ryanodine receptors (a class of intracellular calcium channels), TnI and myosin-binding protein C (see Figure 14-1). These drugs are the most potent myocardial stimulants, each causing increased contractility. However, depending on the drug, potent peripheral vasomotor responses may limit their use clinically as positive inotropes but may also justify their use as pressor agents.

Dopamine

Dopamine is an endogenous catecholamine (norepinephrine) precursor with selective β_1 activity. It is widely used as a cardiac stimulant. Because it stimulates the release of norepinephrine, however, it has α -receptor-, β_2 -receptor-, and dopaminergicreceptor-mediated actions as well. Its inotropic effects are due to β_1 -receptor stimulation in the heart. At low doses (4 µg/kg per minute) in dogs, dopamine increases stroke volume and cardiac output and stimulates renal dopaminergic receptors, causing increased renal blood flow and diuresis. This is useful during situations of systemic vasoconstriction (e.g., shock), during which it is important to maintain renal blood flow. At high doses, however, it causes α -adrenergic stimulation and vasoconstriction. This may potentially reduce renal blood flow. Vasoconstriction can be reversed with alpha-adrenergic blocking drugs (e.g, phenothiazines). Dopamine appears to increase systolic pressure without significantly affecting diastolic pressure.

Dopamine is not effectively absorbed orally. It is rapidly metabolized by the body by monoamine oxidize and catechol *O*-methyl transferase (COMT) and has a half-life of less than 2 minutes. Dopamine is most commonly marketed as a solution that is further diluted with saline or dextrose. The drug is administered intravenously. Because the pharmacologic effects of dopamine are short lived, it is usually administered by constant infusion, and rate of administration can be used to control the intensity of effects.

KEY POINT 14-47 Beta agonists markedly increase myocardial oxygen demand and thus are arrythmogenic.

Cardiac arrhythmias may occur following dopamine therapy due to α -adrenergic activity. Dopamine should not be used in the hypovolemic patient (in part because of the potential for enhanced vasoconstriction in response to α -adrenergic activity). Tissue sloughing may occur in the event of perivascular leakage. Indications include cardiogenic, or endotoxic, shock and oliguria. Dopamine has been compared to norepinephrine as a pressor agent in humans; although statistical difference in 28 day mortality could not be demonstrated between the two groups, dopamine was associated with more life-threatening arrhythmias.^{223a} Dopamine can be diluted in a variety of fluids; an exception is fluids containing sodium bicarbonate or other alkaline infusions that will inactivate the drug. It will remain stable for at least 24 h after dilution.

Dopamine receptors are present in the cat, with D1 receptors identified in the feline renal cortex. The concentration appears to be lower than that in rats, dogs, and humans. The status of dopamine receptors in the feline renal vasculature is not clear. However, fenoldopam, a dopamine agonist, exhibits 300-fold greater affinity than dopamine for feline dopamine receptors, suggesting that failure of feline renal response to dopamine reflects a lack of dopamine receptors.²²⁵ This suggestion is supported by the observation that low-dose dopamine can provide effective diuresis in the dog but not the cat, yet higher doses of dopamine do increase diuresis and natriuresis in the cat.^{225,226} Fenaldopam is used for treatment of emergency hypertension and to stimulate systemic vasodilation, natriuresis, and diuresis in human patients with renal disease.²²⁷ Dopamine is likewise indicated in veterinary patients to induce diuresis in dogs with oliguric renal failure, in dogs and cats as a pressor agent in the presence of hypotension, and to provide inotropic support in the failing congestive heart.

Dobutamine

Dobutamine is a synthetic drug that is similar to dopamine but with the addition of a large bulky molecule that reduces non- β_1 effects. Dobutamine is a more effective inotrope than dopamine and is not associated with increased cardiac rates at lower doses. Therapeutic and pharmacologic ranges, respectively, are 0.1-10 µM; 10-100 µM.²²⁸ Dobutamine appears to increase cardiac contractility with less cardiac oxygen consumption than other catecholamines. Dobutamine does not dilate the renal vascular bed as does dopamine, although in a canine model of endotoxic shock it increased urine output and mesenteric blood flow at 5 and 10 µg/kg per minute, probably resulting from cardiac effects.²²⁹ Because of its greater selective effect on contractility as opposed to increasing heart rate, it is preferred to dopamine as a positive inotrope for treatment of CHF that is severe and eminently life threatening. Its arrhythmogenicity is less than that of epinephrine and is not likely to

occur (in normal dogs or dogs with ventricular ectopic beats) until therapeutic doses have been exceeded.

Dobutamine is not effective orally and has a plasma halflife of approximately 2 minutes because of metabolism by COMT. It is therefore usually administered by constant-rate intravenous infusion. The drug is metabolized in the liver to inactive glucuronide conjugates. Like dopamine, dobutamine is prepared as a solution to be diluted with dextrose or variety of fluids, but is inactivated by alkaline solutions such as those containing sodium bicarbonate. It is stable for only 6 hours after dilution. The major indication for dobutamine is shortterm therapy for refractory CHF. It is the preferred drug (e.g., compared with digoxin) because its short half-life reduces the potential for toxicity and the inotropic effects of dobutamine are greater. Treatment beyond 48 hours is discouraged, in part because of the development of tolerance. In people, however, a residual effect occurs for up to several months. Dobutamine and volume replacement are indicated for treatment of hemorrhagic shock.²³⁰ Likewise, in dogs with septic shock, dobutamine (5 to 10 µg/kg per minute) increases mesenteric blood flow and urine output when administered in conjunction with fluid therapy.229

The dose generally recommended is 2.5 to 20 μ g/kg/min in dogs and 0.5-5 μ g/kg/min in cats, starting with an initial dose of 2.5 to 5 μ g/kg/min and increasing 1-2 μ g/kg/min every 5 to 30 minutes. Improvement should occur within 30 minutes. The most common side effect is ventricular arrhythmias, which are less likely to occur if doses of 15 μ g/kg per minute are not exceeded. Arrhythmias should not be treated with β -adrenergic blockers; rather, the dose should be decreased until arrhythmias resolve. Animals with very severe CHF and very poor myocardial function may not be able to respond to dobutamine because of little contractile reserve. Tachyphylaxis may occur within 72 hours of continuous treatment owing to downregulation of β 1 - receptors.

Epinephrine

Epinephrine is one of the most potent vasopressor drugs known. It causes an immediate rise in blood pressure as a result of (1) direct myocardial stimulation and a positive inotropic effect, (2) an increased heart rate or positive chronotropic effect, and (3) vasoconstriction in many vascular beds. As with the other catecholamines, its cardiac effects are due to direct interaction with β_1 -receptors and cells of the pacemaker and conducting tissues. Cardiac systole is shorter and more powerful. Because the formation of cAMP requires ATP, however, epinephrine causes the greatest increase in the rate of energy usage and myocardial oxygen demand. This increase in oxygen need may be detrimental to the failing heart. Increased work and myocardial oxygen consumption result in *reduced* cardiac efficiency.

Epinephrine is rapidly metabolized in the gastrointestinal tract and does not reach therapeutic plasma concentrations after oral administration. Absorption is more rapid after intramuscular versus subcutaneous administration because of local vasoconstriction. Epinephrine is rapidly metabolized by the body. The liver plays an important but not essential role in the metabolism of epinephrine. Two enzymes catalyze its degradation: COMT and monoamine oxidase.

Epinephrine is available in several forms of solution that can be used for intravenous, inhalation, and nasal administration. Because of the decreased efficiency of cardiac work, epinephrine is not used simply as a positive inotropic agent. Ventricular arrhythmias can be expected. In addition, central nervous system signs may occur. The primary indication for epinephrine in treatment of cardiac disease is acute cardiac life support (see the discussion of "crash cart" drugs) or for pressor support in patients insufficiently responsive to norepinephrine.

Isoproterenol

Isoproterenol is a nonspecific β -agonist that, like epinephrine, increases myocardial oxygen demand. Tachycardia and the potential for other arrhythmias tend to exclude its use for the cardiac patient.

Miscellaneous Agents

Miscellaneous inotropic agents include calcium when given as a slow intravenous injection or infusion. Care must be taken with the administration of calcium because it can cause cardiac rigor and standstill at high doses; attention must be given to the amount of calcium per dosing unit (e.g., ml or oral dosing form) among the different oral or injectable salts (see Table 14-3). The gluconate form is preferred to calcium chloride. Glucagon is also a positive inotropic agent.

Phenylpropanolamine is used primarily to treat urinary incontinence, but toxicity is manifested predominantly in the cardiac system. Toxicity was reported in a 5-year-old, female Labrador Retriever receiving 48 mg/kg. Clinical signs included tachypnea, tachycardia, and ataxia. Cardiac arrhythmias were characterized by multiform ventricular tachycardia, left ventricular dilation with a focal dyskinetic region in the dorsal intraventricular septum, and elevations in creatinine kinase and cardiac troponin I. Diagnostic tests were attributed to myocardial necrosis following transient infarction or directed myocardial toxicity. All abnormalities resolved within 6 months.¹⁷⁴

Coenzyme Q, also called ubiquinone, is a natural fat-soluble compound similar to vitamin K in structure and ubiquitous in plants and animals. It acts as an antioxidant to protect cell membranes from free radical activity. Coenzyme Q plays a role in the conversion of 95% of energy needs; organs with the highest energy needs have the highest coenzyme Q concentrations. The use of the compound has been in patients with severe CHF (150 to 225 mg/day), particularly for those whose endogenous concentrations fall below 2 µg/mL. The effects of coenzyme Q on myocardial cells is controversial. In cultured myocardial cells, coenzyme Q stimulates beating activity, probably by stimulating the formation of mitochondrial ATP.²³¹ In humans undergoing valve replacement, coenzyme Q appeared to scavenge hydroxyl but not superoxide anions.²³² Singh and coworkers²³³ demonstrated a protective effect of coenzyme Q in patients receiving the compound within 3 days after acute myocardial infarction. However, a lack of effect on ventricular function was reported in patients with CHF.²³⁴ Coenzyme Q may block apoptosis.²³⁵ Foods highest in coenzyme Q include

beef, spinach, sardines, albacore tuna, and peanuts. Beta blockers, statin (cholesterol-lowering drugs) and other cardiovascular drugs can decrease coenzyme Q. Coenzyme Q is available as a dietary supplement, generally in capsules ranging in size from 10 to 60 mg.

Nutritional intervention with essential nutrients, including L-arginine and L-carnitine, also has been recommended as effective adjunctive therapy for prevention and control of cardiovascular disease.²³⁶

NEGATIVE INOTROPES

The negative inotropes most commonly used in clinical practice are those that block β -receptors (propranolol, which is nonselective, or atenolol, which selectively blocks β_1 -receptors) or CCBs (diltiazem). By virtue of their mechanisms of action, drugs in either of these categories also tend to act as negative chronotropes; often this action is desirable. Both groups of drugs have been previously discussed as antiarrhythmics. These drugs are further discussed under treatment of HCM.

The primary indication for the use of negative chronotropes in veterinary medicine is feline HCM, a cardiac disease characterized by a thickened cardiac muscle; poor distensibility and compliance, and thus poor cardiac filling; and, depending on the degree of ventricular hypertrophy, obstruction to cardiac outflow. Atrial fibrillation is not uncommon in this syndrome and generally causes a tachycardia that worsens this syndrome. Thus the negative chronotropic effects of these drugs are of benefit in cats suffering from hypertrophic cardiomegaly.

TREATMENT OF SPECIFIC VASCULAR DISORDERS

Acquired Valvular Diseases

Chronic Mitral Valve Insufficiency

Pathophysiology. Chronic mitral valve insufficiency (CMVI; chronic valvular disease) results from endocardiosis of the mitral valve. It is the most common cardiovascular disorder in the dog, leading to death resulting from CHF in 7% of all dogs before the age of 10 years. The pathophysiology has been well reviewed.²³⁷ The initiating cause is unknown. However, because the leaflets are stiff and malformed, their motion is abnormal. Because they fail to accurately oppose one another during systole, blood regurgitates into the left atrium. The abnormal motion and regurgitant fraction contribute to sheer stress on the valve leaflets. Endothelial damage may result in an imbalance in local growth factors. The progression of disease reflects a number of factors, including the volume of forward (reduced) and backward (regurgitant) flow, the size of the left atrium, and the compliance of the atria and pulmonary arterial tree. The progression of disease and the manifestations of clinical signs reflect both the underlying disease and compensatory mechanisms. The decrease in forward flow and thus cardiac output activates neural, humoral, and renal compensatory mechanisms as well as remodeling (hypertrophy and dilation) of the left atrium and ventricles.

Increased circulating blood volume and arterial resistance generally are sufficient to support cardiac output, even for a number of years. The compensatory mechanisms, including cardiac remodeling, that maintain forward flow do so, however, at the cost of worsening the regurgitant fraction. The regurgitant fraction that accompanies CMVI is determined by the degree of valvular deformity; the amount of afterload (systemic impedance) placed on the left ventricle; and, as disease progresses, the amount of dilation of the valvular annulus and misalignment of papillary muscles as the left ventricle enlarges.⁹⁰ Mitral regurgitation becomes uncompensated (symptomatic) when the leaking valves are no longer able to keep pulmonary capillary pressures from exceeding the threshold associated with pulmonary edema or maintaining forward cardiac output.²³⁷ Decreased myocardial contractility will inevitably emerge, although progression will be slow. However, the point at which impaired contractility contributes significantly to pathophysiology and clinical signs is not clear.237

Clinical signs indicative of cardiac disease may reflect left atrial overfilling and decreased atrial compliance rather than myocardial dysfunction. The development of pulmonary congestion and edema reflects pressure in the left atrium, which in turn depends on volume of the left atrium and compliance in the left atrial wall. If the rate of increase of the regurgitant fraction is sufficiently slow, left atrial compliance can gradually increase, and pulmonary congestion does not develop until later in the disease. In contrast, a sudden increase in the regurgitant volume such as might occur with a ruptured chordae tendineae will cause a rapid rise in atrial and thus pulmonary capillary pressure and pulmonary edema.⁹⁰ Coughing associated with pulmonary edema may reflect edema of the bronchial walls and the accumulation of excess mucus. Left atrial enlargement can be great, with two potential sequelae. Pressure on the mainstem bronchus or the recurrent laryngeal nerve may stimulate coughing. In addition, the enlarged atria are predisposed to atrial tachycardias (premature supraventricular beats, atrial flutter, atrial fibrillation). Ventricular dilation also can predispose the development of ventricular tachycardia. Any of the arrhythmias can contribute to the progression of disease. Occasionally, the left atrial wall can rupture, leading to hemopericardium and cardiac tamponade.⁹⁰ Although not well described in dogs, remodeling as described in multiple animal models should be assumed to contribute to the progression of CHF in dogs.

Clinical signs associated with CMVI that require medical management are variable, in part because of variable progression of the disease and the different pathophysiologic sequelae, each characterized by its own set of overlapping clinical signs. Decreased forward flow may result in weakness, decreased stamina, or syncope; enlarged left atria with mainstem compression (or primary bronchomalacia^{240a}) can present as coughing (which can be sufficiently paroxysmal as to cause syncope); elevated left atrial and pulmonary capillary pressures may result in respiratory distress (tachypnea, loss of sinus arrhythmia, or dyspnea), coughing (deep and resonant), wheezing, or orthopnea if increase is sufficiently slow or fulminating, pulmonary edema, ventricular fibrillation, and sudden death if rapid; or right heart failure characterized by pleural effusion and ascites.⁹⁰ Among the difficulties in recognizing the need for treatment is distinguishing clinical signs associated with mitral regurgitation and its sequelae from similar clinical signs that may be associated with a host of illnesses unrelated to myocardial disease. As noted by Haggstrom and coworkers,²³⁷ the tendency is to overdiagnose pulmonary edema-associated CHF. The role of molecular or other markers of disease (e.g., brain natriuretic peptide [BNP] or caninespecific N-terminal brain natriuretic peptide [NT-proBNP]) in the the diagnosis of disease is being defined and may assist in the diagnosis of cardiac disease as a cause of respiratory distress.^{237a} Clinical signs, coupled with sequential radiography, should help clinicians distinguish early signs of mitral regurgitation from other causes.

KEY POINT 14-48 Care must be taken not to overdiagnose pulmonary edema and prematurely implement therapy for treatment of chronic mitral valve insufficiency.

Drug Therapy. The goals of therapy for CHF associated with CMVI are to increase tissue perfusion in order to relieve symptoms such that quality of life is improved; stabilize the disease, thus reducing hospital admissions; and decrease mortality or prolong survival by either slowing the progression of or, ideally, reversing myocardial systolic or diastolic dysfunction associated with left ventricular myocardial remodeling. The severity of symptoms of CHF may vary dramatically, with acute episodes of cardiac decompensation often accompanying comorbidity.

The traditional approach to treatment of CHF has been in response to resolution of clinical signs. During the last 2 decades, therapy focused on minimizing the impact of compensatory neurohumoral endocrine mechanisms. These included volume overload and increased afterload. Targets of therapy include decreasing fluid volume with diuretics (spironolactone, furosemide) and ACE inhibitors; decreasing afterload (ACE inhibitors, arterial dilators); and minimizing cardiac arrhythmias. Arrhythmias requiring management, most commonly are supraventricular tachycardias (β blockers, CCBs, or digoxin) but occasionally include ventricular arrhythmias (e.g., procainamide, melixetine, sotalol). Because impaired myocardial contractility does not emerge until late in the progression, positive inotropes (digoxin, pimobendan) generally have been the last class of drugs to be added to the armentarium.

KEY POINT 14-49 The traditional therapeutic goals of congestive heart failure—targeting compensatory mechanisms—should be expanded to include slowed progression of myocardial damage.

However, as in humans, treatment of CHF increasing will be oriented toward preventing myocardial remodeling that occurs in response to the compensatory changes. These treatments will include new applications of traditional drugs, as well as the addition of new drugs for traditional targets and new drugs for new targets.

Various pharmacotherapies in humans have been reviewed by Lonn et al.²³⁸ Those clearly associated with improved survival are the ACE inhibitors and β -blockers, whereas diuretics and digoxin improve clinical signs. In contrast, class I antiarrhythmics, CCBs (including class IV antiarrhythmics), and digoxin have been associated with increased mortality rates. Newer classes of drugs in use (e.g., calcium sensitizers) have not been available for a sufficient length of time for data to have been generated for review. Future classes of drugs may include drugs that target ANP, such as neutral endopeptidase inhibitors (e.g., ecadotril), or drugs that target myocardial inflammation and remodeling, including antioxidants and anticytokines.

Currently, the cornerstones of pharmacotherapy in dogs for CHF include diuretics (preload reduction), drugs that impair the renin-angiotensin-aldosterone axis, β -adrenoceptor antagonists, vasodilators (afterload reduction), and, in some cases, positive inotropic drugs. The standard of care for treatment includes, at a minimum, an afterload reducer, ACE inhibitor, a β blocker, and the addition of a diuretic as needed to treat congestion. Digoxin, an aldosterone antagonist, and an angiotensin receptor antagonist are added as indicated in selected patients (Table 14-2). Although these therapies are based on clinical trials that have demonstrated subsequent decreased mortality or morbidity with the addition of each agent, the actual proportion of patients responding to therapy has been small, indicating a need for improved medical management.²³⁸ Because the progression of CHF in dogs appears similar to that in humans, it is reasonable to assume that pharmacodynamic effects on the slowing of progression of myocardial disease may be similar in both species. ^{238a-e}

Among the factors confounding treatment of CHF in dogs (or cats) is the lack of pharmacokinetic studies supporting the design of effective and safe dosing regimens. Enatiomers, active metabolites, drug interactions, and the impact of disease or its treatment on drug disposition are just some of the factors that complicate effective use of cardioactive drugs in dogs and cats. The lack of pharmacokinetic studies is consistent limitation for many human-approved drugs used in dogs or cats. Also among the difficulties associated with effective management of CHF is the point at which therapy is initiated. This is particulary problematic for the patient with mitral regurgitation which may be characterized by a long preclinical stage.²⁴⁰ Preferences among clinicians may reflect experience rather than scientific studies. Several considerations may guide choices. Animals with left atrial enlargement and mainstem bronchus compression may have normal myocardial function. Reduction of systemic resistance (afterload) may allow more blood to exit the aortic valve, thus decreasing the regurgitant fraction through the mitral valve and left atrium such that coughing is resolved. The size of the left ventricle also may decrease, which may reduce the size of the mitral annulus, further reducing the regurgitant fraction. ACE inhibitors initially, followed by amlodipine and/or hydralazine, are indicated to decrease systemic vascular resistance in early phase II CHF.^{237,239,240} Theophylline, hydrocodone, or butorphanol might be considered for control of cough in early phases of the disease. 237,240 In addition to their effects on afterload, in the patient with evidence of compensatory mechanisms, ACE inhibitors have the added advantage of decreasing sodium and water retention and thus blood volume, helping to reduce the regurgitant fraction. As disease progresses, ACE inhibitors may be favored over amlopdipine by virtue of their, the beneficial effects on myocardial remodeling. Although hydralazine might also support myocardial revascularization and impart cardioprotection its positive inotropic effects may not be desireable in early stages of insufficiency. However, it may be indicated in dogs coughing due to mainstem bronchi compression that do not sufficiently respond to ACE inhibitors and may be useful for reducing.²⁴¹ Care should be taken with all afterload reducers to avoid hypotension and potential activation of the RAAS.

As clinical signs progress, diuretics are indicated for reduction of sodium and water retention. Treatment of patients with pulmonary (interstitial) congestion does not differ much from treatment of atrial enlargement. Pulmonary congestion implies that atrial compliance is high, resulting in increased left atrial pressures and pulmonary capillary pressure. Afterload reduction and diuretics are indicated in that order, depending on the severity of clinical signs; positive inotropes are indicated in the presence of myocardial dysfunction. Diuretics initially may play a more active role in the presence of pulmonary edema, but a decreasing need may be evident after several weeks of therapy. Although diuretics are among the first classes of drugs used to treat the sequelae of CMVI, caution is recommended. Overuse can lead to reduced cardiac output, hypokalemia, acid-base imbalances, and activation of the RAAS and its associated negative sequelae. As such, use might be reserved for late phase II or early phase III CHF.²⁴⁰ The need for diuretics might be offset by the use of ACE inhibitors; further, and once diuretic therapy is begun, ACE inhibitors may allow for a substantial (up to 50%) dose reduction.37,240a Spironolactone might be considered first not only because its mechanism targets aldosterone but also because it imparts cardioprotective effects.^{240a,242} However, its efficacy as a diuretic is probably least, whereas fursosimide is the most effective. In the case of acute cardiogenic pulmonary edema (i.e., that which is life threatening), nitroprusside may be indicated for afterload reduction and nitroglycerin for pre-load reduction. Morphine may be helpful. Its central effects may reduce stress and anxiety and the negative sequelae of vascular responses to stress. Respirations may deepen and slow, resulting in improved ventilation. In addition, ventilation may result in pooling of blood in the splanchnic vasculature, reducing preload. The enlargement of the left atrium may be associated with supraventricular tachycardias. Ventricular rates greater than 180 beats per minute (bpm) may reduce cardiac output; therapy should target reduction to 150 to 160 bpm or less. Digoxin has been the preferred antiarrhythmic drug because of its impact not only on heart rate but also on baroreceptor function. Either diltiazem or selective β_1 -blockers or metoprolol are added if response is insufficient. However, recent revelations of the impact that β -blockers have on myocardial remodeling

may support their initial use for treatment of supraventricular tachycardia. Cardiac decompensation may occur in some patients if the heart rate drops below 150 bpm; animals whose heart rate depends on sympathetic activity may be particularly sensitive to β -blockade.⁹⁰

KEY POINT 14-50 As with vasodilators, overuse of diuretics may result in activation or worsening of neurohumoral compensatory mechanisms.

Until recently, digoxin has been the only orally bioavailable positive inotrope recommended for improved contractility.⁹⁰ In the absence of afterload reducers, increased myocardial contractility actually might increase the regurgitant fraction. Thus its use should be limited to animals that have not responded to afterload reduction alone or in combination with diuretic therapy. The use of pimobendan for treatment of CMVI is increasing. Patients benefit from both positive inotropic effects of vasodilation; the American College of Veterinary Internal Medicine's "Guidelines for the diagnosis and treatment of canine chronic valvular heart disease" recommends its use for management of both actue and chronic heart failure.^{242a} The use of pimobendan in canine patients with heart disease was previuosly discussed and has recently been reviewed again.^{242b}

Right-sided heart failure is described as a common complication of CMVI.⁹⁰ Because the right ventricular wall is thinner than the left ventricular wall, it is more compliant and thus better able to adjust to the increased volume associated with tricuspid insufficiency. It does not, however, adjust as well to increases in pulmonary pressure. Right ventricular stroke volume can markedly decrease in the face of very small increases in pulmonary pressure, resulting in decreased delivery to the left ventricle and decreased cardiac output. The use of systemic vasodilators in the presence of pulmonary hypertension may further decrease cardiac output. Unfortunately, pulmonary hypertension often does not respond selectively to pharmacologic management (see the section on pulmonary hypertension).

Rupture of the chordae tendineae has been described as possibly the most frequently encountered complication of CMVI.⁹⁰ The sequelae of rupture appear more dependent on the type (i.e., first, second, or third order) rather than the number of those that rupture. The negative sequelae generally reflect the inability of the left atrium to accommodate to the rapid increase in left atrial pressure. Patients may present in severe respiratory distress as pulmonary capillary pressure and pulmonary (interstitial and alveolar) edema develop. Right-sided heart failure (manifested as pleural effusion or ascites) also may be present. Treatment includes aggressive diuretic therapy (furosemide at 8 mg/kg intravenously every 6 hours). Rapidly acting positive inotropes (dobutamine or dopamine) may facilitate emptying of the left ventricle and thus decrease the size of the mitral annulus. Afterload reducing agents appear to be of no benefit and may be deleterious if cardiac output decreases. Preload reducing agents are probably less beneficial with right-sided failure.

Tricuspid Valvular Insufficiency

Because a normally functioning left ventricle ensures forward movement of blood in the right ventricle, incompetence of the tricuspid valve generally does not lead to cardiac insufficiency unless accompanied by an underlying disease (e.g., pulmonary hypertension, heartworm disease, CMVI). Identification of any underlying disorder leading to tricuspid valvular insufficiency is critical to successful management of cardiac insufficiency. Loop diuretics (furosemide) or aldosterone antagonists (spironolactone) (or a combination thereof) may be indicated for management of ascites. Spironoloactone may be more effective for right-sided, compared to left-sided therapy. Digoxin may be helpful in the presence of myocardial failure, and antiarrhythmic drugs may be necessary to control tachycardia.⁹⁰ Treatment of pulmonary hypertension associated with heart failure is discussed below.

Diseases of the Myocardium

Dilated Cardiomyopathy (DCM)

Pathology. The cause of DCM in dogs is not known, although a number of causes have been proposed (e.g., viral, nutritional, toxins, hereditary). Often, secondary changes cannot be distinguished from primary changes (i.e., which is cause and which is effect). Biochemical changes similar to those accompanying DCM in humans have been identified in dogs, including decreased myocardial carnitine or myoglobin concentration, decreased β-receptor-mediated cAMP (e.g., downregulation of receptors or decreased intracellular proteins), decreased intracellular regulatory proteins (e.g., light chains), or altered calcium release from the sarcoplasmic reticulum. Among these causes, decreased carnitine has received the most attention.²⁴³ Carnitine is responsible for the transport of fatty acids into mitochondria, where they are subjected to β-oxidation; carnitine deficiency then might be characterized by altered energy metabolism and lipid accumulation in the myocardium. Clinical trials have, however, suggested that carnitine deficiency is a secondary rather than a primary disorder of DCM. In contrast to the cat, taurine deficiency is not a common disorder accompanying DCM in dogs. Although decreased plasma concentrations of both taurine and carnitine have been reported in American Cocker Spaniels with DCM, amino acid supplementation alone does not appear to resolve the disease.^{190,243} A reversible taurine-deficient DCM has been described in related Golden Retrievers (n=5). Improvement occurred within 3 to 6 months of taurine supplementation. Substantial systolic function was maintained with cardiac drugs (but not taurine) discontinued in four of five dogs.²⁴⁵

All four cardiac chambers are enlarged in dogs with DCM, although left-sided enlargement predominates in some breeds (e.g., Boxers, Doberman Pinschers).¹⁹⁰ The myocardial muscle generally is pale, thin (compared with chamber size), and flabby. The mitral annular ring is dilated, and papillary muscles are often atrophied. The primary physiologic dysfunction accompanying the pathologic changes is poor systolic ventricular function characterized by decreased rate of ventricular development, reduced fractional shortening, ejection fraction, and rate. Diastolic dysfunction is characterized by increased

end-diastolic pressures in the ventricles, atria, and venous circulation.¹⁹⁰ Valvular insufficiency, cardiac arrhythmias, and compensatory neurohumoral and renal mechanisms complicate therapy.

As with CMVI, a number of clinical signs develop in DCM, depending on the severity of dysfunction and the level of compensation by neurohumoral and renal mechanisms. In contrast to CMVI, myocardial dysfunction characterizes DCM at the outset, and positive inotropic support is the mainstay of therapy. In addition, the use of afterload reducers may offset the progression of disease, potentially prolonging the life of the animal.¹⁹⁰ The variable clinical signs are similar among breeds, although their frequencies may vary among selected breeds. Giant breeds are more likely to present with clinical signs reflecting right-sided heart failure (ascites, weight loss, fatigue), whereas clinical signs of left-sided heart failure are more common in Boxers and Doberman Pinschers.¹⁹⁰ In working dogs, exercise intolerance may serve as an indicator of dysfunction relatively early in the disease compared with nonworking dogs for whom the disease might present as a rapid progression of deterioration.

Although myocardial dysfunction characterizes DCM, many dogs are diagnosed before overt heart failure occurs. Syncope or episodic weakness may be the primary clinical sign in animals in which disease is characterized by cardiac arrhythmias. Variability in the cardiac dysfunction also occurs among breeds, and recognition of these differences may direct drug therapy. For example, up to one third of Boxers diagnosed with DCM are asymptomatic, with DCM characterized by ventricular arrhythmias but normal myocardial indices.¹⁹⁰ Asymptomatic giant breeds may have atrial fibrillation with only mild changes in myocardial function. In contrast, disease in asymptomatic Doberman Pinschers generally is characterized by ventricular arrhythmias and marked impairment of myocardial function.¹⁹⁰ Whereas atrial fibrillation is a common finding in giant breeds, sudden death in otherwise asymptomatic Doberman Pinschers and Boxers is more common than in other breeds because of the advent of fatal ventricular arrhythmias.¹⁹⁰

Clinical signs of DCM that may direct drug therapy include weak arterial pulses, irregular pulses with pulse deficits (indicative of ventricular or atrial arrhythmias), pulsus alternans (alternating arterial pulse in the absence of cardiac arrhythmias, indicative of severe myocardial failure), lung sounds indicative of pulmonary interstitial edema, and clinical signs associated with right-sided heart failure (previously discussed). A number of changes in clinical pathologic parameters also may modify drug selection. Of concern is evidence of renal dysfunction or, particularly in patients with right-sided failure, hepatic dysfunction, which may lead to modification of the dosing regimen of cardiac drugs or might predispose the patient to worsening renal disease (e.g., use of ACE inhibitors or diuretics). Electrocardiography and echocardiography are important tools for the selection of myocardial drugs and subsequent monitoring of efficacy in the dog with DCM. An electrocardiogram should be used to confirm the type and severity of cardiac arrhythmia. Echocardiography can be used, in concert with clinical signs and an electrocardiogram,

to assess prognosis or response to drug therapy. Assessment might include the degree of chamber dilation, mitral valve configuration and closure, and systolic performance. Ejection phase indices including left ventricular fractional shortening, ejection fraction, and velocity of circumferential shortening decline with decreasing systolic function.¹⁹⁰

KEY POINT 14-51 When treating dilated cardiomyopathy with drugs excreted renally, care must be taken to modify the dosing regimen as renal function declines (or improves) with cardiac function.

Drug Therapy. The best-case scenario to be expected when treating DCM has been improved quality and length of life. Therapy should be selected such that clinical signs are minimized; additionally, use of appropriate therapy may slow the progression of myocardial dysfunction. During the progression of diseases, diuretics, positive inotropes, vasodilators, ACE inhibitors, and antiarrhythmics are apt to play a role in drug management. They are used in a variety of combinations, depending on the nature and severity of clinical signs associated with the disease in the individual animal. Individualization of therapy is paramount to proper use of the drugs and thus to achieving the goals of drug management. Therapeutic drug monitoring is indicated when drugs are used for which monitoring is available (see Chapter 5).

Antiarrhythmic drugs may or may not be indicated for the patient with DCM associated with atrial or ventricular arrhythmias but without clinical signs of CHF. Despite the fact that sudden death may be a sequela of ventricular arrhythmias, no evidence exists that their control with antiarrhythmics prolongs life. Indeed, in human patients antiarrhythmic drugs may be proarrhythmic in some cases, thus increasing the risk of sudden death.^{246a} The proarrhythmic effects of these drugs occur in dogs as well, although reports largely relate to experimental situations. Well-controlled clinical trials regarding the use of antiarrhythmic drugs for dogs with DCM are lacking. Among the drugs reported to cause variable levels of success in the treatment of ventricular arrhythmias are procainamide,²⁴⁶ tocainide,²⁴⁷ and propranolol.²⁴⁶ Historically, Sisson and Thomas^{247a} recommend the use of procainamide to treat frequent ventricular premature depolarizations or ventricular tachycardias in dogs with DCM. Refractory arrhythmias can be treated with the addition of propranolol or a change to quinidine, tocainide, or mexiletine.

Antiarrhythmic therapy when supplemented with conventional therapy for CHF (ACE inhibitors, furosemide, and digoxin) is associated with a longer life span in Doberman Pinschers (n=19) with DCM and sudden ventricular tachycardia: median (and range) survival from the first episode increased from 11 (3 to 38) to 197 (78 to 345) days, respectively. Treatment consisted of tocainide (n=6; 15 to 20 mg/kg every 8 hours) or mexiletine (n=7; 5 to 8 mg/kg every 8 hours), with the addition of procainamide (15 to 20 mg every 8 hours), quinidine gluconate (8 to 9 mg/kg every 8 hours), amiodarone (10 mg/kg every 12 hours for 1 to 2 weeks, followed by 5 to 10 mg/kg every 24 hours) or β -adrenergic antagonists

(propranolol 0.5 mg/kg every 8 hours, or metoprolol or atenolol at 0.5 mg/kg every 12 hours).²⁵³

KEY POINT 14-52 Control of ventricular arrhythmias in the patient with dilated cardiomyopathy with currently available drugs is controversial and evidence thus far does not clearly support benefits.

Atrial fibrillation is among the most common atrial arrhythmias associated with DCM. Digoxin is the antiarrhythmic drug of choice not only for its negative chronotropic effect (including atrioventricular nodal impulse suppression) but also for its positive inotropic effects (discussed previously in this chapter). Although only a weak positive inotrope, digoxin remains useful because it slows heart rate and normalizes baroreceptor function.²⁴⁰ However, the positive inotropic effects can be marked in some dogs with DCM.^{248,249} Negative chronotropic effects likewise will benefit most patients.²⁵⁰ Both pharmacologic effects act to reduce activation of the RAAS.²⁴⁹ Studies in human patients with DCM have detailed the reduction of clinical manifestations, improved capacity for exercise, and slowed progression of disease induced by digoxin therapy.¹⁸⁹ The RADIANCE and DIG trials in humans showed that patients in heart failure denied digoxin had worsening of signs, quality of life, exercise tolerance, and hemodynamic status. Digoxin has been indicated for treatment of heart failure in dogs with supraventricular tachycardia. Use in dogs with normal myocardial function should be pursued cautiously; however, discretion must be used in treatment of these dogs because other drugs will control signs with less danger of toxicity. In general, digoxin should be instituted in late phase II in the presence of myocardial failure (to treat atrial fibrillation) and reserved for phase III (as diuretic therapy is initiated) in dogs without myocardial failure.²⁴⁰ Its use as a positive inotrope has largely been replaced by pimobendan.

Should digoxin fail to control the heart rate, a CCB (e.g., diltiazem) or a β -adrenergic blocking drug (propranolol, atenolol) is indicated. Either type of drug also can be used to treat persistent sinus tachycardias. Although no study has documented increased efficacy of one class of drugs over another for dogs, β -blockade apparently has improved survival rates for human patients with cardiac failure. Although the risk of sudden detrimental effects on myocardial function and cardiovascular effects has lead to a call for caution when β -blockers are used in the patient with severe heart failure, evidence regarding improvement in human patients suggests otherwise. Selected CCBs can have a similar effect; diltiazem may be the least likely to detrimentally affect cardiac function in patients with severe disease.¹⁹⁰

The role of β -blockade in dogs with DCM is controversial. The role of β -blockers for treatment of heart failure is currently being investigated (see discussion under antiarrhythmics) as a means of decreasing the progression of myocardial disease. Metoprolol and carvedilol are the most promising.¹⁵¹

KEY POINT 14-53 Digoxin may be the drug of choice for treatment of atrial fibrillation associated with myocardial failure.

ACE inhibitors are indicated for dogs with DCM and clinical signs of cardiac failure. In a clinical trial of 110 dogs in 15 locations throughout the United States, when enalapril was used in combination with other drugs indicated for treatment of DCM, the mean number of days until treatment failure increased from 56.6 (placebo) to 143 (enalapril).⁸⁸ Less clear is the indication in the absence of clinical signs. Both increased afterload and preload (sodium and water retention) may be contributing to the progression of disease without causing overt clinical signs of decompensation. The presence of an ACE inhibitor may reduce the necessary dose of other drugs used to control clinical signs (e.g., furosemide). ACE inhibitors have been the cornerstone of chronic heart failure therapy, being implemented as early as phase II. In addition to their effects on afterload reduction and reduction of electrolyte abnormalities, they may blunt pathologic remodeling such that the progression of heart failure is slowed. Both duration and quality of life may be improved with their use. When used in combination with diuretics, the diuretic dose should be reduced; The dose of the ACE inhibitor might be increased (doubled for enalapril) in patients that fail to respond; it is not clear if dose increase results in enhanced response.

Diuretics are indicated for patients with signs of congestion. For severe pulmonary edema, therapy should be aggressive (intravenous, high doses). Oral therapy is indicated for control and long-term management. Dogs should be closely monitored for the advent of dehydration, excessive preload reduction, and subsequent decreases in cardiac output or azotemia. Although not common, hypokalemia may occur. In patients that are refractory (e.g., pleural effusion or ascites) to furosemide (particularly those with right-sided heart failure in which oral absorption may be reduced), parenteral rather than oral therapy may improve response. Alternatively, butamide is more orally bioavailable than furosemide in humans and may likewise be better absorbed in dogs.¹⁹⁰ Alternative managements include the addition of a thiazide diuretic to furosemide therapy, a venodilator, or an ACE inhibitor.

Extreme sodium restriction activates the RAAS and may contribute to renal dysfunction; use of ACE inhibitors may compound renal dysfunction. Thus diuretic therapy (and a marked dietary sodium restriction) should not be used indiscriminately. Some clinicians suggest that diuretic therapy should be implemented only in conjunction with ACE inhibitors.²³⁷ Combined use should allow the diuretic dose to be decreased by 50% or more in earlier phases of disease, although higher doses may be necessary to affect sufficient diuresis in later stages. Furosemide has been the cornerstone of therapy; potassium-sparing diuretics may be added for more effective therapy. However, spironolactone increasingly should be considered because of the importance of aldosterone-receptor blockade (including contributions to altered myocardial remodeling) in cardiovascular therapy.

The evidence for use of pimobendan to treat congestive heart failure associated with dilated cardiomyopathy was previously discussed whether to use it prior to the onset of clinical signs associated with heart failure is not clear; the PROTECT study currently in process aims to evaluate timing of pimobendan treatment in DCV.

Therapy also should target neurohormonal abnormalities.²⁴⁰ These include ACE inhibitors (as previously described), aldosterone antagonists, β blockers (e.g., carvedilol or metoprolol), which blunt adrenergic (sympathetic) responses; neutral endopeptidase inhibitors (e.g. ecadotril), which prevents the breakdown of ANP (thus moderating activation of the RAAS; and AGII receptor blockers (e.g. losartan). Antioxidants and anticytokine therapies will increase as more information becomes available.

Both milrinone and amrinone are used short term in human patients with heart failure. The vasodilating properties of these positive inotropic drugs are beneficial. In dogs with DCM, the positive inotropic effects of milrinone improve hemodynamic function and clinical signs.²⁵² Long-term use of milrinone has been limited by evidence of increased mortality rates in human patients.¹⁹⁰ The absence of coronary arterial disease in dogs may, however, minimizes the risk associated with the use of milrinone for long-term treatment of DCM. Despite its potential benefits, milrinone is not generally used to treat DCM. The positive inotropes dobutamine, dopamine, and amrinone are recommended less frequently than in the past, except for emergency therapy (rescue) of myocardial failure (phase IV). These drugs markedly increase oxygen demand, influence ion flow and may worsen arrhythmias (including tachycardia). Dobutamine is the preferred drug; vasodilators should be used simultaneously. Miscellaneous agents such as morphine (redistribution of blood volume), epinephrine, and calcium chloride should be used for specific indications in phase IV severe heart failure or as rescue drugs for cardiopulmonary rescuscitation.²⁴⁰

Nutritional agents may also have a role in treatment of myocardial disease. Taurine has essentially eliminated DCM in cats. The role of carnitine in dogs is less clear. Support for use includes treatment of DCM in Cocker Spaniels with taurine and carnitine. Other potential nutritional therapy includes supplementation with omega fatty acids (oil of fish origin), which may improve appetite and blunt cardiac cachexia.

Pentoxifylline therapy in human patients with DCM positively correlated to improved left ventricular function.^{24,252} The use of pentoxifylline as an adjunctive therapy for CHF in adult Doberman Pinschers with idiopathic DCM has been studied in a double-blinded, placebo-controlled clinical trial when added to conventional heart failure therapy (ACE inhibitor, diuretics, and digoxin).²⁴

Treatment of catastrophic CHF includes use of sodium nitroprusside and dobutamine.

Feline Dilated Cardiomyopathy

The recognition that DCM in cats was largely reversible with the administration of taurine has all but eliminated DCM in cats.^{244,254} Most commercial feline diets now contain sufficient taurine to prevent the syndrome. A history of unconventional foods or homemade diets will help identify the occasional cat with cardiac disease associated with taurine deficiency. The clinical presentation of DCM in cats is similar to that in dogs, although pleural effusions are more common. Systemic thromboembolism is another potential complication. Plasma taurine concentrations are often but not always low (<30 nM/mL). Systemic thromboembolism apparently can increase, and fasting can decrease, plasma taurine concentrations. Taurine supplementation largely reverses the clinical signs and elec-trocardiographic abnormalities associated with taurine deficiency. Most animals respond to taurine supplementation (250 to 300 mg/day orally) within 3 to 6 weeks of therapy. Mortality rates are highest, however, during the initial 2 to 3 weeks of therapy. Echocardiography is the preferred method for monitoring response to therapy because response times can markedly vary. Adjuvant therapy may be necessary until clinical response.

Diuretics (furosemide) can be used to manage pulmonary edema and pleural effusions; differences in dosing regimens for cats compared with dogs should be observed. Cats may appear to be dehydrated (based on skin turgor), but this is more likely to represent redistribution of fluids to the pleural cavity or lungs. Fluid may be necessary in the presence of azotemia associated with low-output failure and hypotension but should only be administered cautiously and slowly. Digoxin (0.0035 to 0.0055 mg orally every 12 to 24 hours) may be indicated until the response to taurine is evident. The use of pimobendan for treatment of poor myocardial contractility has not been reported in cats. Differences in response compared with that of dogs might be anticipated if cats do not metabolize pimobendan to an active metabolite. However, anecdotally, cats appear to respond to the positive inotropic effects. Emergency management of myocardial failure may require administration of dobutamine (2 to 5 µg/kg per minute); common side effects of dobutamine administration in cats include seizures and vomiting. Vasodilator therapy should be implemented. Afterload reduction might be accomplished with ACE inhibitors in the presence of compensatory neurohumoral mechanisms or amlodipine (or both). Renal function should be closely monitored, however, particularly in the patient with azotemia.

Alternative therapies include hydralazine (0.5 to 0.8 mg/kg every 12 hours) to control systemic resistance and 2% nitroglycerin topically (1/4 inch topically every 8 to 12 hours) for (short-term management) preload reduction. Adjuvant therapy may be required to treat or prevent thromboembolism. Provided that a properly prepared diet is fed, most drugs and taurine supplementation generally can be discontinued within 2 to 3 months of therapy. Failure to respond, particularly in the presence of normal plasma taurine concentrations, may indicate an idiopathic DCM.

Thromboembolism

Treatment of thromboembolism is addressed in depth in Chapter 15.

Feline Aortic Thromboembolism

Feline aortic thromboembolism (FATE) is not an uncommon sequela of feline cardiomyopathy. Thrombus formation reflects the combined result of altered endocardial surface (exposed collagen, von Willebrand factor or tissue factor, hemostatic/ inflammatory blood components [e.g., hypercoagulability] and blood flow). In the cat the underlying defect in blood components has not been identified, although vitamin B_{12} and arginine have been identified as deficient in one study (as reviewed by Smith and Tobias).²⁵⁵ Blood flow derangements usually accompany and may be correlated with the magnitude of left atrial enlargement. Cats with any type of cardiomyopathy are at risk to develop FATE. The pathophysiology and treatment were reviewed by Smith and Tobias,²⁵⁵ and use of selected antithrombotic agents for its treatment also is discussed in Chapter 15.

The goals of therapy include, in addition to rest, control of pain, improved systemic perfusion, (including prevention of further embolism), and supportive therapy as necessary. The latter should address treatment of primary cardiac disease. Newer NSAIDs preferentially target COX-2. As such, the inhibitory effects of prostacyclin will be subdued while the pro-platelet activity will not be. Accordingly, other than the use of aspirin, which is recognized for its unique antiplatelet effect, NSAIDs - particularly those known to be preferential for COX-2, - should be avoided in cats with FATE or cardiac disease in general, unless scientific studies support their use. The use of alternative antiplatelet drugs is discussed in Chapter 16. Opioids and tramadol are reasonable drugs for controlling pain. Resolution of embolism and reinstitution of perfusion are difficult. No controlled clinical trials have established appropriate therapy. Fluid therapy appropriate for the cardiac status is indicated. Scientific evidence regarding the efficacy of acepromazine (as an arterial dilator) is lacking, and the risk of contributing to hypotensive shock warrants avoidance. Smith and Tobias²⁵⁵ reviewed the use of tissue type plasminogen activator (see Chapter 15). The treatment is expensive, and although reperfusion may occur, the risk of mortality associated with FATE, hyperkalemia, and other complications is 50% to 70%.

Hypertrophic Cardiomyopathy

Pathophysiology. HCM is a disease that principally affects cats but occasionally is diagnosed in dogs. It is characterized by hypertrophy of the nondilated left ventricular free wall not associated with any other disease that can cause cardiac hypertrophy. Baty²⁵⁶ and Abbott^{256a} have reviewed feline HCM. Several etiologies of HCM are likely in cats, including altered muscle proteins, calcium transport, catecholamine physiology, or trophic factors.¹⁹⁰ A familial basis probably contributes to risk.²⁵⁶ Hyperthyroidism and possibly hypertension are likely causes of HCM that may require drug management. The syndrome can be symmetric or asymmetric (disproportionate hypertrophy of the intraventricular septum, left ventricular free wall, or papillary muscles). Recognition of different forms of HCM may lead to different approaches to drug therapy. Regardless of the cause or type of HCM, the primary physiologic abnormality of HCM is diastolic dysfunction with systolic anterior motion of the mitral valve and increasingly recognized component, contributing to outflow obstruction and often accompanied by mitral regurgitation.^{256a} Causes of the dysfunction include increased wall thickness, impaired ventricular relaxation, and ischemic myocardial fibrosis.¹⁹⁰ Obstruction to systolic outflow may occur in some cats, but it is not clear if the obstruction is the cause or the effect of HCM, nor is the clinical relevance of the obstruction well described. Clinical manifestations of HCM may include manifestations of the possible sequelae of HCM, including pleural effusions and arterial thromboembolism. Diagnosis is based on echocardiography, with adjuvant diagnostics as indicated to identify the underlying cause. The role of increased circulating concentrations of cardiac troponin I (CTnI) in diagnosis and response to treatment is evolving.²⁵⁶

Treatment. Treatment for HCM should be based on physical examination and radiographic, electrocardiographic, and echocardiographic findings. The goals of drug therapy, depending on the severity of disease, include improvement in diastolic ventricular filling and treatment or prevention of pulmonary edema and thromboembolism. Drug therapy may not be indicated in asymptomatic cats. Left atrial enlargement, outflow obstruction (left ventricular), or serious cardiac arrhythmias are, however, indications for drug management.¹⁹⁰

Acute pulmonary edema requires both oxygen and diuretic therapy. Diuresis generally is accomplished with furosemide. In severe cases of acute edema, nitroglycerin ointment may be indicated. Improvement in diastolic function generally has been accomplished with either β -blockade or CCBs. Both act to decrease cardiac rate and myocardial contractility. Both propranolol (a β blocker) and diltiazem (a CCB) have been studied. Propranolol, a nonselective β blocker, was the original cornerstone of therapy, although no clinical trial provides evidence of its efficacy in cats.²⁵⁷ Selective β blockers are used long term to increase ventricular volume, decrease contractility, and reduce outflow tract obstruction. The most important effect of β blockade appears to be antagonism of catecholamine effects.²⁵⁷ Benefits in cats include decreased heart rate and reduced severity of left ventricular outflow obstruction. In human patients myocardial perfusion also is improved. Beta blockade may have a minimal effect on systolic function if used at proper doses.²⁵⁷ Note that the oral dose of propranolol should be reduced by 25% to 50% in cats with hyperthyroidism because of increased bioavailability.146

The choice of treatment for HCM may reflect cardiologist preference more than direction by clinical trials. Beta blockade may be preferred in the presence of left ventricular outflow obstruction. A test dose of esmolol may provide further support of a β-blocking drug.¹⁹⁰ A disadvantage of nonselective blockade by propranolol is potential respiratory distress secondary to bronchoconstriction that may accompany blockade of β_2 -receptors of the smooth muscle of the bronchial tree. Both atenolol (atenolol [cats] 12.5 mg once daily orally, increase 50% or administer twice daily if heart rate does not slow sufficiently; treat on an individual basis), a selective β_1 receptor blocker, and diltiazem will minimize the risk of bronchospasm. β blockers also are preferred by some cardiologists if the heart rate is increased. An added advantage of atenolol is once-daily therapy, which may improve owner compliance. Controversy exists regarding preference of propranolol or other β blockers versus diltiazem. Some consideration might be given to selection of β-blockers based on penetrability of the myocardium; atenolol may be characterized by the least penetrability. The role of carvedilol in treatment of feline HCM is currently unclear.

In cats diltiazem has proved efficacious for the treatment of HCM because of its both negative inotropic and chronotropic effects. Compared with propranolol, diltiazem may have the additional benefit of directly enhancing myocardial relaxation and dilating coronary vessels.^{258,259} Comparisons between propranolol and verapamil in human patients with HCM support the additional benefits of CCBs compared with β -blockade. Propranolol caused deterioration of systolic performance without improving diastolic function.

KEY POINT 14-54 The choice of diltiazem versus a β blocker for treatment of feline hypertrophic cardiomyopathy may largely be a matter of clinician preference.

Compared with verapamil, diltiazem can minimally affect the inotropic state of the heart or peripheral vasculature at doses that produce coronary vasodilation.^{258,259} A controlled clinical trial in 17 cats with HCM compared responses to diltiazem, verapamil, and propranolol. Cats receiving propranolol or verapamil in general did poorly, with so few surviving that data analysis was precluded. In contrast, all cats (12) receiving diltiazem improved to the point of becoming asymptomatic with no adverse effects at 1.75 to 2.5 mg/kg orally administrated every 8 hours. Diuretic and aspirin therapies were discontinued without the development of circulatory congestion or thromboembolism. The survival rate for the diltiazemtreated cats was threefold greater than for the propranolol cats. Thickness of the left ventricular wall improved in cats after therapy with diltiazem. Mean heart rate decreased in diltiazem-treated cats; however, heart rate increased during stressful conditions. This might be interpreted as reduction in the resting rate reflects improved cardiac performance rather than depression of electrical activity in the sinoatrial node, which is a more physiologically appealing approach to control of cardiac rate. The authors found that cats receiving diltiazem did not require the addition of propranolol for control of their disease. This might suggest that propranolol (or atenolol) be reserved for cats whose heart rate exceeds 270 bpm.^{258,259} Cats with HCM secondary to hyperthyroidism also appear to benefit from diltiazem therapy.

Two preparations of diltiazem (0.5 to 1.5 mg/kg orally [dog]; 1.75 to 2.45 mg/kg 2 to 3 times daily orally [cat]) are available to facilitate ease of administration. Diltiazem CD can be given at a rate of 10 mg/kg once daily orally. Diltiazem XR is prepared as a capsule that contains four 60-mg pellets (total 240-mg capsule). Cats can be dosed by removing one of the pellets and administering half of the pellet once daily. An intravenous preparation of diltiazem is also available for emergency life-threatening supraventricular tachycardias (0.2 to 0.4 mg/kg administered intravenously, followed by 0.4 mg/kg per minute). Response to therapy is manifested as clinical improvement, including resolution of pulmonary edema and reduction in heart rate.

The role of ACE inhibitors in cats with HCM is not clear. A retrospective study (as reviewed by Baty)²⁵⁶ found that enalapril might improve clinical signs and reduce outflow obstruction. In a clinical study in Switzerland, left ventricular wall thickness was reduced compared with baseline in cats with HCM (n=32) receiving standard therapy (diltiazem 9 mg/ kg once daily, at 6 plus-minus aspirin) with benazapril (0.33-0.75 mg/kg once daily) but did not decrease in cats receiving standard therapy alone.¹⁰⁰ In another study, as reviewed by Abott, outcome measures including echocardiograhic findings and diastolic function were not significantly improved by ramipril compared to placebo in Maine coon cats with HCM but without heart failure. Likewise, 4 months of spironolactone therapy did not improve echocardiograhic indicators of diastolic functioin in a similar colony of Maine coon cats. ^{100a} However, limitations in sample size must be considered before these negative findings are interpreted as evidence against efficacy; assuming proper precautions are taken with use, either an ACE in hibitor or spironolactone might be considered in the treatment of HCM. In her review Baty²⁵⁶ also addressed a large clinical trial comparing atenolol, diltiazem (long acting), and enalapril in addition to furosemide in cats; results were not yet available at the time of publication. The use of these and other drugs known to reduce the impact of neurohumoral signals on myocardial remodeling in the treatment of hypertrophic cardiomyopathy is being defined.

In cats with HCM, only those cardiac arrhythmias that are symptomatic or life threatening should be treated with antiarrhythmic drugs. Examples include sustained or paroxysmal ventricular tachycardia.¹⁹⁰ Prevention of arterial thromboembolism generally should be implemented as previously discussed. The use of aspirin for prevention of thromboembolism in cats with HCM, however, remains controversial. Aspirin does impair feline platelet activity when dosed at 25 mg/kg every 3 days. Collateral circulation also may improve.²⁵⁷ Yet no controlled studies provide proof of efficacy. One study reports a 75% incidence of recurrent thromboembolic disease in cats receiving aspirin therapy.²⁵⁷

A small number of cats are afflicted with intermediate or intergrade cardiomyopathies. This poorly categorized and poorly understood form of myocardial disease (often referred to as restrictive cardiomyopathy because of the presence of extensive endocardial fibrosis) is characterized by normal to modestly decreased systolic function, dilated atria, and normal to dilated ventricular chambers. Some cats have mild obstruction or mitral regurgitation. Diastolic dysfunction is generally more detrimental than systolic dysfunction. As with HCM, CHF, pleural effusion, pulmonary edema, and arterial thromboembolism are potential complications associated with these cardiomyopathies. Because of the variable manifestations of this form of myocardial disease, treatment likewise is variable and not clear. Furosemide is indicated for control of pulmonary edema and pleural effusions. Caution is recommended when a β -blocker or a CCB is used in the presence of decreased diastolic function. Nitroglycerin or ACE inhibitors may be indicated in some cases. Digoxin is indicated in the presence of atrial tachycardia or fibrillation associated with reduced systolic function. Supraventricular tachycardia that does not respond to digoxin may respond to propranolol, atenolol, or diltiazem.

Myocardial hypertrophy associated with hyperthyroidism reflects high volume overload, increased sympathetic tone, systemic hypertension, and the direct effect of thyroid hormones on myocardial contractile proteins. Both systolic and diastolic pressures are often elevated. Increased systemic pressures reflect in part increased vascular resistance caused by high sympathetic outflow, vascular remodeling, and potentially renal disease. A variety of cardiac arrhythmias (ranging from tachycardia to heart block) are associated with hyperthyroidism. Cardiac drugs generally are not necessary, however, if hyperthyroidism is not associated with CHF and in the absence of marked cardiomegaly. Propranolol and diltiazem are beneficial in the patient with HCM associated with hyperthyroidism; verapamil does not appear to be of benefit.^{258,259} In the presence of cardiac disease, diuretics, antithyroid medications, ACE inhibitors or other vasodilators (for hypertension), and digoxin (for DCM) should be used as previously described.

Hypertension

Systemic Hypertension

Systemic hypertension occurs in both cats and dogs, although more commonly in cats, and is associated with a number of underlying causes. The most likely are hyperthyroidism (23% to 87% of afflicted cats) and chronic renal disease. The pathophysiologic cause of hypertension in renal disease is not well known but may include abnormal salt excretion, activation of the sympathetic nervous system or RAAS, altered renopressor mediators, and anemia-induced increased cardiac output.43 Hyperthyroidism apparently causes hypertension by increasing β -receptor number and activity in the myocardium. A thyroid-hormone-specific adenylyl cyclase system mediates the cardiovascular response. Other causes of systemic hypertension include diabetes mellitus, acromegaly, and primary aldosteronism.¹⁹⁰ Occasionally, the recent history may include therapy with steroids (glucocorticoids, progestogens, anabolic steroids).43 An underlying cause cannot, however, be identified for all cases of systemic hypertension.

Clinical signs of hypertension in the cat include signs related to the underlying disease or signs specific to hypertension. The most common sign specific to hypertension is blindness (83% in one study) associated with retinal detachment or hyphema. Less commonly, signs related to cerebral vascular accident (e.g., seizures, ataxia, sudden collapse) may occur. Diagnostic tests may reveal the underlying causes or associated abnormalities that may require medical management.⁴³ Azotemia may not be evident despite chronic renal disease as the precipitating cause. Kidneys may be small. Systolic murmurs and gallop rhythms may be auscultated, but tachycardia is not common. Mild to moderate cardiomegaly may be evident radiographically, but pleural effusion and pulmonary edema are unusual; renal disease will increase the likelihood of abnormal fluid retention. Left ventricular hypertrophy is likely but should not be confused with HCM. Ocular changes are easy to monitor and should be used to establish a baseline before implementation of therapy. Hemorrhage may be present in any chamber of the eye. Retinal hemorrhage should be interpreted as an indication of hypertension. Cats with retinal detachment have a higher pressure than cats without detachment.⁴³ Retinal arteries may be tortuous.

Proper measurement of blood pressure is paramount to successful management of systemic hypertension. Measurements should be taken after an animal has had proper time to acclimate to its surroundings and under conditions of minimal stress.43 Among the indirect methods used to measure systemic blood pressure in cats, the Doppler and photoplethysmographic methods are probably preferred.¹⁹⁰ Care must be taken to follow proper techniques with the appropriate equipment when blood pressure is indirectly measured.43 Several readings should be taken over several days unless contraindicated by clinical signs of hypertension. With indirect methods, normal blood pressure (mm Hg) in the unsedated cat is 118 (Doppler leg method) to 123/81.2 (mean arterial pressure 96.8)⁴³ and in dogs is 133/76 (Dinamap on the tail). Antihypertensive therapy is indicated if the indirect systolic pressure or diastolic pressure is greater than 170 or 100 mm Hg, respectively.43

KEY POINT 14-55 Effective treatment of hypertension is vitally dependent on valid measurement of blood pressure.

Returning systolic pressure to normal (i.e., 120 mm Hg) may be an unrealistic goal of therapy; targeting less than 170 mm Hg in cats is more reasonable.⁴³ Response to therapy should be based on appetite and body weight, ophthalmic examinations, and monitoring of blood pressure. Management of hypertension associated with renal disease should include medical management of that disorder. Additional management includes dietary manipulation (low sodium); diuretics; propranolol; and arterial vasodilators, including α -receptor antagonists, CCBs (amlodipine), hydralazine, and ACE inhibitors.¹⁹⁰ Dietary changes probably should be postponed until drug therapy is stabilized.

Amlodipine is generally the preferred medication for treatment of systemic feline hypertension, followed by a combination of amlodipine with either an ACE inhibitor or a β -blocker in refractory cases. Hydralazine should be reserved for cases that continue to fail to respond, in part because of the potential for activation of the RAAS.⁴³ For cats with severe ocular manifestations or neurologic signs, therapy must be more aggressive. Sodium nitroprusside can be given as a constantrate infusion, but the risk of adverse reactions to this arterial and venous dilator requires administration by an infusion pump with constant monitoring. Alternatively, hydralazine coupled with furosemide can be administered, with the addition of a β -blocker (propranolol or atenolol) if response is not sufficient within 12 hours.⁴³

Long-term management should be based on repetitive monitoring of blood pressure (weekly until the animal is stable at a sufficiently low pressure) and body weight, as well as the underlying disease causing hypertension. If renal disease is the underlying cause, monitoring also should include an ocular examination and serum potassium concentrations. Once control is acceptable, monitoring should take place at 3-month intervals. Multiple drug combinations are more likely to be associated with adverse effects (including sleeping, ataxia, and anorexia).

Emergency treatment of hypertension might be accomplished orally, although a loading dose may be necessary for amlodipine. Nitroprusside tends to be the preferred treatment for intravenous administration because of ease of titration. Acepromazine can be used as well, although its longer halflife precludes titration and hypotension associated with higher doses may negatively affect renal function. Sedation may be an unwanted side effect.

Use of enalapril and amlodipine has been studied in dogs with experimentally induced myocardial infarction. Although both drugs preserved left ventricular volume and function during the healing process, enalapril more effectively limited hypertrophy.²⁶⁰ The role of carvedilol in the management of feline hypertension has not yet been well described.

Pulmonary Hypertension

The pulmonary vasculature is a low-resistance, low-pressure, high-capacitance system. It is influenced by right ventricular cardiac output, pulmonary venous pressure, and pulmonary vascular resistance. Pulmonary hypertension (sustained mean pulmonary arterial pressure [PAP] >30 mm Hg; normal 10 to 14 mm Hg) has been categorized by the World Health Organization, largely on the basis of underlying disease, into five categories: (pulmonary) arterial hypertension (I), (pulmonary) venous hypertension (II), chronic alveolar hypoxia (III), chronic thromboembolic disease (IV), and miscellaneous causes (V). Classes II, III, and IV are most relevant to dogs or cats. As reviewed by Johnson and coworkers^{261a} in a retrospective study of pulmonary hypertension in dogs (n=53), increased venous pressure caused by myocardial disease, including PDA, represented 46% of cases, followed by alveolar hypoxia (pulmonary fibrosis, pneumonia, others; 23%), and thromboembolism (including that associated with heartworm disease; 20%), with 9% of cases associated with miscellaneous causes. Pulmonary vascular changes (in addition to thromboembolism) that influence hypertension include vasoconstriction, and proliferation of smooth muscle and endothelium.

A number of mediators influence pulmonary vascular response. Arachidonic acid metabolites balance one another by either inhibiting (e.g., prostacyclin, released from endothelial cells in response to prostacyclin synthase) or stimulating (e.g., thromboxane, mediated by thromboxane synthase) vasoconstriction, platelet aggregation, and vascular proliferation. Endothelin and serotonin cause potent vasoconstriction and pulmonary arteriolar smooth muscle proliferation and, for endothelin, potentially fibrosis. In contrast, NO and vasoactive intestinal peptides cause vasodilation and inhibit platelet activation and vascular smooth muscle proliferation. In human patients hypertension is associated with a decrease of vasodilatory mediators (e.g., prostacyclin, NO) and an increase in vasoconstrictive mediators (e.g., thromboxane, serotonin, endothelin). The role of mediators in pulmonary hypertension of dogs is not well defined, although endothelin has been demonstrated to be higher in dogs with heartworm disease compared with other diseases that might cause pulmonary hypertension. However, chronic pulmonary overcirculation is associated with pulmonary vascular remodeling in the dog characterized by pulmonary arterial hypertrophy and increased resistance that may exceed systemic pressure, resulting in right to left shunts. In contrast, pulmonary venous hypertension such as that associated with myocardial disease generally is reduced by pulmonary edema with alveolar hypoxia as a compensatory response that minimizes pulmonary perfusion to poorly ventilated airways. Chronic hypoxia also can lead to pulmonary vascular remodeling.

Treatment of pulmonary hypertension in dogs was recently reviewed.^{261b} Treatment of pulmonary hypertension focuses on treatment of underlying disease. Oxygen therapy induces vasodilation and is the only therapy associated with decreased mortality in humans. Vasodilatory drug therapy is implemented if the underlying cause cannot be identified or effectively treated. Vasodilators associated with variable efficacy include hydralazine, CCBs, prostacyclin analogs (e.g., epoprostenol), endothelin receptor antagonists (e.g., bosentan) and PDE inhibitors (e.g., sildenfil). Response and justification for long-term therapy is based on the magnitude by which pulmonary arterial pressure is reduced.

KEY POINT 14-56 Vasodilators are variably effective in the treatment of pulmonary hypertension; treatment is best accomplished if the underlying cause is corrected.

PDE-V is located (in humans) in the pulmonary vasculature and the corpus cavernosum. Other locations may occur in dogs. Inhibition of PDE-V specifically results in accumulation of cGMP. Drugs that specifically targeted PDE-V include, but are not limited to, sildenafil and the longer-acting tadalafil. Sildenafil (2 mg/kg once or twice daily; range 0.5 to 3mg/kg orally every 8 to 24 hours) has been studied retrospectively in dogs (n = 13)with pulmonary hypertension PAP≥ 25 mm Hg at rest for a duration of 3 days to 5 months.²⁶² Underlying causes included chronic pulmonary diseases, valvular heart disease, patent ductus arteriosus, and pulmonary thromboembolism; a cause was not identified in five dogs. Ten of the dogs were receiving concurrent mediations oriented toward treating underlying disease. In six of eight dogs for which PAPW as determined before and after treatment, PAP decreased from 4 to 37 mm Hg at approximately 2 days into therapy. However, systolic pressure also decreased a median of 33 mm Hg (beginning pressure was 135/90 mm Hg). A number of clinical signs resolved among treated dogs, including cardiogenic ascites, which resolved in one of two dogs. Median survival time was increased 91 days. Complications associated with therapy were difficult to discern in part because of the number of other drugs dogs were receiving; one dog died after discharge when treated with nitroglycerin. The reported use of tadalafil in dogs is limited to a case report in a Yorkshire Terrier with idiopathic hypertension.²⁶³ Treatment (1 mg/kg every 48 hours) resulted in a 20% reduction (105 to 80 mm Hg) in pulmonary arterial hypertension. However, systemic hypotension occurred, and the dog was euthanized 10 days after therapy began.

Pimobendan has been effective in reducing (but not significantly) the ratio of pulmonary to systemic vascular resistance in human patients with chronic emphysema^{263a} However, pimobendan was associated with an actue reduction of tricuspid regurgitation flow velocity and NTproBNP in dogs with pulmonary hypertension associated with mitral insufficiency.^{237b}

Hydralazine may induce preferential dilation of the pulmonary arterial tree compared with the systemic vasculature. Hydralazine decreases pulmonary vascular resistance in both normal lungs and in lungs with experimentally induced embolization.²⁶¹ Because hypoxia can worsen pulmonary arterial vasoconstriction, oxygen therapy is critical to the treatment of pulmonary hypertension associated with CMVI. Aggressive diuretic therapy is indicated to reduce pulmonary edema as well as pulmonary hypertension. Bronchodilator therapy may facilitate bronchiolar smooth muscle spasm, facilitating air movement. In humans CCBs (e.g., diltiazem, nifedipine) are effective in only 10% of patients and only at high doses. A 20% reduction in pulmonary arterial hypertension supports long-term therapy.

Prostacyclin is both a systemic and pulmonary vasodilator. When administered by continuous intravenous infusion it improves mortality and exercise tolerance in human patients with primary pulmonary hypertension. Intravenous prostacyclin also improves right-sided heart structure and function.²¹⁰ Prostacyclin analogs are characterized by half-lives longer than the endogenous compound but sufficiently short that constant infusion is necessary. Most problematic is the cost, which is likely to be prohibitively expensive. Examples include epoprostenol (intravenous) and treprostinil (subcutaneous). Two alternative route preparations are available in the U.S. Iloprost is an inhalant form that is administered 6 to 12 times daily; beraprost is an oral preparation administered every 6 hours. A low dose of a systemic PDE III inhibitor may enhance the cAMP-dependent pulmonary vasodilatory response to inhaled prostacyclin.²¹⁰ Studies do not appear to have addressed their use in dogs or cats.

Endothelin-receptor antagonists include bosentan, which targets both ET-A and -B and is approved in the United States. Cost may be prohibitive. Drugs available outside the United States include sitaxentan and ambrisentan, both ET-A antagonists. As such, vasoconstriction is minimized (ET-A blockade), but ET-B remains responsive to endothelin, thus promoting its clearance and contributing to vasodilation.

Theophylline is a nonselective PDE inhibitor. Additional benefits include fair bronchodilation, as well as some antiinflammatory control. However, is can be associated with ventilation perfusion mismatching, particularly with intravenous administration. Therefore oxygenation is important. The impact of theophylline in mismatching in patients suffering from hypertension is not known.

L-arginine, a substrate of NO synthase, anecdotally has been associated with reduction in pulmonary arterial hypertension.

Unless hyperthyroidism is accompanied by renal insufficiency, the degree of hypertension associated with hyperthyroidism generally is mild. Because hyperthyroidism-induced hypertension is due to high adrenergic output (causing increased cardiac inotropy and rate), β blockers are preferred to calcium channel blockers. However, the addition of amlodipine may be indicated in hyperthyroid hypertensive cats with renal insufficiency.

Cardiac Arrhythmias

Treatment of cardiac arrhythmias is not innocuous and should be pursued with caution. The greater the extent of myocardial disease, the greater the risk of cardiac arrhythmias, including sudden death. No clear guidelines have emerged among cardiologists regarding first-choice antiarrhythmics or which arrhythmias should be treated. However, a consensus does indicate that not all arrhythmias require treatment. Arrhythmias associated with sudden death (e.g., ventricular arrhythmias, severe bradyarrhythmias including third-degree heart block), syncope, or clinical signs reflecting myocardial failure such as weakness should be treated.

Supraventricular Arrhythmias

Supraventricular Premature Contractions. Ectopic foci that generate premature contractions in the region of the sinoatrial node, atria, atrioventricular node, or junctional tissue generally are not serious enough to cause clinical signs and, as such, require no medical therapy. If clinical signs are evident, therapy should be directed toward the underlying disease. If antiarrhythmic therapy is deemed necessary, drugs are selected for their ability to slow atrioventricular nodal conjunction (e.g., digitalis glycosides, β - blockers, or CCBs). Drugs associated with negative inotropic effects should be used cautiously if myocardial failure is associated with the supraventricular premature contractions.

Supraventricular Tachycardias

Supraventricular tachycardia includes sinus, atrial, or junctional tachycardia; atrial flutter; and atrial fibrillation. Therapy should be considered for heart rates above 220 or 260 bpm in the dog and cat, respectively. The most likely underlying cause is atrial enlargement resulting from dilation. Sinus tachycardia is the most common type of supraventricular tachycardia in dogs and is generated by increased sympathetic tone. Treatment includes digitalis glycosides (if CHF is present), the β blockers (e.g., nonselective propranolol or the preferred selective blockers atenolol, metoprolol, or carvedilol), the class III antiarrhythmic amiodarone (less ideal), or the CCBs (e.g., diltiazem). The most appropriate drug should be based on the underlying cause of the tachycardia. Atrial tachycardia may reflect an autonomic dysfunction (generally not amenable to treatment) or, less commonly, a reentrant circuit. For reentrant causes, class IA antiarrhythmics (especially quinidine), digitalis, or a ß blocker is indicated. Atrioventricular nodal or junctional tachycardias can be similarly treated.

Gelzer and Kraus²⁶⁴ reviewed the management of atrial fibrillation. Atrial fibrillation occurs in the presence of multiple reentering wavelets; its development is facilitated by a large atrium. The authors²⁶⁴ suggest that treatment is indicated when the average heart rate from a Holter recording exceeds 150 bpm in dogs and at any heart rate in cats with atrial fibrillation. The most efficacious antiarrhythmic drugs are those that increase the wavelength (distance traveled by the depolarization impulse during the refractory period). Although this might be accomplished by either increasing the speed of conduction or increasing the refractory period, the former is not a recognized mechanism of action of antiarrhythmic drugs. Treatment may be unnecessary if the ventricular rate is less than 150 bpm in asymptomatic dogs with no evidence of cardiac disease. Treatment of atrial fibrillation should focus on slowing the ventricular response such that cardiac filling improves and myocardial oxygen demand decreases. In symptomatic dogs the atria can be targeted with class IA drugs (quinidine or, less preferred, procainamide), or conduction through the atrioventricular node can be targeted with digitalis, glycosides, CCBs, or β blockers. Although quinidine prolongs wavelength, its paradoxical acceleration (induced by anticholinergic effects) may increase the ventricular response rate, leading to worsening clinical signs. Quinidine can be used to convert atrial fibrillation to a sinus rhythm in dogs. Successful conversion is, however, generally limited to largebreed dogs with no evidence of underlying cardiac disease and is not recommended in dogs with cardiac failure.

Among the drugs, digitalis probably is the preferred treatment for atrial fibrillation despite the fact that it facilitates the arrhythmia by decreasing the impulse wavelength.²⁶⁴ Although Gelzer and Kraus²⁶⁴ recommend monitoring a trough sample 3 to 7 days after starting therapy, for reasons previously discussed, both a peak and trough sample might be prudent to determine half-life at baseline and in response to therapy. Decreased conduction within the atrioventricular node will decrease the ventricular rate. Additionally, positive inotropic effects may benefit the patient with myocardial failure. Previously mentioned precautions should be followed when negative chronotropes that also are negative inotropes are used; CCBs and β blockers may need to be reserved for patients that have not sufficiently responded to digoxin. According to Gelzer and Kraus,²⁶⁴ a CCB is preferred in animals with a rapid ventricular rate resulting from enhanced sympathetic tone. An exception can be made for acute management, in which case digitalis is begun simultaneously with a CCB; β blockers are generally reserved for cases that do not respond to other drugs. Because of a potential protective effect on the diseased myocardium, however, β blockers might be indicated earlier and perhaps preferentially to diltiazem or other CCBs if chronic activation of the sympathetic system is contributing to cardiac failure.

KEY POINT 14-57 Digoxin is probably the preferred drug for treatment of atrial fibrillation. However, treatment in dogs may not be indicated unless the heart rate exceeds 150 bpm. Atrial fibrillation should be treated in all cats.

Emergency management of supraventricular arrhythmias is indicated in the presence of sustained arrhythmias in patients that are hemodynamically unstable. Beta blocker therapy includes propranolol (0.02-0.06 mg/kg, slow intravenous administration every 8 hours) or esmolol. Esmolol (0.05-0.1 mg/kg intravenously every 5 minutes up to 0.5 mg/kg) has a shorter half-life compared to propranolol. Failure to convert can be followed with CCB therapy with little risk of negative inotropic effects. Diltiazem (0.25 mg/kg intravenously over 2 minutes followed by 0.25 mg/kg every 15 minutes) can be implemented until conversion occurs, up to a maximum dose of 0.75 mg/kg. Verapamil also has been used (0.05 mg/kg, slow intravenous administration up to 0.15 mg/kg).

KEY POINT 14-58 Emergency management of supraventricular or ventricular arrhythmias is indicated in the presence of sustained arrhythmias in patients that are hemodynamically unstable.

Despite the traditional consensus that lidocaine is indicated only for ventricular arrhythmias, Johnson and coworkers¹²⁵ described the impact of lidocaine at a standard dose in five dogs with complex supraventricular arrhythmias. In each case normal sinus rhythm was achieved and then maintained with mexiletine.

Ventricular Arrhythmias

The importance of any ventricular arrhythmia depends on the ventricular rate, duration of the arrhythmia (tachycardia), and the severity of underlying cardiac disease. The clinical sequelae of a detrimentally rapid ventricular rate and insufficient ventricular filling include weakness, syncope, seizures, collapse, and clinical signs indicative of CHF.

Ventricular tachycardias are caused by a variety of underlying disorders, including but not limited to primary cardiac disease, metabolic disorders causing acid-base or electrolyte imbalances, infectious disorders, neoplasia, and trauma. Resolution of the underlying cause is paramount to successful therapy of ventricular tachycardias. Not all ventricular premature contractions require treatment. Generally, ventricular premature contractions that are multifocal, occur more frequently than 25 per minute, or occur in repetitive runs that result in a heart rate of 130 bpm or more should be medically managed. Those that are associated with clinical signs or those that occur in breeds at risk for sudden death (e.g., German Shepherd Dogs, Boxers) might also be treated, although this is controversial.

Ventricular arrhythmias that are considered life threatening should be managed with intravenously administered lidocaine. Generally, a slow intravenous bolus (4 to 8 mg/kg [dogs]; 0.5 to 1 mg/kg [cats]) is followed by a constant infusion (22 to 66 µg/kg per minute [dogs]; 10 to 20 µg/kg per minute [cats]). Once sufficient response has occurred, oral therapy can be phased in. Procainamide can be administered intravenously (2 to 20 mg/kg over 30 minutes followed by a constant infusion of 2 to 40 µg/kg per minute [dogs]; 1 to 2 mg/kg intravenous bolus followed by 10 to 20 µg/kg per minute infusion [cats]) or, in less critical patients, intramuscularly or orally (6.6 to 22 mg/kg every 2 to 6 hours [dogs]) in patients that do not respond to lidocaine. Quinidine also can be used (6.6 to 22 mg/kg orally, intramuscularly every 6 hours). Eradication of the ventricular arrhythmia may not be a reasonable expectation. Insufficient response should lead to confirmation of the

diagnosis; evaluation of acid–base or electrolyte disturbance; and, if necessary, addition of a second class IA antiarrhythmic or β blocker (see discussion of precautions in myocardial failure). Ventricular pacing devices may be necessary for animals that continue to fail to respond to antiarrhythmic therapy.

Response (hemodynamic, antiarrhythmic, and adverse) to a single intravenous bolus dose of procainamide was demonstrated to not differ from a single intravenous dose of lidocaine in dogs with postoperative ventricular arrhythmias.²⁶⁵ Neither drug was associated with undesirable hemodynamic changes. Specific information regarding the study (e.g., doses) could not be found.

Bradyarrhythmias

Bradycardia is defined as a heart rate of less than 70 bpm and usually results from sinus nodal or atrioventricular conduction disturbances. Both conduction and automaticity (decreased) disturbances cause bradycardias. In general, medical management of bradyarrhythmias is unreliable, and placement of a pacemaker device is the preferred method of management.

Sinus brachycardia usually is clinically asymptomatic, with the most common clinical sign being syncope or episodic weakness. For animals that are symptomatic, long-acting anticholinergic drugs (e.g., propantheline) might be helpful. Failure to respond will require pacemaker placement.

Atrioventricular nodal block can be first, second, or third degree, depending on the severity. With third-degree block, there is no conduction between the atria and the ventricles. The ventricular escape rhythm approximates 40 bpm. Pacemaker placement is the preferred method of treatment, but emergency cases can be treated with isoproterenol (constantrate infusion). If the ventricular rate increases in response to atropine, an orally active long-acting (relative to atropine) anticholinergic such as propantheline might be effective. Diphenoxylate reportedly also has been useful.

Pericardial Effusion

Pathophysiology

Accumulation of fluid in the pericardial sac most commonly reflects a disorder of the pericardium but can also occur as a manifestation of myocardial failure.^{190,266} Causes include but are not limited to pericarditis (septic or foreign body), neoplasia, and idiopathic hemorrhage. If accumulation is severe, cardiac tamponade may develop. Increased intrapericardial pressure and diastolic collapse of the right atrium and potentially the right ventricle can result in reduced preload to the left ventricle, decreased cardiac output, and hypotension. Systemic compensatory mechanisms may be activated in an attempt to maintain cardiac output. Chronic disease ultimately can lead to pleural effusion and (in extreme cases) pulmonary edema.

Pharmacologic Management

Because pericardial effusion often does not respond sufficiently to pharmacologic management, pericardiocentesis and surgical alternatives such as pericardiectomy or balloon dilation should be anticipated if the underlying cause cannot be rapidly resolved. In cats with feline infectious peritonitis, high doses of glucocorticoids may decrease the accumulation of pericardial fluid. Glucocorticoids also have been recommended for dogs with idiopathic hemorrhagic pericardial effusion that has not responded to pericardiocentesis.

HYPERTHERMIA

Hyperthermia requires treatment in dogs and cats when temperatures exceed 106° F. Temperatures below 106° F may be beneficial (e.g., inhibition of viral replication, stimulation of white blood cell function). In contrast, temperatures of 107° F are life threatening and may lead to permanent organ damage, alkalosis or superimposed acidosis, electrolyte derangements (hypernatremia or hyponatremia, hypokalemia, hypophosphatemia, and hypocalcemia), disseminated intravascular coagulopathy, and acute renal failure (particularly with exertional heat stroke). Hyperthermia can occur for a variety of reasons, most classified as either true fever (endogenous or exogenous pyrogens directly alter the hypothalamic thermostat) or inadequate heat dissipation (e.g., classic heat stroke or exertional heat stroke associated with excessive exercise). Pathologic hyperthermia is less common and includes malignant hyperthermia, a muscular disorder that appears to reflect drug- (e.g., halothane) induced alterations in calcium kinetics. In all cases treatment begins by removing the inciting cause. Antipyretics (e.g., dipyrone or other NSAIDs) are indicated in situations involving a reset thermostat (i.e., a true fever) but only if the body temperature is 106° F or higher. Injectable preparations are preferred. Relatively selective COX inhibitors (e.g., carprofen) may be equally or more effective than nonselective drugs because prostaglandins formed by COX-2 are responsible for mediating fever.

Phenothiazines may also be beneficial, in part by inducing peripheral vasodilation. Use of α -agonists or other drugs that induce peripheral vasoconstriction is discouraged. Treatment of hyperthermia associated with inadequate heat dissipation focuses on rapid cooling of the body, correction of electrolyte and fluid imbalances, and prevention of complications. Cold water should be avoided for cooling because it may induce vasoconstriction, decrease heat dissipation, and rebound hyperthermia.²⁶⁷ Spraying the patient with cool water in the presence of fans is the preferred method of cooling. Crystalloid therapy should be aggressive; colloidal therapy may be indicated. The use of NSAIDs in treatment of hyperthermia resulting from inadequate heat dissipation should not be ruled out, in part because of the inhibitory effects timely administration of these drugs can have on multiorgan failure associated with cytokine and other mediator release. Malignant hyperthermia is less likely to respond to external cooling, although this should be implemented; bromocriptine and neuromuscular paralysis (e.g., pancuronium) may help control muscle rigidity.²⁶⁷

SHOCK

Shock reflects a state in which tissue perfusion is inadequate to meet tissue metabolic needs.²⁶⁸ Tissue perfusion may be inadequate because of low or unevenly distributed blood flow.²⁶⁹ Selection of the most appropriate therapy is facilitated by categorizing shock first as to the functional disturbance and second as to primary cause.

Classification Of Shock

Hypovolemic Shock

Hypovolemic shock is one of the more common causes of shock in small animals.²⁶⁸ Causes include but are not limited to hemorrhage, trauma, and severe dehydration such as that which accompanies renal dysfunction, vomiting, or hypoadrenocorticism.²⁶⁹ Physiologically, hypovolemic shock can present in three stages. The earliest stage is accompanied by compensatory mechanisms (e.g., increased heart rate, increased vascular resistance) designed to maintain blood pressure. As volume loss progresses, the second or middle stage is characterized by tachycardia with low systemic blood pressure and hypothermia. Capillary refill time is prolonged, and pulse pressure is poor. Blood is shunted away from less vital organs to the brain and heart, and blood clotting abnormalities may be accompanied by increased capillary permeability. Urine output decreases. If hypovolemia persists, the final stage of decompensation occurs. This stage is largely irreversible²⁶⁸ and is characterized by vascular dilation and pooling of blood in peripheral tissues. Poor cardiac filling leads to insufficient cardiac and brain perfusion. Death reflects myocardial failure, cardiac arrhythmias, respiratory failure associated with pulmonary edema, and cardiopulmonary arrest.²⁶⁸

Cardiogenic Shock

Cardiogenic shock is a state of low cardiac output associated with diastolic or systolic dysfunction. The heart is unable to function as a pump, and blood delivery to organs is insufficient. Causes include myocardial failure (acquired or congenital) and cardiac arrhythmias. Iatrogenic cardiogenic shock also can be drug induced.²⁶⁹ Clinically, because the underlying cause of shock is inadequate blood flow, cardiogenic shock presents similarly to hypovolemic shock, with the primary difference of increased atrial filling pressures accompanied by pulmonary edema.²⁶⁹

Distributive Shock

Distributive shock occurs when blood flow is distributed improperly to tissues. Improper distribution reflects a rapid, marked increase in peripheral vasodilation, vascular capacitance, and peripheral pooling of blood.²⁶⁹ Causes generally include those associated with the release of vasoactive mediators, most notably endotoxemia (see Chapter 8) or other causes of sepsis and anaphylaxis or anaphylactoid reactions. Injured and ischemic tissues (e.g., due to hypovolemic or cardiogenic shock) also lead to the release of vasoactive and procoagulant mediators. Vascular occlusive diseases such as saddle thrombi and pulmonary thromboembolism (e.g., dirofilariasis) also cause distributive shock.²⁶⁹ For example, with sepsis distributive shock might initially be "warm" in that blood flow is increased in peripheral tissues. As shock progresses and venous pooling continues, fluid is lost from the vascular space, venous return decreases, cardiac output decreases, and tissues become underperfused or "cool."

Pathophysiology

Ideally, treatment of shock should focus on early reversal based on the underlying cause. As shock progresses, the underlying pathophysiology is the same, and treatment is oriented toward prevention and reversal of inadequate tissue perfusion. Some type of damage is likely to occur in any tissue subjected to a period of hypotension (mean arterial blood pressure <50 mm Hg). These include cell ischemia, inadequate oxygen delivery, and the generation of proinflammatory/procoagulant mediators.²⁶⁹

Sequelae of cellular ischemia. Tissues suffer damage from inadequate tissue oxygenation in 5 to 10 minutes, and the damage is irreversible at 15 to 20 minutes.²⁶⁹ Mitochondrial dysfunction accompanies ATP depletion, leading to anaerobic metabolism and lactic acid accumulation. Cell membrane (ATPase) pumps become disrupted, and intracellular destructive enzymes are released. Accumulation of intracellular calcium leads to the activation of enzymes that disrupt cellular homeostasis. Intracellular sodium and chloride increase, and magnesium and potassium decrease. ATP breakdown yields hypoxanthine and generation of xanthine oxidase (converted from xanthine dehydrogenase), which produces oxygen free radicals.²⁶⁹ With reperfusion, hyperemia occurs once blood flow is reestablished if the period of impaired oxygenation or poor tissue perfusion is short. The duration of hyperemia is determined by the extent of mediator release (potassium, hydrogen, NO, adenosine, adrenomedullin, the latter a hypotensive peptide first discovered in pheochromocytomas). On the other hand, if blood flow is less than 20% of normal for longer than 5 minutes, reperfusion after perfusion failure leads to reoxygenation injury. Injury reflects the production of selfdestructive enzymes and metabolites and derangements in blood clotting.²⁶⁹ Together the consequences of reperfusion injury include uneven distribution of blood flow and focal ischemia (perhaps exacerbated by inappropriate thrombosis), swelling of capillary endothelial cells and subsequent plugging by leukocytes migrating to the area, and increased microvascular viscosity and interstitial edema.269

Oxygen free radicals. The generation of oxygen free radicals by mitochondria, macrophages, and neutrophils sets the stage for reperfusion injury should blood flow be reestablished after a sufficiently long period of poor perfusion, causing perhaps the most detrimental sequelae of shock²⁶⁹ Xanthine oxidase metabolizes molecular oxygen into radicals such as superoxide anion, hydrogen peroxide, and the hydroxyl radical (see Chapter 29). Enzymes that normally scavenge oxygen free radicals (e.g., superoxide dismutase, catalase, and glutathione) are overwhelmed as tissues reperfuse. Production of oxygen free radicals is exacerbated by mediators released in response to oxygen free radicals, including cytokines (including TNF), interleukins (which also induce procoagulant activity), and prostaglandins.²⁶⁹

Role of nitric oxide. NO can be either protective or detrimental in the patient with sepsis and endotoxemia. Under basal physiologic conditions, NO serves as a free oxygen radical scavenger, limiting toxicity associated with superoxide and other radicals. Inhibition of platelet aggregation and leukocyte adhesion limits ischemia–reperfusion injuries.²¹ During shock large amounts of iNOS are formed; as such, NO becomes a major contributor to the pathophysiology of shock.^{21,269} Peroxynitrous acid, generated from the reaction of NO with oxygen free radicals, destroys cellular macromolecules, causing mitochondrial and cell membrane dysfunction, production of prostaglandins, and programmed cell death (apoptosis). The coagulation cascade is activated, ultimately leading to disseminated intravascular coagulation. Arteriovenous shunting (possibly caused by iNOS) contributes to maldistribution of blood flow, particularly in endotoxic and other septic shock, and may be a cause of irreversibility.²⁶⁹

Thus, although the initial responses of the body to iNOS might lead to important compensatory responses, ultimately the responses may prove to be detrimental. Nevertheless, inhibition of NOS is undesirable because systemic vascular resistance is improved only at the cost of loss of blood flow to vital organs. Platelet aggregation increases, along with the risk of thrombus formation and disseminated intravascular coagulation.²⁶⁹ Analogs of L-arginine, such as L-NAME (*N*-nitro-L-arginine methyl ester) competitively inhibit NO production by either cNOS or iNOS from L-arginine. Treatment of human patients in septic shock with L-NAME, however, led to pulmonary hypertension and reduced cardiac output.²⁷⁰ Drugs that selectively inhibit iNOS but not cNOS may be a more appropriate focus of investigation.

Gastrointestinal barrier. The sequelae of ischemia and hypoxia in the gut have profound clinical implications for the patient undergoing shock. Potent vasoconstrictors (endothelins), cytokines, and other mediators act in concert with leukocyte migration and epithelial necrosis to increase capillary permeability, transcapillary fluid filtration, and interstitial edema. Diarrhea is a common clinical complication of resuscitation from shock and may indicate the loss of the protective mucosal barrier in the gastrointestinal tract. Bacterial translocation and endotoxin absorption result in release of massive quantities of proinflammatory mediators, predisposing the patient to septicemia and, ultimately, to the systemic inflammatory response syndrome (see Chapter 29).²⁶⁹ This syndrome is characterized by multiorgan dysfunction.

The compensatory mechanisms implemented to counter the pathophysiologic sequelae (decreased tissue perfusion and oxygen delivery) of shock involve the neural, hormonal, and renal reflexes previously described for cardiovascular diseases. Vasoconstriction maintains arterial blood pressure and redistributes blood flow to vital organs (cerebral and coronary vessels). Cardiac output is increased by increasing heart rate and a fluid shift from interstitial to intravascular sites. Although compensatory mechanisms support the patient during the initial stages of shock, increased vascular resistance and myocardial oxygen demand ultimately will contribute to the demise of the patient.

Treatment

Successful therapy for shock focuses on reestablishing blood flow, blood pressure, and blood volume to normal or above normal (see Table 14-4).²⁶⁹ Monitoring response to therapy can, however, be difficult. Muir²⁶⁹ recommends that response to therapy and a good prognosis be based on frequent monitoring of behavior, level of consciousness, arterial blood pressure, tissue oxygenation, heart and respiratory rate and rhythm, mucous membrane color, capillary refill time, and urine output. Clinical pathology data should focus on packed cell volume, total protein, and serum lactate.

KEY POINT 14-59 Successful therapy for shock focuses on reestablishing blood flow, blood pressure, and blood volume to normal or above normal.

Treatment of shock should maximize tissue perfusion and oxygen delivery to and consumption by peripheral tissues and minimize the effects of proinflammatory and procoagulant mediators. For septic shock (discussed more extensively in Chapter 8) therapy also focuses more aggressively on prevention of endotoxin release and its effects. Regardless of the cause of shock, appropriate therapy is summarized by the acronym VIP: Ventilation to facilitate blood oxygenation, Infusion of fluids to restore blood volume, and support of the myocardial **P**ump to facilitate blood delivery (flow) to tissues.²⁶⁹

Fluid therapy. Fluid therapy should be aggressive but not overzealous. Care should be taken not to reduce packed cell volume and total protein to less than 20% and 3.5 g/dL, respectively, to minimize the risk of pulmonary or interstitial edema. Administration of hypertonic saline provides rapid but short-term (30 to 120 minutes) hemodynamic improvement in hypovolemic or endotoxic shock; duration of improvement can be extended if hypertonic saline is combined with a colloid.

Blood and blood substitutes. Treatment of hypotensive shock secondary to hemorrhage in which 25 mL/kg or more of blood is lost should include whole blood or packed red blood cells. Blood substitutes should be used when blood products are not available or for animals for which the risk of a transfusion reaction is too great.

Pressor drugs. Positive inotropic drugs are indicated to maintain arterial blood pressure and regional blood flow in patients whose myocardial function does not improve sufficiently after administration of fluids. Pressor drugs also are indicated for patients whose cardiac contractile activity is compromised. Dopamine and dobutamine have been the preferred pressor drugs; dopamine may be preferred for bradycardic animals. ²²⁹ Improved blood flow to the gastrointestinal tract will help minimize the risk of gastrointestinal mucosal damage and subsequent multiorgan failure.²²⁹ Volume replacement must occur before either drug can be used successfully. Refractory hypotension is often associated with septic shock. Underlying mechanisms include vasopressin deficiency, activation of ATP-sensitive K⁺ channels (in response to accumulation of lactate and hydrogen), and overproduction of NO (which precludes vascular smooth muscle contraction). Activation of K⁺ channels causes hyperpolarization, precluding interaction of vasoconstrictors with smooth muscle receptors. Among the current therapies is treatment with vasopressin. ^{269a} In patients with septic or hypovolemic shock, vasopressin is released biphasically. Osmotic overstimulation may cause rapid release of endogenous vasopressin. However, only 20% of the total pool is available for rapid release. Slower release results in relative deficiency by 1 hour of sustained hypovolemic shock in humans. Whereas arterial pressure is minimally affected in healthy subjects, patients in vasodilatory shock express an exaggerated response to exogenous vasopressin therapy. Mechanisms include replacement of endogenous stores, inhibition of K⁺ channels, and decreased synthesis of nitric acid. Treatment at physiologic doses (0.01-0.04 units [70-kg human adult]) has been described as the best vasopressor drug; doses of first-line vasoproessors can be reduced, thus reducing the risk of adverse effects with these drugs. The drug can be given intratracheally.^{269b} Yoo^{269c} described a vasopressin dose determination study in dogs with experimentallyinduced hemorrhagic shock. A dose of 0.4 IU/kg was the most effective dose, providing more hemodynamic response in decompensated shock compred to 1.6 IU/kg. Treatment ideally occurs when endogenous concentrations are lowest. Other benefits of vasopressin include increase urine output; improved cerebral, coronary, and pulmonary blood flow; and increased serum cortisol. Side effects occurring at nonphysiologic doses include platelet aggregation and renal, mesenteric, pulmonary, and coronary vasoconstriction. Vasopressin should be used only with caution in patients with cardiovascular disease. The use of glucocorticoids may be indicated in patients non-responsive to pressor agents as a result of functional adrenocorticodeficiency (See Chapter 30).

Miscellaneous drugs. The use of drugs intended to minimize the damage of oxygen free radicals has not been well established in animals such that a standard protocol can be followed. The use of glucocorticoids is controversial (see Chapter 30). Their potential benefits to the endotoxic shock patient have been delineated. In general, the efficacy of these products to limit vascular response to vasoactive compounds depends on the time of administration. Efficacy is greatest when administered before or within several hours of the onset of the pathophysiologic response to shock. Although survival (several hours) has been documented after use of glucocorticoids (compared with placebo) in human and animal clinical trials, long-term survival (beyond several days) has not been documented. Use of glucocorticoids in human patients with endotoxic or septic shock has been associated with an increased risk of infection in some studies but no increased risk in others. The use of glucocorticoids in veterinary medicine remains controversial. Of the drugs to be used, methylprednisolone may be preferred in most causes of shock because of its potential ability to scavenge oxygen free radicals. Administration should be short term.

KEY POINT 14-60 The use of drugs intended to minimize the damage of oxygen free radicals has not been well established in animals.

A number of NSAIDs have been studied for their ability to block response to mediators of endotoxic shock. Indomethacin and ibuprofen have shown efficacy in human patients. Flunixin meglumine has been studied in dogs. As with glucocorticoids, however, the effects of NSAIDs must be realized within the first 2 hours of the onset of endotoxic shock (i.e., before mediators have been able to stimulate response). Prolonged therapy with NSAIDs is not advised because of toxic effects. Although gastrointestinal toxicity is the major concern in most animals, the patient suffering from endotoxic shock may be more predisposed.

Despite the lack of scientific data to support clinical response to drugs that scavenge oxygen free radicals, their use should be strongly considered, particularly if there is little risk of toxicity (See Chapter 29).

The use of antimicrobials in patients suffering from or predisposed to endotoxic or septic shock is discussed elsewhere (see Chapter 8). Patients that have suffered vascular compromise are at risk of suffering the consequences of translocation of enteric pathogens. Prophylactic therapy should be oriented toward minimization of gastric erosion or ulceration (see Chapter 19) and selective decontamination of the digestive tract (targeting gram-negative aerobic pathogens). In humans oral antimicrobials that are not absorbed are recommended: a paste containing 2% polymyxin, 2% tobramycin, and 2% amphotericin (to target fungal organisms) for the oral cavity and a solution of polymixin (100 mg), tobramycin (80 mg), and amphotericin B (500 mg) for the gastrointestinal tract (about 0.1 mL/kg every 6 hours) have been recommended.²⁷¹ However, this therapy is intended to reduce the incidence of nosocomial infections in the intensive care environment. The incidence of pneumonia, urinary tract infections, and catheter-related septicemia can be decreased. The role of selective digestive decontamination in patients subject to shock (with the exception of endotoxic shock) is less clear.

Cardiopulmonary Cerebrovascular Resuscitation

Generally, the goal of cardiopulmonary cerebrovascular resuscitation (CPCR) is to maintain or preserve neurologic function. It is beyond the scope of this chapter to discuss the causes of and recognition of the need for CPCR. Obviously, prevention is the key to success, and treatment of underlying diseases likely to cause cardiopulmonary arrest should be reviewed. Success is more likely if the cardiopulmonary arrest is associated with reversible conditions (e.g., anesthetic overdose, upper airway obstruction, hemorrhage, electrolyte imbalances). The focus of this discussion is on drugs used in CPCR. Which drugs are proper and when their use is indicated in the patient are controversial. Cardiac rather than respiratory arrest is discussed. The pharmacologic effects, side effects, and other pertinent clinical pharmacologic data for each of the drugs have been discussed elsewhere; discussion here is limited to the use of the drugs during or immediately after CPCR.

"Crash Cart" Drugs

Drugs that should be carried in a crash cart include epinephrine, atropine, magnesium chloride, naloxone, lidocaine, sodium bicarbonate, and bretylium tosylate.²⁷²

Epinephrine remains the mainstay of acute cardiac life support. It is intended to promote systemic vasoconstriction such that blood flow is diverted to the coronary and cerebral circulation. It is indicated for pulseless ventricular tachycardia, ventricular fibrillation, electromechanical dissociation (pulseless electrical activity), and ventricular asystole. The standard dose is 10 to 20 μ g/kg (1 mg in humans) or 10 mL of a 1:10,000 solution repeated every 3 to 5 minutes. The optimal dose may be very high, ranging from 0.45 to 2 mg/kg (Table 14-4). For humans the American Heart Association has recommended a fivefold increase in the dose to 5 mg if there is no response to the initial 1 mg dose.²⁶⁷

KEY POINT 14-61 Epinephrine remains the mainstay of acute cardiac life support.

Atropine has little indication in CPCR with the exception of bradycardia, pulseless electrical activity, and ventricular asystole. The dose for electromechanical dissociation and asystole is 1 mg intravenously, repeated every 3 to 5 minutes. In humans complete vagal blockade occurs at 0.04 mg/kg (3 mg); this dose is discouraged. Likewise, a total dose below 0.5 mg can cause parasympathomimetic effects and also is discouraged.²⁶⁷

Isoproterenol is a pure, nonselective β -agonist drug. As such, it is a positive inotrope but can also cause peripheral vasodilation. It will increase myocardial oxygen demand. Currently, its use is limited to bradyarrhythmias that do not respond to atropine.²⁷²

Bicarbonate provides little benefit and may in fact harm patients in metabolic acidosis. Acidosis associated with cardiac arrest is best treated with ventilatory and circulatory support. Potentially harmful effects of bicarbonate include arrhythmogenic alkalemia; increased generation of CO₂; hyperosmolarity; hypokalemia; paradoxical central nervous system and myocardial intracellular acidosis; and a leftward shift in the oxyhemoglobin dissociation curve, limiting delivery of O2 to tissues.²⁶⁷ When used, bicarbonate therapy ideally should be guided by blood gas analysis (pH <7.15 to 7.2).²⁶⁷ Indications or situations in which bicarbonate may prove beneficial for humans requiring CPCR include hyperkalemia; tricyclic antidepressant overdose; prolonged cardiac arrest (protracted hypoperfusion-induced acidosis); and postresuscitation, bicarbonate-responsive, and anaerobic lactic acidoses.²⁶⁷ Sodium bicarbonate (1 mEq/kg intravenously) may be used after epinephrine in patients suffering from a prolonged cardiac arrest who have shown improvement in cardiovascular or cerebral recovery. It should be followed by correction of any deficit (monitored) that is greater than 5 mEq/kg. The bicarbonate-induced hypercarbia tends to be transient and generally harmless to the heart if used in conjunction with epinephrine.272

KEY POINT 14-62 Bicarbonate provides little benefit and may in fact harm patients in metabolic acidosis.

Calcium administration does not appear to enhance cardiac performance during CPCR. Ischemia associated with cardiac arrest causes intracellular accumulation of calcium, which can disrupt membranes and uncouple oxidative phosphorylation. Calcium can cause coronary vasospasm and will exacerbate the arrhythmic tendency of the unstable myocardium and impair relaxation.^{267,272} It will also exacerbate digoxin toxicity. Calcium causes precipitation when combined with sodium bicarbonate. Calcium is not recommended except in cases of prolonged cardiac arrest or absent or ineffective pump activity. Calcium chloride (10% solution contains 100 mg/mL Ca²⁺) is associated with the longest and most predictable increase in plasma ionized calcium.²⁷² In human patients 1 g of calcium chloride (approximately 15 mg/kg) is generally sufficient, although toxicity may occur at this dose. Other indications for calcium include hyperkalemia, ionized hypocalcemia, and CCB overdose.²⁶⁷

Crystalloids (including hypertonic resuscitation and balanced electrolyte solutions) are indicated if the cause of cardiac arrest is hypovolemia. Inappropriate fluid load can, however, contribute to decreased cerebral blood flow and decreased coronary blood flow.²⁷² The production of lactic acid will be enhanced in critically ill hyperglycemic patients, which can lead to or contribute to cell injury. Dextrose infusions are considered by the American Heart Association to be harmful to humans.²⁶⁷ As such, dextrose-containing fluids should be avoided. Isotonic saline or Ringer's lactate is preferred as the resuscitation fluid.

KEY POINT 14-63 If crystalloid therapy is indicated in the shock patient, isotonic saline containing fluids free of dextrose is indicated.

Several routes of drug administration can be used to support resuscitation. Central venous catheter placement is ideal for immediate drug delivery to the heart. A sufficient bolus of a compatible isotonic fluid should follow any drug administered through peripheral tubing. Intracardiac injections probably offer no increased benefit compared with central intravenous administration. Potential complications include cardiac tamponade, coronary vessel laceration, and pneumothorax. Intracardiac bolus may destabilize the electrical properties of the heart.

Alternative routes of administration can be considered in the absence of venous access. Intratracheal administration is an effective alternative route to central intravenous administration for selected drugs during CPCR.²⁷² In general, the dose is doubled and the drug is administered through a catheter in 10 to 20 mL of liquid for the drugs to reach the alveoli, where they will be subsequently absorbed. Insufflation will facilitate drug absorption. Doses of all drugs administered intratracheally should be increased by twofold to 2.5-fold. The duration of action of the drugs may be longer after intratracheal administration than after intravenous administration. Drugs shown to be effective after intratracheal administration include epinephrine, lidocaine, atropine, and naloxone. There are several drugs that should not be given via intratracheal administration because of the risk of tissue damage. Examples include sodium bicarbonate (depletes surfactant), norepinephrine, and calcium chloride.²⁶⁷ Drugs should not be mixed in the same syringe before intratracheal administration.

Table 14-4 Crash Cart Drugs						
Drug	Indication	Dose	Comments			
Amiodarone	Defibrillation	*5-10 mg/kg IV				
Atropine	Bradycardia, asystole, PEA	0.022-0.04 mg/kg IV	Repeat at 3 to 5 intervals as needed. Avoid more than 0.04 mg/kg and less than 0.5 mg total dose; exception may be PEA, which may require 0.4 mg/kg IV			
Bicarbonate	Hyperkalemia, prolonged cardiac arrest	1 meq/kg IV	Therapy should be guided by blood gases and generally is reserved for resuscitative attempts lasting longer than 20 minutes. Ventilatory sup- port critical.			
Bretylium	Ventricular flutter	5-10 mg/kg IV				
Calcium chloride	Prolonged cardiac arrest with ineffective activity, severe hypocalcemia, severe hyperkalemia	15 mg/kg slow IV	Monitor electrocardiogram. 10% solu- tion of calcium chloride contains more calcium per mL than other calcium salts			
Calcium gluconate	Prolonged cardiac arrest with ineffective activity, severe hypocalcemia, severe hyperkalemia	10 mg/kg/hr in any fluid	Monitor electrocardiogram. 10% solu- tion of calcium gluconate contains less calcium per mL than calcium chloride.			
Dexamethasone	Pulseless idioventricular arrhythmia	2-4 mg/kg IV				
Dobutamine	Positive chronotrope, positive inotrope	2.5-10 μg/kg/min (D)	Any IV fluid			
Dopamine hydrochloride	Positive chronotrope, positive inotrope Low dose (renal vasodilation) Mid dose High dose	5-20 μg/kg/min, to effect 1-4 μg/kg/min 5-10 μg/kg/min 10-20 μg/kg/min	Any nonalkaline IV fluid			
Epinephrine	Fine ventricular fibrillation, PEA, asys- tole, positive inotropic and vascular support, status asthmaticus	10-20 µg/kg (0.02 mg/kg)	Repeat at 3- to 5-minute intervals as needed. Up to 0.2 mg/kg total dose may be indicated. IV(double dose if IT)			
		10 mL of 1:10,000 sol	Repeat at 3- to 5-minute intervals as needed			
		0.005-1.5 μg/kg/min, to effect CRI				
Flumezanil	Diazepam reversal	0.02 mg/kg, IV				
Isoproterenol	Bradyarrhythmias		Limit to atropine nonresponders			
Lidocaine	Ventricular tachycardia, flutter	Initial dose: 2-6 mg/kg	May be of more benefit post-resuscita- tion; use in 5% dextrose. 0.9% NaCl less preferred			
		Followed by: 25-80 µg/kg	•			
Magnesium chloride	Ventricular tachycardia Ventricular flutter	5-10 ml of 2% solution, IV 25 to 40 mg/kg, IV	IV over 5 minutes followed by CRI			
Magnesium sulfate 25%	None	Up to 1 mEq/kg/day	5% dextrose, diluted to <20%			
Naloxone	Narcotic reversal, PEA	0.02-0.04 mg/kg, IV				
Nitroprusside	Hypertensive crisis	1-10 μg/kg/min	5% dextrose			
	Pulmonary edema	0.5-5 μg/kg/min.	Start low, and increase slowly. Monitor blood pressure			
Procainamide	Ventricular tachycardia, flutter	4-8 mg/kg IV	40-60 μg/kg/min			
Vasopressin	Vascular support, asystole Post-resuscitation vascular support	0.04 to 0.8 units/kg, IV 0.001 units/kg/hr				
Yohimbine	Anesthetic reversal	0.1 to 0.2 mg/kg, IV				

IV, Intravenous; *PEA*, pulseless electrical activity; *IT*, intratracheal; *CRI*, constant-rate infusion. *Chemical defibrillation (in absence of electrical defibrillation): 1 mg potassium chloride and 6 mg acetylcholine/kg, followed by 1 mL/10 kg 10% calcium chloride. Amiodarone also has been suggested at 5-10 mg/kg IV. Chemical defibrillation is rarely effective.

Intraosseous administration is another alternative to intravenous use in small animals. The bone marrow provides a large venous access; the most common sites during CPCR are either the trochanteric fossa of the femur or distal cranial femur.²⁷²

Specific Conditions

Cardiac asystole refers to the complete absence of electrical activity. Therapy is oriented toward stimulating any electrical activity and then modifying the activity to generate a rhythm with a pulse.²⁶⁷ Epinephrine generally remains the drug of choice for cardiac arrest. Doses should be sufficient (> 0.01 mg/ kg) to cause positive inotropic and peripheral vasoconstrictive effects yet low enough (<0.2 mg/kg) to avoid ventricular fibrillation. In an experimental model of cardiac arrest in dogs, declining renal function was positively correlated with the amount of epinephrine administered and the energy required for defibrillation.²⁷³ Because of its short duration of action, epinephrine should be administered every 3 minutes. Longer-term inotropic support should be provided with a less effective pressor drug such as dopamine or dobutamine. Electrolyte imbalance should be treated with the appropriate electrolyte. Bicarbonate is useful only in the previously described indications.

Ventricular fibrillation is best converted to a normal rhythm by electrical defibrillation. Potassium chloride, bretylium, and magnesium chloride have been used to pharmacologically treat defibrillation in the dog. Among these, magnesium chloride (5 to 10 mL of a 2% solution administered intravenously) may be best. Once an organized rhythm has been established, epinephrine may be beneficial for increasing vascular tone and improving blood flow to the brain. The initial dose should be low (0.02 mg/kg) and increased tenfold (0.2 mg/kg) in nonresponsive patients. Very high doses may, however, excessively increase myocardial oxygen demand. Lidocaine may prove useful for "coarsening" fibrillation, rendering it more amenable to electroconversion. In addition, it may increase vascular tone response to epinephrine.²⁶⁷ Bretylium has proved useful in some human cases of refractory ventricular fibrillation. The drug is administered immediately (1 minute) before electrical defibrillation. Refractory cases also may require correction of severe acidosis. Precaution is, however, taken to ensure that the pH is increased to no higher than 7.5 because of increased resistance to defibrillation.267

Ventricular tachycardia also is most amenable to electrical shock. Lidocaine is the drug of choice for control of ventricular tachycardia. Alternatives include procainamide (and, for humans, bretylium). Magnesium sulfate (25 to 40 mg/kg intravenously over 5 minutes) may be useful in refractory cases or in cases of ventricular flutter; constant-rate infusion over 4 to 8 hours is indicated if the patient responds.

Electromechanical dissociation (EMD; pulseless electrical activity) generally is fatal when caused by myocardial diseases. Treatable causes in humans include hypovolemia (e.g., acute blood loss, which should be treated with volume replacers), pericardial tamponade, and tension pneumothorax.²⁶⁷ Epinephrine or atropine (0.04 to 0.08 mg/kg intravenously) may be useful when EMD is associated with hypotension or pleural or pericardial disorders. Pulseless electrical activity

is likewise accompanied by a poor prognosis, although naloxone, dexamethasone sodium phosphate, and calcium have been recommended. Calcium is most likely to be of benefit with hypocalcemia or extreme hyperkalemia.²⁶⁷

Bradyarrhythmias are most amenable to nondrug therapy. The slower the rate and the wider the ventricular complex on the electrocardiogram, the more ineffective will be the cardiac contractility.²⁶⁷ Atropine is most useful with narrow complex bradyarrhythmias. However, atropine should be used cautiously such that potentially lethal tachycardia might be prevented in hypoxic patients. A low dose (0.022 mg/kg) is indicated unless vagolytic arrest is present. Dopamine and epinephrine may be helpful for inotropic support. Isoproterenol is controversial because of peripheral vasodilation.

Anesthetic or narcotic overdoses should be reversed if posssible. Naloxone (0.02-0.04 mg/kg intravenously) is indicated for any narcotic. Yohimbine or atipamezole (0.1 to 0.2 mg/kg intravenously) is indicated in the presence of α -2 antagonists and may be effective for other chemical restraining agent, including ketamine or barbiturates.^{267a,b} Flumazenil (0.02 mg/ kg intravenously) is indicated for reversal of diazepine depressant effects.

Postresuscitation monitoring and care are critical to successful CPCR. Dobutamine is preferred to dopamine by many clinicians for postresuscitation inotropic support. SBP should be maintained above 90 mm Hg. Urine formation should be maintained at 1 to 2 mL/kg per hour. Furosemide may be indicated in the face of decreasing urine output. Neurologic function should be assessed along with the need for iron chelators, CCBs, or oxygen free radical scavengers. Vasopressin (0.04 to 0.8 units/kg intravenously or 0.001 units/kg/hr) may be indicated in patients whose vasculature remains nonresponsive to epinephrine.

HYPERLIPIDEMIA

The metabolic pathway of lipid formation and metabolism is complex,^{274,275} offering several targets of pharmacologic control. Although coronary artery disease associated with atherosclerotic plaques is not a disease of dogs and cats, drug therapies for the disease play role in the treatment of hyperlipidemias in animals. As such, an in-depth discussion of lipid metabolism is warranted. Lipoproteins are macromolecules consisting of lipids (cholesterols, triglycerides, phospholipids) and proteins (apolipoproteins or apoproteins; e.g., apo-A [I-V], apo-B, apo-C [II and III], and apo-E). Together, cholesterol and triglycerides comprise the major lipid particles in the body, with each having important functions. Cholesterol provides stability to cell membranes, facilitates membrane transport, and serves as a basis for the synthesis of steroids and bile acids. Triglycerides serve as a source of energy storage, being lightweight compared to glycogen. Cardiac and skeletal muscle extract triglycerides from circulating proteins and, through lipolysis, convert them to fatty acids as an energy source (Kreb's cycle for ATP production and gluconeogenesis in selected tissues) and glycerol.

Both cholesterol and triglycerides are insoluble in water, and as such they circulate as lipoproteins, with apoproteins providing structural rigidity to lipoproteins. However, the proteins also serve as ligands or cofactors in lipoprotein metabolism. Spherical lipoproteins are structured such that the most water-soluble components (apoproteins, phospholipids, and unesterified cholesterol) face outward and surround the most lipid-soluble core components (cholesterol esters, triglycerides). In addition to transport, apoproteins facilitate recognition of enzymes that remove or process the lipids within the lipoprotein. Several classes of lipoproteins have been classified according to their density, lipid content, and surface protein. These include in order of density chylomicrons (least dense at ≤ 0.95 g/mL), very low-density lipoprotein (VLDL) cholesterol, intermediate-density lipoprotein (IDL) cholesterol, lowdensity lipoprotein (LDL) cholesterol ("bad" cholesterol), and high-density lipoprotein (HDL) cholesterol ("good cholesterol") (most dense at 1.06g/mL). Generally, total cholesterol, triglycerides, and HDL are measured directly, with VLDL and LDL estimated though calculation.

Three pathways exist for formation of lipoproteins. The exogenous pathway of lipoprotein formation begins with digestion and absorption of dietary fat. Dietary cholesterol must be esterified, a process mediated by acyl coenzyme A cholesterol acyltransferase (ACAT-2,) located in both the intestinal epithelial cell and liver. In the epithelial cell, cholesterol and triglyceride are packaged into chylomicrons. Chylomicrons contain the largest proportion of triglycerides (fat) of any of the lipoproteins, with a triglyceride to cholesterol ratio of 10:1 (i.e., more than 90% triglycerides). Therefore, although chylomicrons are very large, their fat content renders them the least dense of the lipoproteins. The high fat content of chylomicrons also provides the buoyancy necessary for their accumulation at the top of undisturbed (>12 hours) plasma. Formation of chylomicrons depends on microsomal triglyceride transfer protein (MTP), which acts to transfer the triglyceride to an apolipoprotein. The apolipoproteins will form the outside surface of chylomicrons and are synthesized in intestinal epithelial cells or are acquired from HDLs once the chylomicron is secreted into lymph. Chylomicrons enter plasma at the thoracic duct. Once in circulation, fatty acids are released from the triglycerides in chylomicrons in tissue that produce lipoprotein lipase (LPL); insulin provides a permissive effect. Its absence in humans is associated with severe hypertriglyceridemia and pancreatitis. Tissues that contain LPL are exemplified by adipose tissue and skeletal and cardiac muscles. Fatty acids released from triglycerides are either immediately used as a source of energy by surrounding tissues or stored for future energy needs in adipocytes. The chylomicron remnants that remain once triglycerides have been removed contain dietary cholesterol and they are rapidly metabolized by the liver.

The *endogenous pathway* for generation of lipoproteins reflects hepatic synthesis of VLDLs and subsequent uptake of circulating VLDLs by tissues. Triglyceride synthesis is regulated in the liver and other tissues through coenzyme A (CoA) diacylglycerol acyltransferase enzymes that catalyze the final step. Triglycerides intended for lipoprotein synthesis are transferred (along with other lipids) to the endoplasmic reticulum,

where they, along with cholesterol, will combine with newly synthesized apoB-100 to form VLDLs. Transfer cannot occur without MTP, and its absence (or the absence of triglycerides) prevents formation of VLDLs and subsequent lipoproteins. Like chylomicrons, VLDLs are very large, containing a large amount of core triglyceride (ratio of triglycerides: cholesterol of 5:1). Although VLDLs contribute to plasma turbidity, they do not float with chylomicrons on the surface of undisturbed plasma. The VLDLs are synthesized in the liver endoplasmic reticulum in response to increased free fatty acids.

The VLDLs are released into circulation, taken up by tissues that produce LPL, and processed by LPL to yield fatty acids, glycerol, and a VLDL remnant or IDLs. The free fatty acids are either used as an energy source or stored in the cell as fat (Box 14-1).

The IDLs either are removed by the liver in response to LPL or are metabolized by way of hepatic triglyceride lipase to form LDLs. The LDLs are composed primarily of cholesterol esters and contain essentially no triglycerides. Because they have a longer half-life than other lipoproteins, LDLs accumulate to a higher plasma concentration compared with either VLDLs or IDLs. Hence the LDLs carry the majority of cholesterol (the "bad" cholesterol) in the body. The LDLs also are removed from circulation primarily by the liver in proportion to LDL receptor expression, with a smaller amount taken up by LDL receptors in tissues. Tissue uptake results in the release of free cholesterol, which is subsequently esterified such that it accumulates in cells. Most clearance occurs in the liver. Increased expression of LDL receptor expression is a major means by which cells regulate free cholesterol content. A number of signals increase LDL receptor expression, thereby decreasing circulating LDL, including thyroxin and estrogen, decreased consumption of saturated fats and cholesterol, and pharmacologic anticholesterol drugs (statins).

Among LDLs, densities vary, with the smaller, denser, less buoyant particles potentially more amenable to oxidation.²⁷⁴ Oxidized (radical) lipoproteins damage vascular endothelium and are scavenged by a receptor mediated process in macrophages (forming foam cells). It is the inflammatory and immunologic response to oxidized LDL and at the vascular endothelium of coronary vessels that contributes to atherosclerosis and its subsequent morbidity in humans. Although it is cholesterol that is considered "bad", it appears that it is the fatty acids, not cholesterol, that are oxidized to atherogenic metabolites. As such, triglycerides, not cholesterol, are the source of atherosclerotic mediators, and thus the lipoproteins containing the largest component of triglycerides should be considered the greatest risk. What is not clear is why transport of cholesterol by HDL would decrease this risk.

HDLs facilitate the transport of cholesterol from peripheral tissues (including atherogenic plaques) to the liver. As such, HDLs contain more cholesterol (as ester) than triglyceride in their core compared with other lipoproteins and are of higher density than the other lipoproteins. This mechanism of "reverse cholesterol transport," the third pathway of lipid metabolism, is complex and not well understood.²⁷⁴

Box 14-1

Fatty Acids

Fatty acids contain variable lengths of carbons that may or may not include double bonds. Nomenclature of fatty acids involves an ending with "oic" [or simply "ic"] acid [the acid referring to the carboxylic acid that each contains] with the number of carbons followed by the number of double bonds [e.g., arachidonic acid, C 20:0, contains 20 carbons and no double bonds, whereas arachidonic acid C20:4 contains 4 double bonds]. A saturated fat contains carbons with as many hydrogens as possible, meaning it contains no double bonds or functional groups. Such fats are straight and as such, can be packed very tightly, thus allowing storage of a lot of energy in a small space. Such fats also offer no opportunity for lipid peroxidation. Unsaturated fats contain variable numbers of functional groups or, more commonly, (alkene) carbon double bonds. The more double bonds, the greater the risk of oxygen radical formation (peroxidation). The fatty acid that extends on either side of each double bond can exist in one of two configurations: cis, for which both ends are on the same side of the double bond, or trans, for which each end is on a different side. Steric hindrance presented with fatty acid ends being on the same side of the bond as in cis fatty acids causes the molecule to bend or kink. However, the ends of a trans fat are on opposite sides, do not compete for space and thus remain largely straight, such as might occur with saturated fats. Most naturally occurring unsaturated fatty acids contain only three double bonds, each in the cis position. The few naturally occurring trans fatty acids are generally found in the meat and dairy products of ruminant animals (originating from the rumen). Saturated fats and trans unsaturated fats tend to be solid at room temperature and are less amenable to

oxidation. The term trans is used when referring to fats because it is the common name used to refer to all unsaturated fats. This probably reflects the fact that most fats that are consumed are unsaturated plant fats that are artificially partially hydrogenated such that a trans configuration is produced. Because they are more saturated, they are less conducive to oxidation (degradation) into smaller fatty acids, ketones, and aldehydes, and because they are less likely to become rancid, their shelf-life is prolonged. Presumably, fats that contain unsaturated (oxidizable) double bonds should be less safe than the fats whose carbon bonds are "saturated" with hydrogen. However, because unsaturated fats might also be considered more fluid, thus allowing flexibility in cell membranes, polyunsaturated fats have also been considered safer, although absorption of unsaturated dietary fats that are oxidized during the cooking of food may increase their atherogenecity. Despite the fact that trans, partially hydrogenated (unsaturated) fats are less oxidizable, the amount of trans fats in the diet correlates with the advent of atherosclerosis. Although the mechanism is not well understood, it may simply reflect increased total unsaturated fat content. Coronary heart disease in humans correlates with the amount of both saturated and unsaturated fat; however, saturated fats appear to be less atherogenic than disproportionate carbohydrates in the diet [the latter perhaps contributing to increased formation of saturated fat formation in the body]; fish also decreases the risk of alherosclerosis. Trans fats in particular seem to reduce the amount of HDL, thus increasing the risk of coronary artery disease. Thus consumption of trans fats is recommended to be as low as possible.

Pathophysiology of Dislipidemias

Hyperlipidemia is defined as increased concentrations of triglycerides or cholesterol. In humans hyperlipidemia results from a combination of dietary, genetic, and metabolic factors.²⁷⁵ In veterinary medicine, primary idiopathic hyperlipidemia appears to be familiar in Miniature Schnauzers and Beagles but has been reported in other breeds and occasionally in cats. Secondary hyperlipiemia is associated with other disorders, such as diabetes mellitus, hyperadrenocorticism, pancreatitis, and hypothyroidism.

Treatment of Hyperlipidemia

In humans the choices for treatment of hypertriglyceridemia vary with the category, three of which are defined according to concentration (mg/dL) of triglycerides (borderline high [150-199], high [200-499], or very high [≥500]), with a focus on the risk of coronary heart disease. Pharmacotherapy targets synthesis of cholesterol and includes the statins, niacin, bile acid sequestrants, and fibric acid derivatives.

Statins. Statins competitively inhibit (hepatic) HMG-CoA reductase and thus block the rate-limiting step in cholesterol synthesis. At higher doses the more potent drugs (e.g., atorvastatin, simvastatin) also reduce triglycerides associated with increased VLDL. In humans statins have proved effective in reducing morbidity and mortality associated with hyperlipidemia and coronary heart disease.²⁷⁵ Six products are approved for use in the United States, with lovastatin, simvastatin, and

pravastatin the most commonly prescribed. Each statin is structurally similar to HMG-CoA. LDL receptor expression increases, causing LDL-C concentrations to decrease. Humans taking the highest doses of the most potent statins realize up to a 45% reduction in triglycerides. A similar reduction can be achieved with niacin and fibric acid derivatives, but fibric acid may not decrease LDL-C. The statins have a number of nonlipid-lowering cardioprotective effects, although mechanisms are not known. These include inhibition of enhanced vascular endothelial nitric oxide production, inhibition of vascular smooth muscle proliferation, facilitation of apoptosis, and stabilization of vascular atherosclerotic plaques. Platelet aggregation is decreased. Oral bioavailability is variable among drugs (30% to 85%); simvastatin and lovastatin are administered as prodrugs.²⁷⁵ All undergo extensive firstpass metabolism, resulting in systemic bioavailability of 5% to 30%. Atorvastatin, lovastatin, simvastatin, and others (but not pravastatin, fluvastatin, and rosuvastatin) are metabolized by CYP 3A4, increasing the risk of drug interactions. Entry into the liver for several statins is mediated by transport proteins, which may compete with other drugs. Most metabolites have some degree of activity. Those products that make it to systemic circulation are highly bound to proteins. Elimination half-lives are generally less than 4 hours (exceptions are 20-hour atorvastatin and rosuvastatin), and effect appears to be time dependent in that lovastatin is slightly more effective when given as 40 mg twice daily, as opposed to 80 mg once daily. Elimination of parent and metabolites is largely biliary. Two potentially serious side effects of statins have been reported: hepatotoxicity and myopathy. Statins cause increased liver enzymes in 3% of human patients. However, the incidence of serious hepatotoxicity is rare (1 case per million users annually). Hepatic enzymes should be measured at baseline and repeated at 3 to 6 months, then yearly thereafter if normal. Myopathy (rhabdomyolysis; approximately 0.01%) and monitored by serum creatine kinase) appears to be dose dependent and is most commonly associated with gemfibrozil. Myopathy can be associated with myoglobinuria and, rarely, death. Niacin will increase the risk (discussed later), as will macrolide antimicrobials, cyclosporine, imidazole antifungals, and inhibitors of CYP3A4. Creatine kinase might be monitored in at-risk patients (e.g., drug interactions).²⁷⁵ Combined use of statins with other drugs can reduce either LDLC-C or triglycerides greater than statin use alone; current treatment of dyslipidemias (such as that which characterizes prediabetes) increasingly is based on combination therapy. Combination with bile acid sequestrants can reduce LDL-C by another 20% to 30%; the addition of niacin will reduce concentrations even further (up to 70% in humans), although the risk of myopathy increases with high statin and niacin doses. Combination with fibrates is particularly effective when treating hypertriglyceridemia.275

Niacin. Niacin (nicotinic acid) is a water-soluble compound that in its amide form (nicotinamide) acts as a B vitamin complex. However, only niacin lowers lipids (although nicotinamide can act as a source of niacin) and only at doses higher than that associated with B vitamin activity.²⁷⁵ Triglycerides may reduce up to 45%; LDL-Cholesterol (LDL-C) decreases up to 30%, and HDL-C increases up to 40% (humans). The mechanism reflects inhibition of hormone-sensitive lipaseinduced lipolysis in adipose tissue. The transport and esterification of free fatty acids to the liver is inhibited, and hepatic triglyceride synthesis is decreased. Adipocyte adenylyl cyclase may be the ultimate enzyme inhibited. Niacin may also inhibit diacylglycerol acyltransferase 2, the rate-limiting enzyme of triglyceride synthesis. Niacin also enhances LPL activity, thus promoting the clearance of chylomicrons and VLDL triglycerides. The identification of a niacin receptor may ultimately lead to development of drugs that target the receptor.²⁷⁵ In humans administration of regular or crystalline niacin (2 to 6 g divided into 2 to 3 daily doses) causes maximal effects within 4 to 7 days. The high dose is necessary to ensure sufficient niacin; at lower doses most is converted to nicotinamide. The half-life of niacin is only 30 to 60 minutes in humans, necessitating at least twice-daily dosing; an extended-release preparation allows once-daily dosing. Use in humans is limited by cutaneous flushing, skin rashes, and dyspepsia. Flushing, interestingly, resolves after 1 to 2 weeks of stable dosing but will return if several doses are missed and is minimized by starting at a low dose (e.g., 100 mg twice daily in humans) that is gradually increased (weekly) to a maximum total daily dose of 2 g. Co-administration of aspirin also will reduce flushing.²⁷⁵ Dyspepsia is reduced if administered with a meal. Niacin is contraindicated in patients with gastrointestinal ulceration.

Hepatotoxicity is a serious but rare adverse reaction to niacin. All sustained-release niacin (over-the-counter) preparations have been associated with hepatotoxicity (including fulminating hepatic necrosis), particularly at high doses; the risk may be less with Niaspin an FDA-approved extended release coated tablet. Toxicity may take several years to develop and has occurred in human patients who tolerated crystalline niacin. Niacin increases the risk of statin-induced myopathy; the statin dose should be reduced to approximately 25% when used in combination.²⁷⁵ Niacin should either be avoided or used cautiously in diabetics (types I or II); any change in insulin need should be anticipated for insulin-dependent diabetics. The risk of niacin-induced hyperglycemia might be reduced (but probably not avoided) in the diabetic patient with use of sustained-release niacin.²⁷⁵

Bile acid (resin) sequestrants. Cholestyramine and colestipol are anion-exchange resins prepared as hygroscopic powders and administered as chloride salts.²⁷⁵ The highly positively charged particles bind to the negatively charged bile acids, precluding their absorption. Hepatic synthesis consequently increases, resulting in lowered cholesterol. As with statins, LDL receptors increase and LDL-C decreases. However, because statins are more effective, generally resins are used as second-line treatment. Unfortunately, resin-induced increase in bile-acid production causes an increase in hepatic triglyceride synthesis, leading to potentially marked increases in serum triglyceride concentrations, and severe hypertriglyceridemia is a contraindication for use; an exception is colesevelam, which does not appear to significantly increase triglycerides. Resins are not orally absorbed. Rarely, hyperchloremic acidosis may occur. Cholestyramine and colestipol are administered as a slurry, which is associated with gastrointestinal upset (including dyspepsia and bloating); again, the exception is colesevelam, which is administered as a soft-gel capsule. Cholesteramine and colestipol will impair the absorption of many drugs. Resins generally are administered before or with a meal. Although colesevelam is less likely to affect absorption of other drugs, it nonetheless should be administered 1 hour after or 3 to 4 hours before any other orally administered drug. Additional flavoring may facilitate administration of cholesteryamine and colestipol.275

Fibric acid. The ester form of ethyl chlorophenoxyisobutyric (clofibrate) was the first to be approved in the United States, but its use was not associated with a reduction in mortality associated with coronary heart disease. Gemfibrozil is a nonhalogenated phenoxypentanoic acid and as such is not halogenated fibrates. Its use has been demonstrated to reduce mortality rates in men. The mechanism by which fibric acid derivatives decrease cholesterol is not certain, but they appear to interact with and stimulate peroxisome proliferator-activated receptors. Fatty acid oxidation is stimulated, LPL synthesis and apoA-I and II expression increase, and apoC-III (an inhibitor of lipolytic processing) expression is reduced. Most fibric acids also are antithrombotic, inhibiting coagulation and enhancing fibrinolysis. Those (human) patients most likely to respond are those with dysßlipoproteinemia (type III). In human patients with mild hypertriglyceridemia, gemfibrozil

may cause triglyceride to decrease up to 50% without a change in LDL-C. In contrast, with second-generation drugs (fenofibrate, bezafibrate, ciprofibrate) LDL may decrease up to 20% and up to 30% in patients with marked hypertriglyceridemia (400-1000 mg/dL). Fibric acids have been the drugs of choice for treatment of severe triglyceridemia and chylomicronemia. Fibric acid compounds usually are well tolerated. Side effects are not uncommon, occurring in 5% to 10% of human patients; however, discontinuation of the drug is generally unnecessary. Side effects reflect the gastrointestinal tract, cutaneous lesions (rash, urticaria, alopecia), increased liver enzymes, and myalgias. Myopathies may occur in patients receiving clofibrate, gemfibrozil, or fenofibrate, including up to 5% of patients receiving a combination of statins with gemfibrozil. Minor increases in liver transaminases and alkaline phosphatase have been reported. Gemfibrozil will inhibit transport-mediated hepatic uptake of statins and compete with statins for glucuronidation (an exception being fenofibrate), potentially increasing concentrations of both drugs. Effects of oral anticoagulants are potentiated, and the risk of choleliths may increase. Both renal and hepatic diseases are contraindications to fibric acid administration.

Inhibition of dietary cholesterol absorption. Ezetimibe appears to inhibit a transport protein specific to cholesterol (and plant sterol) absorption. Whereas cholesterol absorption may be markedly decreased, triglyceride absorption will not be affected; serum cholesterol concentrations may decrease up to 50%, whereas triglyceride may decrease only up to 5%. Cholesterol synthesis generally increases; hence ezetimibe is often coupled with a statin. Increased LDL receptor expression is accompanied by decreased LDL-C. Because ezetimibe is insoluble in water, it has not been studied intravenously, and bioavailability is not known. However, after intestinal epithelial glucuronidation, it is absorbed to undergo enterohepatic recirculation, with 70% excreted in the feces and about 10% in the urine. Ezetimibe has been associated with rare allergic reactions.

Dirlotapide is a selective inhibitor of MTP. MTP is required for the assembly and secretion of apolipoprotein B (apoB)containing lipoproteins, the primary structural protein of plasma VLDLs. Consequently, MTP inhibitors block the assembly and release of lipoproteins into the blood stream. In field trials, serum lipids were decreased in obese dogs treated with dirlotapide, but changes were not clinically significant. However, depending on the pathophysiology of hypertriglyceridemia, consideration might be given to the potential for dirlotapide, particularly in combination with other therapies (e.g., gemfibrozil), for treatment.

HEARTWORM DISEASE (DIROFILARIASIS)

Physiology and Pathophysiology

Both the adult worms and the microfilariae of *Dirofilaria immitis* are responsible for the clinical signs associated with heartworm disease. Heartworms live 5 to 7 years in dogs (2 to 3 years in cats) but are most susceptible to adulticide therapy while young. Maximal microfilaria production occurs after 8 to 18 months of adult worm development, and microfilariae live about 18 to 24 months. The adults are covered with a canine antigen that provides an immunologic sanctuary, protecting the worm against immunologic rejection. However, its subsequent absence contributes to a marked inflammatory host response on worm death. The severity of heartworm disease and the onset of clinical signs reflect, in part, the number of infecting worms. Large numbers of worms are more likely to cause greater pulmonary hypertension, thromboembolism, and risk of vena cava syndrome. Experimentally, the endothelium of the pulmonary artery responds to the presence of heartworms within 3 days. Endothelial damage leads to edema associated with vascular permeability. Trophic factors released by platelets and leukocytes stimulate the multiplication of smooth muscle cells, which subsequently migrate from the interna to media, where they continue to rapidly multiply. Cells continue to divide and produce collagen.

Arteries dilate, become tortuous, and develop aneurysms. Obstructed blood flow is rerouted to regions of normal lungs. Interstitial pulmonary edema worsens. Pulmonary disease further worsens as fragments of dead worms are carried distally into the smaller pulmonary arteries. Villous proliferation is coupled with thrombi formation and a granulomatous response to the dead heartworms. Pulmonary blood flow may be totally obstructed, and the caudal pulmonary lung lobes may become consolidated. Decreased endothelium-dependent relaxation can be correlated with pulmonary arterial blood pressure in dogs with heartworms, suggesting that this may be an important factor in the development of dirofilariasis-induced pulmonary hypertension.^{276,277,277a} Increased pulmonary vascular resistance can cause acute right-sided heart failure.

The clinical signs associated with heartworm disease and its treatment again depend on the number of worms present but also on the duration of infection and the host response, which can be quite variable. Coughing and dyspnea, the most common clinical signs, reflect disease of the caudal lung lobe arteries. Pulmonary edema and inflammatory response to dead heartworms are the most likely inciting causes. Dyspnea also might reflect ventilation perfusion mismatching as blood flow is diverted to patent arteries. Exercise intolerance is most likely to be associated with right ventricular hypertrophy and dilation resulting from severe arterial disease and impaired pulmonary blood flow. Mild to moderate hypoxemia worsens pulmonary hypertension. Right-sided CHF increases the magnitude of exercise intolerance and may lead to overt signs of right-sided heart failure such as ascites and an enlarged liver. Thromboembolism worsened by the inflammatory response to dead heartworms often is accompanied by hemoptysis; this was particularly true after treatment with thiacetarsamide. Blood loss resulting from vascular and airway rupture is most likely to occur after coughing in areas of severe vascular and parenchymal disease.

Occult Heartworm Disease

The incidence of occult disease can vary (from 5% to 67% of infected dogs) depending on geographic region. Occult infections may be caused by infection of one sex only

(57% to 85% of occult infections), prepatent infections (particularly in colder months), drug-induced adult worm sterility, or immune-mediated elimination of microfilariae. Immunemediated destruction of microfilariae occurs in the presence of excessive IgG production directed toward the microfilariae. A granulomatous reaction may follow phagocytosis of antibody-microfilaria-leukocyte complexes. Up to 15% of dogs with occult heartworm disease can be expected to develop immune-mediated pneumonitis characterized by coughing and dyspnea. Radiographically, the reaction causes diffuse interstitial and alveolar infiltrates. Tracheal lavage may reveal an eosinophilic exudate, and clinical laboratory tests reveal eosinophilia, basophilia, and hypergammaglobulinemia. Other potential sequelae of immune-mediated destruction of microfilariae include CHF, vena cava syndrome, and severely enlarged pulmonary arteries.

Therapy

Current recommendations for treatment and prevention of heartworm disease as recommended by the American Heartworm Society can be reviewed at http://www.heartwormsociety.org.^{277a}

Pretreatment Assessment

Pretreatment evaluation should focus on assessment of the risk of complications after adulticide therapy. In general, the risk of treatment was greater for thiacetarsemide compared to melarsomine, the currently approved canine adulticide. Diagnostic measures weigh the likelihood of success against the risk of side effects or complications. The extent and type of supportive therapy should be determined on the basis of the severity of infection before treatment. The development of thromboembolism is the complication most amenable to pretreatment assessment.

Up to 70% of dogs with severe heartworm disease may have an occult infection; as the number of adult heartworms increases, the number of microfilariae produced by each female decreases.²⁷⁷ The presence of occult disease also may indicate a greater likelihood of immune-mediated microfilarial disease. Infection indicated by positive tests should be confirmed before adulticide therapy is implemented. Antigen tests that quantitate antigen indirectly provide information regarding the adult heartworm load and can be of benefit in the assessment of the severity of infection. Radiographs are an important baseline test for assessing the severity of disease, with a focus on the caudal pulmonary lung field. Right ventricular enlargement should be assessed carefully by radiographic means. Cardiac ultrasonography is the preferred method of assessing right ventricular function and the extent and impact of pulmonary hypertension. Ultrasonography also might be helpful in identifying those animals with a high worm burden.

Ideally, a minimum database consisting of a complete blood count, routine serum chemistries, and urinalysis should be collected as part of the pretreatment evaluation. Findings of hypoalbuminemia, increased liver enzyme activity, azotemia, and proteinuria should lead to more intensive assessment of renal and hepatic function. Although renal dysfunction should be interpreted as a cause for concern, evidence of hepatic dysfunction should be expected in some animals, particularly those with evidence of right-sided CHF, and is not necessarily indicative of a decision not to treat. Up to a tenfold increase in liver enzyme activity can be tolerated before treatment. Leukocytosis is indicative of an inflammatory response in the lung parenchyma. Evidence of thrombocytopenia should lead to more aggressive evaluation of thromboembolic disease, including the presence of low-grade disseminated intravascular coagulopathy. Overt signs of bleeding and abnormal coagulation parameters may be absent in patients with low-grade disseminated intravascular coagulopathy; however, thrombocytopenia should persist.

Severe Pulmonary Arterial Disease and Pretreatment Therapy

Severe pulmonary arterial disease is indicated by the tortuosity and enlargement of the pulmonary lobar arteries, which in normal animals should not exceed in diameter the width of the ninth rib. Approximately 10% of infected dogs can be expected to have severe disease. Evidence of pulmonary thromboembolism before treatment should lead to a pretreatment course of glucocorticoids (1 to 2 mg/kg per day) until clinical and radiographic indicators of thromboembolism begin to resolve (generally 3 to 7 days). Glucocorticoids should not, however, be used routinely because of their ability to increase survival of adult heartworms. Because of the role that platelets have in causing the thromboembolic (including inflammatory) response, drugs such as aspirin, which impair platelet activity, may be beneficial. However, care should be taken to avoid COX-2 preferential drugs that may increase the risk of thromboembolism.

Anticoagulants such as heparin can increase pulmonary blood flow and reduce the severity and incidence of thromboembolic disease, including associated signs such as coughing and hemoptysis. Antithrombotic therapy generally consists of aspirin (4 to 6 mg/kg per day) for 2 to 3 weeks before treatment. Aspirin therapy is continued during and 3 to 4 weeks after adulticide therapy. Attention should be paid to the development of gastrointestinal side effects with protracted aspirin use, although they are less likely to occur with the low dose used for thromboembolic disease. Aspirin should not be used in the presence of hemoptysis. Evidence of gastrointestinal side effects should lead to therapy with sucralfate and H₂-receptor blockers; misoprostol might be avoided because of the unknown impact of this prostaglandin on pulmonary blood flow in the face of pulmonary arterial disease. Low-dose heparin (50 to 70 U/kg subcutaneously every 8 hours) may further increase survivability after therapy²⁷⁸ and is particularly crucial if there is evidence of disseminated intravascular coagulopathy (decreasing platelet count). For such patients heparin therapy should be continued for at least 7 days, and until the platelet count exceeds 150,000/µL, therapy can be continued for several weeks if needed.

If the severity of pulmonary arterial disease reflects a large burden of adult worms, the likelihood of fatal complications after adulticide therapy can be decreased by reducing the adult heartworm burden surgically (by way of the jugular vein), partial adulticide therapy (with melarsomine dihydrochloride), or cage confinement and antithrombotic therapy. Partial adulticide therapy (see package insert) involves injecting only the first of the two adulticide injections of drug, followed by a 30-day hiatus in patient activity. At the end of 1 month, the full treatment protocol is implemented. Because up to 50% of animals with severe pulmonary arterial disease can be expected to have signs associated with right-sided CHF, therapy with diuretics and a low-sodium diet may be indicated.

KEY POINT 14-64 To prevent fatal complications in patients with dirofilariasis, large worm burdens should be decreased before full adulticide therapy.

KEY POINT 14-65 The duration of retroprotection of macrolides varies with the drug but generally ranges from 3 to 4 months.

Pneumonitis

Glucocorticoids (prednisone 1 to 2 mg/kg per day or dexamethasone 0.2 to 0.4 mg/kg per day) are indicated to control the inflammatory response of pneumonitis. A parenteral route can be used for severely affected animals. Clinical improvement should occur within the first 24 hours, with radiographic resolution of pulmonary infiltrates associated with the pneumonitis in 3 to 5 days. Glucocorticoids should be discontinued when radiographic lesions are maximally resolved. Adulticide therapy should begin as soon as possible.

Prophylactic Therapy

Prophylaxis may be seasonal or throughout the year, depending on geographic location. Prophylaxis between May and October may be sufficient in the northern half of the country. Prophylaxis may contribute to collateral protection of unprotected dogs by decreasing the reservoir population, particularly in areas where mosquito and dog populations are low. Therapy should begin at 6 to 8 weeks of age if the season is appropriate. Once-daily administration of diethylcarbamazine (DEC) has been replaced with a macrolide antibiotic. Diethylcarbamazine (2.5 to 3 mg/kg orally once daily) affected L3 to L5 molting stage; however, efficacy may be lost with as little as three missed doses. DEC was safe when given to heartwormnegative dogs. But when administered to a dog infected with as few as 50 microfilariae/mL blood, DEC causes a severe anaphylactic-like reaction in up to 85% of animals. The reaction is characterized by depression, lethargy, vomiting, diarrhea, bradycardia, and shock, followed by death. Hepatomegaly and thrombocytopenia occur. Treatment is supportive (e.g., fluids, shock doses of glucocorticoids).

The macrolide antimicrobials are effective for the prevention of heartworm disease when given monthly, a distinct advantage to DEC therapy, particularly for owners whose compliance with daily therapy is poor. Macrolides are effective against microfiariae, third- and fourth-stage larvae, and potentially adult worms, with younger worms most susceptible to their effects. Efficacy is greatest for 1 month, but an additional month generally can be expected. Moxidectin is unique in its longer half-life of 20 days, its chemical side chains (compared with other avermectins), and its availability in slow-release microspheres. Oral choices of macrolide antibiotics include ivermectin (2-day half-life) (Heartgard; Merck; 6 to 12 µg/kg by mouth monthly at 6 weeks or older; 24 µg/kg by mouth monthly in cats), milbemycin oxime (Interceptor; Novartis; 0.5 to 1 mg/kg or 500 to 1000 µg/kg monthly by mouth) in dogs at 8 weeks or older; and moxidectin (ProHeart, Fort Dodge; 3 to 6 µg/kg by mouth monthly). Topical options include selamectin (Revolution, Pfizer; 6 to 12 mg/kg, topical in dogs 6 weeks or older), and moxidectin topical (with imidacloprid; Advantage Multi for dogs).²⁷⁹ Moxidectin also is available as an injectable slow-release product (ProHeart, Fort Dodge, 170 µg/ kg as microspheres subcutaneously every 6 months in dogs 6 months or older) in several countries.²⁸⁰ It was voluntarily withdrawn in the United States (but not other countries) in 2004 for potential and controversial safety issues but was reintroduced in 2008. An advantage of this product is retroprotection of 4 months and full protection that extends beyond its 6-month labeled claim. Ivermectin is highly effective in preventing heartworm infections in dogs when given monthly (5.98 µg/kg). It does not control other helminthes but is available in a combination product with pyrantel, which controls hookworms and roundworms. Milbemycin controls roundworms, hookworms, and whipworms. Selamectin is effective against hookworms and roundworms, as well as fleas (adults), ear and sarcoptic mange mites, and selected ticks.

The duration of retroactive protection varies with the macrolide. Ivermectin, but not milbemycin, appears to retroactively protect against infection if given as long as 4 months after infection. Both drugs are effective at 3 months after infection. Retroactive efficacy (and partial adulticide effects of ivermectin) may warrant prophylactic therapy during the off season, particularly in light of a recent survey finding that 80% of respondents failed to give their dogs monthly heartworm preventive on the due date. Unlike DEC, the avermectins do not appear to cause adversity when given as preventives to heartwormpositive dogs. In a review, McCall²⁸¹ summarizes the "safetynet" (reachback) and adulticide effects of macrocyclic lactones. Up to 95% efficacy against adults may be realized, but treatment requires 9 to 30 months, with continuous monthly therapy resulting in better efficacy. Increased dose and shorter intervals do not appear to affect efficacy. The effect is greater on younger worms than on older worms, supporting better efficacy with earlier as opposed to later treatment. Among the drugs, efficacy in killing mature worms is ranked ivermectin > selamectin and moxidectin injectable > milbemycin.

The microfilaricidal effect of macrolides at prophylactic doses has several implications. First, adulticide therapy need not be followed by microfilaricide therapy; prophylactic therapy will lead to resolution of microfilaria. Second, microfilaria testing should precede initiation of prophylaxis therapy to prevent mistaking pretreatment infection for therapeutic failure and to minimize the risk of the sequelae of rapid microfilaria kill. Third, administration of a macrolide antibiotic

Table 14	c Doses of .actones in A s ²⁸²	ABCB1		
	Labeled (Safe) Doses Toxic Doses		Doses
	μ g/k g	g/month	μ g/kg	
Drug	Oral	Topical	ABCB1 (-)	Wild type

Milbemycin	50 to 1000		12,500 PO	200,000 PO
Moxidectin	3	2500	90 PO (oral form) 1000 PO (topical form)*	>900 PO
Selemectin		6000	60,000 topical 15,000 PO	

PO, By mouth.

*As might occur with accidental ingestion.

(except moxidectin) at prophylactic doses is the most frequent cause of iatrogenic occult infections resulting from either microfilaricidal effects or sterilization of the female adult worm. Most adult infections become occult within 6 (2 to 9) months after beginning therapy. It is important that antigen testing rather than concentration tests be used as screening procedures in animals to be treated prophylactically.

The American Heartworm Society suggests that efficacy of prophylactic products should be tested at 3 months (4 for injectable 6-month product), after the start of the new product, or at the restart of lapsed prophylaxis. A negative status should be confirmed by testing before the change (i.e., change in drugs or re-initiation of lapsed prophylaxis). A positive test before the change or at 3 months indicates failure of the original drug or infection during the lapse in therapy. A negative test at 3 months should be followed by retesting at 8 to 9 months; a positive result at that time indicates that infection may have occurred before or during transition to the new drug, or failure of the new drug. A positive test after 9 months indicates failure of the new product or noncompliance.

Adverse reactions associated with macrocyclic lactones were addressed in Chapter 4. Adversities generally involve the central nervous system. Mealey²⁸² reviewed the impact of the MDR1 (currently ABCB1) gene product P-glycoprotein on the safe use of macrocyclic lactones in dogs. Mealey²⁸² underscores the fact that all macrocyclic lactones are safe in all dogs, regardless of the presence of the deletion, when used at the approved preventive dose (Table 14-5). Adversities occur when used off label (e.g., treatment of mange at daily doses of 300 to 600 µg/kg). Accidental overdose is more likely with large animal preparations because of unintentional exposure²⁸³ or intentional exposure with a miscalculated compounded product.²⁸² Internet-based recipes offered by lay users will contribute to increased risk of toxicity with off-label use of large animal products.²⁸² Known safe and toxic doses (in µg/kg) in gene-deficient dogs are provided in Table 14-5. Because the proposed mechanism

of central nervous system adversities (disorientation to seizures) reflects enhanced chloride ion flow through gabachannels, anticonvulsant drugs that do not target the GABA receptor (e.g., levetiracetam, zonisamide to a lesser degree) might be preferred over those that do (e.g., benzodiazepines, phenobarbital).

KEY POINT 14-66 P-glyocoprotein deficiency leading to macrocyclic lactone toxicity in Collies and working breeds of dogs can be detected on the basis of a molecular test.

In 2004 Proheart (injectable moxidectin) was voluntarily withdrawn from the U.S. market; no other country withdrew the product. In support of its reintroduction in 2008, Fort Dodge provided to the Center for Veterinary Medicine a review of adverse events associated with its injectable product and two other unnamed oral monthly products. The data, which were collected from medical records of animals receiving the drugs or vaccines (alone or in combination), have been published.²⁸⁴ In addition to the adverse events, the report offers a reasonable perspective on the difficulties associated with assessing adverse events as they currently are reported in veterinary medicine. Among the adverse events examined was association of treatment with cancers. Differences were limited to the incidence per 10,000 days at risk for mast cell tumors (0.024 for animals treated with one of the heartworm preparations, 0.043 for animals receiving vaccinations only, and 0.072 for Proheart 6 only), with no relationship demonstrated regarding the number of doses received (from 1 to 5). Allergic rates and all other safety profiles were similar among the three preventives studied. Interestingly, all heartworm preventives studied were associated with an increased incidence of allergic reactions. The apparent lack of substantial differences in adverse events for Proheart 6 compared with monthly preventives should be weighed against the risk of the sequelae of therapeutic failure as a result of poor compliance.

Adulticide Therapy

Melarsomine

Melarsomine is a trivalent arsenical that offers several advantages to the older arsenical, thiacetarsamide.²⁸⁵ Because it is unstable in an aqueous solution, it is manufactured as a lyophilized powder that must be reconstituted immediately before use. Although its mechanism of action is not clear, it is equal to or better in efficacy for treatment of dirofilariasis based on controlled clinical trial in dogs with class 2 (moderate) heartworm disease. Melarsomine also is characterized by a wider therapeutic index than thiacetarsamide, although the margin is still considered low. Death associated with pulmonary inflammation can occur with as little as three times the recommended dose. However, melarsomine may be less likely than thiacetarsamide to cause pulmonary arterial vasoconstriction.²⁸⁶ Melarsomine is administered deeply through an intramuscular route (2.5 mg/kg twice at 24-hour intervals) in dogs with mild to moderate disease. One half of worms, primarily males, die after the first injection; the remaining die with second treatments. According to the package insert, a 10% death

rate is expected in dogs with class III disease when two doses are given initially. As such, in dogs with severe heartworm disease (see package insert for characteristics), an alternative dosing regimen consisting of one 2.5 mg/kg injection, followed 1 month later by the full regimen, is recommended. However, the alternative regimen increasingly is being implemented as the rule rather than the exception, regardless of the state of disease. The American Heartworm Society cites the alternative regimen as being not only safer but also more effective, resulting in fewer treatment failures. Reaction to the intramuscular injection can be expected in at least 30% of animals being treated and is minimized by making sure that the injection is deep. Care should be taken to ensure that the needle is appropriate for the depth of muscle, that injection is complete before needle withdrawal, and that sites of injection are alternated. Local reaction should be limited to edema and slight pain. Other side effects to mesarlomine reflect reaction to the dead heartworms or the drug (hepatotoxicity).

Clinically ill patients should be stabilized before treatment. Instead of melarsomine, macrocyclic lactones delivered at prophylactic doses may be administered with the intent to kill adult worms. The American Heartworm Society recommends treatment with a macrocyclic lactone for 6 months if immediate therapeutic intervention is not necessary. Treatment also will decrease circulating microfilariae and kill migrating larvae. Reduction in antigenic mass may reduce the risk of thromboembolism. In worms less than 4 months in development, ivermectin will also stunt immature worms and reduce female worms. Finally, administration for at least 3 months (or injection of slow-release moxidectin) will allow development of immature worms to a stage susceptible to melarsomine killing.

Efficacy varies with the drug and duration. Efficacy generally requires at least 1 year of therapy, with older worms requiring up to 2 years of therapy. When administered as prophylactic doses, ivermectin and selamectin reduce adult numbers by 56% after 16 months of therapy; abnormalities in surviving worms may decrease their life span. Precardiac larvae and young (less than 7 months) worms are most susceptible to ivermectin, with susceptibility inversely correlated with worm age. Treatment of older worms may require melarsomine to prevent continued development of disease as worms slowly die. Moxidectin (parenteral) and milbemycin are associated with rapid microfilaria killing and therefore should be used cautiously. Further, milbemycin does not appear to reduce worm counts, although it may sterilize female worms. The slow death of adults associated with macrocycline lactones may decrease the risk of thromboembolic disease; however, animals should be monitored at least every 4 to 6 months until worms are dead.

Complete killing of adult worms may not be necessary for clinical improvement. Further, clinical signs may not improve if residual worms are killed (i.e., through retreatment). Because surviving worms may not produce microfilariae, antigen testing is the most accurate method of evaluating successful therapy. Worms continue to die for up to 1 month after therapy; therefore antigen testing generally should occur at 5 to 6 months after therapy. Worms that survive adulticide therapy tend to be antigen-producing females; accordingly, the absence of antigen at 6 months indicates successful therapy. The presence of antigens at a later date (after a negative test) is indicative of reinfection rather than therapeutic failure.

Alternative Adulticides

The impact of preventives on maturing or adult heartworms was addressed under prophylaxis. Alternative adulticides do not appear to be effective. Levamisole efficacy is variable and unpredictable and generates iatrogenic occult infections. Side effects, including emesis, nervousness, ataxia, hallucinations, and seizures, are not unusual. Interestingly, tetracycline antimicrobials decrease microfilaria production and some adulticide effects in Onchocerca spp. owing to death of a symbiotic gut microbe (Wolbachia spp. of the order Rickettsiales). A surface protein on the organisms may contribute to pulmonary and renal inflammation. Tetracyclines also may cause infertility in female worms. McCall²⁸⁷ reported that the combination of doxycycline (10 µg/kg) with ivermectin (6 µg/ kg) for several months will eliminate heartworms. The study involved six groups of five dogs experimentally infected with adult heartworms. Groups received either placebo, ivermectin (6 µg/kg for 36 weeks), doxycycline (10 µg/kg/day for 18/36 weeks), or both drugs with or without melarsomine. All dogs treated with the combination were amicrofilaremic after week 9, and antigen test scores gradually decreased in these animals. In dogs treated with either ivermectin or doxycycline, counts decreased but some microfilariae were still present at 36 weeks. With regard to the adult worms, the percentage of reduction was 20% for ivermectin, 9% for doxycycline, and 78% for the combination. In dogs also treated with melarsomine, the percentage of reduction was 100% for melarsomine alone compared with 93% for melarsomine, ivermectin, and doxycycline. On the basis of these findings, further clinical studies are warranted to assess the use of tetracyclines (specifically doxycycline) in the treatment of heartworms.

The risk of pulmonary embolism is greater with a larger worm load and rapid kill and in dogs with moderate to severe radiographic changes. Small dogs (<15 kg) may be at greater risk. Clinical signs of embolism (fever, cough, hempotysis, right-sided heart failure) generally occur within 7 to 10 days but may occur at any time up to 4 to 6 weeks after treatment; exercise often is not restricted in afflicted animals. The most critical therapy for preventing thromboembolism is exercise restrictions for at least 1 month after therapy. Glucocorticoids have been recommended (0.5 mg/kg alternate days) for clinically affected animals; impact on efficacy of melarsomine has not been determined. Routine use of aspirin for prevention of pulmonary thromboembolism is not recommended and, according to the American Heartworm Society, may be contraindicated. Other potential reactions to dead or dying worms include exsanguination because of disseminated intravascular coagulopathy. Treatment of pulmonary thromboembolism is controversial and includes careful fluid therapy; use of heparin (75 IU/kg subcutaneously thrice daily until platelet count has normalized [5-7 days]) and aspirin (5 to 7 mg/kg/day) has been advocated by some but remains controversial. Cough suppressants should be used as indicated; antimicrobial use should be implemented only in the face of nonresponsive fever. The role of vasodilator therapy in management of pulmonary thromboembolism is controversial. Hydralazine has shown some efficacy in improved cardiac output in dogs with heart failure associated with heartworm disease. Alternative therapies recommended by Atkins and coworkers⁵³ include amlodipine or diltiazem.

Right-sided heart failure may accompany pulmonary thromboembolism or postcaval syndrome. Treatment may include diuretics (furosemide, spironolactone), ACE inhibitors (targeting fluid retention and myocardial remodeling), and aspirin (targeting thromboembolic disease). Digoxin has not proved effective and is not generally recommended unless treatment focuses on supraventricular arrhythmias or refractory heart failure.

Microfilaricide Therapy

Because of the microfilaricide effect of macrocyclic lactones, the need for microfilaricide therapy is increasingly considered unnecessary as a follow-up to adulticide therapy. Regardless of the drug used, microfilariae generally resolve after several months of prophylactic therapy in the treated or untreated heartworm-infested dog. No drug is approved for use as a microfilaricide in the United States. However, if rapid removal of microfilariae is warranted, the macrocyclic lactones can be used, although duration of efficacy varies. A single dose may be insufficient to clear microfilariae; subsequent doses can be administered as needed. Ivermectin (unapproved as a microfilaricide) is 90% effective after a single dose (0.05 mg/kg or 50 µg/kg orally; approximately 8 times the preventive dose) 4 weeks after adulticide therapy is complete. Large animal preparations have been diluted 1 to 9 mL with propylene glycol (Ivomec) or water (Eqvalan) and administered at a rate of 1 mL/20 kg; however, this may increase the risk of adverse reactions. Administration in the morning is recommended to allow observation for the day. Care should be taken to avoid overdosing, particularly in Collie or related breeds that might be predisposed to toxicity (discussed later). Because milbemycin is the most potent and potentially more consistently effective microfilaricide, it can be used for rapid kill (0.5 mg/kg). Alternatively, prophylactic doses of any macrolide could be reduced to a 2-week interval. Animals should be hospitalized for the first 8 hours after therapy, particularly if rapid-kill doses are administered. Rapid kill of large numbers of microfilariae 4 to 8 hours after the first dose rarely is accompanied by acute circulatory collapse. Predisposed animals include dogs weighing less than 16 kg or harboring more than 10,000 microfilariae per mL of blood, although reactions have occurred in animals with as few as 5000 microfilariae per mL of blood. Pretreatment with antihistamines and glucocortocoids should be considered in predisposed animals. Therapy includes fluid support and shock doses of short-acting glucocorticoids. Pretreatment with prednisolone may decrease adverse effects in dogs with a high microfilarial load. Clinical signs are not likely with subsequent microfilaricide treatment. Predisposed

animals might also be treated with prophylactic doses of ivermectin. Moxidectin and selamectin also are microfilaricidal, although an appropriate dose has not been recommended.

Avermectin Toxicities

Adverse reactions to ivermectin and milbemycin microfilaricide therapy are more likely in Collies and Collielike dogs, including Border Collies and Old English Sheepdogs, than in the general population. Toxicity reflects a gene mutation in the p-glycoprotein efflux pump (homozygous or affected present in 35% of studied collies). Toxicity is characterized by acute ataxia, mydriasis, weakness, and seizures. Coma and death may follow. Toxicity predictably occurs at 10 times the recommended dose (50 µg/kg) for ivermectin and 5 times for milbemycin. Moxidectin and selamectin appear to be safe in collies at 10 times and 5 times, respectively, the prophylactic dose. Less common (<5%) toxicities occur in other dogs and are limited to lethargy and vomiting, which generally occur within 2 hours after drug administration. Occasionally, tachycardia, tachypnea, weakness, and pale mucous membranes accompany therapy. Treatment of toxicity includes fluid administration, glucocorticoids, and other supportive therapy. Animals with a very high microfilarial load may be more likely to have an adverse reaction to microfilaricide doses; adversity might be reduced in such animals by reduction of the dose of ivermectin by one third.

A concentration microfilarial test should be performed 3 to 4 weeks after microfilaricide treatment with ivermectin. Persistence of microfilariae after adulticide treatment (within the past year) may reflect failure of microfilaricide therapy (approximately 10% of animals) or a surviving gravid female. Microfilaricide therapy should be repeated, and, should microfilaria still persist, an adult antigen test should be repeated 60 to 90 days after adulticide. If the test is positive, the adult worms most likely are young females, and repeated adulticide therapy may not be effective. Therapy should be withheld for 1 year, but microfilaricide therapy should begin. When given at doses that are microfilaricidal, ivermectin also will prevent infection. Ivermectin can be used as a preventive in older or severely affected animals that are heartworm positive but for which adulticide therapy is not immediately or ever anticipated. Ivermectin not only will prevent further infection in these animals but also will reduce the microfilarial load, thus decreasing the risk of future adulticide complications. When a microfilaricide is administered, any animal will be protected against reinfection that may have occurred during the 1 to 2 months that elapsed between adulticide and microfilaricide therapy. Because the prophylactic doses of ivermectin can reduce microfilariae, causing an occult disease (generally within 6 months of prophylactic therapy), antigen testing rather than microfilarial concentration is the recommended method of screening for heartworm disease in animals on a monthly preventive program.

A number of other drugs are microfilaricidal, including fenthion, diethylcarbamazine, levamisole (11 mg/kg orally once daily for 7 to 10 days), and dithiazanine iodide (4.4 to 8.8 mg/kg orally once daily for 7 to 10 days); the latter drug is approved by the Food and Drug Administration for this use in dogs. The safety and efficacy of these products are not, however, predictable.²⁸⁸ Treatment usually requires multiple days of therapy.

Feline Heartworm Disease

Differences exist in the pathyophysiology of heartworm infection as it occurs in the cat compared with the dog. Cats are more resistant to infection; accordingly, the rate of infection is lower²⁷⁷ both in incidence and worm count (generally less than 6 and often only 2 or 3); further, the life expectancy of adult worms is shorter (2 to 3 years). Diagnostic limitations caused by low antigen load may underestimate the true prevalence of infection in cats. Despite the low worm load, the pathophysiology of the disease is similar in cats but more exaggerated, and sudden death is more frequent. Proliferation and inflammation are marked in the cat, and trophic factors from leukocytes may largely be responsible for the differences in the magnitude of response.²⁷⁷ However, worm-mediated immune suppression may preclude emergence of clinical signs. The magnitude of thromboembolism apparently does not correlate with the number of infecting worms. Pulmonary infiltrates with eosinophils may develop. Paroxysmal coughing and dyspnea are the most common presenting signs, yet vomiting may be the only sign in some cats. Acute pulmonary thromboembolism is not unusual. Other clinical signs that may require pharmacologic management include tachycardia or bradycardia and neurologic disturbances (e.g., ataxia, blindness, seizures). Right-sided heart failure may occur with chronic disease, as might pleural effusions. Diagnosis of heartworm disease in the cat is more difficult than in the dog. Microfilariae usually are absent, and antigen testing tends to be less sensitive than in the dog because of the low worm burden. Even very sensitive tests, capable of detecting one female worm, may fail as a result of the frequency of unisex (male) infections in cats. Although antibody tests can detect either sex of larva or adult, they cannot discriminate active from past infection. Further, tests vary with the age of larvae. Nonselective angiography and echocardiography can be helpful in diagnosing feline heartworm diseases, although serologic testing based on adult antigens should be used to confirm the diagnosis.

Several preventives are currently approved in the United States for use in cats, including ivermectin (Heartgard for Cats: 55 µg/cat up to 2.3 kg or 5 lb; 165 µg/cat up to 7 kg or 15 lb, oral;), selamectin (Revolution for cats; 15 mg/cat if 2.3 kg or less, 45 mg for cats > 2.3 kg, topical) and moxidectin topical (with imidacloprid; Advantage Multiplex for Cats, 2.3, 4, and 8 mg topical for <2.3 kg (5 lb), 2.3 to 4.1 kg and > 4.1 kg (9 lb) cats, respectively).^{289,290} The need for adulticide therapy in cats is controversial. Infection may be self-limiting in asymptomatic cats or in cats with mild pulmonary infiltrates with eosinophils. Cats may respond to low doses of glucocorticoids. Adulticide should be reserved for cats that maintain clinical signs despite glucocorticoid therapy. Cats with low worm burden are more amenable to treatment. The worm burden might be surgically reduced in cats with a larger worm number. Thiacetarsemide has been studied in uninfected cats (n=14), and all but one cat reacted adversely; 66% developed lethargy, depression, and anorexia, and at least one third vomited.²⁹¹ Three of

14 cats undergoing the treatment protocol developed clinical signs consistent with fulminating pulmonary edema typical of anaphylaxis or an anaphylactoid reaction. All three of the cats died. Nine other cats developed acute respiratory signs. A follow-up study²⁹² with 23 cats (17 with heartworms) found no adversity to thiacetarsamide therapy. Yet Rawlings and Calvert²⁷⁷ report findings similar to those of Turner et al.²⁹¹ when treating cats with spontaneous infections. Melarsomine appears to be more toxic to cats than dogs; the American Heartworm Society notes that doses as low as 3.5 mg/kg may be toxic. Of the macrolide antimicrobials, ivermectin (24 µg/kg every 30 days for 2 years) has been demonstrated to reduce worm burden by 65% compared to untreated cats.

Cats also are at risk of developing acute pulmonary thromboembolism within the first 3 weeks of adulticide therapy. Glucocorticoids and heparin (50 to 70 U/kg subcutaneously every 8 hours) with or without aspirin therapy should be administered in the face of thromboembolism. Platelet counts should be monitored and antithrombotic therapy implemented if counts decrease below 100,000/mL. The presence of allergic pneumonitis may delay adulticide therapy. Treatment with prednisolone (1 to 2 mg/kg per day) for several days should resolve clinical signs, but clinical signs may return during adulticide therapy.

Microfilaricide therapy is largely unnecessary for cats because of the low incidence of microfilariae-positive disease. If microfilariae are present, ivermectin is an effective microfilaricide. Prophylaxis can be implemented with ivermectin (24 μ g/kg), milbemycin oxime (2 mg/kg), or selamectin (6 to 12 mg/kg).

Geographic differences in infection incidence is marked, with differences reflecting weather, economic foundation, and so forth. Clinicians should be aware that disease can occur at 3 months. Heartworms secrete substances that prevent vascular responses, and stimulate (possibly protective) inflammation. Note that the disease includes several processes. These include fibrosis, scarring, and similar lesions at the microcapillary level; alveolar capillary fibrosis; lesions up to the fourth or fifth obstruction of cross-sectional area of right or left caudal lobar arteries, and reduced blood flow. Occult disease with adult worms producing microfilariae worsens the disease (eosinophilic infiltrates or pneumonitis).

Bone Marrow Regulation

The bone marrow contains nonhematopoietic (osteoblasts, of pluripotential stromal origin) and hematopoietic (osteoclasts, of macrophage/monocyte origin) stem cells as well as nonosteogenic cells such as platelets and lymphocytes. Interaction is critical to hematopoiesis, with both nonhematopoietic and nonosteogenic cells contributing to regulation of hematopoietic cells and medullary poiesis. Multiple factors control the commitment, proliferation, and differentiation of bone cell precursors. These include but are not limited to cytokines, growth factors, systemic hormones, and transcriptional regulators. Cell-cell and cell-matrix interactions maintain contact between osteoblastic cells and osteoclast marrow precursors and between the stroma and hematopoietic cells. Among the interacting signals are adhesion molecules, including but not limited to integrins, selectins, and cadherins. Osteoclastogenesis is stimulated by interleukin (IL)-1 and tumor necrosis factor (TNF). The latter is released from marrow mononuclear cell lines in response to NFkB ligand (RANKL), IL-6, IL-11, macrophage colonystimulating factor (M-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) released from the stroma. Megakaryocytes appear to play a major role in the regulation of hematopoiesis through expression of a number of mediators such as RANKL, n-methyl d aspartate-type glutamate receptors, calcium-sensing receptors, osteonectin, and osteocalcin. Another example is thrombopoietin, which simultaneously regulates megakaryopoeisis and inhibits osteoclastogenesis.1

Red Blood Cell Formation Hematopoiesis

Hematopoiesis occurs through differentiation of stem cells that are formed early in embryonic life. Differentiation occurs in a series of steps in which burst-forming units (BFUs) and colony-forming units (CFUs) are formed for each of the major cell lines. These undifferentiated cells continue to proliferate and differentiate under the influence of a number of cellular and humoral factors that are produced by bone marrow and peripheral tissues.

Erythropoietin (EPO) is the most important regulator of the proliferation of committed erythroid cells (see the discussion of erythropoiesis-stimulating agents [ESAs]) (Figure 15-1).² The kidney is the major site of EPO production, where it is released in response to anemia or hypoxia. Among the more important regulators of the myeloid series are granulocyte colony-stimulating factor (G-CSF) and granulocyte/macrophage colony-stimulating factor (GM-CSF). Several vitamins are needed for red and white blood cell formation (hematopoiesis and granulopoiesis, respectively).^{2,3}

Drugs Affecting Red Blood Cell Formation

Pharmacologic therapy (Table 15-1) for anemia is oriented toward (1) providing components needed for red blood cell (RBC) production (e.g., proteins, vitamin B_{12} , and folic acid), including hemoglobin synthesis (iron and other minerals); and (2) stimulating bone marrow formation of RBCs.

KEY POINT 15-1 Blood cell formation cannot occur without adequate nutritional support, regardless of the effectiveness of drug therapy.

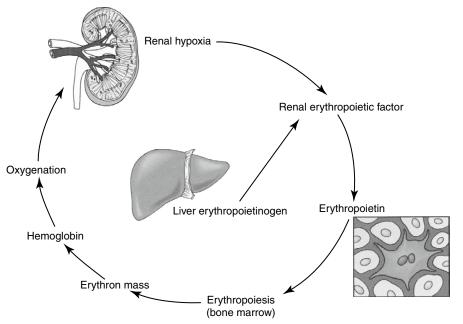

Figure 15-1 Red blood cell formation is stimulated in the kidney. Erythropoietic factor release is stimulated by hypoxia. Erythropoietin stimulates erythroid precursors and the release of reticulocytes into circulation.

Components Needed for Red Blood Cell Production

Vitamin B₁₂

Vitamin B_{12} (cyanocobalamin), the "maturation factor," is essential for DNA synthesis, and its deficiency inhibits nuclear maturation and division. Because cells that rapidly multiply are affected first, reduced RBC proliferation and a "maturation arrest" in the bone marrow are among the first indications of a vitamin B_{12} deficiency. The erythroblast cannot continue to divide, becomes very large, and is referred to as a *megaloblast* (megaloblastic anemia). The mature erythrocyte is also large and is referred to as a *macrocyte*. Although its oxygen-carrying capacity is adequate, the enlarged cell is very fragile because of its large size, and it has a reduced life span.^{2,3}

Vitamin B₁₂ is a porphyrin-like compound with a ring containing a centrally located cobalt.² It can be acquired from both the diet and microbes in the gastrointestinal tract. Most microbial production is in the large intestine, however, where B₁₂ is not readily absorbed because it is dependent upon receptor mediated uptake. Dietary deficiency of B₁₂ is unlikely and usually results from poor absorption (including pancreatic enzyme deficiency) from the gastrointestinal tract. Absorption of B₁₂ is complicated (Figure 15-2) and depends on several factors.² Gastric acid and pancreatic enzymes are needed to release B₁₂ from dietary and salivary binding proteins.² To avoid being digested, B₁₂ is protected by binding to intrinsic factor (excreted by the exocrine pancreas in cats⁴) and R protein, which are secreted by the parietal cells. The bound B_{12} complex is carried to the ileum, where B₁₂ is adsorbed to highly specific receptor sites on the brush border. Vitamin B₁₂ enters the cell by pinocytosis and then enters the blood, where it is bound with transcobalamin, the plasma carrier. Excessive vitamin B_{12} is stored in large quantities in the liver and is slowly released as needed. Vitamin B_{12} is excreted into the bile but undergoes enterohepatic cycling. Interference with absorption by the ileum will result in continuous depletion of B_{12} . Many months of defective vitamin B_{12} absorption are necessary, however, before vitamin B_{12} deficiency occurs. The anemia resulting from B_{12} deficiency is also referred to as *pernicious anemia*. Exclusive uptake of cobalamine in the ileum as led to its detection in serum as a tool for diagnosing disease of the ileum.⁴ Deficiency has been described (in cats) by increased serum methylmalonic acid (MMA) coupled with serum cobalamine at or below 100 ng/mL (the lowest detectable concentration). However, the description of clinical and biochemical signs associated with deficiency focused on the gastrointestinal tract and did not address tests indicative of anemia.

Vitamin B₁₂ is available as a parenteral preparation in the pure form of cyanocobalamin or the more highly protein bound hydroxocobalamin. Hydroxocobalamin may provide more sustained effects than cyanocobalamin when given by injection.² Vitamin B₁₂ is also available for oral administration in the pure form or in combination with other vitamins and minerals. Methylcobalamin is another congener of vitamin B₁₂ and represents one of the two intracellular active forms of the vitamin (the other being deoxyadenosylcobalamin).² Foods high in vitamin B₁₂ include selected microbial sources and animal (meat) products. There are no significant toxicities associated with therapy. Indications for B_{12} therapy are limited to situations of B₁₂ malabsorption such as ileectomy, gastrectomy, malabsorption syndromes, or chronic administration of cimetidine or other antisecretory drugs because an acid environment is necessary for release of B12 from the diet and for intrinsic factor activity. In one study⁴ response to cobalamin treatment (250 µg subcutaneously once weekly in cats (n = 19) with gastrointestinal disease was prospectively studied, with a focus on indicators

Drug	Dose	Route	Frequency (Days)	
Aspirin	0.5 mg/kg (normal dogs)	PO	12	
(antithrombotic)	5-10 mg/kg (heartworm)	PO	24

	0.5 mg/kg (cat)	PO	24	

PO, By mouth; SC, subcutaneous; IV, intravenous; DIC, disseminated intravascular coagulation; IM, intramuscular. Dose for the oral preparation has not been substantiated. As of this writing, the acetate preparation is no longer available in the United States.

*Monitor packed cell volume twice weekly for the first several months, and modify dose as appropriate. #Adjust dose by monitoring activated partial thromboplastin time to 1.5 to 2.5 times baseline.

[§]Or in blood products, incubated for 30 minutes before administration. ^{II}No more than 50 mg/10 min. Dose is reduced if time lapses between heparin overdose and protamine administration.

[¶]Approved for use in dogs and cats.

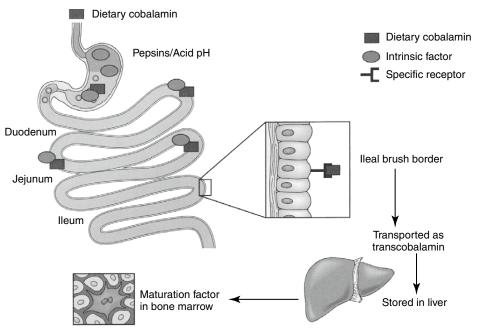

Figure 15-2 The absorption of vitamin B_{12} from the gastrointestinal tract is complicated and depends on the release of intrinsic factor and hydrochloric acid from the stomach. The drug complexes with a receptor. This complex is protected as it passes to the ileum, where it is absorbed by receptor-mediated pinocytosis.

of gastrointestinal health. Indicators of cobalamin deficiency (serum MMA, cysteine) improved and were correlated with weight gain and folic acid use, however, improvements in indices of red blood cell health were not addressed.

Folic Acid

Folic acid (pteroylglutamic acid) is a cofactor needed for DNA synthesis because it promotes the formation of a nucleotide necessary for DNA formation. Folic acid is also necessary for RNA synthesis, and it serves as a methyl donor for the formation of vitamin B₁₂.² Folic acid is acquired from the diet, although it can also be formed by microbes. Dietary sources include yeast, liver, kidney, and green vegetables. Folic acid is also stored in the liver but not as avidly as is vitamin B_{12} . It undergoes enterohepatic circulation but is destroyed daily by catabolic processes. Daily requirements are high, and serum levels will fall rapidly several days after dietary deficiency. Gastrointestinal absorption of folic acid is not as complex as that of vitamin B₁₂, although it requires protein digestion and the presence of dihydrofolate reductase in the small intestine. Jejunal pathology can result in folate deficiency. The degree of folic acid binding to plasma proteins is not well understood.

Folic acid is available as both a parenteral and an oral (pure or combined product) form. The minimum daily requirement in humans is 50 μ g/day, but this can increase to 100 to 200 or more in patients with high cell turnover rates (e.g., hemolytic anemia).² In humans the most popular form of folic acid supplementation is as part of a multivitamin preparation containing 400 to 500 μ g of pteroylglutamic acid. In high disease states, 1 to 2 1-mg tablets are consumed. This dose may be the source of the recommended dose for cats and dogs. Compared with commercially available products, the dose recommended for small animals seems excessive, and it is not clear that such a high dose is necessary. There are, however, no apparent significant toxicities associated with therapy.

Indications for therapy are inadequate intake as a result of the administration of several drugs (methotrexate, potentiated sulfonamide antibiotics, some anticonvulsants such as phenytoin), liver diseases, malabsorption, or other chronic debilitating diseases. Folinic acid (leucovorin) is a formyl derivative of tetrahydrofolic acid and as such does not require the action of dihydrofolate reductase in order to act as a folate by contributing a carbon moiety. In humans, administration of folinic acid increases serum folate activity owing to 5-methyltetrahydrofolate. Folinic acid apparently serves as a substrate for inhibitors of dihydrofolate reductase such as methotrexate, or diaminopyrimidines such as trimethoprim or ormetoprim, and as such, can resolve some deficiencies associated with folic acid deficiency. However, it will not replace deficient folic acid or any of its derivatives prior to the tetrahydrofolate step in folic acid use.² As such, leucovorin can be used clinically to circumvent the actions of dihydrofolate reductase (e.g., methotrexate) and replace materials in the folic acid pathway beyond tetrahydrofolate, but can not prevent folic acid deficiency. Leucovoran also inhibits thymidylate synthtase and as such, facilitates anticancer efficacy of 5-fluorouracil.

Hemoglobin Synthesis: Iron

Hemoglobin consists of a heme portion and a globin portion. The heme portion is formed from a pyrrole ring, four of which combine to form a protoporphyrin compound. This in turn combines with iron to form heme. Four hemes combine with the globulin globin to form hemoglobin. Several factors are necessary for hemoglobin formation.

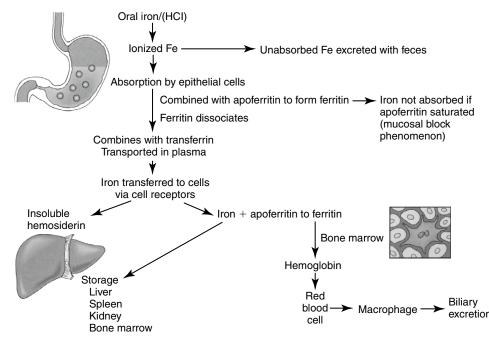

Figure 15-3 Absorption of usable iron from the gastrointestinal tract is maximized in an acidic environment. Iron combines with apoferritin in cells to form ferritin, the soluble form of iron. Iron is bound to transferrin in plasma. Saturation of apoferritin leads to saturation of transferrin. Excessive iron is stored as hemosiderin, a nonsoluble form of iron. In the presence of saturation, iron is eliminated in the gastrointestinal tract.

Iron is a component of hemoglobin, myoglobin, and other substances, such as those found in cytochrome and electron transport systems.^{2,3} Approximately 65% of total body iron is present in hemoglobin, 4% as myoglobin, and 1% in cytochromes and electron transport systems. The remaining 15% to 30% is stored as either ferritin, the soluble form of iron stores, or hemosiderin, the insoluble stores. Oral absorption of iron is slow, complicated, and not well understood (Figure 15-3). It is available in the diet in either a heme form, which makes up a small percentage of the total but readily absorbed form, or in a nonheme (ferric oxide) form. The nonheme form represents the largest dietary fraction, but its absorption is profoundly affected by dietary factors. Nonheme iron must be converted to the ferrous form for absorption to occur; conversion depends on an acidic environment. Absorption of iron is increased by hydrochloric acid and decreased in situations that decrease acid production in the stomach (e.g., chronic use of antisecretory drugs).

Iron is absorbed primarily from the proximal jejunum, where it immediately combines in the enterocyte with apoferritin to form ferritin. When transferred out of the enterocyte, ferritin dissociates, and iron combines with the globulin transferrin. Iron is transported in the plasma in this form, but the binding is loose so iron can be easily transferred to tissues. Iron is transferred to cells by way of specific receptors that interact with transferrin, especially in the liver. In cells, iron again combines with apoferritin to become ferritin. Small quantities are also stored as the very insoluble hemosiderin; the quantity of this storage form increases when the total quantity of iron in the body is much more than apoferritin can accommodate. When apoferritin is saturated, transferrin cannot release iron, and it thus becomes close to 100% bound (estimated iron stores).

There is no mechanism for the excretion of iron other than by the gastrointestinal tract. Gastrointestinal tract elimination occurs by (1) exfoliation of enterocytes containing iron, (2) biliary elimination, and (3) elimination in diet of iron not absorbed. Total body iron is regulated by altering the rate of absorption. If all the apoferritin in the enterocyte is combined with iron, the amount of iron in the enterocyte is high, and absorption from the diet is slowed. Absorption is faster if iron stores are depleted. This mechanism has been referred to as the *mucosal block phenomenon*.

Preparations. Iron is available in both oral and parenteral preparations. Oral preparations are prepared as ferrous (bivalent) or ferric (trivalent) salts. Ferrous salts tend to be the treatment of choice for oral supplementation and are dosed according to their iron content.² Examples of bivalent ferrous salts include sulfate (20% iron), gluconate (12%), and fumarate (33%). The ferrous bivalent salts are more soluble in the gastric environment and are absorbed three times faster than the trivalent salts. The efficacy of polysaccharide oral iron products approximates that of ferrous products. Slow-release iron products have not been well studied. These products may be continued for several months; toxicities and side effects are dose related.

KEY POINT 15-2 Response of anemia to iron supplementation should be anticipated only if the cause is iron deficiency. Excessive iron therapy should be avoided because excessive iron cannot be easily excreted. Parenteral preparations are indicated if oral preparations cannot be tolerated or are not feasible. Iron dextran administered by intramuscular injection generally is preferred. Parenteral administration results in a more rapid accumulation of iron stores, which may take months (in humans) with oral therapy. Other indications for parenteral therapy include diseases of the gastrointestinal tract that preclude iron absorption or that will exacerbate another disease (e.g., inflammatory bowel disease) or intolerance of oral supplementation.² Much of the iron given intramuscularly remains at the site of injection for several months. The remaining iron enters the plasma but must first be phagocytized by reticuloendothelial cells for processing. This may take several months, and evaluation of total body iron may be difficult until all of the iron is processed.²

In human patients iron injection is preceded by a test dose (approximately 0.5 mL). It is given only in a large muscle mass and is associated with long-term discomfort, local skin discoloration, and a perceived risk of malignant change at the site of injection. Selected iron dextran preparations also can be administered intravenously. Dosing is based on a conversion of body weight ($0.66 \times$ weight in kilograms) and on the patient's hemoglobin level compared with the desired hemoglobin level (14.8 g/dL).² After an initial 0.5-mL test dose, the calculated dose is given in 2-mL increments each day until completed. Side effects associated with intravenous administration include malaise, fever, arthralgias, urticaria, and generalized lymphadenopathy.²

Drug interactions. Several drugs, including tetracyclines and antacids, and several foods bind to and precipitate iron when given orally. Absorption is enhanced in the presence of ascorbic acid because it reduces ferric iron to its ferrous state and prevents formation of insoluble and unabsorbable iron compounds.⁵

Clinical use. Indications for iron therapy are limited to treatment or prevention of iron deficiency such as occurs with blood loss or successful therapy with anabolic steroids or recombinant EPO in a patient suffering from chronic anemia. The efficacy of "shotgun" products is questionable. As with any hematinic preparation, provision of these compounds will be ineffective if the nutritional status of the animal is poor. Shotgun preparations are products that contain a combination of hematinic agents such as vitamin B₁₂, folic acid, pyridoxine, riboflavin, nicotinic acid, pantothenic acid, thiamine, biotin, ascorbic acid, and vitamin E. The need for inclusion of all of these products is not clear. An exception might be made for ascorbic acid, which enhances oral absorption of iron, and pyridoxine, which is useful in human patients with selected anemias. One human patient with pure red cell aplasia has responded to riboflavin. Occasionally, these products might be considered dangerous because some additives may be sufficiently high to mask clinical signs of other nutrient deficiencies that ultimately may become life threatening.²

Bone Marrow Stimulation

Erythropoiesis-Stimulating Agents

EPO, an endogenous glycosylated protein hormone (MW 30,000 daltons), is the most important regulator of committed erythroid progenitor proliferation.² Extensive glycosylation

is responsible for the activity of the molecule.⁶ The kidney (peritubular cell) is the primary source of endogenous EPO, although the liver produces a small amount in some species. Insufficient oxygen delivery to tissues is the primary stimulus for promotion of the transcription and thus production and secretion of EPO² (see Figure 15-1). Hypoxia or anemia will increase synthesis by a hundredfold or more. However, renal disease, damage to the bone marrow, or deficiencies of iron or other essential vitamins can impair synthesis. Inflammatory cytokines also impair secretion (as well as iron delivery). Prostaglandins appear to increase and nonsteroidal antiinflammatory drugs appear to decrease EPO production.

KEY POINT 15-3 Formation of antibodies to foreign erythropoietin may lead to therapeutic failure as long as 12 months after the beginning of therapy. As such, treatment should be reserved for states of erythropoietin deficiency or for those limited indications for which efficacy has been demonstrated through well-designed clinical trials. Iron deficiency might be anticipated in some animals.

Mechanism of Action

Once released from the renal cell, EPO travels to the bone marrow, where it binds to receptors on the surface of committed erythroid progenitors. The influence of EPO (including ESAs) on RBC production occurs at several steps. EPO binding initiates changes in intracellular phosphorylation.² Additionally, EPO stimulates proliferation and differentiation of erythroid precursors, including BFU–erythroid CFUs: erythroid, erythroblasts, and reticulocytes.² Recombinant human EPO also stimulates the release of reticulocytes from the bone marrow into the blood, where they subsequently mature.⁷⁻¹¹

Preparations

Human EPO has been isolated and cloned and can be synthesized in large quantities with recombinant techniques using a mammalian (hamster cell line). ESAs include two recombinant EPO (rEPO) products. Epoetin is a recombinant human product (rhEPO), available in two products that differ in their glycosylated carbohydrate patterns: alpha (Epogen, Eprex) and beta (Procrit). A second ESA is darbepoetin, a recombinant hyperglycosylated analog of the human protein, often referred to as a second-generation EPO. Hyperglycosylation increases stability. Darbepoetin is dosed in µg/kg, whereas epoetin is dosed as units/kg for epoetin: a dose of 6.25 to 12.5 µg/kg of darbepoeitin is equivalent in humans to a dose of 2500 to 5000 units/kg of rhEPO (0.0025 µg darbepoetin to 1 unit epoetin).¹² Albumin is included as a vehicle in both epoetin alpha and darbepoetin. However, because of the concern regarding potential transmission of disease carried by albumin, alternative vehicles such as polysorbate 80 have been used to formulate epoetin beta.¹³ Products are intended for intravenous or subcutaneous administration. Both canine (rcEPO)¹⁴ and feline (rfEPO)¹⁵ recombinant products have been developed but are not yet commercially available. Canine EPO is more closely homologous to feline EPO compared with rhEPO and will be preferred in cats should rcEPO approval precede the feline product.

Disposition

The disposition of ESAs has not been well characterized in either humans or animals. Glycosylation (addition of carbohydrates) prolongs elimination compared with the endogenous proteins. In humans the elimination half-life of rh-EPO is about 6 to 9 hours after intravenous administration, with a very small volume of distribution (0.055 L/kg). As with most endocrine products, plasma half-life may not necessarily reflect biological half-life.^{9,11} Glycosylation of darbepoetin is greater than that of epoetin, leading to an accordingly longer (threefold) biological half-life in humans. Dosing subsequently can be reduced to every other day (3 times weekly).²

Adverse Effects

Antibody formation. Use of ESAs is associated with immunogenicity, and relevant side effects should be anticipated when administering foreign protein products intended to mimic endogenous protein products.¹⁶ Pure red cell aplasia (PRCA) is a recognized, albeit rare, sequela of rEPO in humans.¹⁷ In 1998 a formulation was approved internationally that varied from the U.S. product by vehicle, storage, and handling. The use of the product was associated with an increased incidence of PRCA, leading to the assumption that the differences increased the immunogenicity of the product.¹⁸ The increased frequency of disease facilitated its characterization.Clinically manifested as a rapid onset of severe anemia, refractoriness to rhEPO therapy, and a low reticulocyte count, PRCA is associated with high concentration of EPO-neutralizing antibodies, probably of IgG origin.^{6,19} Diagnosis is confirmed by the presences of EPO neutralizing antibodies in circulation, absence of bone marrow red cells and normal to elevated transferrin saturation. Testing no longer appears to be available for either eryropoietin or antibodies for dogs or cats. In one study, greater than 95% of human cases afflicted with chronic renal disease received the drug subcutaneously for a mean of nine months before the onset of PRCA. Antibodies resolved in 80% of patients when the drug was discontinued but only in the presence of immunosuppressive therapy.^{13,17,19} A lower incidence of PRCA was found in patients with cancer chemotherapy-related anemia, probably because anticancer therapy led to immunosuppression.¹³ The incidence of PRCA has been reduced by methods intended to reduce immunogenicity. These included changes in processing that contributed to immunogenicity (such as freeze drying), changes in packaging (replacement of rubber stoppers with Teflon, removal of silicone lubricant in prefilled syringes), and a shift from subcutaneous to intravenous administration.¹³ Darbepoetin may be associated with less immunogenicity compared with rhEPO, as is shown by response in one human patient to darbepoetin despite development of rhEPO-induced PRCA.²⁰

Because of the foreign nature of EPO, adverse effects reported in humans also should occur with rhEPO administration in animals. Local and systemic allergic reactions include cellulitis, fever, arthralgia, and mucocutaneous ulcerations, which occurred in 12% of animals treated in a pilot study.²¹⁻²³ Signs resolve with drug withdrawal but may reappear when treatment is resumed. Because antibodies directed toward the

foreign rhEPO may stimulate production of antibodies targeted toward endogenous EPO, RBCs, hematocrit, and hemoglobin may progressively decrease starting as early as 2 weeks of therapy.²¹⁻²³ Antibodies are indicated by a bone marrow myeloid-to-erythroid cell ratio of less than 8. Discontinuation of rhEPO will result in resolution of antibody formation and, to some degree, the anemia (i.e., that caused by antibodies), but drug therapy cannot be reinstituted.²² The incidence of antibody formation is high, developing in 63% to 100% of healthy dogs receiving EPO.24 Red cell aplasia was associated with anti-Epogen antibodies in two out of three dogs treated longer than 90 days and seven out of eight cats treated for 180 days or more. For the cats, 70% were refractory to further EPO therapy, requiring transfusion therapy until anti-epoetin antibody concentrations decreased (2 to 4 months after rhEPO was discontinued. Because both exogenous and native EPO may be impaired, aplastic anemia resulting from bone marrow failure may ultimately occur. Immunosuppressive therapy directed toward antibody formation, although apparently successful in humans, has not been addressed in veterinary medicine. Antibodies generally require 2 to 12 months after therapy is discontinued for eradication. Species specificity of rEPO should minimize the advent of anti-EPO antibodies as has been demonstrated for both the dog^{24,25} and cat.¹⁵ Randolph and coworkers¹⁵ have demonstrated that the feline recombinant product not only does not induce antibodies but also will re-establish erythropoiesis in most cases of rhEPOinduced red cell aplasia. Unfortunately, the same does not appear to be true for the canine recombinant preparation²⁵ in dogs, suggesting that even species-specific origin of rEPO may be associated with antibodies.

Miscellaneous adverse effects. Other adverse effects that may require monitoring in patients receiving EPO include systemic hypertension, iron deficiency, hyperkalemia, and polycythemia.⁸ Flulike symptoms occur in some human patients receiving the drug intravenously. Hypertension occurs in many human patients with renal disease as the hematocrit normalizes. Patients who begin the use of rhEPO when in a state of hypertension are likely to experience a further increase in blood pressure. The mechanism of hypertension is not known but may include increased blood viscosity or peripheral vasoconstriction. Blood pressure increases within as little as 2 weeks of therapy and tends to stabilize by month 4. Increased blood pressure has been reported in 40% to 50% of dogs or cats treated with ESAs.²⁶ It may be necessary to adjust drug therapy for hypertension (e.g., increase amlodipine dose).²⁷ Polycythemia is another likely sequela of ESAs if response to therapy is not monitored on the basis of packed cell volume (PCV).27 Other miscellaneous adverse effects of rhEPO in dogs and cats include seizures (one in six dogs, two of eleven cats²⁶), particularly in animals with moderate to severe azotemia and as a terminal clinical sign.²⁷ Depleted iron stores should be anticipated in patients with iron deficiency (discussed later).²² Pain on subcutaneous injection (a route being used less frequently in humans in order to minimize PRCA) varies with products, with the alpha (e.g., Eprex) being more painful in humans than the beta (Procrit). In an animal model involving renal ablation, rhEPO actually hastened the progression of chronic renal disease. However, the clinical relevance of this finding has not been documented.

Indications and Clinical Use

The primary indication for ESAs in humans is anemia of chronic renal disease (CRD).7,8,21,23,28 Most human patients receiving renal dialysis also receive ESAs. Indications in animals are likely to be similar to those in humans, particularly for renal disease, because clinical signs of weakness, somnolence, depression, and poor appetite associated with CRD in cats (and presumably dogs) is due to anemia. Decisions must be made regarding the product (epoetin, alpha or beta, versus darbepoetin), route (intravenous versus subcutaneous), and dosing regimen (dose and interval). Subcutaneous administration of epoetin—which can cause pain on administration has been associated with better response in humans, although it appears to be more immunogenic. In contrast, darbepoetin appears to be equally efficacious regardless of the route.²⁹ Preference among the ESA products is not yet clear; evaluation of darbopoetin currently is ongoing.³⁰ Advantages of darbopoetin may include faster response time, particularly with front end loading, decreased dosing intervals, and decreased risk of immunogenicity. The average dose of darbepoetin used in human patients with CRD or cancer ranged from 3.5 to 5 µg/kg 1 to 3 times per week; preliminary studies indicate that administration as infrequent as once every 3 weeks may be sufficient.

Because it has been available longer, more information is available regarding rhEPO use in both humans and animals. In humans with CRD, rhEPO normalizes the hematocrit, hemoglobin concentration, and RBCs after administration of 15 to 300 U/kg rhEPO 3 times weekly. Some human patients have required 500 U/kg. A stair-step approach has been used for nonresponding CRD in human patients in that the dosage continues to be increased until the desired response is achieved.8 When the desired response is achieved (a hematocrit of 30% to 40%), a smaller maintenance dose (25 to 100 U/kg three times a week) is given to maintain the hematocrit above 30%.8 Normalizing the PCV in patients with underlying renal disease may be associated with a greater risk of cardiovascular side effects.³¹ Because of convenience and cost, in humans the maintenance dose generally has been given subcutaneously, whereas the induction dose is often given intravenously. However, intravenous administration increasingly is being used for maintenance dosing to minimize the risk of immunogenicity (in human patients).¹⁸ The intravenous route in humans has the added advantage of convenience in those individuals with chronic access ports (i.e., human patients undergoing dialysis), a situation that is less likely in animals.

Erythropoetin therapy is indicated in dogs or cats with a PCV of 20% to 25% or less owing to renal disease (see Table 15-1). To date, of the commercially available products, reports (whether scientific or anecdotal) of use in animals are limited to alpha EPO. Recombinant human EPO has been used in small animals with chronic anemia.^{21,22,23} When administered in uremic animals with CRD, the hematocrit of most

patients normalizes within 3 to 4 weeks of therapy, and the clinical well-being of patients improves. Response to therapy is indicated by reticulocytosis, and an increase in hematocrit of 0.5% to 1% each day. Hypokalemia associated with uremia in cats should also resolve, in part because of improved appetite.²² White blood cells and platelets do not seem to be affected. Caution is indicated for patients that are hypertensive before rhEPO therapy. Informed consent should be obtained before use because of the high incidence of antibody formation. Initial treatment should begin at 100 U/kg (or, if a slower increase is acceptable, 50 to 75 U/kg) subcutaneously 3 times a week until the target hematocrit (originally 37% to 45% in dogs or 30% to 40% in cats; more recently 30% to 35% for dogs and 25% to 30% in cats) has been reached.²⁷ Generally, response requires approximately 4 weeks. The PCV should be measured twice weekly for the first several months of therapy. The dose is decreased to a maintenance dose of 50 to 100 U/kg and the frequency of administration to twice weekly once the target PCV has been achieved. The dose should be titrated to maintain the PCV in the mid-target range. If the PCV does not increase sufficiently, the dose of rhEPO can be increased in 25- to 50-U/kg increments. The maintenance dose will vary for each patient. A maximum dose has not been established in animals, although weekly doses of 300 to 1050 U/kg have been reported.22

Among the more common causes of ESA therapeutic failure in humans is iron deficiency. Iron therapy generally is begun along with rhEPO. Iron therapy is not easily monitored. In humans serum ferritin and transferrin iron saturation are the most common tests used.³² An increasing percentage of hypochromic red blood cells and decreasing content of hemoglobin in reticulocytes may also reveal iron deficiency but will not reveal iron overload. Iron gluconate and iron sucrose are considered the safest of the intravenous iron medications.³² However, because intravenous iron dextran therapy is more expensive and is associated with anaphylactic therapy, oral iron therapy is preferred.^{2,8} Further, the body can control iron content with oral but not intravenous administration. Differences in the gastrointestinal absorption of iron may alter response to rhEPO therapy. Addition of 200 mg of oral iron, however, appears to successfully maintain adequate iron stores in human patients with CRD receiving rhEPO. Oral iron supplementation in dogs is recommended at 100 to 300 mg of ferrous sulfate daily (20- to 60-mg elemental iron) and for cats 50 to 100 mg (10 to 20 elemental).²⁷ Iron dextran (10 to 20 mg/kg for dogs and 50 mg total dose for cats) is recommended by intramuscular administration (deep) for animals that cannot tolerate oral supplementation. Note that oral absorption of iron may not occur until serum ferritin is below 30 to 50 ng/mL (human patients). Erythropoiesis improves, however, even in human patients whose transferrin saturation is above that diagnostic of iron deficiency (16%).33

Anemias other than that associated with CRD also may be associated with decreased levels of endogenous EPO in animals and thus might respond to supplementation. However, the potential application of these indications in veterinary medicine must be balanced by the lack of scientific support and the adversities that are more likely in animals compared with humans if rh-EPO is used (e.g., antibody production). These have been reviewed by Langston and coworkers²⁷ and others.^{2,34} An enzyme-linked immunosorbent assay (ELISA) kit developed to detect canine EPO may be helpful in identifying the need for supplementation although access at the time of publication is not known.³⁵

The most common nonrenal use of ESAs in humans is anticipation of autologous blood transfusion; use of rhEPO increased the number of autologous units collected, and pretreatment may decrease the need for allogenic transfusion therapy. Although the need is less clear, a similar approach should be of benefit in animals; experimentally, pretreatment with iron and rhEPO in dogs resulted in higher hematocrit levels after transfusion than those in pretreatment with iron and saline.²⁷ Selected (nonmyeloid) cancer anemias associated with chemotherapy may respond to EPO supplementation, including multiple myeloma and myelodysplastic diseases (the latter defined on the basis of cytopenia, dysplastic hematopoietic precursor cells and less than 30% blasts in the bone marrow).^{2,27,34} Anemia associated with cancer may reflect an inadequate EPO response; in humans the ratio of measured to predicted EPO (the latter based on population studies) of less than 0.9 is interpreted as an indication of potential response. Response may be related to dose: One retrospective study of multiple myeloma in humans reported a higher overall survival in patients who received a high dose (greater than 60,000 U/week) rather than a lower routine dose.³⁶ The use of ESAs in human cancer patients has been reviewed,³⁸ and guidelines for such use have been published.38,39

A combination of rhEPO and immunosuppressive therapy apparently was not successful in cats with pure red cell aplasia (not associated with previous rhEPO therapy) but may have prolonged survival rates of dogs with myelofibrosis.²⁷ An interesting and potentially relevant application of ESA is for patients in the intensive care unit. In human patients in the intensive care unit, blood loss, including that associated with repetitive phlebotomy for diagnostic testing, can be significant. The veterinary patient-particularly the smaller onemay be similarly predisposed. Relative EPO deficiencies in these patients further predispose to anemias, as is indicated by transferrin saturations of less than 20% in the majority of patients. The use of rhEPO decreases the number of transfusions needed in these patients. The use of exogenous EPO in viral immunosuppressive diseases is tempting but controversial and might best be based on demonstration of endogenous EPO deficiency. Whereas endogenous EPO appears to be low and thus exogenous therapy is of benefit in human patients with HIV-associated anemia, EPO concentrations are increased in feline patients with feline leukemia virus.²⁷ However, the PCV increased after 2 weeks of rhEPO in nonanemic cats positive for feline immunodeficiency virus; antibodies did not appear with this short-course therapy. Other uses of rhEPO in dogs have been characterized by variable success. The use of rHEPO in racing animals is likely to be associated with the production of antibodies and therefore is discouraged not only for ethical and legal reasons but also for health reasons. Human growth factors (granulopoietin and EPO) were associated with bone marrow recovery in a dog with ehrlichiosis.⁴⁰ However, therapy took several months before response in peripheral counts were realized. The use of EPO in patients with pancytopenia associated with parvovirus is controversial, particularly in light of one case of fulminant infection in a human patient with immunodeficiency who was subsequently treated with rhEPO.⁴¹ Evaluating response of drug-induced bone marrow depression to rHEPO is complicated by the impact of discontinuing the inciting drug.

Therapeutic Failure

The most likely reason for a patient not to respond to rhEPO is inappropriate therapy. If the anemia is not associated with CRD, rhEPO therapy may be ineffective if endogenous rhEPO concentrations are maximally increased. Failure in a patient with low endogenous rhEPO may occur for several reasons. The dosage may be insufficient. Failure of an anemic animal to respond to rhEPO may indicate the development of antibodies directed toward rhEPO, as previously discussed.²² Animals that develop antibodies should recover, with antibodies potentially resolving within 3 to 4 weeks in dogs. Recovery may depend in part on the severity of renal disease, with recovery less likely in those animals with severe renal disease. In humans pure red cell aplasia as a result of antibody formation may be treated with a low dose (3.3 mg/kg) of cyclosporine.^{6,42} Differences in vehicles, stabilizers, and handling were identified as possible contributors to autoantibodies in human patients with renal disease who were receiving recombinant EPO; changes in response to these problems has dramatically reduced the incidence of antibody formation.¹⁶ Response to ESAs is likely to require iron supplementation.²² Chronic inflammatory disease decreases response to rhEPO, as do myelophthisic diseases that replace bone marrow with fibrous tissue. Alternatively, anemia may persist because patient nutrition is not sufficient to support increased EPO.

Granulopoietin and Related Products

At least six growth factors influence granulopoiesis.² Formation of both granulocytes and macrophages from multipotential stem cells is stimulated by stem cell factor, a glycoprotein produced by bone marrow stromal cells; IL-1 and IL-6, inflammatory cytokines that mediate many of the systemic manifestations of acute inflammation; and IL-3. GM-CSF, along with G-CSF, is produced by a variety of tissues in response to cytokines such as IL-1, TNF, and endotoxin.^{2,5} Supplementation with exogenous factors stimulates the proliferation of various cell types, with the type affected depending on the factor or combination of factors. IL-3 increases both platelets and granulocytes, and GM-CSF administered by itself stimulates granulocyte and macrophage proliferation. When given in combination with IL-3, however, GM-CSF stimulates thrombopoiesis, and when combined with EPO and IL-3, erythropoiesis is stimulated as well.43

As with EPO, recombinant products have been developed for therapeutic stimulation of granulopoiesis. Both recombinant canine (rcGSF) and recombinant feline (rfGSF) G-CSF have been cloned, but neither is commercially available at this time. Feline GSF has much closer homology with rcGSF than with rhGSF and thus is the preferred product. Despite their lack of availability, the factors are increasingly being studied for treatment of neutrophil disorders in dogs and cats.^{5,44}

In normal dogs G-CSF (5 µg/kg per day) will increase neutrophil counts over fourfold within 24 hours, reaching a maximum of approximately 72,000/mL by 19 days, with counts returning to normal within 5 days after discontinuation of therapy.⁴⁴ In dogs afflicted with cyclic neutropenia, rcGSF (2.5 µg/kg every 12 hours) prevents neutropenia and associated clinical signs, although cycling of neutrophils is not prevented. Chemotherapy-induced neutropenia (induced by mitoxantrone) was minimized in dogs receiving rcGSF for 20 days. Studies in normal cats receiving rcCSF reveal an approximately threefold increase in neutrophil count that persists until the drug is discontinued. No adverse effects occur.44 Cohn et al.⁴⁵ demonstrated that plasma G-CSF concentrations increased just after the onset of neutropenia in puppies (n = 8)experimentally exposed (oronasal) to parvovirus. Neutrophil counts rebounded within 2 to 3 days, and G-CSF concentrations decreased before neutropenia resolved, questioning the benefits of exogenous therapy. However, recombinant human G-CSF did correct canine cyclic hematopoiesis in one study.⁴⁶

Other compounds have been studied for their effect on granulopoiesis. An extract of *Serratia marcescens* activates interferon- α and interferon- γ , as well as IL-1, IL-6, and GM-CSF, and induces myeloproliferation either directly or through release of other cytokines.⁴⁴

Vincristine

Vincristine has demonstrated efficacy in the treatment of thrombocytopenia. Its mechanism is not clear, but several have been proposed. These include decreased upregulation of glycoprotein receptors on platelets, thereby reducing interaction with von Willebrand factor (vWF) and platetet aggregation, or reduction in immunglobulin G (IgG) autoantibodies that damage endothelial cells or suppress von Willebrand factor-cleaving protease activity.47 Other mechanisms suggested in the veterinary literature have included impaired macrophage phagocytosis of platelets and effects at the bone marrow (increased megakaryocyte fragmentation and stimulation of thrombopoiesis).48 For acute episodes of thrombocytopenia purpura in humans, vincristine treatment has been considered a salvage treatment (1.4 mg/m² followed by 1 mg on days 4 and 7).49 However, its success in these patients has led to more frequent use as first-choice therapy. A retrospective study in humans found patient outcome (survival) to be better when vincristine therapy was administered initially as opposed to 3 days into treatment.⁵⁰ The authors subsequently encourage the early, initial use of vincristine as part of combination therapy, including traditional modalities. Dogs with severe immune-mediated thrombocytopenia (IMT; platelet count less than 15,000/ μ L) appear to be respond similarly. In a prospective study, Rozanski and coworkers⁴⁸ found that platetet counts in dogs with IMT increased more rapidly in patients that received prednisone (1.5 to 2 mg/kg/day) and vincristine (0.02 mg/kg)

as opposed to prednisone alone. Further, animals refractory to prednisone alone for 7 days responded rapidly when vincristine was added to therapy. However, all dogs also were treated with doxycycline (10 mg/kg/day) for 7 days. Because IMT in dogs is characterized by increased antiplatelet antibodies on platelet surface, response to vincristine might be expected in this syndrome more than other causes of thrombocytopenia. Because vincristine is a relatively safe drug, initial therapy with vincristine should be considered in dogs with moderate to severe IMT.

TREATMENT OF DISORDERS OF HEMOSTASTIS

Anabolic or Androgenic Steroids

Chemistry

Anabolic steroids are synthetic compounds structurally related to testosterone. They have protein-anabolic activity similar to that of testosterone but ideally minimal androgenic effects (i.e., minimal masculinization) (Table 15-2).^{51,52} Testosterone is the sole endogenous androgen in most mammals. Its androgenic effects and rapid elimination have led to the manufacture of synthetic compounds. Chemical manipulations that have produced clinically useful anabolic steroids include (Figure 15-4) (1) alkylation (addition of a methyl [CH₃] group) at the 17β position (e.g., methyl-testosterone, stanozolol), which impairs hepatic metabolism, thus prolonging elimination half-life; (2) esterification of the 17β hydroxyl group (e.g., Deca-Durabolin) such that absorption from parenteral sites is prolonged; and (3) modification of the steroidal ring structure. The sequelae of changes in the steroidal structure vary with the modification and include prolonged absorption or elimination.

KEY POINT 15-4 The role of anabolic steroids in the treatment of anemia is primarily chronic, nonregenerative anemias that fail to respond to erythropoietin.

Mechanism of Action

The mechanism of hematinic action of anabolic steroids on the cellular level is typical of the steroidal compounds.⁵²⁻⁵⁵ Anabolic steroids enter the RBCs, where they enhance

Table 15-2	Anabolic and Androgenic Activity of Selected Steroids			
Generic Name	Trade Name	Anabolic	Androgenic	
Injectable		(1=low)	(5 = very high)	
Testosterone cypionate, enanthate		4	3-4	
Nandrolone decanoate	Deca-Durabolin	4	2-3	
Stanozolol	Winstrol	2-3	1	
Oral				
Oxymetholone	Anadrol	5	5	
Oxandrolone	Oxydrin	2-3	1	
Stanozolol	Winstrol	2-3	1	

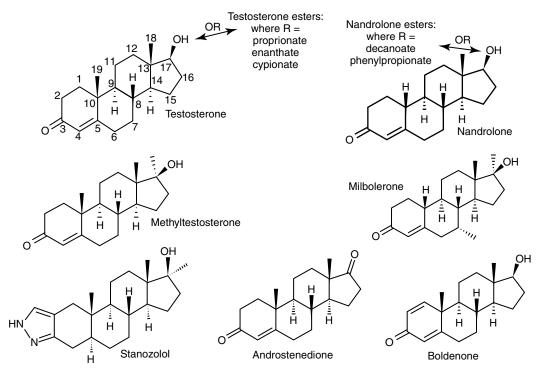

Figure 15-4 Chemical structures of several anabolic steroids. Rings and their positions are indicated for testosterone. Esters on R-groups also alter absorption characteristics. Methylation (methyltestosterone, stanozolol) increases anabolic activity as well as toxicity. Nandrolone is a nonmethylated anabolic steroid. Mibolerone has little anabolic activity, whereas the double bond at C1 and C2 contributes to marked activity with boldenone. Nonmethylated products tend to be less efficacious but less hepatotoxic.

glycolysis and the formation of steroidal 17-keto metabolites. These metabolites are delivered to tissues, including the bone marrow, where they interact with a cytosolic receptor in the appropriate cell and are transferred to the cell nucleus. In the nucleus they induce the formation of RNA and synthesis of an effector protein that brings about the pharmacologic effect.

The sequelae of steroid-induced nuclear transcription are manifold.^{54,55} The proposed sequelae on RBC formation include (1) stimulation of EPO production by way of EPOstimulating factor, (2) differentiation of stem cells into EPOstimulating factor-sensitive cells (e.g., hemocytoblasts), and (3) direct stimulation of erythroid-progenitor cells. Anabolic steroids also increase intracellular concentrations of 2,3-bisphosphoglycerate in erythrocytes; oxygen release into tissues is subsequently increased.

Efficacy of the anabolic steroids on the RBC mass depends on the presence of supportive materials.^{54,55} This includes adequate concentrations of androgen dehydrogenase in the RBC, adequate EPO concentrations, and sufficient bone marrow cellularity. Thus the effectiveness of anabolic steroids in treating anemia may be limited depending on the cause (i.e., renal disease accompanied by low EPO levels). Administration of high doses of these steroids may cause a negative feedback inhibition.

Pharmacologic Effects

The difference in the pharmacologic effects of these drugs among the various tissues and, specifically, whether an androgenic versus an anabolic effect will predominate cannot be attributed to differences in target tissue receptor structure because there appears to be only one androgen receptor type. Differences in response may be concentration dependent (e.g., reproductive tissues requiring higher concentrations than nonreproductive tissues), with drugs differing in their binding to the androgen receptor. However, mibolerone has little anabolic effect despite tight receptor binding and methylation; in contrast, boldenone, which is not methylated, has marked anabolic activity, attributed to a double bond at positions 1 and 2 (see Figure 15-4).⁵⁶

The effect of several anabolic steroids in renal EPO was studied in the perfused canine kidney exposed to 4 hours of hypoxia.⁵⁷ Activities important to secretion of EPO included a double bond at position 4 and 5 and the absence of a methyl group at position 10 (see Figure 15-4). Alternatively, differences in response may reflect conversion of the drug by target tissues to an active metabolite that subsequently causes the pharmacologic effect.^{54,55} In the presence of continued administration, anabolic steroids initiate and maintain a positive nitrogen balance, although the response is short-lived in intact males.^{52,54,55} The anabolic effects of stanozolol have been studied in dogs. Based on urine excretion of urea, retention of intravenously administered radiolabeled amino acid was increased in sled dogs (n = 10) receiving stanozolol either 2 mg/dog orally twice daily (increased from a baseline of 30% to posttreatment retention of 50%), or 25 mg weekly for 4 weeks (increased from 27% to 67%). The authors⁵⁸ concluded that such an effect might be beneficial with acute or chronic conditions characterized by protein loss. Anabolic steroids antagonize glucocorticoid-induced protein catabolism by competitively inhibiting glucocorticoid binding to glucocorticoid receptors. Although anabolic steroids appear to vary in their ability to antagonize the effects of glucocorticoids, protein anabolism may be induced in patients experiencing glucocorticoid-induced protein catabolism. Anabolic steroids also reduce urinary excretion of nitrogen, sodium, potassium, chloride, and calcium.

As part of their anabolic activity, these compounds increase the circulating RBC mass (and possibly granulocytic mass). Red blood cell indices, hemoglobin, and hematocrit increase in various types of anemia. White blood cell mass may increase in cases of pancytopenia, although white blood cell response takes longer than the RBC response. Response by thrombocytes is slower and less predictable.^{52,54,55}

Pharmacokinetics

The absorption and disposition of anabolic steroids depend on the type of preparation, the presence of specific receptors, and the species to which it is administered.^{52,54,55} Most anabolic steroids depend on hepatic metabolism for elimination, with those metabolites that are anaologs of the parent compound accompanied by metabolic activity.⁵⁶ The risk of abuse in athletes (including the racing animal) has led to metabolic profiling of some steroids. Among the steroids, Beagle hepatic microsomal metabolism of steroids yielded hydroxylated and oxidized metabolites testosterone, methyltestosterone, mibolerone, and boldenone, with testosterone a metabolite of boldenone and androstenedione a major metabolite of testosterone (see Figure 15-4).

Preparations

Anabolic steroids have been divided into two categories depending on the presence or absence of an alkyl (CH₃) group at the 17-carbon position, although the relevance of this division is probably less important than the impact of the individual drugs (see Figure 15-4).^{54,55} Oral and parenteral preparations are available, with the alkylated products being better absorbed orally. Oil-based parenteral preparations are intended for slow release. Examples of alkylated anabolic steroids include methyltestosterone, (oral), oxymetholone (oral), stanozolol (oral and parenteral), methandrostenolone, ethylestrenol, and norethandrolone (see Table 15-1). Examples of nonalkylated anabolic steroids include testosterone cypionate or enanthate, oxymetholone, and nandrolone in its decanoate form (parenteral).

Toxicity Versus Efficacy

A review of risks in human athletes includes cardiovascular adversities, increased risk of cancer, behavioral disorders, and increased risk of tendon damage.⁵⁹ Hepatotoxicity is the most common serious adverse effect associated with androgenic or anabolic steroids.^{54,55} Toxicity ranges from mild increases in clinical laboratory tests to hepatocellular carcinoma (in humans). Drugs alkylated at the 17-carbon position are more likely to cause hepatotoxicity (see Figure 15-4). Although the mechanism is not known, the drugs or their metabolites

may be carcinogenic or may increase the metabolism of other drugs to carcinogenic or hepatotoxic compounds. Cholestatic liver damage occurs early and can be significant but is apparently reversible if the drug is discontinued before irreversible hepatic lesions develop. It is not clear if the hepatotoxic effects that occur in humans are likely in dogs or cats.

Masculinization is a major undesirable (or desirable) side effect of anabolic steroids in humans.^{52,54,55,59} Virilization can occur but is seldom objectionable in dogs or cats. In dogs and cats, anabolic steroids increase libido in males, interfere with the female reproductive cycle, and cause masculinization of fetuses if administered during pregnancy. Other undesirable consequences of anabolic steroid therapy in dogs include hyperplasia of the perineal glands and stimulation of androgendependent tumors, such as anal carcinomas and prostatic carcinomas. In humans edema resulting from water retention occurs.^{52,54,55}

Clinical Indications

The use of anabolic steroids for treatment of renal disease and catabolic effects associated with cachexia are addressed in their respective chapters. Human recombinant EPO has largely replaced anabolic steroids in the treatment of chronic anemias, particularly those associated with renal disease. Anabolic steroids are, however, indicated for treatment of chronic, nonregenerative anemias that fail to respond to EPO; for animals that react adversely to EPO; or for hematopoietic diseases that are not typically associated with decreased concentrations of EPO.54,55 Of human patients with aplastic anemias who have failed conventional therapy of anemia, 50% or more have responded to anabolic steroids.54,55 Anabolic steroids have been used in conjunction with anticancer chemotherapeutic drugs to protect bone marrow production of RBCs, thus allowing longer and perhaps more toxic chemotherapy.^{52,54,55} Anabolic steroids presumably help decrease the catabolic effects of cancer. Treatment several weeks before cancer chemotherapy may enhance response to anabolic steroids. Use of anabolic steroids for cancer has not been established in dogs and cats.

Hematopoietic response to anabolic therapy is variable, and the time to clinical improvement is long, frequently 3 or more months. Cellularity of the bone marrow appears to determine rate of response to anabolic steroids. Cessation of therapy may result in recurrence of the underlying diseases. Among the anabolic steroids, nandrolone decanoate has the greatest hematopoietic effect.54,55 Leukocyte and thrombocyte counts may also increase after therapy with anabolic steroids, although these effects are slower in onset and less likely, particularly for thrombocytes. Danazol is the anabolic steroid of choice in the treatment of thrombocytopenia, especially that which is immune mediated. Beneficial effects probably include impaired clearing of IgG-labeled platelets and decreased antibody formation. Response to therapy may take several months, and relapse may occur when danazol therapy is discontinued. Anabolic steroids and, in particular, danazol, have been used with some benefit for patients with hemolytic anemia. Benefits include not only expansion of the RBC mass but also impaired complement activation and binding to RBCs. Human patients

suffering from anemia caused by renal disease respond to continuous administration of anabolic steroids. RBC indices improve, as well as appetite, muscle mass, and strength.

In general, the following approaches should be used with anabolic steroids in dogs and cats (see Table 15-1). State restrictions regarding the use of these drugs should be observed. Nandrolone decanoate is the drug of choice except in cases of thrombocytopenia, for which danazol is the drug of choice. Several months of therapy may be necessary before a clinical response is observed. The dose should be decreased once the maximum therapeutic effect occurs. Relapse of disease may occur once the drug is discontinued, and hepatotoxicity is a potential contraindication for use of these drugs.

A final consideration regarding anabolic steroids is use in racing dogs. In addition to potential performance-enhancing abuse, testosterone, methyltestosterone, and mibolerone are used to prevent estrus.⁵⁶ Detection of urinary metabolites in racing animals is an ongoing field of study.⁵⁶

Oxygen-Carrying Solutions

Oxygen-carrying solutions (often referred to as blood substitutes) offer the advantages of oxygen delivery to tissues similar to that of blood, without the concerns of transmission of disease. Two types of blood substitutes have been developed to both carry and deliver substantial amounts of oxygen to tissues: free hemoglobin-based oxygen-carrying solutions (HBOCs) and fluorocarbons.^{60,61} Fluorocarbons are chemicals that are miscible with blood and can carry as much as 5.25 mL of oxygen per 100 mL of blood, depending on oxygen tension. Although the oxygen-carrying capacity of these compounds is not adequate for total blood replacement, their low viscosity makes them potentially useful in disorders characterized by abnormalities in microcirculation. In addition, use of these agents in nonvascular tissue (e.g., the peritoneal cavity) may enhance supplementing oxygen exchange in tissues during respiratory failure.

Of the two blood substitutes pursued for clinical use, HBOCs (e.g., oxyglobin, approved for use in dogs) have proved most useful. Free, unmodified hemoglobin (purification involves washing, lysing, ultrafiltering, and pasteurizing) is not an effective blood substitute. Free hemoglobin decreases the amount of oxygen released from tissues by reducing concentrations of 2,3-diphosphoglycerate such that the oxyhemoglobin dissociation curve shifts to the left. As a result, the Pa_{50} of oxygen in HBOCs is reduced from 28 mm HG to 10 mm Hg. In addition, the free smaller dimers of hemoglobin are more readily cleared by the kidneys, resulting in a short half-life (20 minutes), as well as an increased risk of nephrotoxicity. Smaller molecules also may be responsible for the increase in vascular (systemic and pulmonary) resistance that may accompany use of HBOCs, including Oxyglobin use. Enlarging the size of the hemoglobin molecules by cross-linking (e.g., with fumarate or dasprin [HemAssist]), polymerization techniques (e.g., using oxidized raffinose [Hemolink] or gluteraldehyde [Oxyglobin and Hemopure]) or surface conjugation reduces the negative sequelae of free smaller molecules.⁶² Surface conjugation techniques have the added advantage of blocking the hemoglobin receptor site that interacts with and blocks nitric oxide, thus reducing the risk of vasoconstriction. Of the HBOC products, Oxyglobin, the first approved for use by the Food and Drug Administration, is a bovine hemoglobin– based product indicated for the treatment of canine anemia. Human hemoglobin–based products also have been developed (PolyHeme, a surface conjugated product); recombinant products are currently being studied. Intended indications for newer products extend beyond supplementation of oxygen in critically anemic patients, including sensitizing of cancer cells or scavenging of nitric oxide.⁶²

Manipulation of the hemoglobin tetramer by cross-linking, polymerization, and other methods yields products with variable molecular weights: for Oxyglobin the average MW is 200 kDa (range 64-500 kDa) whereas conjugation of surface proteins (e.g., polyethylene glycol [Enzon] yields lower molecular weight products (117-125); recombinant products may be as small as 64 kDa. Among the advantages of the larger molecular weight (discussed later) is the ability of the compounds to act as colloids, increasing preload, stroke volume, and cardiac output (similar to hetastarch, plasma, and dextran-70), with the added advantage of increased oxygen delivery.⁶² In general, using experimental canine models of acute hemorrhagic hypovolemia, use of a bovine HBOC either increases oxygen delivery or arterial oxygen content, although studies generally have not been able to consistently demonstrate both occurring.⁶² One study concluded that treatment of acute anemia in dogs with 15 mL/kg of a bovine HBOC was able to increase oxygen content equivalent to packed RBCs.63 In canine models of hemorrhagic hypovolemia, intestinal perfusion and oxygenation appear to be maintained; however, increased systemic vascular resistance and decreased cardiac output have also been demonstrated.

Oxyglobin (Biopure Corp., www.oxyglobin.com; availability at the time of publication is not clear) is a polymerized bovine HBOC fluid. Oxyglobin increases plasma and total hemoglobin concentrations and thus increases arterial oxygen content. Its molecular weight imparts colloidal properties similar to those of dextran 70 and hetastarch. Its polymerized nature precludes renal filtration and renal side effects of hemoglobinuria. Because the solution is free of RBC walls, antigens associated with transfusion reactions are largely absent. Likewise, the absence of plasma reduces reactions associated with isoantibodies. However, antibodies may develop to bovine hemoglobin, and caution is recommended with repeated administration 10 or more days apart. As a foreign protein, anaphylactic reactions are possible.

Oxyglobin is eliminated similarly to hemoglobin by reticuloendothelial cells. Its elimination half-life in dogs is estimated to range between 30 and 40 hours, with 90% of the drug eliminated within 5 to 7 days. Conditions for HBOCs studied in controlled canine clinical trials included immune-mediated hemolysis (n = 30), blood loss (gastrointestinal, traumatic, surgical, rodenticide intoxication; n = 25), and ineffective erythropoiesis (idiopathic, RBC aplasia, ehrlichiosis; n = 9). Relative to pretreatment, plasma hemoglobin concentration significantly increased (P = 0.001) and clinical signs associated with anemia (lethargy/depression, exercise intolerance, and increased heart rate) significantly improved (P = 0.001) after treatment with Oxyglobin. Treatment success was defined as the lack of need for additional oxygen-carrying support (i.e., blood transfusion) for 24 hours after the completion of infusion with the HBOC. Success in the treatment group was 95% compared with 32% in untreated control dogs.⁶⁴

Side effects of HBOCs include circulatory overload and its negative sequelae (e.g., pulmonary edema, pleural effusion, increased central venous pressure, dyspnea, coughing), particularly in patients already suffering from volume overload (e.g., congestive heart failure) or in cases of accidental overdose (>10 mL/kg/hr). Hypertension is a recognized side effect of HBOC use. Smaller molecules are potentially more likely to reduce nitric oxide and subsequent increased vascular resistance.⁶² Species are likely to differ in their vasoactive response. Oxyglobin caused a 30% increase in peripheral vascular resistance in isovolemic dogs; hypertension also has been induced in hypovolemic cats.⁶²

Vasoconstriction may be sufficiently profound that tissue perfusion is compromised. Further, standard methods of assessing adequate volume resuscitation may be ineffective in the presence of HBOCs.⁶⁵ Oxyglobin mildly decreases PCV immediately after infusion and increases total and plasma hemoglobin concentrations for at least 24 hours. PCV and RBC counts are not accurate measures of anemia for 24 hours after administration. Overhydration should be avoided with the use of an HBOC because of its plasma-expanding properties; likewise, administration of other colloidal solutions is discouraged. Central venous pressure or clinical signs indicative of circulatory overload should be monitored during and immediately after administration of Oxyglobin, particularly in normovolemic patients or patients with cardiac disease. Cats also may be predisposed to volume overload: One retrospective study of Oxyglobin use in cats with anemia found that 29 of 72 developed volume overload compared with 37 of 72 that responded to therapy. Hypothermia appeared to increase the risk once body temperature was returned to normal.⁶⁶

Transient changes or side effects after administration of Oxyglobin reported by Biopure Corp. include yellow-orange discoloration of the skin, sclera, and gums; red to dark green discoloration of feces; brown-black discoloration of urine; vomiting; diarrhea; and decreased skin elasticity within 48 hours of dosing. The frequency and intensity of these clinical signs are dose dependent. HBOC solutions may interfere with several laboratory tests, particularly those based on colorimetric procedures (see package insert) or hemostatic tests based on optical methods. Pulse oximetry, blood gas analysis, and related procedures generally are not affected.

Oxyglobin may be warmed to 37° C before administration. As long as it is not frozen, it will remain stable for up to 24 months. Care should be taken to avoid temperatures that are too cold in the refrigerator. Oxyglobin is intended as a onetime use only at a recommended dose of 30 mL/kg intravenously at a rate of up to 10 mL/kg/hr. Although animals may not need the full 30 mL/kg; according to the manufacturer, 10 mL/kg may be sufficient in some cases. The foil bag in which

the product is contained is oxygen impermeable. Once the bag is opened, oxygen can penetrate the plastic bag, resulting in the oxidation of the hemoglobin, as evidenced by the formation of methemoglobinemia. Unlike intact RBCs, which can reduce methemoglobinemia, HBOC solutions cannot. A brown discoloration will appear when approximately 25% of the hemoglobin has been oxidized. The product also offers an excellent environment for bacterial growth, even with refrigeration. The product should be used within 4 days of opening. Retrospective studies using HBOCs have been performed in both dogs67 and cats.66 However, neither study was accompanied by a non-HBOC-treated group, and the retrospective nature of the study precluded implementation of methods to reduce bias. A retrospective study of immune-mediated hemolytic anemia found that all dogs treated with Oxyglobin died, but the study did not address bias introduced by selection of only those most severely afflicted animals for treatment with HBOCs.⁶⁷ Gibson and coworkers⁶⁶ retrospectively studied HBOC use in 72 cats treated for anemia, including hemolytic anemia associated with acetaminophen toxicosis. Although 37 cats improved after a mean dose of 14.6 mL/kg (4.8 mL/hr), adverse events (not necessarily associated with HBOC) occurred in 44, including pleural effusions (n = 21) and pulmonary edema (n = 8). The anemic crisis was survived by 23 cats; euthanasia or death of the remaining cats was attributed to the underlying disease rather than administration of the HBOC.⁶⁶ Oxyglobin also has been used successfully in a variety of other species.⁶²

The use of Oxyglobin was reviewed retrospectively in cats (Germany) (n = 53, treated, 48 studied).⁶⁸ The drug was generally administered by a fluid pump at 5 mL/kg/hr. Bags had been stored for 24 hours or less at 4° C. Some cats were treated more than once in a 24-hour period. The bases of treatment varied but included the general condition of the patient, the current hematocrit or hemoglobin level, and underlying disease. Cats receiving blood products were excluded from the study. Domestic Shorthair represented the predominant breed (n = 37); ages ranged from 0.3 to 14 years. Indications were blood low anemia (n = 25), hemolysis (n = 13), and ineffective erythropoiesis (n = 8). Reasons for administration of Oxyglobin rather than blood included lack of availability of feline blood products (including compatible donor) or to reduce loss of previously opened (within 24 hours) product coupled with reduced availability of feline donors. All patients also received Ringer's lactate. An overall survival rate was not offered, but a survival rate was offered for each group. Hemoglobin changes ranged from -0.8 to 3.3 in the blood loss group (decreased in 5 cats) with a 24-hour survival rate of 72%. In the hemolytic group, hemoglobin changed from 0.2 to 5.2 gm/dL for a 24-hour survival rate of 84%. In the group with ineffective erythropoiesis, hemoblogin changed from -0.5 to 2.4 g/dL, with an 88% survival rate. Of the cats treated, 11 of the 48 had some type of cardiac disease; in this subgroup (which included cats from each of the preceding treatment groups), adverse reactions that might be related to treatment occurred in seven cats. These included pulmonary edema, pleural effusion, or respiratory distress; one of the cats died within 6 hours, and

four died within 28 hours as a result of volume overload after receiving a range of 6.7 to 20 mL/kg in the 24-hour period.

DRUGS ACTING ON COAGULATION OR CLOTTING

Hemostastis has been reviewed⁶⁹ elsewhere. Briefly, it occurs in three steps (Figure 15-5), with the role players varying somewhat with the site or rate of flow: high shear vessels include the smaller to medium arteries, whereas low shear vessels include the larger arteries or veins. Platelet adherence occurs in the presence of damaged tissue or disrupted endothelium; platelets also will adhere to one another. Platelet adherence is mediated by laminin, collagen,or fibrinonectin in low shear vessels and adenosine diphosphate (ADP) and vWF in high shear stress vessels. Adherence is followed by platelet activation, during which granular contents of platelets are released. The contents recruit more platelets but also integrate platelet activation with the inflammatory process through release of mediators such as IL-1, platelet-activating factor, and serotonin. In high shear stress vessels, ADP and vWF are the primary mediators of activation, whereas thromboxane is the primary activator in low shear stress vessels. Thrombin will activate platelets (by way of protease-activated receptors) in any vessel. Because thrombin is not inhibited by cyclooxygenase inhibition, it is considered the strongest of the activators. Platelet adherence and subsequent activation are then followed by assembly of glycoproteins, causing aggregation. Again, the role players vary with the site, with vWF and glycoprotein Ib-IX-V mediating the response in high shear flow rates and fibrinogen in low shear flow vessels. The final common pathway to platelet aggregation is the glycopeptides IIb through IIIa receptors; this protein is the target of several investigative antithrombotic drugs in humans.⁶⁹

Although a number of endogenous compounds play a role in platelet aggregation, a number of exogenous substances do as well (e.g., infectious organisms, complement factors). Further, endogenous factors provide balance, preventing coagulation. Among the most important antiplatelet mediators are nitric oxide and prostacyclin, both released from the

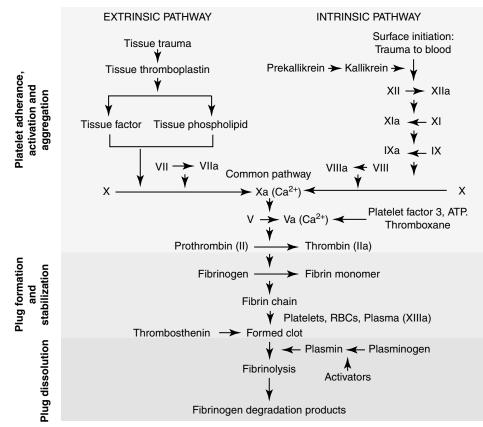

Figure 15-5 Hemostasis occurs in several phases: vascular and platelet, coagulation, and fibrinolysis. Each phase must remain in equilibrium to maintain a normal state of hemostasis. Endogenous procoagulants and anticoagulants function in each phase. The vascular and platelet phase is composed of vascular wall contraction and platelet adherence. Damage to the vessel exposes subendothelial collagen, which stimulates platelet adherence, which, in turn, depends on von Willebrand factor. Activation of the coagulation phase relies on a complex series of interdependent events. Injury results in activation of procoagulant substances in a cascade manner. Activation (designated by a lower case *a*, e.g., Xa) generally occurs as a result of proteolysis of a small molecule from the inactive factor. The major events in the coagulation cascade include formation of thromboplastin as a result of tissue trauma (designated as intrinsic if the blood is damaged and extrinsic if the vascular structures are damaged); transformation of prothrombin to thrombin; and rapid conversion of fibrinogen into fibrin. Calcium is involved as a factor at several steps. The fibrinolytic phase is initiated by the conversion of plasminogen to plasmin, which degrades fibrin.

endothelium. These two mediators appear to act synergistically to inhibit platelet adhesion, activation, and aggregation. Aggregation leads to the organized deposition of coagulation proteins with the formation of a temporary platelet plug. It ultimately should be stabilized in a cross-linked fibrin network. The final step in hemostasis is plug removal, which is accomplished through the initiation of fibrinolysis following activation of plasminogen to plasmin (see Figure 15-5). Disorders reflect not only failed hemostasis but increased risk of thrombosis as a result of a hypercoagulable state induced by disease or, less commonly, drugs.

Hemostatic Drugs

Hemostatic drugs are used to prevent or attenuate bleeding. They can be administered either topically or systemically. In general, topical agents either act as a factor in the coagulation cascade or stimulate some aspect of the coagulation cascade (see Figure 15-5).

Topical

Lyophilized concentrates of one or more clotting factors are available as topical preparations. These preparations usually provide an artificial factor or structural matrix that facilitates clotting (Figure 15-6). An intact hemostatic mechanism is necessary for their efficacy. These are absorbable products and are indicated for capillary oozing from small, superficial vessels. Examples of concentrated factors include thromboplastin (prothrombin is converted to thrombin, used locally in surgery), thrombin (converts fibrinogen to fibrin; available as powder, solution, or sponge), and fibrinogen. Examples of artificial matrices include absorbable gelatin sponge and oxidized cellulose (treated surgical gauze that promotes clotting) (see Figure 15-6).

Astringents act locally by precipitating proteins. These agents do not penetrate tissues and thus are restricted to surface cells. They can be damaging to surrounding tissues. Examples include ferric sulfate, silver nitrate (e.g., sticks; see Figure 15-6), and combinations that include tannic acid (e.g., STA).

Epinephrine and norepinephrine are hemostatic drugs only by virtue of their vasoconstrictive effects. They may be included in topical medications or injectable local anesthetics to decrease blood flow to the tissues.

Systemic

Fresh blood or blood components are hemostatic drugs only in states of (coagulation) factor deficiency. Examples include plasma (contains electrolytes, albumin, and some coagulation factors), fresh frozen plasma (plasma in which factors V and VII are stable), cryoprecipitate, and platelet-rich plasma.

Vitamin K. Vitamin K is a hemostatic drug only in instances of vitamin K deficiency. It is necessary for hepatic synthesis

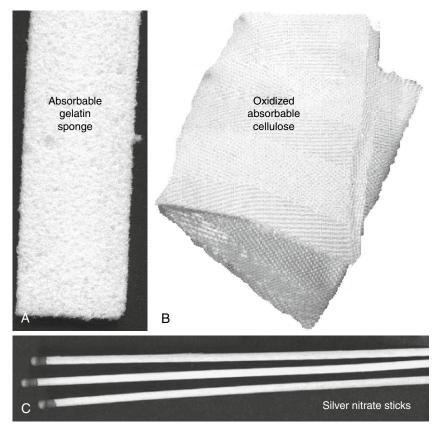

Figure 15-6 Examples of coagulants (A).Oxidized cellulose (Surgicel shown here) provides a matrix for clotting (B). Gelfoam also provides an artificial structural matrix that initiates the clotting process (C). Products that contain silver nitrate (shown here), tannic acid, or salicylic acid precipitate proteins and cause coagulation by destroying tissue. Their use is limited to small, topical lesions.

of coagulation factors II, VII, IX, and X (Figure 15-7). Several forms of vitamin K are available for therapeutic use. Vitamin K_1 (phytonadione), the plant form, can be given parenterally and orally. It is more effective and more rapid in onset compared with other vitamin K analogs. However, anaphylactic reactions have been reported with intravenous administration, particularly with those preparations containing polysorbate 80, a known releaser of histamine in dogs. The drug can also be given intramuscularly. The effects of vitamin K_1 occur within 1 hour of administration,^{3,70} although several hours are needed to resolve bleeding tendencies as coagulation proteins are replaced.

Vitamin K_2 (menaquinone) is the natural animal and microbial form of vitamin K. Vitamin K_3 (menadione) is one of several synthetic forms. It must be metabolized to the active state. Vitamin K_3 usually is absorbed too slowly to be used effectively in acute conditions, but it can be used for chronic therapy once the acute crisis has been resolved. In states of hypocoagulation, vitamin K_1 is the preferred form, administered either subcutaneously or orally (3 mg/kg subcutaneously in multiple sites followed by 1 mg/kg every 24 hours parenterally or orally).⁷¹ Fat will enhance the oral absorption of vitamin K.

The most common use of vitamin K is treatment of rodenticide toxicity (see later discussion of anticoagulants). Duration of treatment for rodenticide poisoning will vary according to the toxicant. Toxicities from rodenticides containing coumarin or warfarin should be treated for 4 to 6 days; intoxication with diphacinone or brodifacoum requires treatment for at least 14 days.⁷¹ For toxicity with longer-acting rodenticides (i.e., indandiones), the dose of vitamin K is often reduced for subsequent weeks:⁷¹ 0.5 mg/kg, week 2; 0.25 mg/kg, weeks 3 and 4. Prothrombin time should be monitored for 2 days after vitamin K is discontinued to detect residual rodenticide toxicity. Screening tests should remain normal for 3 to 4 days after therapy has been discontinued.

Protamine sulfate. Protamine sulfate is a low-molecularweight, positively charged drug that binds to heparin, forming a salt and neutralizing its anticoagulant effects. It is used as a procoagulant only in instances of heparin overdosing. Protamine should be used cautiously because it also has anticoagulant activity, probably by impairing thrombin and fibrinogen. It is difficult to dose accurately because the dose is based on the amount of heparin to be antagonized (1 to 1.5 mg protamine for each 1 mg of heparin). In addition, the dose decreases as time elapses after heparin was administered.⁷² No more than 50 mg should be given in a 10-minute period.

Desmopressin. Desmopressin acetate (deamino 8-Darginine vasopressin) is a synthetic analog of vasopressin and antidiuretic hormone that is used to treat central diabetes insipidus However, the drug also transiently increases serum concentrations of vWF in part through the release of preformed vWF from endothelial cells and macrophages as well as release of preformed Factor VIII.⁷³ Increased release was

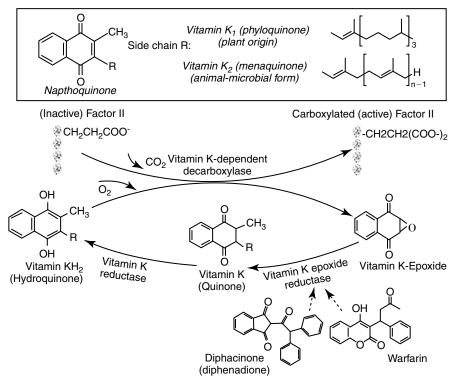

Figure 15-7 Vitamin K catalyzes the carboxylation of factors II, VII, IX, and X. As part of the reaction, the oxidized vitamin must be reduced to continue activation of coagulation factors. Coumarin derivatives block the reduction of vitamin K, rendering it incapable of activating coagulation factors. The arrow on warfarin identifies the chiral carbon that leads to S and R enantiomers. Both isomers are highly (>95%) bound to plasma proteins. Enterohepatic circulation was evident in cats 4 hours after administration.

demonstrated 1 hour after infusion in normal and afflicted dogs, although increase in afflicted dogs was greater.⁷⁴ Kraus and coworkers75 have demonstrated that desmopressin decreases buccal mucosal bleeding time in Doberman Pinschers afflicted with vWF A similar response has been demonstrated for Greyhounds with vWF deficiency treated with 1 mg/kg desmopressin diluted in 1 mL of saline.⁷⁶ The maximum response occurs 1 to 2 hours after treatment, although it may occur after as little as 10 minutes of infusion, with effects lasting 2 hours after intravenous administration.⁶⁹ The increase is sufficient to provide improved coagulation activity in animals suffering from von Willebrand disease that undergo surgery.⁷¹ Desmopressin is generally administered by slow intravenous infusion over 20 to 30 minutes in humans after dilution in a minimum of 100 mL of physiologic saline. However, the intranasal (human) preparation also can be given subcutaneously at 1 U/kg.69 Rapid infusion may result in tachycardia, flushing, tremor, and abdominal discomfort. Repetitive administration results in depletion of the storage pools and loss of procoagulant effect and may increase the risk of tachyphylaxis.^{71,73}

Recombinant human factor VIIa. The role of tissue factor (TF), a transmembrane glycoprotein receptor located in multiple extravascular tissues, is key to the initiation of hemostasis. It is through activation of Factor VII (FVII) bound to receptors located on TF that Factors IX and X are activated, leading to platelet activation and subsequent coagulation. A recombinant FVII product, derived from transfected baby hamster kidney cells, is chemically identical to activated FVII. The drug product was developed for treatment of human hemophiliacs (A and B) who had developed antibodies (following multiple blood transfusions) to Factors VIII or IX.77 Theoretically, although FVIIa should effect hemostasis through a TF factor, afflicted hemophiliacs are not able to mount an effective coagulative response primarily through loss of an amplified response by FVIII and IX. However, supraphysiologic doses appear to stimulate hemostasis (thrombin formation) by way of TF-independent pathways. Although activation of Factor X is not as effectively amplified as in the normal patient, more effective platelet involvement yields a more stable fibrin clot than would be formed in Factor-deficient patients. The fibrin clot is actually denser than that in normal patients. Because rhFVII requires exposed TF and activated platelets, its effects tend to be limited locally. The drug has been used on a compassionate-use basis for treatment of hemophiliacs undergoing procedures associated with a risk of bleeding or in patients suffering from refractory bleeding. The use of rhFVII has been described in dogs, including those suffering from either A or B hemophilia. Use in homozygote von Willebrand's disease was not as successful. However, hypersensitivity reactions developed in several animals within 30 minutes of treatment, and all animals developed antibodies within 2 weeks of therapy. Nonetheless, should safety be improved, suggested potential applications of rhFVII therapy in animals, beyond treatment of factor deficiencies, have included disseminated intravascular coagulation (DIC), thrombocytopenia or thrombocytopathia, anticoagulant rodenticide toxicosis, overzealous

anticoagulant therapy, high-risk surgeries, and liver and gastrointestinal diseases.⁷⁷

Fibrinolysin inhibitors. Fibrinolysin inhibitors prevent the activity of plasmin (fibrinolysin) and therefore promote the persistence of clots (see Figure 15-5). The lysine analog aminocaproic acid is one of the few examples. Its therapeutic use is limited to treatment after an overdose of a fibrinolytic agent. It theoretically acts by substituting for lysine-binding sites, forming a complex with plasminogen, precluding its conversion to plasmin (e.g., inhibits streptokinase).⁷⁸ It was studied after intravenous administration (1750 mg of 250 mg/mL solution followed by 250 mg/mL every hour for 9 hours) in a canine (n = 4; 10-21 kg) model of urokinase and venous injury-induced thrombosis. Aminocaproic acid inhibited plasmin formation completed, compared with heparin (20,000 U intravenously every 3 hours), which inhibited it by approximately 80%.⁷⁹

Antihemostatic Drugs

Feline aortic thromboembolism (FATE) is a useful model for the discussion of treatment of thromboembolic disease. With FATE the goals of therapy are to reduce the formation of the thrombus, prevent embolization, improve collateral blood flow, control pain, and provide supportive care. Because thrombus formation in the heart (atria) is facilitated by blood stasis associated with atrial enlargement and endothelial damage, supportive therapy may include cardiogenic support. Drugs used to limit the formation of thrombi include anticoagulants, thrombolytics, and antithrombotics.

Anticoagulants

Anticoagulants interfere either directly or indirectly with the clotting cascade (see Figure 15-5). Several in vitro anticoagulants are used for blood collection intended for transfusion therapy and should be considered as drugs. Examples include citrate phosphate dextrose, acid citrate dextrose, sodium citrate, and heparin. All except heparin (discussed later) act by effectively removing Ca²⁺ from the cascade system. In vivo anticoagulants include heparin and the vitamin K antagonists.

Heparins

Heparin is a heterogeneous mixture of sulfated (anionic) polysulfated glycosaminoglycans (PSGAG) (Figure 15-8). Glycosaminoglycans are a family of structurally diverse and distinct polyanionic complex carbohydrates. Included in this group are heparin, heparan sulfate, chondroitin 4-sulfate, chondroitin 6-sulfate, dermatan sulfate, keratin sulfate, and hyaluronic acid. Each of the glycosaminoglycans is composed of repeating polysaccharides consisting of an amino sugar (e.g., glucosamine or galactosamine) and uronic (e.g., glucuronic or iduronic) acid or a hexose (galactose; keratin sulfate only). Each is ubiquitous in location. Among them, heparan sulfate proteoglycans are diverse in location with those that are endothelial derived serving as the primary endogenous anticoagulant. They are an integral part of stromal matrices, basement membranes, and almost all cell surfaces where they provide cohesion between vessels and vascular stroma.43 Endogenous

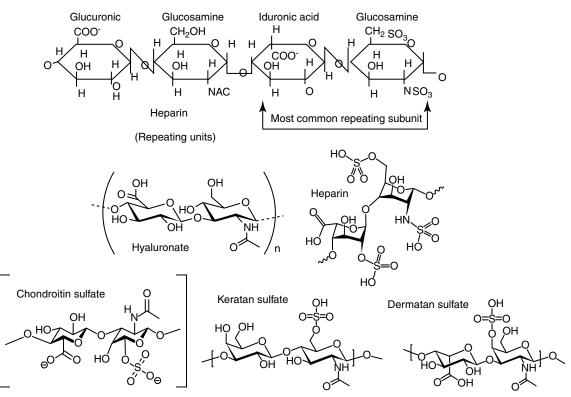

Figure 15-8 Heparin is a heterogeneous mixture of sulfated, anionic, and polysulfated glycosaminoglycans. The subunits include uronic acid, sulfonaminoglycosamine, *N*-acetylglucosamine, and a pentasaccharide sequence. Heparin is one of many polysulfated glycosaminoglycans (PGAGs) found throughout the body. Other structurally similar PGAGS include hyaluronate, heparin sulfates, chondroitin sulfates, keratan sulfates, and dermatan sulfates.

synthesis results in multiple compounds that vary in the lengths of carbohydrate chains Heparin and heparan sulfate are the most complex members of this class of compounds and are characterized by the greatest biologic diversity.⁴³ Proteoglycans are formed when proteins, which serve as the core for the PGAG, are posttranslationally (in the Golgi apparatus) modified with the addition of glycosaminoglycan chains. Each is sulfated to variable degrees, depending on the repeating subunits of which the disaccharide is composed.

Heparin was so named because of its initial discovery in high concentrations in the liver. It is often located attached to serine residues of core proteins (e.g., coagulation factors). Commercially available heparin is prepared from porcine intestinal mucosa and bovine lung. It is stored in mast cells, along with other PGAGs, including chondroitin and dermatan sulfate. Heparin also is stored in the body in basophils and, to a lesser extent, in vascular endothelium. Tissues with high concentrations of mast cells serve as a source of heparin. Heparin is a highly sulfated (generally 2 to 3 per subunit) glycosaminoglycan composed of alternating sequences of sulfoaminoglycosamine and uronic acid units and smaller amounts of N-acetylglucosamine (see Figure 15-8). Its structure also includes a unique and specific sulfated glucosamine pentasaccharide sequence that binds to antithrombin (AT) III and thus serves as the active site of the molecule. The number of active sites in a molecule of heparin is variable, but it is present in only about 30% of the molecules. In its native state, the molecular weight is quite variable, ranging from 3 to 50 kDa. The molecular weight of commercial unfractionated heparin (UFH) generally varies from 1800 to 30,000 daltons (mean 15,000, representing about 45 monosaccharide chains).⁸⁰ However, heparin also has been prepared through filtration methods as fractionated or low-molecular-weight (LMW) heparins, which normally make up less than 5% of endogenous heparin. The LMW heparins generally are only 1000 to 10,000 daltons in size and are specifically defined as an average weight of 8000 daltons or less, with at least 60% of the product being less than 8000 daltons in size (see Figure 15-8). A variety of LMW heparins have been made, with each varying by the method of fractionation or depolymerization. The LMW heparins have much higher affinity for AT (by way of Xa) compared with UFH and thus are more potent, providing 70 units/ mg of antifactor Xa and a ratio of antifactor Xa to AT activity of 1.5 or more.⁸⁰ Doses of fractionated LMW preparations are thus lower than unfractionated products (Table 15-3). Preparations of UFH also contain contaminants such as dermatan sulfate; these contaminants may be present in LMW heparin preparations but in diluted form. Intentional contamination of heparins with oversulfated chondroitin sulfates is addressed with adverse reactions. Some of these compounds also have anticoagulant activity, albeit less than heparin.81

Mechanism of action. Heparin interacts with many proteins, probably by electrostatic forces between the polyionic groups of the glycosaminoglycan and the cationic groups of proteins. Example proteins include proinflammatory chemokines, growth factor, extracellular matrix proteins, and leukocyte

Table 15. Drug	Category	Indication	in and Low Molecular Weig	Route	Interval (h)
Dalteparin	(LMWH)	Thromboembolic disease	100-150 IU/kg (D)	SC	8
Daneparin		Thromboenbone disease	50 mg/cat	30	8 12 (C)
			180 IU/kg (C)	SC	6
Enoxaparin	(LMWH)	Thromboembolic disease	0.8 mg/kg (D)	SC	6
			1.25 mg/kg (C)	SC	6
			5 mg/kg (C)	РО	24
Heparin	(UFH)	Arterial thromboembolism, thrombophlebitis	Initial dose: 100-200 IU/kg. Maxi- mum of 500 IU/kg (D)	IV	Once
			Initial dose: 375 IU/kg (C)	IV	Once
			Maintenance dose: 100-300 IU/kg	SC	6-8
		Prophylaxis	Low dose: 10-50 IU/kg	SC	8-12 (Monitor APTT
					to 1.5 to 2 times pre- treatment baseline)
		Feline thromboembolism asso- ciated with cardiomyopathy	Induction: 1000 IU/kg	IV	Once
			Maintenance: 50 IU/kg	SC	8
		During acute pancreatitis	50-100 IU/kg	SC	8-12
		Disseminated intravascular coagulation	75-100 IU/kg	IV, SC	6-8
			5000 IU/500 mL blood	IV	As needed
		Low dose	5-10 IU/kg	IV infusion	1
		Burns	100-200 IU/kg	IV, SC	$8 \times 1-4$ treatments
		Closed chest lavage	1000 IU/L fluid at 20 mL/kg	Intrathoracic	12
		Lipoprotein lipase provocative test	100 IU/kg	IV	Test lipids before and 15 min after heparin

LMWH, Low-molecular-weight heparin; D, dog; SC, subcutaneous; C, cat; PO, by mouth; UFH, unfractionated heparin; IV, intravenous; APTT, activated partial thromboplastin time.

proteins. Intracellular effects reflect interaction of heparin or heparan sulfates with cell surface-binding proteins (which are not necessarily true receptors) followed by endocytotic internalization.

The most recognized sequelae of protein-heparin interaction are the anticoagulant actions of heparin.43 However, this effect is indirect, reflecting facilitation of the actions of endogenous anticoagulant proteins. The most notable is AT, one of several endogenous serine proteinase inhibitors (serpins) whose thrombin inhibition occurs only in the presence of heparin. Long chains of heparin bind to specific lysine residues on AT. At low heparin concentrations (0.1 to 1 U/mL), AT rapidly inhibits the activity of the clotting factors IIa (thrombin), Xa, and IXa, resulting in prolongation of activated partial thromboplastin time (APTT) and thrombin time (TT); prothrombin time (PT) is only mildly affected. At high heparin concentrations (>5 U/mL), heparin interacts with heparin cofactor II (HCII), which binds only to thrombin, causing further inhibition. Binding of heparin to AT or HCII results in a stable complex (Figure 15-9). Binding induces conformational change in the anticoagulant complex such that the active sites of the inhibitor is exposed, facilitating binding to the clotting factors. As such, heparin increases the velocity, but not magnitude, of interaction between the endogenous anticoagulants and clotting factors. The rate of interaction can increase 10,000-fold

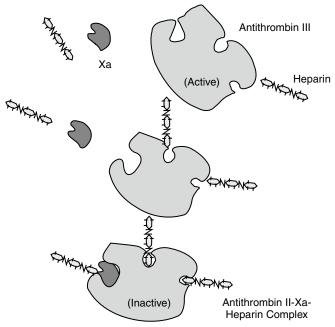

Figure 15-9 The pentasaccharide sequence of heparin interacts with the amino residues of antithrombin III, changing the conformation of antithrombin II and its ability to interact with factors IXa, XIa, XIIa, and, in particular, II and Xa. Heparin may directly interfere with factor X.

in the presence of heparin. The anticoagulant and clotting factor complex will remain intact after activity is inhibited; as such AT is a "suicide" substrate.⁵⁴ In contrast, heparin will be released to interact with other molecules. Other inhibitors, whose concentrations are less than one hundredth of that of AT are also inhibited at high concentrations; these include plasminogen activator inhibitor, protein C inhibitor, and tissue factor pathway factor inhibition of Xa. Heparin also inhibits factors IXa and to some degree Xia; the kallikrein–kinin system and, through binding to complement C1, the complement system are inhibited. Factor VIIa is minimally inhibited.

Because the specific AT-binding site of heparin is generally absent in other glycosaminglycans (limited in heparin sulfates and absent in chondroitin and dermatan sulfates), these latter compounds are characterized by minimal anticoagulant activity.

Simultaneous inhibition of both AT and thrombin requires molecules greater than 5400 MW. LMW heparins generally act through AT inhibition of Xa rather than IIa. Thus LMW heparin fractions are more potent anticoagulants (a lower concentration inhibits Xa) compared with high-molecularweight (HMW) fractions,⁸¹ but HMW heparins may be more effective anticoagulants because their large structure facilitates simultaneous binding of both AT and thrombin simultaneously.⁷² Whereas the ratio of antiXa:IIa activity for UFH is generally 1:1, the same ratios range from 2 to 4:1 up to 9:1 for LMW heparins in humans.⁸² Lower ratios might be expected for dogs because LMW heparin appears to have less effect on AT.

KEY POINT 15-5 Although fractionated low-molecular-weight heparins are more potent inhibitors of Xa, products that contain high-molecular-weight fractions may actually be more effective anticoagulants because their large structure facilitates simultaneous binding of both antithrombin and thrombin.

The effect of heparin on thrombin and Xa occurs only when the factors are not bound to platelets or fibrin; platetet factor IV blocks the interaction between heparin and AT. However, heparins have an antiplatelet effect because of a high affinity for platelet factor IV. Most heparin preparations also inhibit platelet aggregation, negating effects of platelet-derived growth factor on vascular smooth muscle and leading to their descriptor as *platelet-active anticoagulants*. vWF (platelet factor VIII) is among the factors bound and inhibited by heparin.⁸⁰ Heparins also bind to vascular endothelium, causing release of two other endogenous PGAGs and altering vascular endothelial permeability.⁸¹

Heparin has other effects not related to its anticoagulant activity. In human patients heparin may prove useful for prevention of atherosclerosis and for accelerated formation of collateral circulation in the presence of thrombosis (angiogenesis).^{81,83} Heparin can inhibit or modulate selected targets of an allergic inflammatory response, including neutrophils and T cells. Heparins appear to decrease leukocyte adherence to vascular endothelium and facilitate leukocyte migration along a chemoattractant gradient to sites of inflammation. Derivatives of low anticoagulant activity block superoxide anion generation, probably by interacting with superoxide dismutase. Heparin appears to impair mast cell degranulation by altering intracellular calcium release through blockade of inositol 1,4,5-triphosphate receptors.⁴³ Heparin also appears able to influence tumor cell metastasis. Tumor cell invasion from the vasculature probably involves host degradative enzymes, including heparinases, which target both heparin and heparan sulfate. Exogenous heparin inhibits the hydrolysis of heparan sulfate. Heparins with low anticoagulant activity have reduced the metastasis of several tumor types in various experimental models.43 Smooth muscle cell proliferation such as that which accompanies atherosclerosis and bronchial asthma also is influenced by heparin and heparan sulfate.⁸⁴ Heparin inhibits capillary endothelial growth but binds with high affinity to fibroblast growth factors and potentiates their growth-promoting effects.54 As such, heparin facilities growth of smooth muscle of the vasculature (including pulmonary), airways, intestine, and contractile cells such as fibroblasts and renal glomerular mesangial cells. Effects can be correlated with molecular size and sulfation of heparin; heparin and other heparans may serve as reservoir for growth factors. Endogenous heparin has been implicated in diseases characterized by smooth muscle proliferation; manipulation of selected members of the heparins may ultimately prove to be a therapeutic alternative to treatment.43 Finally, heparin liberates lipoprotein lipase and can decrease serum triglyceride concentrations, thus "clearing" lipemia.72,54

Drug disposition. The complex chemistry of heparin and its binding to proteins and cells leads to complex disposition. Absorption and distribution of heparin are limited by the large size and polarity. Studies characterizing heparin elimination are generally based on response to therapy (i.e., changes in the APTT). However, more recent studies in animals have detected the drug chemical in blood.85Absorption of heparin after oral administration or by aerosolization is negligible; as such, heparin is a parenteral anticoagulant. Subcutaneous absorption is rapid; intramuscular administration is generally contraindicated because of the risk of hemorrhage. Heparin is metabolized by heparinase in the liver and by reticuloendothelial cells. Metabolites of heparinase activity are excreted in the urine. The anticoagulant activity of the metabolites apparently has not been addressed. The elimination half-life of heparin appears to depend on molecular weight. The LMW fractions are cleared less rapidly compared with larger molecules, leading to a half-life two to three times longer than that of endogenous heparin. As such, molecules with a higher affinity for AT activity will be cleared more rapidly than those responsible for anti-Xa activity.86 It is perhaps for this reason that UFH remains the preferred heparin in situations in which a rapid resolution of response upon discontinuation of therapy is desired (e.g., surgical patients or other patients at risk for bleeding).

The pharmacodynamics and elimination half-time of response (based on anti Xa activity) of dalteparin (Fragmin; anti-Xa activity of 2500 U/mL) have been reported in dogs (Table 15-4). Targeted therapeutic ranges based on anti-Xa activity approximates 0.3 U/mL for UFH and 0.5 U/mL for LMW heparin.⁸⁷ Dose response indicates increasing effects with increasing dose, with response more rapid in onset and of greater magnitude with intravenous compared with subcutaneous administration. Response occurs in 2 minutes with intravenous administration, compared with 2 hours with subcutaneous administration. Peak APTT and TT at 2 hours after subcutaneous administration of 200 IU/kg were similar to that measured at 1 minute after 25 IU administered intravenously. Peak effects after intravenous administration approximated 1.75 times baseline for APTT and up to 2.5 times baseline (TT); return to baseline occurred at approximately 1 hour. The impact of subcutaneous administration on APTT and TT was muted: peak effect was no more than 1.25 times baseline for either APTT or TT at all doses. Return to baseline appeared to be dose dependent for both routes but generally was faster (1 to 4 hours, but up to 8 hours) after intravenous compared with SC administration (6 to 10 hours). The authors noted that significant anticoagulant activity lasted up to 3 hours, but even the highest subcutaneous doses failed to affect either APTT or TT to a clinically significant degree. The authors also concluded that monitoring LMW heparin administration in dogs would best be accomplished by measuring anti-FXa activity with chromogenic substrates.⁸⁸ The influence of LMW heparin on APTT and TT in dogs appears to be less than that in humans, suggesting species differences in coagulation response. However, this may reflect a shorter APTT in normal dogs compared with normal humans.

The pharmacodynamics (based on anti-Xa activity) of 5 days' treatment of dalteparin (100 IU/kg subcutaneously twice daily) or enoxaparin (1 mg/kg subcutaneously twice daily) was compared with that of UFH (250 IU/kg subcutaneously every 6 hours) in cats (n = 5) using a randomized (for the first treatment) crossover design with a 14-day washout between treatments. Peak activity for all three products occurred at approximately 2 to 4 hours, with the maximum effect of each product in anti-Xa (U/mL) approximating 0.6 (UFH), 0.45 (enoxaparin) and 0.3 (dalteparin). Concentrations reached the

human therapeutic range of 0.5 to 1 U/mL anti-Xa activity in only one cat receiving dalteparin. For each drug mean activity was not detectable before the next dose (trough). These data led the investigators to conclude that higher doses than those studied are indicated,⁸⁷ Vargo and coworkers drew similar conclusions in their study of rhe effect of dalteparin (100 IU/ kg SC, b.i.d, for 13 days) in healthy cats (n = 8) (based on anti-Xa activity). Activity was measurable in only 4 cats; activity present by 4 hr after a single dose (the first sampling time) and returned to baseline by 6 hr; in these cats. Prothrombin time and APTT were not significantly altered by dalteparine administration; although sample size was small, clinical values were essentially unchanged in the cats.^{88a} The half-life of heparin is prolonged in renal or liver failure.⁸¹ Bioavailability (subcutaneously) of the LMW heparins appears to be similar in humans, approximating 80% to 90%,82 and approximates 100% in dogs.89

Preparations. Because heparin is a heterogeneous mixture, only about 33% of the molecules i the drug preparation inhibit coagulation, and correlation between heparin plasma concentration and anticoagulant activity is not possible. Correlation between dose and response is further complicated by differences in effects based on molecular weight. The concentration of heparin is standardized by bioassay as units of activity, with 1 unit of heparin (referred to as a Howell unit) being equivalent to approximately 2 µg of pure heparin, which in turn (according to the Online Medical Dictionary; http://www.onlinemedical-dictionary.org/) is the amount of heparin that will maintain anticoagulant activity in 1 mL of feline blood for 24 hours at 0° C.90 Heparin is available as a sodium or lithium salt. The sodium salt is usually the preferred preparation for in vivo use. LMW heparins currently available for prevention of acute deep vein thrombosis or pulmonary thromboembolism in the United States include dalteparin, enoxaparin (also approved for extended use in prevention of deep vein thrombosis), and ardeparin. The cost for treating a cat with enoxaparin for 1 month has been estimated at \$80 (US). Storage of diluted drug (20 mg/mL) and storage in either glass vial or individual tuberculin syringes for up to 4 weeks does not result in statistical

Table 15-4 Pharmacodynamic Response to Plasma Anti-factorXa (Dalteparin) in Healthy Dogs ^{88,89}							hy Dogs ^{88,89}	
		Max anti Xa	Max APTT (min)	Max TT	Time to	Duration (hr):		Half-life

§Time to max generally was similar for anti-Xa, APTT, and TT.

"Time to return to baseline for APTT and TT, which often differed.

differences of activity. A generic LMW heparain has recently been approved.

Drug interactions and side effects. Heparin stands out as a drug that will interact with many other drugs. Heparin should not be mixed with any other drug. Hemorrhage is the major complication of heparin therapy, occurring in 18% to 22% of human patients receiving heparin.⁸¹ Hemorrhage is less likely to occur with low dosages and constant intravenous infusion (as opposed to intermittent intravenous administration). Hypersensitivity may play a role in hematoma formation.⁹¹ The incidence of hemorrhage can be reduced by (1) confirmation of the need for therapy; (2) use of the appropriate dose and frequency; (3) avoidance of combination therapy with other antihemostatic drugs, including aspirin and other salicylates; and (4) monitoring of the effects of therapy with clotting or coagulation tests. Use of LMW heparin should also be considered. At higher doses the APTT can be useful for assessing the likelihood of hemorrhage. Monitoring APTT is less useful when low doses of heparin are given. Heparin is contraindicated for the bleeding patient and for DIC unless replacement blood or plasma therapy is given (see later discussion of clinical indications). Excessive therapy (theoretically) might be treated with protamine sulfate, a compound that complexes with heparin. It is dosed according to the amount of heparin to be neutralized (see previous discussion of protamine). The risk of bleeding in surgical patients receiving LMW heparin has not been well assessed; however, the longer duration of action of these products may contribute to an increased risk of bleeding. In human patients undergoing cardiovascular surgery, although all antithrombotic drugs studied increased the risk of bleeding, the use of the LMW product enoxaparin was associated with the greatest amount of blood loss and need for blood transfusions.92

Heparin-induced thrombocytopenia has been reported in 5% to 30% of human patients receiving heparin and is more likely to occur with bovine as opposed to porcine preparations.^{81,93,94} Two types (type I and type II, similar to type A and type B adverse reactions) of thrombocytopenia have been described. Several days of therapy are necessary for type I thrombocytopenia to occur; it resolves once therapy is discontinued. Type I thrombocytopenia occurs less frequently with LMW heparins. Type II thrombocytopenia occurs in fewer people, is more severe and rapidly fulminating, and is characterized by a longer time to onset (6 to 10 days). Type II thrombocytopenia may be an allergic response to the secondary and tertiary structures of heparin and has caused paradoxical thrombosis.⁸¹Antibody formation toward heparin bound to platelet factor IV has been demonstrated.⁸⁰ The syndrome is recognized by a greater than 50% decrease in platelets that cannot be explained by other causes and/or skin lesions at the site of injection.⁸⁰ As with type I thrombocytopenia, the incidence of type II thrombocytopenia is likely to be less with LMW heparins. However, cross-reactivity of 20% or more toward heparin antiplatelet antibodies has been reported for LMW heparins; heparanioids such as danaparoid have been suggested for human patients demonstrated to develop heparin-induced thrombocytopenia.

A small number of human patients have developed skin necrosis with both UFH and LMW heparin. Lesions are similar to those caused by toxic epidermal necrolysis and can be lethal. The cause is unknown.

In human patients receiving long-term therapy, heparin has induced osteoporosis. The mechanism is not known but does not seem to involve prostaglandin E_2 . The effect is more dramatic with UFHs. LMW heparins have an osteopenic or calcium-sparing effect, although the sequelae and nature of this effect are not characterized.⁸¹

Liver leakage enzymes increase in up to 93% of human patients receiving heparin. The increases peak approximately 7 days into therapy and then return to normal, with no obvious detrimental clinical sequelae. Heparin also interferes with and falsely increases bile acids. When used as an in vitro anticoagulant, heparin falsely increases blood urea nitrogen, bile acids, and sodium and potassium salts. Finally, heparin can interfere with several hormones. It interferes with thyroid hormones, causing decreases in both thyronine and thyroxine. It is a predictable and potent inhibitor of aldosterone secretion in human patients, causing natriuresis and the potential for hyperkalemia, particularly in predisposed patients.^{95,96} The effects of heparin on the renin–angiotensin–aldosterone system may be responsible for its antihypertensive effects.⁹⁷

A unique side effect of heparin recently identified reflects adulteration of heparin ingredients by the addition of synthetic or animal origin oversulfated (4 sulfates per disaccharide unit) chondroitin sulfates (OSCS). Acute reactions in humans (which are potentially lethal) reflect two mechanisms: direct interaction with kallikrein and release of C3a and C5a anaphylatoxins.⁹⁸ Hypotensive patients (e.g., those undergoing renal dialysis) and patients receiving angiotensinconverting enzyme inhibitors (which inhibit degradation of bradykinin) were at risk of reacting adversely. Because LMW heparins are processed from UFHs, contamination is also possible, although contaminants will be diluted compared with unfractionated preparations. The dog, rat, and pig were studied as models for toxicologic evaluation (as reported by manufacturers Sanofi-Aventis) of contaminated heparins; however, the dog was not selected because cardiovascular toxicity did not occur after administration of doses (0.83, 2.09, 10 mg/kg) considered clinically relevant (although coagulation disorders precluded dosing higher than 10 mg/kg). Consequently, the dog probably is less sensitive to the effects of OSCS, which is consistent with the relative safe use of polysulfated aminoglycans (i.e., Adequan) in dogs compared with humans.

N-acetylcystiene (NAC) manifests some actions similar to heparin. It has been used as a renoprotectant and hepatoprotectant agent in humans undergoing surgery. Compared with placebo controls, human patients receiving 150 mg/kg NAC followed by 150 mg/kg as a 24-hour infusion had lower postoperative PTs and prolonged coagulation times (based on thromboelastometry tracings); further, platelet aggregation also was decreased. Blood loss increased in these patients, leading the investigators to warn that patients receiving NAC preoperatively had an increased risk of bleeding.⁹⁹ *Clinical indications and use.* Clinical indications for heparin therapy include the prevention or treatment of venous or pulmonary embolism (e.g., nephrotic syndrome, autoimmune hemolytic anemia, hyperadrenocorticism, or heartworm disease) and atrial fibrillation with embolization (e.g., feline cardiomyopathy) and as an anticoagulant for diagnostic use and blood transfusion.

Thromboembolism. Heparin remains the drug of choice when rapid anticoagulant activity is necessary in acute thrombosis; in humans heparin is continued for 4 to 5 days to allow time to onset of oral anticoagulants. Generally, heparin is effective only on the fluid phases of thrombin-dependent proteins and is ineffective toward clot-bound factors. However, heparin not only prevents further thrombosis but also appears to facilitate resolution of the thrombus, promoting recanalization through activation of tissue plasminogen activator⁸¹ and stimulating angiogenesis. Efficacy of therapy does not seem to be related to the anatomic location of the thrombus. Heparin and other antithrombotic agents have not been well studied in dogs and cats. Many studies that focus on pharmacokinetics and pharmacodynamics are performed in normal animals; response to drugs may be much different in the face of diseases requiring therapy. In human patients (and possibly dogs), the dose of heparin necessary to control coagulation may be greater than that in the normal patient who is not suffering from a coagulopathy.¹⁰⁰ For thrombosis, heparin is administered parenterally; deep subcutaneous or intrafat injection prolongs persistence of therapeutic concentrations. Large hematomas can occur with deep intramuscular injection. Heparin is also administered intravenously, either intermittently or as a constant infusion. In human patients the use of weight-based nomograms to determine initial and maintenance heparin infusion rates results in a higher percentage of patients reaching the targeted activated thromboplastin time (APTT) range earlier in the course of therapy.¹⁰¹ Monitoring is particularly important to establish effective doses. Doses are variable with author, route, species, and intent. Generally, subcutaneous doses range from 150 to 250 U/kg in dogs and from 250 to 375 U/kg in cats every 8 hours. The dose of heparin in normal cats necessary to maintain therapeutic concentrations of heparin (as established in humans, 0.35 to 0.7 U/mL) in one study was 300 U/kg of heparin every 8 hours.85

For most causes of thromboembolism, therapy is more likely to be successful in patients if heparin is administered at a rate to cause the APTT time to be 1.5 to 2.5 times baseline or the activated clotting time (ACT) to be 1.2 to 1.5 times baseline (prolongation by 15 to 20 seconds).^{80,101-103} However, monitoring APTT generally is ineffectual if low doses of heparin (or LMW heparin) are given. Rather, anti-Xa activity should be measured.⁸⁸ A baseline should be established before therapy is begun, and monitoring should occur 2 hours after a subcutaneous dose; measurements might be immediate. Alternatively, targeting anti-Xa activity of 0.35 to 0.7 IU/mL has been recommended in human patients requiring higher doses of UFH to maintain targeted APTT; less heparin was needed in one study, decreasing the risk of bleeding.⁸⁰ Replacement of AT should accompany heparin therapy when indicated (e.g., nephrotic syndrome, DIC). Gradual discontinuation of heparin therapy has been recommended to prevent a hypercoagulable state.^{102,104} Long-term heparin therapy can be accomplished at home with subcutaneous injections, or warfarin therapy can be implemented (see later discussion of vitamin K antagonists).

LMW heparins (e.g., enoxaparin) have been studied in humans and to some degree in dogs and cats. Advantages when compared with HMW heparins include specificity of action, better absorption after subcutaneous injection, more predictable dose-response relationship because of improved prediction of pharmacokinetics, and prolonged elimination half-life. Reduced incidence of bleeding (in nonsurgical patients) because of more specific targeting of Xa compared with thrombin and other factors, as well as reduced thrombocytopenia, has also been suggested as an advantage of LMW heparins.^{81,105} Because LMW heparin does not effectively affect thrombin, APTT and TT are minimally affected and therefore should not be used to monitor response. Rather, anti-Xa activity should be measured. According to Mischke and Grebe,⁸⁸ in humans an anti-Xa activity target of 0.3 to 0.6 U/mL at 4 hours is suggested for patients at high risk of thrombosis (the lower target intended to minimize the risk of bleeding complications; a target of 0.14 to 0.34 has been recommended for patients with acute myocardial infection already receiving thrombolytic therapy) and 0.4 to 0.9 U/mL for low-risk patients.^{80,88} Whether the targets appropriate for dogs are also appropriate for cats has yet to be established. However, if the same targets are relevant, a dose of 100 U/kg of LMW heparin (dalteparin) would achieve the targeted anti-Xa activity in dogs at 2 to 4 hours (see Table 15-4)

A retrospective study of cats with FATE and treated with dalteparin found the drug, when administered at 99 U/kg either once or twice daily, to be both convenient and effective. Mean follow-up time of 172 days was associated with recurrence in 8 of 43 cats, with complications related to bleeding described as infrequent.¹⁰³ The use of LMW heparin (dalteparin, starting daily dose of 102 IU/kg subcutaneously) has been compared to warfarin (0.08 mg/kgl using PT and an international normalized ratio target of 2 to 3) for treatment of arterial thrombosis in cats.¹⁰⁶ Dalteparin increased mean survival time to 255 days compared with 69 days for warfarin-treated cats, although the differences were not statistically significant, probably due, in part, to small sample size. Further, 17% of the warfarin-treated cats exhibited bleeding adverse events, whereas none of the LMW heparin-treated cats did.

Supportive therapy for treatment of FATE includes the use of analgesics to control pain. The use of newer nonsteroidal antiinflammatories that are more potent for cyclooxygenase 2 (responsible for prostacycline formation) than cyclooxygenase 1 (responsible for thromboxane formation) might prudently be avoided. Their use may shift the balance toward thrombogenesis (see Chapter 29). Use of opioid analgesics, including a fentanyl patch and/or constant-rate infusion, should be considered. Acepromazine should be avoided for either treatment or prevention of thromboemblism; its vasodilatory properties are not likely to facilitate collateral circulation and hypotension-induced decreased blood flow may increase the risk of thrombus growth.¹⁰³

For prevention of pulmonary thromboembolism, heparin can be administered at a lower dose (30 to 75 U/kg). Monitoring ACT or APTT may not be useful at these doses. Hemorrhage, however, remains a potential side effect in at-risk patients (i.e., those undergoing surgery).

A Cochrane review in human medicine found insufficient evidence to recommend use of LMW heparin instead of vitamin K antagonists.¹⁰⁷

In patients suffering from severe heartworm disease, lowdose heparin given 1 to 2 weeks before treatment and 3 to 6 weeks after treatment improves survival rates compared with no treatment or with aspirin therapy.¹⁰⁸ In the event of thrombosis associated with adulticide therapy, heparin should be administered (50 to 70 U/kg every 8 hours) for at least 7 days (assuming the platelet count increases to above 150,000/mm³).

LMW heparins have been recommended as treatment or prevention of thrombosis associated with immune-mediated hemolytic anemia.

Disseminated Intravascular Coagulaopathy

Heparin is used with blood and plasma for the treatment of DIC. The use of heparin for treatment of DIC remains controversial.71 Its efficacy for DIC depends on adequate concentrations of AT (≥40% of normal). Replacement therapy with either whole fresh blood or fresh or fresh frozen plasma is indicated if AT levels are not normal or for actively bleeding patients. A loading dose is generally followed by a maintenance dose; the loading dose can be preincubated with blood or plasma in order to maximize effects on AT Maintenance dosing should be based on changes in APTT rather than on a fixed dose. This is particularly true in patients suffering from DIC because the synthesis of cofactors varies among patients with DIC. Although normal dogs respond rapidly to heparin therapy, identification of changes in APTT in DIC patients may be difficult. Neutralization of heparin with polybrene (hexadimethrine bromide)⁷¹ can be used to distinguish changes in the APTT due to heparin from those due to DIC once a baseline APTT has been established. The recommended dose of heparin is markedly variable, ranging from a low of 75 to 100 U/kg administered subcutaneously (a dose unlikely to change APTT but likely to be sufficient to target AT) to a high of 750 to 1000 U/kg (severe disease with organ damage caused by microthrombosis) every 8 hours. An intravenous bolus of 5000 U or 80 U/kg followed by constant-rate infusion of 5 to 18 U/kg/hr also has been recommended. For a hypercoagulable state, a subcutaneous dose of 200 to 300 U/kg every 6 hours is recommended. The APTT should be monitored every 6 hours. In general, if higher doses are used, the APTT should be prolonged by 1.5-fold to twofold. Once a therapeutic response is established, the APTT and platelet count should be monitored daily. Heparin should not be abruptly discontinued in patients with DIC because of the risk of rebound hypercoagulability associated with AT deficiency. Nonanticoagulant uses of heparin are increasing in human medicine. Anecdotal reports in humans indicate that heparin

can be beneficial for the treatment of asthma and allergic inflammation.

DIC has been reviewed in cats,¹⁰⁹ including its treatment. Of the 46 cats studied retrospectively, 43 died or were euthanized, precluding conclusions regarding the most effective therapies.

Vitamin K Antagonists (Oral Anticoagulants)

The oral anticoagulants differ primarily in their duration and magnitude of effect. Studies of their importance in veterinary medicine have focused primarily on their toxic rather than their therapeutic indications,¹¹ although these drugs are being used increasingly to treat thromboembolic diseases.

Chemistry. The vitamin K antagonists consist of two groups: the coumarin derivatives (dicoumarol and warfarin) and the indandione anticoagulants. Both interfere with the hepatic synthesis of vitamin K-dependent clotting factors II, VII, IX, and X and anticoagulant proteins C and S (see Figure 15-7).95 They block the reduction of vitamin K by vitamin K epoxide after its use in factor synthesis, thus effectively reducing the concentration of vitamin K. Two points related to this mechanism are important. First, the anticoagulant activity occurs only in vivo; second, there is a delay in anticoagulant activity (and therefore therapeutic or toxic effect) for 8 to 12 hours because of the persistence of factors synthesized before administration. Factor VII has the shortest half-life and therefore is the first factor to become deficient. Antithrombotic effects occur in 4 to 6 days after therapy is begun, however, as serum concentrations of factors IX and X decrease. Serum concentrations of the anticoagulant protein C also decrease but more rapidly than clotting factors, thus possibly rendering the patient hypercoagulable. Other factors that might contribute to the hypercoagulable state increased thrombin generation as a result of the release of procoagulant platelet-derived factors, expression of tissue factor in response to damaged endothelium, and release of platelet factor IV by activated platelets with subsequent neutralization of heparin.⁸⁰ Heparin therapy might be used for the first 2 to 5 days after warfarin therapy is begun to prevent this hypercoagulable state.

Disposition. Warfarin contains a chiral carbon (see Figure 15-7) and is marketed as a racemic mixture. The S isomer is approximately 5.5 times more potent than the R isomer with regard to anticoagulant activity in all species pharmacodynamically studied.¹¹⁰ The vitamin K antagonists are rapidly and completely orally absorbed. Warfarin is 75,000 times more soluble in water than is dicoumarol and is characterized by much better oral bioavailability.⁷² Peak levels occur in 1 hour. There are, however, marked differences in product bioavailability, and products should be interchanged with caution. For products used as rodenticides, warfarin derivatives often have a drug half-life up to 7 days, whereas the indandione diphacinone has an elimination half-life of 30 days.¹¹ All coumarin derivatives are highly bound to serum albumin, limiting the distribution volume to plasma volume. Vitamin K antagonists are metabolized by the liver to inactive metabolites by the cytochrome P450 system and subsequently conjugated to glucuronide. They undergo an enterohepatic cycle.

Although response does not relate in a dose-dependent manner to plasma drug concentrations, the disposition of warfarin, including its enantiomers, has been reported in cats (n = 10) after single intravenous administration of 0.5 mg/ kg and then at 0.1, 0.25, and 0.5 mg/kg (n = 4) orally of the racemic mixture.110 The disposition of the S isomer resulted in significantly higher area under the curve compared with the R isomer, in part because of longer mean residence time and half-life, which were approximately twice as long in the S (approximately 24 hours) compared with the R (11 hours) isomers. Variability was great, with a range that varied almost threefold (11 to 38 hours) for both half-life and mean residence time for the S isomer. A dose-dependent effect was evident. Problematically, distribution of warfarin throughout the study tablets was even. Anticoagulant potency of the two isomers was not studied in cats.

Preparations. Vitamin K antagonists are prepared for therapeutic use as tablets and solutions (e.g., warfarin, dicoumarol). They are, however, more commonly used as oral rodenticides.

Drug interactions. A variety of factors can increase the activity of warfarin anticoagulants. Hypoproteinemia, antimicrobial therapy, hepatic disease, hypermetabolic states, pregnancy, and the nephrotic syndromes are some examples. Drug interactions are most significant when used therapeutically for chronic treatment. Because they are highly protein bound, they will be displaced by (or will displace) other drugs that are protein bound, and their anticoagulant effects may be increased to the point of toxicity. Examples include acetyl-salicylic acid and other nonsteroidal antiinflammatory drugs. Drug interactions occur with other antihemostatic agents.

Clinical use. Clinical use of the coumarin derivatives in dogs and cats is increasing as monitoring techniques improve and doses are refined. The high incidence of recurrent thromboembolism in cats receiving aspirin has led to renewed interest in the use of warfarin for management of arterial thromboembolism. Currently, cardiologists are recommending use of warfarin even in the absence of prior thromboembolic events once adequate left atrial enlargement (left atrial to aortic ratio <2) has been confirmed by echocardiography.¹¹¹ The drug is discontinued if atrial size should normalize (ratio of <1.25).

Warfarin therapy for humans is characterized by doses that vary as much as twentyfold. Variability should be anticipated as a result of species differences in drug disposition, warfarin preparations, the target disease, and the presence of other drugs that may interact with warfarin. Accurate dosing should be based on drug-response monitoring. For long-term anticoagulant needs, or in combination with heparin (100 U/kg every 8 hours) for acute treatment of thromboembolism, warfarin can be administered at 0.1 to 0.2 mg/kg (or one fourth to one half of a 1-mg tablet in cats) orally every 24 hours.^{70,111}

The PT should be measured at baseline before initiation of therapy. Heparin therapy (when also being used) may prolong the prothrombin (as well as ACT and APTT), but a baseline should still be established. Warfarin therapy should be monitored by 4 to 5 days of therapy. Beginning monitoring earlier may help detect changes more easily. Monitoring techniques should be standardized. An optimum sampling time of 2 hours has been recommended.¹¹¹ The target response to warfarin therapy varies. Recommendations have included an increase in baseline prothrombin of 1.3 to 1.6 times baseline to 1.5 to 2.5 times baseline.¹¹¹

A standardized approach to interpreting prothrombin response has been recommended based on an international reference preparation of standardized human brain thromboplastin. The international normalized ratio (INR) is determined for the patient (INR = patient prothrombin/control PT^{ISI}), where ISI is the international sensitivity index of the thromboplastin control used to determine the prothrombin. The ISI is provided by the manufacturer of the thromboplastin control. Standardization is important because controls can vary by more than twofold. A target INR of 2 to 3 has been recommended for prevention of feline thromboembolism while minimizing the risk of bleeding. Either the dose or the interval can be manipulated to achieve the target INR (or prothrombin). Tablet size restrictions may, however, make it difficult to finetune warfarin therapy. The dosing interval might be prolonged to as long as 48 hours for some patients.¹⁰² Heparin therapy can be discontinued approximately 3 days after warfarin therapy is begun; prothrombin should be expected to decrease as a result. After the patient is sent home, monitoring can be decreased to 2-week intervals.

Warfarin therapy has been combined with aspirin to treat or prevent recurrent thromboembolism or increased risk of thromboembolism. Although the combination is rational, the risk of bleeding is intensified. Not only are both platelets and coagulation factors targeted with this combination, but drug interactions between these two highly protein-bound drugs can also complicate safe therapy.

Toxicity. Toxicity manifested as hemorrhage has been the major veterinary medical concern with vitamin K antagonists. Secondary poisoning resulting from the ingestion of a rodent that has eaten treated bait is the most common cause of toxicity. Toxicity can also occur, however, by overdosing warfarin for treatment of thromboembolism. Treatment for anticoagulant rodenticide toxicity is symptomatic and specific. Specific therapy is vitamin K. Vitamin K_1 is a very effective antidote, but it must be given as long as the anticoagulant is present in the body at toxic levels. This time varies, depending on the drug, from several days to several weeks after ingestion. Vitamin K_3 (menadione) is much less expensive but is also far less effective and never should be used as the sole antidote in cases of severe coagulopathy. Treatment with vitamin K will preclude the therapeutic benefits of warfarin for up to 3 weeks.

Fibrinolytics (Thrombolytics)

Fibrinolytic agents increase the activity of plasmin (fibrinolysin), the endogenous compound that is responsible for dissolving clots.¹¹²

Streptokinase and Streptodornase

Streptokinase and streptodornase are synthesized by streptococcal organisms. Urokinase is prepared from cultures of human renal cells. Streptokinase, streptodornase, and urokinase are used in the treatment of wounds that do not respond to antibacterial therapy, burns, ulcers, chronic eczemas, ear hematomas, otitis externa, osteomyelitis, chronic sinusitis, or other chronic lesions. They are available as powders for local or systemic administration. Streptokinase may be useful for the treatment of feline thromboembolic disease. In an experimental model, streptokinase reduced mean thrombus weight after administration of a loading dose (90,000 IU/cat) and a constant maintenance infusion of 45,000 IU (studied for only 3 hours). Clinical use of streptokinase has not been reported.⁷⁰

Tissue Plasminogen Activator

Tissue-type plasminogen activator (tPA) activates plasminogen bound to fibrin. Its use should be limited to cases of thrombosis (rather than prevention). Some studies have indicated a potential use for tPA for dissolution of thrombi in cats, but side effects should be minimized before general use of the drug can be accepted. Although 50% of cats with spontaneous aortic thrombosis treated with tPA (0.25 to 1 mg/kg per hour for a total dose of 1 to 10 mg/kg) had resolution of clinical signs, 70% of the cats treated died from reperfusion injury, heart failure, or other side effects.⁷⁰

Clinical Use

Cost and lack of refined doses and selectivity have limited the use of thrombolytic drugs for treatment of (pulmonary) thromboembolism in dogs and cats.

Antithrombotics

Platelet activity is controlled by substances generated both outside and inside the platelet. Adenophosphate, prostaglandins, thromboxane, serotonin, cAMP, and GMP are generated within the platelet, where they interact with platelet receptors or with the platelet itself. Modulation of all platelet activity can be achieved by interaction with these compounds. Among platelet receptors are two P2YP type purinergic receptors that are activated by ADP and coupled with G-protein (Gq). Activation causes platelet shape to change, induces phosphatidylinositol turnover and platelet aggretation. This response is offset by a second receptor type coupled to Gi. Activation of this receptor by ADP inhibits adenylyl cyclase and decreases cAMP, resulting in muted platelet activation. Both receptors must be stimulated for platelets to activate.

The thienopyridines ticlopidine and clopidogrel are ADP antagonists with antiplatelet activity. Their inhibitory effects on P_{2Y12} G1-coupled adenosine receptors are irreversible, targeting both primary and secondary aggregation to a variety of agonists. Ticlopidine has been extensively studied in human patients with thromboembolic disease. Inhibition occurs in 2 to 5 days. The thienopyridines also inhibit the conformation change of glycoprotein IIb/IIa induced by ADP. Because binding of fibrinogen and vWF is prevented, thrombrus progression is inhibited. Because both ticlopidine and clopidrogel are prodrugs, pharmacodynamic tests must occur in vivo and pharmacokinetics must be based on the active metabolite. The enzyme responsible for metabolism has not yet been identified.⁵⁴ Maximum effects are delayed up to 8 to 11 days; a loading dose (twice maintenance) is suggested in humans. Effects

persist for several days after discontinuation of therapy; this may reflect an irreversible nature of inhibition and the need for new platelets. Serious side effects are rare in humans but include neutropenia and thrombocytopenia. The drug has proved equal to aspirin in the prevention of human stroke. Ticlopidine has been studied in dogs. A dose of 62 mg/kg every 24 hours inhibits platelet aggregation in normal dogs, but higher doses may be necessary in the presence of thromboembolic disease.^{3,113} It is not clear if the cat metabolizes ticlopidine to the active drug. However, ticlopidine also has been studied in cats (n = 8) at 50, 100, and 200 mg/cat once daily orally and 250 mg/cat every 12 hours for 10 days using (apparently) a nonrandomized crossover design with at least 14 days between treatments.¹¹⁴ Outcome measures included oral mucosal bleeding times and platelet aggregation (blood aggregometry). Significant reduction in platelet aggregation occurred with doses at 100 mg and above, although effects were present on all three test days (3, 7, and 10) only for the 250-mg twice-daily dose. Ticlopidine was associated with dose-dependent anorexia and vomiting, which occurred shortly after dosing, causing the authors to conclude that clinical utility of ticlopidine was limited. However, cats developed tolerance to these side effects. One of the eight cats was removed from the study because of sudden death, although the death could not be attributed to the drug.

Clopidogrel is related to ticlopidine and is less likely to cause neutropenia. Also a prodrug, its onset of action also is slow, with the loading dose in humans being 4 times the maintenance dose. Clopidogrel has been studied for its effect on thrombolysis, based on the observation that platelet activation may decrease thrombolysis or facilitate rethrombosis.¹¹⁵ Clopidogrel had no impact on thrombolysis in cats with experimentally induced (tPA) thrombosis after 3 days of oral therapy (75 mg), although only three cats were studied. However, a follow-up study in blood collected from cats (n = 9) found no effect.¹¹⁵ The pharmacokinetic-pharmacodynamic relationship of clopidregel was described in dogs (n = 8) receiving approximately 1 mg/kg PO every 24 hr for 3 days followed by either 0.5 or 1 mg/kg every 24 hr for 3 days (n = 5).^{115a} Indices of platelet inhibition (e.g, ADP-induced platelet aggregation decreased by 80 to 93% from baseline) were present by day 3 in either treatment group, with the duration of effect lasting 3 to 7 days. Peak metabolite concentration 210 + 200 ng/ml occurred 1 hour after administration; the rapid disappearance and low (below detectable) concentrations of the metabolite precluded complete pharmacokinetic description. Experimentally, clopidogrel (5 mg/kg) proved more effective than aspirin (5 mg/kg) when combined with t-PA (80 µg/kg) or heparin (200 U/kg) for prevention of experimentally induced coronary artery occlusion.115b

Dipyridamole is a vasodilator that inhibits cAMP phosphodiesterase and increases cAMP in the platelet. When used alone, it minimally affects platelet activity but acts synergistically with aspirin to inhibit platelet activity.¹¹⁶

Aspirin causes an irreversible and thus long-lasting negative effect on platelet activity, which is clinically manifested as prolonged bleeding time. Aspirin irreversibly inactivates prostaglandin G and H synthetase, the enzyme that catalyzes the initial conversion of arachidonic acid to thromboxane A₂. Two types of this enzyme are present: the constitutive form responsible for conversion of arachidonic acid to prostaglandin H (and ultimately thromboxane) and an inducible form that activates cells in response to growth factors during inflammation. The antiplatelet effects of aspirin result from acetylation of the constitutive form of the enzyme.¹¹⁷ Platelets are not able to synthesize proteins and thus cannot regenerate the enzyme necessary for thromboxane formation. The irreversible nature of platelet inhibition allows aspirin administration to occur at 3-day or longer intervals. Reduced formation of the various eicosanoids responsible for platelet aggregation and coagulation accounts for the variety of different pharmacologic (therapeutic and toxic) responses to aspirin. Side effects of aspirin can, however, be minimized by taking advantage of the dose-response relationship between aspirin and its many pharmacologic effects.

Prospective, controlled studies that support the efficacy of aspirin as an antithrombotic either as a preventive or treatment for FATE are limited. In a retrospective study of cats with acute FATE, survival did not differ between cats receiving 5 mg (n = 12) versus \geq 40 mg/cat (n = 34) every 72 hours.¹¹⁸ An advantage of the lower dose might be inhibition of thromboxane synthetase (causing platelet aggregation) without inhibition of prostacyclin synthetase (inhibition of platelet aggregation). However, the power of the study to detect a treatment difference was not described, and failure to detect a significant difference should not be interpreted as equal efficacy between the two doses. On the other hand, the incidence of side effects was lower in the low-dose aspirin group.

One study reported that a very high dose of aspirin (650 mg/cat) in cats before initiation of thrombus formation improved collateral circulation compared with controls that did not receive aspirin,¹¹⁹ suggesting that aspirin prophylaxis might help reduce recurrence and that therapy should be initiated as soon as possible in the acute event.

The antiplatelet effect of aspirin can be separated to a large degree from its other actions by administration of a low dose (0.5 mg/kg every 12 hours in a normal dog). One retrospective study of the use of an ultralow dose of aspirin (0.5 mg/ kg) versus (unfractionated) heparin (75-125 U/kg every 6 to 8 hours) in 151 dogs with immune-mediated hemolytic anemia being treated with prednisolone and azathioprine found the percentage of animals surviving the hospital stay to be 84% for the aspirin group versus approximately 54% for either the heparin-treated or no-antihemostatic-drug-treated group.¹²⁰ Survival at 1 year was 67% for the aspirin-treated group versus 46% for the heparin-treated group and 34% for the noantihemostatic-drug-treated group. The study was biased by the assignment of treatments: Coagulopathy was worse in the heparin group compared with the aspirin group. Nonetheless, the study supports the potential efficacy of aspirin at very low doses compared with no antihemostatic drug; its inclusion in the treatment regimen is made more prudent because of the potential for glucocorticoid therapy to worsen the risk of thromboemblism (see Chapter 30).

Other "low doses" suggested for aspirin include 10 mg/kg in heartworm-infested dogs and 25 mg/kg twice weekly in cats.^{72,117,121} Although experimental studies reveal antiplatelet activity for aspirin, clinical response is variable.^{122,123} Aspirin, however, remains a component of therapy directed toward prevention and treatment of arterial thrombosis,^{2,117,124} including severe pulmonary arterial thrombosis associated with heartworm disease.¹⁰⁸ Coupled with cage confinement, aspirin (4 to 6 mg/kg per day) administered for 2 to 3 weeks before caparsolate therapy may improve survival after treatment.¹⁰⁸ Aspirin is still the most commonly used drug for prevention of arterial thrombosis in cats (25 mg/kg orally every 72 hours) despite the lack of clinical proof of efficacy.⁷⁰ Recurrence of thrombosis may, however, be as high as 75%.

Interestingly, one report in a canine model of coronary thrombosis describes a synergistic antiplatelet effect when administered with metoclopramide.¹²⁵ Aspirin was administered at 0.03 to 0.1 mg/kg intravenously and metoclopramide at 0.1 or 0.3 mg/kg intravenously. The effect of metoclopramide was attributed to either s5HT₂ or antagonism of alpha₂.

Other drugs with antiplatelet activity are available but have not been sufficiently studied in animals. These include the tirofiban and abciximab, inhibitors of glycoprotein (IIb/IIIa), a platelet surface integrin that serves as a receptor for fibrinogen and vWF. For example, abciximab is the Fab fragment of a human monoclonal antibody directed toward the receptor used to treat coronary thromboembolism. Propranolol has been found to be ineffective as an inhibitor of platelet activity.^{71,126}

Homocysteine

The recognition of arterial damage in two infants with inborn errors of metabolism resulting in an increase of homocysteine led to the investigation of the possible role of homocysteine in thromboembolic disease.¹²⁷ However, homocysteine accumulation generally is accompanied by an increase of its precursor, S-adenosylhomocysteine (SAH). This demethylated product of numerous S-adenosylmethionine (SAM)-dependent transmethylation reactions may cause a potent feedback inhibition, resulting in hypomethylation of reactions critical to thrombogenic control. In homocystinuria, lowered plasma homocysteine is accompanied by lowered SAH concentrations and restored transmethylation reactions. It is not clear if increased homocysteine (or SAH) is a cause or effect (and thus a marker) of thromboembolic disorders. Because the kidneys are responsible for clearing up to 70% of homocysteine, concentrations increase in concert with creatinine in patients with renal disease, reaching increases of threefold to fivefold above baseline. Other factors that increase homocysteine include decreased folate and vitamin B concentrations and cardiovascular disease itself.

PHYSIOLOGY

Water

Water accounts for 60% of lean body weight in adult animals, with variation between species. This percentage is affected by fat and age. Obese and older animals tend to have a smaller percentage of body weight composed of water, whereas up to 90% of body weight in neonates is water. Approximately two thirds of this water is present within cells (intracellular fluid [ICF] compartment) and one third is extracellular fluid (ECF). Of the ECF, three fourths is interstitial fluid and one fourth of the ECF volume is plasma. Thus plasma accounts for only 5% of body weight.^{1,2}

Water freely diffuses through cell membranes. Consequently, all body compartments have approximately the same osmolality (290 to 310 mOsm/kg in dogs and 300 to 330 mOsm/kg in cats).³ Osmotic force is the prime determinant of distribution of water across cell membranes (i.e., the partitioning of water between the ECF and ICF). Plasma sodium is the primary determinant of ECF osmolality. Glucose and urea make minor contributions as well, which is reflected in the following calculation:

Plasma osmolality (mOsm / kg) = 2[Na + K] + [serum glucose in mg / dL ÷ 18] + [BUN in mg / dL ÷ 2.8]

In the laboratory osmolality is measured by freezing point depression or vapor pressure osmometry. The measured value is often higher than the calculated value because this equation does not include all osmotically active particles present in plasma.

As can be seen from the preceding formula, sodium is principally responsible for ECF osmolality. Osmolality in the ICF is principally determined by potassium, magnesium, phosphates, and proteins. To promote water movement from one compartment to another, the osmolality of one or more compartments must change.⁴ Tonicity, or effective osmolality, refers to the osmotic pressure of a solution-Osmotic pressure is the pressure required to prevent water movement across a semipermeable membrane. When the relationship between tonicity and osmolality is under consideration, it is important to distinguish between permeant and impermeant solutes. Permeant solutes (e.g., urea) move freely across cell membranes and do not induce net water movement when introduced into a solution (i.e., they are ineffective osmoles). Impermeant solutes (e.g., sodium and glucose) induce water movement when introduced into a solution and are called effective osmoles, because they do not readily cross cell membranes. Glucose, to the extent that it causes hyperglycemia, is an impermeant solute and does contribute to ECF osmolality. However, glucose administration usually does not cause hyperglycemia because it is rapidly taken up by cells in the presence of insulin. The implication is that tonicity is less then osmolality.

The capillary walls are freely permeable to sodium, chloride, and glucose. As a result, these substances are osmotically inactive across capillary membranes. However, plasma proteins are limited in their ability to cross capillary membranes, and plasma volume is ultimately maintained by the colloid osmotic pressure (COP), COP is the force created by macromolecules present within the vasculature that prevents water from escaping to the extravascular space. Thus, COP is essentially the pressure exerted by plasma proteins. Albumin contributes to roughly 75% of COP in healthy patients, with globulins making up the remainder. At the venous end of the capillary bed, plasma proteins exert an osmotic force in excess of the hydrostatic gradient, resulting in a net fluid flux from the interstitium into the vessels. Thus albumin is important for distribution of water between the intravascular and interstitial compartments, and plasma proteins in general play a key role in the maintenance of intravascular fluid volume.1 This is in contrast to the osmotic equilibrium governing water distribution across the ECF and ICF compartments.

The amount of available water in the body is determined by a balance between intake and loss.¹ Water intake occurs by drinking and eating, which are controlled by thirst and hunger. Alterations in water intake can occur with neurologic disease and congenital abnormalities. Animals normally lose water through urine, feces, and expired air. To a lesser extent, evaporation from the skin surface promotes water flux across the epidermis. Obligatory urinary and fecal losses are determined by the solute load that must be excreted. Respiratory losses of water are affected by ambient temperature and humidity. Water losses may increase as a result of vomiting, diarrhea, and polyuria. Rarely, clinically relevant water losses arise through traumatized tissues or with cavitary effusions. Fever also can be responsible for increasing loss of water.⁵ Fluid losses, such as those incurred by vomiting, diarrhea, and polyuria, are often classified as isotonic (i.e., small solutes are lost in proportion to their concentration in plasma), but more commonly these losses are slightly hypotonic, with sodium concentrations of 80 to 120 mg/dL. This is manifested by hypernatremia, which is commonly observed with dehydration. To maintain hydration homeostasis, urine output *may* exceed the obligatory urine output, the latter being the volume required for elimination of solutes. While the term *free water* is well recognized and accepted, this fluid resembles a hypotonic crystalloid in content, as opposed to water. Water excretion is due to modification of antidiuretic hormone (ADH) secretion. ADH is normally released from the posterior pituitary gland when osmoreceptors in the hypothalamus detect hypertonicity or when baroreceptors in the cardiovascular system sense hypovolemia. Release of ADH promotes water retention. For water to be excreted by the kidneys, there must be adequate delivery of tubular fluid to the ascending limb of the loop of Henle, and the renal collecting ducts must remain impermeable to water in the absence of ADH.⁶

Sodium

Sodium is the osmolar skeleton of the ECF. Under normal conditions the kidneys regulate its elimination, excreting as much sodium as is ingested. Renal sodium excretion is normally regulated by aldosterone, atrial natriuretic factors (ANF), and intrinsic renal mechanisms (e.g., renal blood flow [RBF], glomerular filtration rate [GFR], and glomerulotubular balance). Glomerulotubular balance refers to the ability of the kidney to maintain a relatively constant fractional reabsorption of sodium, despite changes in GFR. If there is expansion of the effective circulating volume (i.e., overhydration, hypervolemia), the cardiac atria distend with subsequent release of ANF. ANF and other natriuretic factors inhibit both the formation and effects of angiotensin and decrease sodium reabsorption from the renal medullary collecting ducts. Conversely, when atrial receptors detect a decrease in volume, sympathetic tone is increased and ANF release is inhibited. Further, decrements in renal perfusion and the associated decrease in delivery of sodium (and/or chloride) to the macula densa activate the renin-angiotensin-aldosterone system, promoting sodium to be reabsorbed from the renal tubules and collecting ducts.7

Potassium

The regulation of total body and plasma potassium concentration is important to the extent that potassium alterations may profoundly affect the resting membrane potential (RMP) of cardiac and neuromuscular cells.⁸ Hypokalemia lowers the RMP, making it more difficult to achieve an action potential with subsequent contraction of a muscle. Hyperkalemia raises the RMP, which may result in an action potential of decreased amplitude or, in extreme cases, continuous depolarization of the cell membrane. Although the majority of the body's potassium is found within cells, it is the plasma concentration that corresponds with and contributes to relevant myocardial and neuromuscular abnormalities.

Potassium homeostasis can be conceptualized as having both an internal and an external balance. *External balance* refers to the total amount of potassium in the body and is determined by the balance between intake versus loss. Potassium enters the body principally through ingestion, and almost all ingested potassium is absorbed. A small amount of potassium is normally excreted in the feces, although the colon may serve as an important route for potassium excretion in disease states. Normal potassium loss occurs predominantly through the kidneys, the amount determined by ECF potassium concentration, delivery of sodium and water to the distal tubule and collecting ducts, as well as the secretion of aldosterone. Although the kidneys normally eliminate potassium efficiently, renal mechanisms cannot maintain normal plasma serum potassium concentrations when grossly excessive amounts of potassium are ingested.⁹

Internal potassium balance refers to the distribution of potassium between the ICF and ECF compartments. The Na-K ATPase enzyme pump found in cellular membranes actively transports potassium into the cell and maintains a high intracellular potassium concentration (i.e., approximately 150 mEq/L) relative to the ECF (approximately 4 mEq/L). In hyperkalemic states insulin and β 2-adrenergic activity augment the transport of potassium into the cells, safely storing additional potassium until it can be eliminated.⁹ The internal balance mechanisms may be thought of as a temporary measure designed to allow the kidneys and, to a lesser extent, the colon time to restore potassium balance.^{8,10}

Acid–Base Balance

The body must deal with very large amounts of acid (H⁺) that are generated daily by normal metabolic processes. This is important because H⁺ is very reactive, and small amounts (i.e., nanoequivalents) can have detrimental effects on protein structure and function (i.e., enzymes, cell membranes, and receptors). Normal blood pH is 7.40. Many metabolic functions are exquisitely sensitive to pH, and normal function can only occur within a very narrow pH range. If, for example, a patient's pH falls to 7.20 (which represents an increase of approximately 20 nEq H⁺/L), myocardial dysfunction, vasodilation, or dysrhythmias may be observed.^{11,12}

Changes in $[H^+]$ are opposed by buffer systems within the body. These systems consist of a buffer pair of an acid (H⁺ donator) and its conjugate base (H⁺ acceptor) as follows:

$$HA \leftrightarrow H^+ + A^-_{base}$$

Weak acids and their conjugate bases constitute the most effective buffer pairs in the body, insofar as they are minimally dissociated and readily capable of accepting or donating H⁺ in the presence of changes in H⁺ load. This is in contrast to strong acids, which are highly dissociated in most biological fluids.

It was noted 100 years ago that the hydration of CO_2 in the presence of carbonic anhydrase forms H_2CO_3 (carbonic acid), and carbonic acid acid will ionize into and achieve equilibrium with its conjugate base, bicarbonate (HCO_3^-), and H^+ , almost instantaneously:

$$CO_2 + H_2O \xleftarrow{carbonic}{anhydrase} H_2CO_3 \longleftrightarrow HCO_3^- + H^-$$

By rearranging the variables in the preceding equation, applying laws of mass action, and recognizing that H_2CO_3 exists in almost continuous equilibrium with dissolved CO_2 ,

the value of dissolved CO_2 was substituted, giving rise to the following equation:

$$[H^+] = K_a \left(\frac{[CO_2]}{HCO_3^-} \right)$$

Ultimately, the partial pressure of CO_2 in the blood (p CO_2) was substituted for dissolved CO_2 , the concept of pH was defined (the negative logarithm of [H⁺]), and the following equation was derived:

$$pH = pK_a + \log\left(\frac{HCO_3^-}{PCO_2xSC}\right)$$

where pKa is the logarithm of the ionization constant K_a for H_2CO_3 and SC is the solubility coefficient of CO_2 in blood (0.03).

This is the classic *Henderson–Hasselbalch equation*, fundamental to appreciating traditional acid–base chemistry and interpreting acid–base derangements. This equation shows that the pH of the ECF varies when either $[HCO_3^-]$ or pCO_2 is altered.

There are two categories of acid found in the body: nonvolatile (produced by metabolism of proteins) and volatile (derived from CO₂) produced by cellular respiration throughout the body.¹¹ Nonvolatile (also called *fixed*) acid (H⁺) is primarily excreted by the kidneys, whereas volatile acid (CO₂) is eliminated by way of the lungs. On a daily basis, small pH changes within the body are counteracted by multiple complex and often opposing physiochemical processes that, for the sake of simplicity, are presented as (1) the actions of intracellular and extracellular buffering systems (chemical buffering), (2) modulation of ventilation (physiologic buffering), and (3) renal reclamation and elimination. There are many buffer systems throughout the body. The principle intracellular buffers are hemoglobin, phosphate, and proteins, which are capable of buffering both volatile and nonvolatile acids. The principle extracellular buffer systems are calcium carbonate and phosphate of bone, in addition to the bicarbonate-carbonic acid system, which reacts only with nonvolatile acid. Hemoglobin and albumin account for most of the nonbicarbonate buffering capacity. The HCO₃⁻ buffering system is capable of responding to an acute change in $[H^+]$, and the HCO₃⁻/H₂CO₃/CO₂ equilibrium equation (see Equation 16-1) allows changes in pH to be further modulated by changes in ventilation. This "open system" greatly enhances the buffering capacity of the HCO₃⁻ system and is capable of buffering changes in pH within minutes of an acid or alkali load. Finally, the kidneys play a major role in maintaining pH by increasing or decreasing acid elimination in the urine. Although hours to days may be required for this system's buffering ability to reach completion, it is clinically the most reliable of all the adaptive mechanisms to normalize pH.

Acid–base physiology may be viewed as having an external and an internal balance, as described for potassium. *External balance* refers to the elimination of acid from the body, whereas internal balance allows for the body to safely sequester excessive acid until it can be excreted. The pH of the ECF is largely determined by how effectively these mechanisms function.

A perceived limitation to traditional acid-base physiology is that it is too simplistic, ascribing changes in pH to either respiratory (changes in pCO₂) or metabolic (changes in bicarbonate) causes, thereby neglecting the contribution of other variables in solution. To address this, nontraditional or quantitative approaches to acid-base chemistry and analysis are described.¹³ The terms Stewart approach and Fencl-Leith approach are variants of the often confusing and misunderstood nontraditional approaches to acid-base analysis. The nontraditional approach subdivides metabolic causes into two independent variables, those associated with a strong ion difference (SID) ions that are totally dissociated (e.g., sodium, chloride, potassium, lactate) and A_{TOT} (ions of weak acids that are partially dissociated, e.g., phosphate and albumin). The nontraditional approach defines the pCO₂ (respiratory contribution) as an independent variable. According to the quantitative approach, changes in HCO₃ are explained by alterations in SID, A_{TOT} , and pCO₂. It has been demonstrated that if enough A_{TOT} and SID determinants are measured, an approximate pH can be calculated. The perceived strength of the quantitative approach is that it provides an estimate of the "contribution" of individual electrolyte derangements to an acid-base imbalance when pH is not measured. However, the quantitative approach is only a means of estimating the metabolic contribution to pH when it is not otherwise measured, but not the pH itself; the pH is also highly dependent on the respiratory component, the pCO₂. The traditional system utilizes an overview parameter such as bicarbonate, total CO_2 , or base deficit to quantify the metabolic contribution. The Stewart approach breaks down the metabolic component into two large groups: SID and ATOT; however, it does not further define the contributions. The Fencl-Leith modification is the only truly semiquantitative approach, insofar as it it breaks down the metabolic contribution into six individual components (water [marked by serum sodium], bicarbonate [marked by chloride], albumin, lactate, ketones [if measured], phosphate, and the effect of unmeasured ions). Advocates of the nontraditional approach find that it is more accurate, avoiding some of the oversimplifications associated with the traditional, albeit more familiar, Henderson-Hasselbalch equation. Both are simplifications of a complex dynamic system, and both suffer from inherent inaccuracies.¹³ For practical purposes, benefits of the nontraditional approach are best appreciated when pH and a blood gas analyzer are not available to the clinician. Other advantages to this approach, when compared with traditional acid-base chemistry, are less clear and remain a topic of recurrent deliberations. Importantly the astute clinician should appreciate that all methods of acid-base analysis merely quantitate the magnitude of a disorder. Similarly, acid-base findings may provide subtle clues to pathogenetic mechanisms, but they do not characterize or define a disease or its management. Such inferences mandate evaluation of the complete history, thorough physical examination, and results of other laboratory tests. To remain consistent with concepts taught in most clinical settings, the traditional approach (Henderson-Hasselbalch) to analyzing acid-base disturbances is discussed.

The blood bicarbonate concentration is normally regulated by the kidneys. The kidneys reabsorb filtered bicarbonate and regenerate bicarbonate that has been consumed in the process of buffering acid. In this way, bicarbonate may be conceptualized as a kind of conveyer belt, combining with nonvolatile acid (i.e., H⁺), thereby maintaining a stable pH in the face of an acid load. When bicarbonate combines with H^+ , carbonic acid (H_2CO_3) is formed, which dissociates to form CO₂ and water. CO₂ is eliminated by ventilation (see Equation 16-1). When organic anions (e.g., lactate, pyruvate, gluconate, acetate, citrate, ketones) are metabolized, a hydrogen ion is carried along in the process. This alters the carbonic acid $H_2CO_3 \leftrightarrow H^+ + HCO_3$ equilibrium (mass action), shifting it rightward, generating new bicarbonate. Many processes in the body directly or indirectly use a chloride-bicarbonate counterporter. When chloride is excreted (e.g., into the stomach lumen), a "new" bicarbonate anion moves in the opposite direction (into the ECF). Similar counterporters exist in red blood cells, renal tubules, and small intestinal epithelial cells.

When nonvolatile acid is present in excess, it reacts with bicarbonate and other buffer systems, especially intracellular protein and phosphate.¹⁴ The plasma bicarbonate concentration decreases as the bicarbonate combines with H⁺ and forms H₂CO₃, the pH decreases, which by definition is an acidosis. More specifically, it is a metabolic acidosis because the disorder promotes the accumulation of excessive nonvolatile acid. The body will try to reestablish pH by lowering the pCO_2 (hyperventilation). This is the appropriate and anticipated compensatory response. Although less common, excessive loss of HCO_3^- (as occurs with some types of diarrhea) may cause a metabolic acidosis with a similar compensatory response.¹⁵ When the primary derangement promotes accumulation of excess volatile acid (an increase in pCO_2), pH decreases and the acid-base disorder is described as a respiratory acidosis. Respiratory acidosis, by definition is an increase in pCO₂,. In patients with primary respiratory acidosis, the kidneys respond by increasing excretion of acid.¹⁵

By definition, metabolic alkalosis is an elevation in pH caused by excessive plasma bicarbonate. Alkalosis decreases pulmonary ventilation, which elevates the pCO_2 Conversely, reduction of pCO_2 produces an alkalosis, the terms hyperventilation and respiratory alkalosis often used interchangeably. In response to a primary respiratory alkalosis, renal acid excretion is reduced.¹⁶

The kidneys respond to respiratory acid-base disorders over several hours to days. The pulmonary response to metabolic acid-base disorders occurs in a matter of minutes. In dogs it is possible to predict the approximate degree of a compensation; anticipated compensation is less clear or predictable in cats. Compensatory mechanisms are not efficient enough to return the pH within the normal range. These defense mechanisms do not correct the acid-base disturbance but merely minimize the change in pH imposed by the disturbance. Moreover, overcompensation for a primary acid–base disorder does not occur,¹¹

DISEASE-INDUCED CHANGES

Sodium

Changes in plasma sodium concentration usually reflect changes in total body water content. Hyponatremia and hypernatremia primarily cause clinical problems by promoting neuronal edema or dehydration (ICF), respectively. The severity of clinical signs is thought to correspond with the rate of change rather than with the magnitude of hyponatremia or hypernatremia. If changes in serum sodium occur slowly, the brain can usually adjust the number of osmotically active molecules to prevent cerebral fluid gain or loss. This underscores the fact that severe hyponatremia or hypernatremia should be corrected gradually rather than quickly.¹⁷ When the serum sodium abnormality has been gradual in onset, the patient's sodium should be corrected slowly, not lowered faster than 1 mmol/L/hr or increased at a rate exceeding 0.5 mmol/L/hr.

Hypernatremia

Naturally occurring disease processes resulting in hypernatremia are usually disorders of free water loss.^{7,18} Rarely, hypernatremia results from the addition of sodium (e.g., ocean water ingestion, hypertonic saline or sodium bicarbonate administration). Hypernatremia is a reflection of inadequate water relative to sodium content in the ECF. While ECF volume is determined by the total sodium content (not concentration) in the body, plasma sodium concentration is not a measurement of a patient's volume status. The thirst mechanism is so effective that hypernatremia seldom occurs in animals that have access to adequate amounts of water and are not vomiting or regurgitating. Hypernatremia often develops in hospitalized patients, and a methodical preemptive diagnostic approach, including serial evaluation of electrolytes and quantification of fluid intake and loss, permits rapid recognition of water imbalance and prevent wide variations in serum sodium. Hypernatremia should prompt consideration of the disorders listed in Box 16-1.

Hyponatremia

Because naturally occurring diseases rarely produce sodium losses in excess of water, hyponatremia in the clinical setting is almost invariably due to excess water in the ECF.

Hyponatremia may be caused by several mechanisms, and a systematic approach to cause and correction is advised. Sodium and its attendant ions account for approximately 95% of the osmotically active substances in extracellular water. While hyponatremia is commonly associated with hypoosmolality, plasma osmolality must be assessed to appropriately determine of the cause of hyponatremia (Box 16-2).⁷

Hyponatremia with concurrent normal plasma osmolality suggests laboratory error or pseudohyponatremia. Pseudohyponatremia may occur with hyperlipidemia because the lipid occupies space in the volume of serum obtained for analysis; the concentration of sodium itself is not affected. Hyponatremia with concurrent plasma hyperosmolality suggests that other osmotically active particles (e.g., glucose, mannitol) are drawing water out of the ICF and into the plasma, thus diluting the sodium that is present.^{7,19} This is often called

Box 16-1

Causes of Hypernatremia

Normal Loss of Free Water with Inadequate Replacement

Failure to provide water to an animal that can drink Inadequate fluid therapy for an animal that cannot drink Unconscious animal Animal that is not being fed or watered by mouth

Animal with an oral, pharyngeal, or esophageal disease that prevents ingestion

Adipsia

Excessive Loss of Free Water with Inadequate Replacement Diabetes insipidus

Heat stroke Fever, hyperthermia Hypotonic fluid losses Diarrhea Vomiting Polyuria Excessive intake of sodium Salt poisoning Administration of sodium Hypertonic saline Sodium bicarbonate

Box 16-2

Evaluation of the Patient with Hyponatremia

Normoosmolal Patients

Look for artifact (i.e., pseudohyponatremia due to hyperproteinemia)

Hypoosmolal Patients

Hypovolemic patients

Gastrointestinal loss of hypotonic fluid with water replacement Hypoadrenocorticism Salt-losing nephropathies

Sequestration of fluids or sodium in third spaces

Hypervolemic Patients

Congestive heart failure Nephrotic syndrome Hepatic disease (especially cirrhosis)

Normovolemic Patients

Primary polydipsia Administration of hypotonic fluids

translocational hyponatremia because it is caused by translocation of sodium across cell membranes.

Hypoosmolar hyponatremia in a patient producing large volumes of dilute urine reflects impaired free water excretion (e.g., inappropriate ADH secretion).

Volume and hydration status may further suggest causes of hyponatremia. Overtly hypovolemic patients often have an obvious source of fluid loss. Hyponatremia in an overhydrated patient is often observed with (but is not the cause of) cavitary effusions associated with congestive heart failure, advanced oliguric renal failure, or severe hepatic disease (usually cirrhosis). These disorders may be associated with such exuberant water retention that patients become hyponatremic in the face of total body sodium excess. Patients with congestive heart disease or cirrhosis are often described as having decreased effective circulating volume (ECV). ECV is the volume of arterial blood effectively perfusing tissue. ECV is a dynamic quantity and not a measurable, distinct compartment. The fluid retention seen with ineffective cardiac output is appropriate (because of release of ADH and angiotensin II), whereas the fluid retention observed with renal failure and cirrhosis is a component of the disease process itself. These patients have decreased ECV and consequent reduction in GFR and RBF; as a result, the body attempts, albeit ineffectively, to retain the fluid within the ECF.⁷

Hypoosmolar hyponatremia may be seen with chronic gastrointestinal disease. These patients may be hypernatremic early in the course of their disease, but sustained ADH release, excessive water consumption, or both may ultimately lead to hyponatremia. Diseases associated with third-space losses (e.g., pancreatitis, peritonitis) promote ADH release, and hyponatremia may be seen in affected patients. It is a common misunderstanding that hyponatremia in this setting is a result of the fluid accumulation itself. The hyponatremia, however, is due to changes in ADH, and fluid accumulation is not the proximate cause. Cutaneous fluid losses (e.g., burns) may be isonatremic with little change in plasma sodium or may be associated with hyponatremia.^{7,19}

Similarly, sodium may be lost from the body as a result of hypoadrenocorticism or following administration of thiazide diuretics. Diuretics decrease the kidney's diluting capacity and increase sodium excretion. These patients may be distinguished from those with gastrointestinal loss of hypotonic fluid by evaluating the urinary sodium concentration (fractional excretion of sodium [FE Na⁺]). FE Na⁺ is not a test but rather a calculation based on the concentrations of sodium and creatinine in blood and urine.

Under normal circumstances, the body's response to hypovolemia and hyponatremia is to impede renal sodium losses as a means of restoring ECF. Consequently, little sodium would be found in the urine (FE Na⁺ <1%). Animals in which renal losses are the cause of the hyponatremia will, however, have substantial urinary sodium concentrations (FE Na⁺ >3%).¹⁹

Hyponatremia and hypoosmolality occur uncommonly in well-hydrated euvolemic dogs and cats. Although rare, primary polydipsia (also called *psychogenic polydipsia*) syndromes associated with inappropriate ADH release or overzealous administration of hypotonic fluids are described, and are possible causes of hyponatremia in this setting.⁷

Chloride

Most often, changes in plasma chloride concentration are clinically relevant because they affect acid-base status. In particular, hypochloremia is associated with metabolic processes that are coupled with alkalosis.²⁰ Similarly, hyperchloremia tends to be associated with acidosis.

Hypochloremia

The major causes of hypochloremia are increased loss caused by vomiting of gastric contents or excessive administration of loop diuretics (e.g., furosemide).²¹ Chloride losses caused by gastric vomiting are usually associated with hypokalemia and metabolic alkalosis. Occasionally, a paradoxical aciduria is also seen. Physical examination and laboratory findings often corroborate a history of vomiting. Rarely, administration of large doses of sodium without corresponding administration of chloride (e.g., high doses of sodium penicillin or sodium bicarbonate) may cause hypochloremia. When a hypochloremic patient is also hyponatremic, hyperkalemic, or both, the clinician should consider hypoadrenocorticism. If, however, the clinician corrects the plasma chloride concentration to account for changes in plasma free water, for example:

[Dogs: Corrected Cl⁻= plasma Cl in mEq/L × (146 plasma Na in mEq/L) Cats: Corrected Cl⁻= plasma Cl in mEq/L × (156 plasma Na in mEq/L)]

patients with hypoadrenocorticism may have a normal or increased corrected chloride concentration.²⁰ Changes in chloride are often interpreted with changes in free water, which alters sodium and chloride concentrations proportionally. This can be done by correcting the chloride concentration for changes in sodium using the preceding formulas. Primary disorders of chloride (i.e., acid–base disturbances) have abnormal corrected chloride values, whereas disorders of free water do not; determination of corrected chloride values seldom affects diagnostic or therapeutic decisions in a given patient. Its determination is only to permit the interested clinician to quantitatively assess the contribution of bicarbonate (marked by changes in chloride) to the metabolic component of an acid–base disturbance.

Hyperchloremia

Hyperchloremia is principally found in animals that are simultaneously hypernatremic as a result of the loss of free water and in patients that have received fluids containing proportionally more chloride than sodium relative to plasma values. Examples include administration of 0.9% saline, hypertonic saline, parenteral nutrition, and especially 0.9% saline supplemented with potassium chloride. Hyperchloremia may also be observed in patients that have a metabolic acidosis associated with a normal anion gap (i.e., hyperchloremic metabolic acidosis). This biochemical finding is commonly seen in animals with small bowel diarrhea caused by loss of bicarbonate-rich, chloridepoor fluid.²⁰ It can also be seen with regurgitation or vomiting of duodenal contents and in patients with renal tubular acidosis.

Potassium

Changes in the plasma potassium concentration are clinically important because of the effect of potassium on cellular metabolism, RMPs, and the subsequent strength of contraction when an action potential is generated.⁹ Hypokalemia and hyperkalemia both cause muscular weakness and predispose to cardiac dysrhythmias. Although there is variation between patients, plasma potassium concentrations \geq 8.0 mEq/L or \leq 2.0 mEq/L are generally considered life threatening, although less dramatic changes can be dangerous if there are concomitant electrolyte derangements (e.g., hyponatremia, hypocalcemia, or hypercalcemia) or if the changes occur rapidly.¹⁰ Potassium is highly labile, and changes in pH of the ECF may cause significant alterations in serum potassium, particularly in critically ill patients.

Hyperkalemia

Hyperkalemia may be artifactual (i.e., pseudohyperkalemia) or real. If hyperkalemia is real, it is either iatrogenic (increased intake or administration) or spontaneous. The major cause of spontaneous hyperkalemia is decreased urinary excretion caused by renal, urinary tract or adrenal disease (Box 16-3).¹⁰

Pseudohyperkalemia, an in vitro increase in potassium concentration, may be observed with marked thrombocytosis (generally \geq 800,000/ul). Because the elevation in potassium in this setting is due to leakage from disrupted or dying cells, it is important to measure plasma or serum potassium concentrations shortly after a sample is obtained to avoid drawing erroneous conclusions about a patient's electrolyte status. Similarly, animals with white blood cell counts equal to or greater than 100,000/ul (e.g., leukemia) may rarely have pseudohyperkalemia because of transcellular leakage of potassium.^{22,23} Neonates, Akitas, and English springer spaniels are known to have a high potassium content within their red blood cells and hemolysis may cause hyperkalemia ²⁴ If there is doubt as to whether the hyperkalemia is artifactual or real, one should obtain a lithium heparin-anticoagulated blood sample and promptly harvest the plasma.²¹

The list of drugs that may cause hyperkalemia is extensive.¹⁰ With the exception of overexuberant infusion of potassium chloride in intravenous fluids and administration of drugs that inhibit production or activity of aldosterone (e.g., enalapril, spironolactone), significant hyperkalemia caused by drug administration is rare and generally only occurs if there is underlying renal or adrenal dysfunction. Only the more common causes are provided in Box 16-3.

Decreased urinary potassium excretion may be due to severe primary renal dysfunction (e.g., typically anuric or oliguric primary renal failure), postrenal causes (e.g., uroperitoneum, uretheral obstruction) or to secondary renal dysfunction resulting from aldosterone deficiency (i.e., hypoadrenocorticism). Disorders promoting development of edema or cavitary effusions or enteritis (especially whipworm infection)²⁵⁻²⁷ are sometimes associated with the development of mild hyperkalemia, the exact pathogenetic mechanism of which remains unclear . The clinician should rule in or rule out hypoadrenocorticism early in the diagnostic evaluation because it has an excellent prognosis if recognized and treated promptly. An adrenocorticotropic hormone (ACTH)–stimulation test is required for definitive diagnosis, although resting serum cortisol concentrations may be used to screen for its

presence. Dogs with resting cortisol levels of more than 2 ug/ dL rarely have hypoadrenocorticism,²⁸ and in such cases the submission of a post-ACTH (stimulated) cortisol sample may not be indicated.

Hypokalemia

Hypokalemia results from reductions in dietary intake or increased losses through the urinary or gastrointestinal tract. Decreased intake is unlikely to cause hypokalemia unless the diet is severely deficient or when potassium-free intravenous fluids are administered to an inappetent patient. Potassium translocation from ECF to ICF may be seen in patients receiving parenteral nutrition, insulin, sodium bicarbonate, or glucose-containing fluids.^{8,9} Similarly, alkalemia may reduce serum potassium levels as extracellular potassium moves intracellularly in exchange for hydrogen ions.

Increased loss of potassium is the most important cause of hypokalemia in dogs and cats. Vomiting and diarrhea lead to gastrointestinal losses, whereas drug therapy (e.g., furosemide) and renal failure or polyuria result in renal losses. The latter is commonly observed in older cats and may be detected in the absence of azotemia. Hyperaldosteronism is an uncommon disorder of cats that may cause profound hypokalemia. If the cause of hypokalemia is unclear after routine evaluations, the clinician may calculate the fractional excretion of potassium (FE_K). Animals that are hypokalemic as a result of nonrenal causes should have normal (approximately 4% to 6%) to decreased FE_K, whereas cats with potassium-losing nephropathies usually have values above 6% to 10%.^{8,29,30}

Miscellaneous Minerals

Miscellaneous minerals that occasionally are of concern to the clinician are phosphorus and magnesium. Severe hypophosphatemia capable of causing clinical signs is principally seen in ketoacidotic diabetic patients that are overtreated with insulin and occasionally in emaciated cats receiving enteral or parenteral nutrition,^{31,32} although hypophosphatemia can be seen from time to time in patients with other diseases.³³ The most clinically relevant consequence of hypophosphatemia is hemolysis. Hyperphosphatemia is commonly seen in patients with renal disease but seldom requires special considerations when formulating fluid therapy. Magnesium is primarily absorbed in the jejunum and ileum, while the kidneys regulate magnesium balance. Hypomagnesemia is primarily due to renal or gastrointestinal losses.³⁴ Hypomagnesemia may cause cardiac dysrhythmias and neuromuscular irritability. Hypomagnesemia is increasingly recognized feature of ketoacidotic diabetes mellitus. It is also seen in dogs with severe protein-losing enteropathy.³⁵ Depletion of magnesium has a permissive effect on potassium exit from the ICF leading to ECF accumulation of potassium, which is subsequently lost from the body. This potassium deficiency is refractory to supplementation until the magnesium deficit is also corrected. Similarly, hypocalcemia may occur as a secondary electrolyte abnormality when there is a magnesium deficit. Hypermagnesemia is primarily associated with renal disease. Excessive provision of magnesium (e.g., in diet or intravenous fluids) is also reported.^{36,37}

Acid–Base Status

Traditional evaluation of acid–base status is best accomplished by blood gas analysis, integrating information provided by the pH, pCO₂, and bicarbonate. When evaluating blood gas values, consideration is first given to pH.¹¹ The normal pH of blood analyzed at 37° C is 7.35-7.45. If the pH is abnormal, is the patient acidemic (pH < 7.35) or alkalemic (pH > 7.45) If it is abnormal, by definition an acid–base disorder exists. If the pH is normal, an acid–base disorder is unlikely but should not be ruled out, because there may be a mixed acid-base disturbance (i.e., more than one primary acid–base disturbance occurring concurrently) or (uncommonly) a fully compensated acid– base disturbance. These circumstances are not always readily distinguishable. The reader is referred to other references for information on mixed disorders.³⁸

If the pH is abnormal, the clinician should try to determine which component (respiratory or metabolic) is the primary contributor (Table 16-1). Subsequently, evaluation for appropriate compensation of the primary disorder is undertaken. Generally, the pH will vary in the direction of the primary disorder. The other component is the secondary or compensatory component attempting to restore pH to normal. When both components vary in the same direction at the pH, both disorders are primary, i.e., a mixed disorder is present. In the dog there are guidelines for expected compensation in acidbase disorders (see Table 16-1); however, it is not possible to extrapolate these guidelines from the dog to the cat. Results of blood gas analysis are interpreted in light of anamnesis and

Table 16	-1	Expected Findings and Compensation in Normal Dogs with Simple Acid–Base Disturbances			
pH		Primary Abnormality	Normal Compensatory Response		
Metabolic acidosis	ţ	↓ HCO ₃	↓ P _{CO2} by 0.7 mm for each 1 mEq/L↓ in HCO ₃

Respiratory alkalosis Acute Chronic	Ţ	↓ P _{CO2}	$\begin{array}{l} \downarrow HCO_3 \text{ by } 2.5 \text{ mEq/L for} \\ \text{ each } 10 \text{ mm} \downarrow \text{ in } P_{CO2} \\ \downarrow HCO_3 \text{ by } 5.5 \text{ mEq/L for} \\ \text{ each } 10 \text{ mm} \downarrow \text{ in } P_{CO2} \end{array}$		

clinical examination findings to most appropriately determine the most probable cause of the acid-base disorder.¹¹

Metabolic Acidosis

Metabolic acidosis is probably the most widely recognized canine and feline acid-base disorder . The most common causes of metabolic acidosis in these species are listed in Box 16-4. Acidosis from accumulation of lactic acid is thought to be the most common cause of metabolic acidosis. In the setting of poor peripheral perfusion, anaerobic metabolism often predominates, with subsequent production of lactic acid.³⁹ The acidemia is not actually due to dissociation of the lactate; the lactate simply reflects the anaerobic metabolism that has released protons. Therefore lactic acidosis may be seen in conjunction with other disorders. Lactic acidosis is usually diagnosed by elimination of other causes of acidosis, presence of elevated anion gap, and physical examination findings suggesting ischemia or volume depletion. Blood lactate levels may be measured (i.e., hand-held monitors or standard blood gas analyzers).^{20,21,40} The anion gap, although reported with other serum chemistry measurements, is actually a calculated value $[(Na + K) - (HCO_3 + Cl)]$. The electrolytes used in the formula are called measured cations (Na, K) and measured anions (HCO₃, Cl). Ions not included in the formula are called unmeasured cations and unmeasured anions.

Most dogs and cats with diarrhea do not develop a significant acidosis. Occasionally, patients with profuse diarrhea lose excessive amounts of bicarbonate in the feces and consequently develop an inorganic (hyperchloremic) metabolic acidosis. This acidosis may occur simultaneously with lactic acidosis in some patients with concomitant dehydration or hypovolemia.²⁰

Renal failure causes acidosis when the kidneys cannot adequately excrete H⁺, regenerate HCO₃⁻, or both. Renal ammonium excretion is the principle means of eliminating protons, and this is usually adequate until renal failure becomes severe. Acidosis from renal dysfunction may have a normal anion gap

Box 16-4
Common Causes of Metabolic Acidosis
Lactic acidosis caused by decreased perfusion Dehydration Poor cardiac output
Renal failure Diabetic ketoacidosis
Hypoadrenocorticism Addition of acid to the body Ethylene glycol intoxication
Salicylate intoxication Ammonium chloride

initially, but an increased anion gap is expected in more severely uremic patients as unmeasured anions accumulate. Hypoadrenocorticism causes an acidosis in part because aldosterone is needed for the secretion of H⁺ into collecting duct fluid; thus it may be thought of as a functional renal disease (i.e., without structural nephron damage). Specific renal tubular defects (renal tubular acidosis) are uncommon in dogs and cats but should be on the list of differential diagnoses for patients with a hyperchloremic acidosis and normal anion gap.²⁰

Diabetic ketoacidosis occurs when there is excessive production of ketone bodies, especially b-hydroxybutyrate, generally causing an increased anion gap acidosis.⁴¹

When ethylene glycol is ingested, it is metabolized by the liver to glycolic acid. This often results in severe acidemia that is refractory to standard treatments, largely because acid metabolites continue to be produced until all of the ethylene glycol is metabolized.⁴² The acidosis typically occurs before there is any evidence of renal injury. History may be informative, and several quantitative colorimetric in-house test kits are available. Calcium oxalate crystalluria often precedes overt renal failure. Both monohydrate (i.e., "picket fence") and dihydrate (i.e., "Maltese cross") calcium oxalate crystals may be observed in urine sediment. Markedly increased anion and osmolol gaps are seen shortly after exposure.⁴³ A high anion gap acidosis may be documented within 3 hours and persists for at least 24 hours.

Metabolic Alkalosis

Clinically significant metabolic alkalosis in dogs and cats is usually due to vomiting of gastric contents, diuretic therapy, or excessive administration of bicarbonate. Other causes of alkalemia (e.g., severe hypokalemia, severe hypomagnesemia) are clinically less important.^{16,20}

Vomiting of gastric contents causes loss of H⁺ as well as loss of Cl⁻ and water. Hypovolemia and concurrent hypochloremia prevent the relative excess of bicarbonate from being eliminated in the urine, reflecting the body's priority of restoring ECF volume. To restore ECF volume, the body reclaims sodium and water from the renal tubules. To efficiently reabsorb sodium (a cation), a negatively charged ion(s) must be reabsorbed (generally Cl⁻ or HCO₃⁻) simultaneously to maintain electroneutrality. If insufficient amounts of Cl⁻ are present to accompany the reclaimed sodium, bicarbonate will be reabsorbed instead, even though total body bicarbonate is in excess.²⁰ Similar pathogenic mechanisms may be observed when excessive furosemide administration promotes a brisk diuresis with chloride-rich urine. Both of these circumstances are considered chloride-responsive alkaloses because complete resolution can only occur if chloride-replete fluids are a component of therapy. Clinically important chloride-resistant alkalosis is uncommon in dogs and cats.²⁰

Respiratory Alkalosis

Respiratory alkalosis, or primary hypocapnia, is relatively common, occurring when alveolar ventilation exceeds the amount required to eliminate the CO_2 produced by metabolism; hyperventilation from any cause (e.g., excitement, pain, fear, hypoxemia, sepsis, liver disease) causes PCO_2 to decrease and can result in an alkalosis.^{44,45} The alkalosis itself, however, rarely causes detrimental effects in the patient, but this should not dissuade the clinician from seeking out the underlying cause.

Respiratory Acidosis

Respiratory acidosis, or primary hypercapnia, is occasionally diagnosed in dogs or cats with naturally occurring diseases; more commonly it is associated with sedation and anesthesia. Carbon dioxide diffuses more rapidly across the alveolar membrane than oxygen, and hypoventilation is for all practical purposes the only cause of, and therefore defines, respiratory acidosis. Primary hypoventilation may be seen in patients with upper airway obstruction, neuromuscular weakness that impairs breathing (e.g., myasthenia gravis, hypokalemia, botulism), muscular rigidity that prevents breathing (e.g., tetanus, seizures), chest wall or pleural cavity disorders (e.g., pneumothorax, pleural effusion, flail chest), and chronic obstructive pulmonary disease.⁴⁶

Blood Gas Analysis

Blood gas analysis mandates precise technique and thus properly trained support staff.^{11,21} Hand-held "point-of-care" units have made blood gas analysis feasible for many practices.⁴⁷ However, the total serum CO_2 (TCO₂) available on most chemistry panels from commercial veterinary laboratories may be used as a rough surrogate marker for HCO₃⁻ and as such may be used as an approximation of the metabolic contribution to acid–base derangements when HCO₃ is not measured.²¹

Although TCO₂ is less expensive and is more widely available than blood gas analyzers, relying on this measurement requires the clinician to make assumptions that may be incorrect for a given patient.²¹ One must speculate whether an abnormal bicarbonate concentration is due to a primary metabolic or a respiratory derangement. Suppositions should be supported by careful evaluation of history, physical examination, and ancillary laboratory data. Major alterations in bicarbonate concentrations are often but not invariably primary events (i.e., low or high TCO₂ representing primary metabolic acid–base disorders). It is reasonable to rely on the TCO₂ provided that the apparent acid–base abnormality is consistent

with what the clinician infers from the history and physical examination findings. However, compensation of primary disturbance cannot be assessed, particularly if a pH value is not available.

FLUIDS

Calculation

Fluid therapy is a complex topic and this section is not all encompassing. However, basic principles of fluid therapy are discussed. Planning fluid therapy requires consideration of maintenance needs, estimated hydration deficit, and assessment of ongoing losses.

Maintenance Fluid Needs

Maintenance fluid requirements (i.e., the amount of fluid necessary to replace insensible losses and obligatory urinary losses) vary with the animal's size, age, and occasionally diet (i.e., eating a diet containing excessive solute such as sodium increases the patient's water requirements for maintenance). Ambient temperature and humidity also affect maintenance requirements. Studies have been performed evaluating basal metabolic rate in companion animals. The optimal formula for determining the maintenance needs for dogs and cats is controversial. In general, smaller animals need more milliliters per kilogram daily than do larger animals. For most domestic species, estimates of daily water requirements range from 40 mL/kg/day (large dogs) to 60 mL/kg/day (cats and small dogs).48,49 The daily maintenance water requirement for a healthy cat or dog weighing between 6 and 60 kg is as follows: (30 x BW[kg]) + 70. Studies using indirect calorimetry suggest that for animals weighing less than 10 kg or more than 50 kg, a more precise formula is as follows: $97 \times body$ weight (0.655).⁵⁰ Water is present in foods and is generated as foods are metabolized. Maintenance requirements should be provided to patients not consuming sufficient quantities of water on their own.

The combination of variables (e.g., age, hydration status, perfusion, cardiac and renal function) makes it difficult to calculate exactly how much fluid an individual patient needs. In general, as long as the estimated amount of required fluids is provided and the patient is assessed frequently, clinically significant problems referable to fluid therapy are likely to be avoided. With the exception of the conditions listed in subsequent sections, providing slightly more fluid than is believed necessary is in most cases recommended insofar as it is more common to underestimate fluid needs than to overestimate them. However, patients with myocardial dysfunction, oliguric renal disease, severe anemia, severe hypoalbuminemia, or pulmonary edema can be seriously harmed by excessive fluid administration.

Deficit Fluid Needs

Fluid deficit should be estimated when patients are initially examined. Although there are guidelines for estimating degree of dehydration (Table 16-2), there are many pitfalls in this approach. Any excited or dyspneic animal that is breathing

Table 16-2	Determination of Degree of Dehydration

through its mouth may have dry, tacky oral mucous membranes, whereas nauseated animals may have moist membranes in the face of dehydration. Weight loss causes some degree of decreased skin turgor, while but obese animals may not have changes in skin turgor even when they are 8% to 10% dehydrated.⁵¹

Findings of increased hematocrit and plasma proteins support the clinical suspicion of dehydration (i.e., animals that are hemoconcentrated and hyperproteinemic are usually dehydrated). However the clinician seldom knows what these parameters were shortly before the animal became ill, and the hematocrit and total protein values by themselves are not a reliable means to assess hydration status. Many animals with chronic illness have anemia of chronic disease; dehydration may cause them to have a spuriously normal hematocrit value. Likewise, patients can be hypoproteinemic, and dehydration may cause them to have a seemingly normal serum protein concentration. There are many possible causes for a well-hydrated dog or cat to be hyperproteinemic, generally due to elevated globulin fraction (e.g., heartworm disease, ehrlichiosis, chronic dermatitis, feline infectious peritonitis). Alterations in body weight may be useful in assessing changes in hydration status because changes in body weight generally reflect changes in fluid content. When treating dehydrated patients, the clinician may interpret an increase in body weight as an encouraging sign that hydration is being restored. However, an increase in body weight in a well-hydrated patient may be an early indicator of fluid overload. Patient history should not be overlooked. Any animal that is not drinking or eating but has ongoing losses (e.g., vomiting, diarrhea, polyuria, tachypnea) is or will become dehydrated.

In general, because of the problems associated with determining the degree of dehydration, slightly overestimating the deficit is recommended unless the patient has syndromes mentioned in the discussion of maintenance fluid requirements. The dehydration deficit is determined by the following formula:

Body weight (kg) × estimated percentage dehydration × 1000 = milliliters needed

Deficit fluids can be administered more rapidly than maintenance fluids when patients are closely and frequently monitored. One half of the dehydration deficit can be administered as a bolus, with the remainder replaced as a constant rate infusion over 12 to 24 hours. Cats have smaller blood volumes per body weight than dogs (i.e., 50 to 60 mL/kg as opposed to 80 to 90 mL/kg in the dog) and can become fluid overloaded with smaller fluid doses than dogs. Once the estimated deficit is replaced, the animal should be re-examined, assessing for evidence of further deficits.⁵¹

Ongoing Losses

Ongoing losses can be divided into normal, insensible losses (e.g., from respiration, normal urine and fecal losses, skin evaporation) and those that are not normal (e.g., vomiting, diarrhea, polyuria, fever, tachypnea). In general, insensible respiratory losses involve water but not electrolytes (i.e., "free water"), whereas abnormal losses often involve electrolytes as well as water. Therefore the clinician should characterize the nature of fluid losses when choosing a fluid to administer. Careful assessment of body weight (i.e., with an accurate scale that measures ounces or tenths of a pound) remains a reliable means of monitoring for ongoing fluid balance in an individual patient. It is also important to weigh the animal after it has urinated and before it is fed. Because approximately 60% of body weight, rapid changes in body weight usually reflect changes in body water content as opposed to muscle mass or fat. One kilogram represents approximately 1000 mL of water. Frequent measurement or close estimation and matching of "ins and outs" (e.g., oral intake, parenteral fluids, urine production, vomiting, and diarrhea) can help prevent gross errors in approximation of patient requirements.

Choice of Fluid

There are several categories of fluids and additives available (Box 16-5). Crystalloid solutions (e.g., physiologic saline solution [PSS; 0.9% saline solution], 5% dextrose in water [D5W], Ringer's solution) are composed of electrolytes and nonelectrolytes that can pass freely out of the vascular space. Isotonic replacement crystalloids have an electrolyte composition similar to that of extracellular fluid, with a relatively high sodium and low potassium concentration. The terms high and low refer to the concentrations of sodium and potassium relative to each other in the fluid bag itself; it is important to note that the sodium and potassium are both essentially normal when compared with ECF and plasma. The most widely available isotonic replacement solutions are 0.9% saline, lactated Ringer's solution (LRS), Plasmalyte A (Baxter Healthcare Corp), and Normosol-R (Hospira, Inc). In true hypovolemia a very small concentration gradient exists between ECF and ICF spaces. Consequently, water shifts do not occur across the cell membrane. Intravascular crystalloid equilibrates with the interstitial space, with 20% to 25% of the infused volume remaining within the intravascular space 1 hour after infusion. Metabolism of the lactate in LRS or acetate and gluconate in Normosol-R or Plasmalyte A provides base to the body. When used for long-term therapy, there is a tendency for patients to develop mild to moderate hypokalemia. Normal ongoing losses typically have lower sodium and higher potassium than normal ECF, and therefore administering replacement solutions does not provide adequate potassium. Hypernatremia is less often encountered

with use of replacement solutions for ongoing losses, unless renal sodium excretion is impaired. Thus potassium supplementation is almost always indicated, but switching to a commercially available isotonic maintenance fluid with a lower sodium concentration (e.g. Normosol-M [Hospira, Inc]) for long-term therapy after rehydration is not always necessary. Commercially available maintenance solutions (Table 16-3) are designed to fulfill the electrolyte requirements of patients with normal daily losses that are unable to maintain adequate fluid and electrolyte intake, and may be used to replenish obligate and insensible net ongoing losses. As these fluids have a relatively high potassium concentration (13 mEq/L), they should not be administered rapidly (0.5 mEq/kg/hr [suggested maximum rate of potassium administration] \times 13 mEq/L = 38.5 mL/kg/hr = maximum rate of administration). Hypotonic solutions include Normosol M (Hospira), D5W, and 0.45% saline. Although the osmolality of D5W is 252 mOsm/L (which is close to being isotonic), the glucose is rapidly taken up by cells and metabolized after it is administered to the patient. Therefore administering glucose solutions is essentially equivalent to giving free water (unless hyperglycemic diuresis with subsequent dehydration results). Administration of D5W does not significantly contribute to meeting caloric needs (D5W has 170 kcal/L) and it is not intended to treat severe hypoglycemia. Symptomatic hypoglycemia is initially treated with bolus injection of 25% or 50% dextrose. Subsequently, adding a sufficient volume of 50% dextrose to a balanced isotonic crystalloid to produce a final dextrose concentration of 2.5% to 5% is usually sufficient for maintaining glycemic status on a nonemergent basis. Rapid infusion of hypotonic solutions can cause severe dilution of serum electrolytes, especially sodium. Although there are rare indications for hypotonic fluids

Table 16-3	Electrolyte Composition of Commercially Available Fluids							
	Glucose (g/L)	Sodium (mEq/L)	Chlorine (mEq/L)	Potassium (mEq/L)	Calcium (mEq/L)	Magnesium (mEq/L)	Buffer (mEq/L)	Osmolality (mOsm/L)

D10W, 10% dextrose in water; D5W, 5% dextrose in water; D2.5W, 2.5% dextrose in water; PSS, physiologic (i.e., 0.9%) saline solution; LRS, lactated Ringer's solution; ½ PSS, 0.45% saline solution.

Modified from Chew DJ, DiBartola SP: Manual of small animal nephrology and urology, New York, 1986, Churchill Livingstone.

(e.g., recalcitrant hypernatremia or as a vehicle for delivery of specific drugs), they are seldom required in most clinical situations. Infusion of hypertonic (7.5%) saline creates a large osmotic gradient, and water is drawn from the intracellular and, to a lesser extent, interstitial compartment causing a rapid, albeit transient (<30 min), expansion of intravascular volume. Combining hypertonic saline with 6% hetastarch or dextran 70 prolongs the beneficial effects. Hypertonic solutions are reported to be safe and effective for the treatment of hypovolemic hypotension and may have a role in minimizing intracranial pressure. Their use is contraindicated with hypernatremia and dehydration, and as is true with all crystalloids, excessive volume is associated with cardiac failure. Crystalloids containing preservatives (e.g., benzyl alcohol) are not recommended because they may have adverse effects, especially in cats.52

Colloidal solutions (e.g., dextran 70, hetastarch 6%, Oxyglobin) are retained in the intravascular space to a greater degree than crystalloids and draw fluids from the cellular and interstitial compartments into this compartment.⁵¹ Although both colloids and isotonic crystalloids can be used to rapidly expand intravascular volume in animals in shock, colloids are generally more effective (and effective at lower doses) than crystalloids.53 It generally requires two to four times as much isotonic crystalloid solution to expand the ECF compartment as it does with dextran or hetastarch. Hetastarch and dextrans are primarily indicated for rapid volume expansion. Dextrans and hetastarch may also be used to maintain plasma COP in patients with severe hypoalbuminemia. Anaphylactic reactions have been reported with both hetastarch and dextrans, but they are uncommonly observed. Low-molecular-weight dextrans (i.e., dextran 40) have been reported to cause renal failure, and they are not routinely employed in clinical practice. Both hetastarch and dextrans may also cause coagulation abnormalities when administered at high doses. Clinically significant hemorrhage is rare.

Purified hemoglobin both acts as a strong colloid and increases the oxygen-carrying capacity of the blood. Stromafree, hemoglbin-based, oxygen-carrying solutions (e.g., Oxyglobin) are used to treat anemia in a variety of species. Indications also include volume resuscitation in hypovolemic states. The greatest advantage of Oxyglobin is its ability to carry oxygen to tissues and offload oxygen more effectively than blood because it is not limited by red cell flow; it has also been shown to improve microvascular perfusion, thus improving oxygen tension in injured tissues. Human serum albumin (HSA) obtained from purified human plasma is available commercially and has been used in critically ill companion animals with pancreatitis, peritonitis, acute hepatic failure, and protein-losing enteropathy. In addition to its role in maintaining colloid osmotic pressure, albumin has many other properties that may benefit critically ill patients, including maintenance of the selective permeability of the microvascular barrier, and as a carrier of a number of substances, including bilirubin, fatty acids, hormones, and drugs. Most commercially available albumin products are prepared as 5% or 25% solutions. The chemical structure of human albumin is not identical to canine or feline albumin, and type III hypersensitivity reactions, which are sometimes severe and fatal, are reported after the administration of HSA in healthy dogs.⁵⁴ Until further studies suggest otherwise, routine use of HSA is discouraged unless all other means of restoring albumin or colloid osmotic pressure have failed. Lyophilized canine albumin has recently become available commercially. If this product is shown to have a favorable side effect profile (compared with human albumin products), it would be expected to prove useful in the management of severely ill hypoalbuminemic dogs with correspondingly low colloid osmotic pressure.

Clinicians often need to tailor a fluid for a specific patient. This is usually done by adding potassium chloride, 50% glucose, potassium phosphate, calcium gluconate, calcium chloride, magnesium sulfate, sodium bicarbonate, or a combination thereof. The specific amounts are discussed under specific disorders.

Route of Administration

Fluids may be administered orally, intravenously, subcutaneously, intraosseously, or peritoneally.55 Whenever oral intake is inadequate or not feasible (e.g., subject refuses to drink adequate volumes, vomits, does not absorb fluids sufficiently quickly for desired effect), parenteral administration is preferred. Intravenous administration is the quickest way to replenish an underexpanded ECF and is the standard of care for acute replacement of fluid losses (e.g., due to shock) or maintaining ECF volume during anesthetic procedures. This route allows uninterrupted infusion, which is expected to be advantageous to severely ill, hemodynamically unstable animals. Venous catheter access can be difficult because of the patient's size or temperament, vascular collapse, or prior use of veins for catheters or venipuncture. Routine catheter care is mandatory to prevent infection, phlebitis, extravasation, and clotting within the catheter lumen.

Subcutaneous fluid administration is technically easier than intravenous administration and is usually adequate when the need for fluids is not severe or acute. Owners can usually be taught to administer subcutaneous fluids at home. From 50 to 200 mL may be injected per site, and several sites may be injected at one time. Poor absorption may be observed if excessive fluids are administered at one site. Although more commonly administered once daily, subcutaneous fluids may be given as frequently as every 6 hours if clinically indicated and tolerated by the patient. If fluid from the prior injections has not been absorbed, however, it is necessary to determine the reason before more fluids are administered. Severely dehydrated animals may absorb subcutaneous fluids very slowly because of poor peripheral vascular perfusion. Furthermore, administration of hypertonic or irritating solutions under the skin is discouraged, because fluids may be drawn from the central compartment or cause injury to local and adjacent tissues.55 Subcutaneous fluids are often considered to be relatively safe in patients with heart disease, but this is an incorrect assumption and fluid overload may rapidly ensue.

Intraperitoneal administration permits the infusion of large volumes of fluids, and absorption generally occurs more quickly than with subcutaneous administration. This route is occasionally used for neonates whose veins are not readily accessible with a catheter. The clinician can administer a warmed (not hot) isotonic fluid aseptically with a 23- to 20-gauge needle or similar bore size over-the-needle catheter. Fluids given by this route may be administered over a short period (i.e., less than 5 minutes) until the abdomen becomes obviously distended (usually about 20 mL/kg). Patient discomfort and respiratory distress indicate that an excessive volume was administered into the peritoneal cavity. Aseptic technique must be used so that bacteria are not introduced. On balance, intraperitoneal administration does not offer clear advantages over intravenous, intraosseous, or subcutaneous routes, which are preferred.

Intraosseous administration⁵⁶ is accomplished by using either a specifically designed needle, a bone marrow aspiration needle, or an 18- to 20-gauge spinal or hypodermic needle. The needle is inserted into the marrow cavity of the humerus or femur; less common sites are the tibia and ilium. Fluids are then administered as for intravenous administration. Gravity drip rates of approximately 10 mL/min may be reached. Absorption occurs more quickly than with subcutaneously administered fluids, and it may be easier to obtain access to the marrow cavity in very small animals than to the jugular or cephalic vein.⁵⁵⁻⁵⁸ In rare cases pain may be seen as a consequence of infection, administration of cold solutions, or excessive administration rate.

The administration of crystalloid solutions rectally as an enema is described, because the normal colon will avidly absorb intraluminal water. This technique is seldom used in the clinical setting for provision of fluid deficits. Moreover, intravenous administration is mandatory for volume-depleted patients, and subcutaneous fluids are so easy to administer that there is essentially no reason for rectal administration. However, it may be used in select emergencies to modify core body temperature in a severely hypothermic or hyperthermic patient.

Determining Adequacy of Fluid Therapy

Fluid requirements should be evaluated and adjusted regularly. Generally fluid therapy is not abruptly discontinued but rather is gradually tapered to maintenance, or lower than maintenance rates over 12 to 24 hours. A common mistake with long-term intravenous fluid therapy is failing to adjust fluid rates as the condition of the pet changes. Close monitoring of body weight is useful to corroborate the observed efficacy of fluid therapy. Physical examination parameters compatible with dehydration (e.g., skin turgor, dry oral mucous membranes) should improve with appropriate fluid therapy, assuming there are no intercurrent disease processes associated with weight loss or development of tachypnea. Frequent observation of respiratory rate and effort and thoracic auscultation are expected to permit early detection of pulmonary edema. Similarly, new cardiac murmurs or gallop rhythms not audible before fluid therapy was instituted often presage overt clinical signs of fluid overload.

Because urine output is affected by myriad factors, it is not possible to define what constitutes normal urine output for many patients. As a general rule, urine output should be 1 to 2 mL/kg/hr. Although urine output is seldom quantified, it should be apparent if a patient is producing reasonable volumes of urine that is not extremely concentrated. This is not reliable for patients with renal failure, and some attempt must be made to quantify urine output when oligoanuria is a concern (e.g., weighing urine-soaked diapers, catching all urine in ambulatory patients) if a urinary catheter and closed collection system is not in place. Central venous pressure (CVP) is a measure of the hydrostatic pressure within the central venous compartment that provides an assessment of intravascular blood volume and cardiac function. It is typically measured by a percutaneously placed jugular catheter, which has its tip in the cranial vena cava. The catheter can be attached to either an electric pressure transducer or a water manometer. When interpreted in concert with other diagnostic findings, CVP is most useful for guiding fluid therapy in seriously ill animals with oliguric renal disease or myocardial dysfunction.⁵⁵

ELECTROLYTES

Considerations for Therapy

Therapy for electrolyte disorders primarily consists of supplementing electrolytes or decreasing their plasma concentrations by promoting excretion, dilution, or sequestration. The major electrolyte disturbances capable of causing clinical signs in dogs and cats, and thus requiring therapy, are hypokalemia and hyperkalemia. It is rarely necessary to address hyponatremia specifically, except with regard to some patients with hypoadrenocorticism. Hypoadrenocorticism is relatively uncommon, but volume replacement and management of hyperkalemia are usually the major goals for such patients in a crisis. Similar to hyponatremia, hypernatremia usually does not require specific treatment and often will correct itself as the underlying disease is being treated.

Hyponatremia

Hyponatremia is almost universally due to retention of free water except in patients with hypoadrenocorticism. Primary sodium loss (e.g. diarrhea) is not common. Unless the hyponatremia is severe enough to cause clinical signs, the clinician should first identify and correct the underlying disorder. Neurologic clinical manifestations (due to an osmotic shift of water into brain cells) are rarely observed with acute hyponatremia. To prevent rapid changes in the patient's sodium, the initial fluid chosen should have a sodium concentration similar to the serum sodium. It is recommended that sodium be raided no faster than 1 mEq/L/hour, although there is debate regarding the pace and degree of sodium correction. There is a risk of neurologic complications (myelinolysis), which typically occurs 3 to 4 days after aggressive correction of hyponatremia and may include weakness, ataxia, quadriparesis, and hypermetria.^{59,60} Buffered isotonic crystalloids such as LRS are generally preferable to PSS for this purpose because plasma normally has approximately 145 mEq Na/L and 110 mEq Cl/L. PSS contains 154 mEq of each per liter, whereas LRS has 130 mEq Na/L and 109 mEq Cl/L. The sodium concentration in Normosol-R (140 mEq/L) is slightly greater than that of LRS. Therefore administration of PSS adds too much chloride relative to the amount of sodium, although this is seldom clinically significant. It is rare that hypertonic saline solutions are needed to replace sodium in small animals.7,17

Hypernatremia

Spontaneous hypernatremia is almost always due to loss of free water, and is not a reflection of total body sodium content. Sodium gain (e.g., ocean water ingestion or overzealous fluid administration) is less common. If the patient is hypovolemic, rapid administration of isotonic crystalloid (including saline) is likely to cause rapid changes in sodium and therefore is discouraged. The initial fluid for correcting volume deficits should have a sodium equal to (or slightly below) that of the patient so as not to change sodium too rapidly. Subsequently, *slow* administration of a hypotonic crystalloid (e.g., D5W, 0.45% NaCl) may be appropriate. Hypernatremia by itself is seldom associated with signs, and lowering the plasma sodium concentration too quickly is likely, be more detrimental to the patient than the actual hypernatremia. If the hypernatremia existed for more than a few hours, it is often appropriate to administer PSS, a mixture of physiological saline solution plus 5% dextrose in water, or 0.45% NaCl/2.5% dextrose. Conservative administration of either solution decreases serum tonicity slowly enough to prevent neurologic complications. To minimize the risk of neuronal overhydration, serum sodium should not be lowered at a rate exceeding 0.5 mEq/L/hr.^{7,61}

Hypochloremia

Hypochloremia is principally found in patients with excessive losses caused by gastric vomiting or diuretic administration and is of clinical relevance principally because of its effects on systemic acid–base balance. Administration of PSS with or without potassium chloride is usually adequate to replace the chloride and resolve the problem.

Hyperchloremia

Hyperchloremia may be managed by administration of an alkalinizing fluid such as LRS (Cl = 98 mEq/L), Plasmalyte, or Normosol-R (Cl = 110 mEq/L). Isotonic saline (Cl = 154 mEq/L) is seldom indicated for treating hyperchloremia, even for the initial management of patients with hyponatremia caused by hypoadrenocorticism. Even in patients with true hyperchloremia (i.e., not corrected for water), hypotonic fluids should not be administered without careful assessment of sodium status.

Hypokalemia

Supplemental administration of potassium is routine in small animal medicine because hypokalemia is a common abnormality, especially in inappetent hospitalized patients receiving more than 2 to 3 days of intravenous fluids. With rare exceptions, all anorexic animals on maintenance fluids should receive potassium in excess of that contained in most replacement fluids because of obligatory losses of potassium into the urine. Animals with polyuria or other avenues of potassium loss may have even greater needs. Only pets that have or are prone to hyperkalemia should not receive potassium supplementation. It is not possible to predict with confidence exactly how much potassium a particular patient will need; therefore the patient's plasma potassium concentration should be periodically monitored when receiving supplemental potassium.

If the patient can accept oral fluids and is not vomiting, oral administration of potassium gluconate is usually an efficient means of replenishing plasma potassium.⁶² There is great interpatient variability in the amount of enteral potassium needed to correct hypokalemia.^{29,30,63}

Intravenous supplementation of potassium is common but mandates frequent monitoring of both the patient and the serum potassium concentration. As a general rule, potassium should not be infused at a rate exceeding 0.5 mEq/kg per hour, although if necessary, carefully monitored patients may receive greater rates without consequence. If it is necessary to administer 0.5 mEq/kg per hour or more, continuous electrocardiographic monitoring for cardiotoxic effects (i.e., bradycardia, tall T waves, small P waves, ventricular arrhythmias, ventricular fibrillation, and asystole) is recommended. Table 16-4, in addition to the other tables in this chapter, provides guidelines for determining how much potassium to add to fluids for intravenous administration. Many clinicians routinely start by adding 15 to 20 mEq K/L to maintenance fluids while periodically monitoring the animal's plasma potassium concentration.

Potassium may also be added to fluids intended for subcutaneous administration, the safe amount depending on the *total osmolality* of the solution and *not the potassium concentration* in the fluid bag. General guidelines suggest that solutions containing potassium in quantities greater than 35 mEq/L should not be given subcutaneously.⁸ If the clinician experiences difficulty correcting hypokalemia despite seemingly appropriate potassium supplementation, the serum magnesium concentration should be checked.^{64,65}

Hyperkalemia

Therapy for hyperkalemia depends on the severity of clinical signs and the magnitude of the hyperkalemia. The clinician should always look for the cause of hyperkalemia, because it often indicates significant renal or adrenal disease. If hyperkalemia is mild (e.g., 5.5 to 6.5 mEq/L) and is not expected to rise rapidly, it is appropriate to screen for common associated syndromes (e.g., hypoadrenocorticism, renal failure, iatrogenic potassium administration). Administration of potassium-free fluids (e.g. 0.9% NaCl) is often advised without qualification. However, isotonic replacement solutions $(K \le 4 \text{ mEq/L})$ will similarly "dilute" a hyperkalemic patient and augment renal potassium excretion. Therapy with any balanced, buffered isotonic crystalloid may be appropriately selected for treating mild hyperkalemia, particularly insofar as many patients will be somewhat dehydrated. If the patient is also hyponatremic (i.e., hypoadrenocorticism), 0.9% saline (higher concentration of sodium compared with buffered

Table 16-4	able 16-4Approximate Amount of Potassium to Add to Fluids for Intravenous Administration					
Maximum Rate Serum Potassium mEq Potassium of Infusion (mEq/L) to Add to Fluids (mL/kg/H)						
3.5-4.0		15/L	30			
3.0-3.5		28/L	16			
2.5-3.0		40/L	12			
2.0-2.5		60/L	8			
<2.0		80/L	6			

isotonic solutions) may be administered if the clinician monitors for excessive rate of lowering of plasma sodium. If the patient has hyperkalemia of sufficient magnitude to cause cardiotoxicity (i.e., usually ≥ 8 mEq/L), additional therapy may be warranted (Table 16-5).¹⁰ The routine use of sodium bicarbonate for managing hyperkalemia is generally discouraged. However, this drug may be given in an acute setting to a patient that has concurrent metabolic acidosis. Administration of dextrose and insulin decreases blood potassium concentration but can also decrease serum phosphorus concentration, which only rarely causes problems (i.e., hemolytic anemia).⁶⁶ Slow administration of 10% calcium gluconate may be administered for rapid correction of hyperkalemic cardiotoxicity. It does not lower the potassium level but transiently protects the heart until other measures (i.e., fluid administration) decrease the plasma potassium concentration.8

Hypophosphatemia

Optimal management of hypophosphatemia depends somewhat on whether the clinician is trying to prevent hypophosphatemia or to treat associated problems (e.g., hemolytic anemia) caused by hypophosphatemia. Severe hypophosphatemia is often seen as a complication of diabetic ketoacidosos. Other causes include hyperparathyroidism and hyperalimenation. If the patient has a dangerously low serum phosphorus concentration (e.g., 1.0 to 1.5 mg/dL) but does not yet have clinical signs, a simple rule of thumb is to provide one quarter of the maintenance potassium being given in the intravenous fluids (assuming maintenance rates are being used) as potassium phosphates and the remainder as potassium chloride.⁶⁶ The patient's serum phosphorus concentration is then monitored two to three times daily until it is out of the danger zone (i.e., serum phosphorus >2 mg/dL), at which time the phosphorus supplementation is stopped. If the animal is experiencing hemolysis, then a constant-rate infusion of 0.01 to 0.03 mmol phosphate/kg per hour may be given.^{31,32,66} Greater rates of phosphorus adminstration (e.g., 0.05 to 0.1 mmol/kg per hour) are described but seldom required to treat hypophosphatemia.³¹ The patient must be monitored three to four times daily, however, to ensure that the serum phosphorus concentration is increasing and that the serum calcium concentration is not decreasing. Severe, symptomatic hypocalcemia might result from excessive phosphorus administration.

Table 16-5	Symptomatic Therapy for Hyperkalemia			
Treatment		Dose		
Potassium-free fluids		Physiologic saline solution or 5% dextrose		
Calcium gluconat	e	0.5-1.0 mL 10% calcium gluconate/kg intravenously (10-15 minutes)		
Dextrose and insulin		0.5 U regular insulin/kg + 2 g dextrose per unit insulin		
Sodium bicarbona	ate	Based on blood gas analysis or 1-2 mEq/kg		

Hypomagnesemia

If hypomagnesemia needs to be treated or prevented, magnesium sulfate or magnesium chloride should be administered in D5W or 0.9% NaCL. Initial dosing guidelines are 0.75 to 1 mEq/kg/day given intravenously by constant-rate infusion, although 0.15 to 0.30 mEq/kg may be given over 10 to 15 minutes for life-threatening cardiac arrhythmias.⁶⁷ Because magnesium is a divalent ion, 1 mEq is equivalent to 0.5 mmol. Magnesium should not be added to LRS, or given in the same fluid line as calcium-containing fluids or insulin.

ACID-BASE STATUS

Considerations for Therapy

In general, the clinician should always attempt to determine the underlying cause of the acid-base abnormality and correct it. If the acidemia or alkalemia is so severe that it puts the patient at significant risk, however, symptomatic therapy is needed.

Metabolic Acidosis

A blood pH below 7.20 puts a patient at risk for arrhythmia, hypotension, and myocardial dysfunction. For such patients administration of sodium bicarbonate may be considered. A patient with blood pH below 7.1 is considered to be at high risk for cardiovascular complications, and prompt bicarbonate therapy should be considered. The goal of such therapy is to raise the pH to approximately 7.20 or slightly greater, not to correct the pH so that it returns to the normal range. Sodium bicarbonate should not be given to patients with respiratory acidosis or decreased respiratory drive. If too much base is administered, a patient may become alkalemic after the cause of the acidemia (e.g., diabetic ketoacidosis, lactic acidosis) is corrected.²⁰

Metabolic Alkalosis

Alkalosis is important because of the chloride abnormalities that may be associated with it. The alkalosis does not cause the hypochloremia but may potentiate it and therefore enhance the effects of high pH on the myocardium. Most dogs and cats with clinically important metabolic alkalosis have a chlorideresponsive condition (e.g., vomiting gastric contents, excessive furosemide administration in anorexic animals). Correction of volume depletion and supplementation with chloride (e.g., PSS occasionally with potassium chloride supplemented) is usually adequate to correct the problem.²⁰

Respiratory Acidosis and Alkalosis

Respiratory acidosis and alkalosis require therapy directed at the cause of the problem and seldom require symptomatic therapy.

Drugs Used to Correct Acid-Base Abnormalities

The main drugs used to alter blood and body pH are sodium bicarbonate and fluids containing bicarbonate precursors. In particular, LRS has often been used to treat acidosis. Under

normal circumstances, hepatic metabolism of lactate causes consumption and elimination of protons (i.e., H++), thus raising the pH.²⁰ If the lactate is not metabolized (e.g., the patient already has lactic acidosis), LRS may cause a mild dilutional acidosis similar to saline or will not affect acid-base status. Moreover, the lactate in LRS will never cause a lactic acidosis because it is a salt. Even when the lactate is not metabolized, however, expanding the ECF may improve peripheral perfusion. Similar fluids such as Normosol-R and Plasmalyte are considered to be just as effective. Sodium bicarbonate (NaHCO₃) can be used to correct acidemia. It works rapidly by providing base, which titrates H⁺. Sodium bicarbonate is not always beneficial and is seldom required for acidotic patients. Its use is particularly controversial for patients with lactic acidosis.^{68,69} When NaHCO₃ is added to the blood, a small percentage of it is converted to CO₂ almost immediately. Traditionally, if this CO₂ cannot be exhaled, it may exacerbate preexisting acidemia. More commonly, however, the respiratory acidosis offsets the bicarbonate-induced metabolic alkalosis, with negligible, if any, increase in pH. Clinicians should appreciate that when NaHCO₃ is given to patients with diabetic ketoacidosis, they may become alkalotic after the ketone bodies are metabolized (rebound phenomenon). Physiologically, most patients can deal with alkalosis better than with acidosis.

Various formulas can be used to help the clinician decide how much bicarbonate (HCO₃) to administer.²⁰ The following is suggested for most situations when NaHCO₃ is indicated:

mEq to administer

= body weight in kg \times 0.3 \times calculated HCO₃ deficit

The body weight is multiplied by 0.3 to approximate the ECF volume, which is where the HCO_3 will first be distributed. There will eventually be diffusion of HCO_3 into the cells, and additional HCO_3 may have to be administered to retain the desired effect in the ECF. For that reason some clinicians utilize a factor of 0.5 instead of 0.3.

The calculated HCO₃ deficit *to treat* is not the same as "base deficit" (a calculation provided by a blood gas analysis). To calculate the HCO₃ deficit *to treat*, the clinician must first decide what plasma concentration of HCO₃ is desired. It is appropriate to aim for a plasma concentration of approximately 14 to 15 mEq/L if the HCO₃ concentration is less than that initially. The patient's HCO₃ concentration (e.g., 15 mEq/L). The resulting number is the calculated HCO₃ deficit *to treat* for this patient at this time. Once the total amount of HCO₃ to be administered is calculated, it is administered intravenously, usually over 1 to 4 hours. After several hours, this HCO₃ will distribute to the ECF and later to the ICF, and the patient should be reevaluated to determine whether more HCO₃ is needed.

 $NaHCO_3$ is not a benign drug, although severe adverse effects are rare and complications can be minimized if it is used judiciously. Hypernatremia, hypervolemia, hypokalemia, ionized hypocalcemia, hypotension, nausea, and

paradoxical intracellular acidosis, are possible.⁷⁰ The recognition of potential adverse effects of NaHCO₃ led investigators to develop other forms of base that could be administered to restore acid-base status while circumventing the problems associated with NaHCO₃. THAM (tris hydroxymethyl aminomethane) is sodium free and has a free amino group that buffers protons. THAM administration doesn't result in generation of CO₂. This drug never gained widespread acceptance, in part because of reported side effects including respiratory depression, hyperkalemia, and hepatotoxicity. Carbicarb (1:1 mixture of sodium bicarbonate and sodium carbonate) has been shown in animal studies of metabolic acidosis to be superior to NaHCO₃ in preserving or improving cardiac output and intracellular pH. However, further development of this drug was abandoned, in large part because it was not convincingly demonstrated to be superior to NaHCO₃. Ethylene glycol intoxication often necessitates aggressive NaHCO₃ therapy. Large amounts of acid are produced as ethylene glycol is metabolized to glycolic acid²⁰; therefore it may be difficult to give NaHCO₃ in sufficient amounts to maintain a safe pH, depending on how much ethylene glycol was ingested.

SPECIAL CONSIDERATIONS

Shock

Shock is a syndrome characterized by the presence of severe clinical signs, including altered mental status, mucous membrane color, capillary refill time, heart rate, and pulse quality. Shock may be classified as hypovolemic, cardiogenic, or distributive. Obstructive shock, as described, is less commonly discussed as a distinct entity as its pathophysiology is believed to overlap with other classifications. Classification schemes, including this one, tend to be oversimplifications because relatively few global clinical parameters represent many complex dynamic processes occurring at the cellular level. Hypovolemic shock occurs when loss of blood volume causes a severe decrease in tissue perfusion and oxygenation. Causes include hemorrhage and severe dehydration. Cardiogenic shock is caused by myocardial failure with or without arrhythmias that decrease cardiac output. In obstructive shock inadequate tissue perfusion results from obstruction of blood flow within the vasculature. Obstructive shock may be seen in animals with massive pulmonary thromboembolism, pericardial effusion, or gastric dilation/volvulus. Distributive shock is characterized by nonuniform loss of peripheral vascular resistance. Resistance in specific tissue beds may be increased, decreased, or normal. Although cardiac output may be increased, the clinical picture is generally one of vasodilation. The vascular and cellular events result in the global release of inflammatory mediators, leading to the systemic inflammatory response syndrome (SIRS). Sepsis may lead to distributive shock. If there is refractory hypotension, it is further defined as septic shock. Further, patients may have distributive shock subsequent to trauma or other severe inflammatory processes in the absence of an infectious cause (e.g., pancreatitis, anaphylaxis).⁷¹ Appropriate treatment of a patient in shock requires characterizing the shock syndrome present in a given patient.^{53,72}

Hypovolemic Shock

The immediate need is to reestablish effective circulating blood volume. Appropriate resuscitation fluids are isotonic crystalloids (e.g., LRS, PSS, Normosol R) with or without the addition of colloids or hypertonic saline. If isotonic crystalloids are used alone in patients with ongoing blood loss, a decrease in vascular volume may be expected after initial resuscitation as redistribution occurs across the extracellular space. With colloids a more steady state of vascular volume expansion is expected. Hypertonic saline should be used cautiously or not at all for patients that are already hypernatremic. Colloids (e.g., dextran 70, 6% hetastarch) are sometimes used with hypertonic saline; or they may be used alone. Hetastarch is given at a dose of 5 to 20 mL/kg in dogs and 5 mL/kg in cats over 5 to 10 minutes, although doses of up to 40 mL/kg per day are described. To prevent hypervolemia, the rate of infusion of isotonic crystalloids should be decreased by 40% to 60% after colloids are started. In the face of ongoing blood loss, optimal therapy ideally should include blood products. If the patient is symptomatic for anemia and blood products are not available, Oxyglobin may be given.53,58,72-74

Unless there is suspicion for hypoadrenocorticism, steroids are generally not recommended. Vasopressors are not generally indicated for hypovolemic patients. In particular, clinicians should avoid α -agonists that increase blood pressure by causing vasoconstriction, unless patients are severely hypotensive and the clinician must time while other interventions are implemented.⁵³

Obstructive Shock

Gastric dilation/volvulus (GDV) is the prototype disorder characterized by obstructive shock. Distention of the stomach with food and air compresses the portal vein and vena cava. This compression can occur with dilation and does not require volvulus. Fluids for resuscitation should be administered through large-bore cephalic catheters because fluid administration through saphenous catheters will be ineffective. Balanced electrolyte solutions are administered at 60 to 90 mL/kg in the initial hour of treatment. Hypertonic saline/ dextran solutions can also be used initially (5 mL/kg over 5 to 10 minutes) but must be followed by isotonic crystalloids to maintain perfusion.⁷⁵ Once resuscitation is under way, the stomach is decompressed by carefully passing an orogastric tube. If passage of the tube is not possible, the stomach is trocarized. Because ischemia and reperfusion appear to be important mechanisms of injury, administration of free radical scavengers may eventually become important in the early treatment of this disorder. There is no evidence supporting the use of glucocorticoids or nonsteroidal inflammatory agents in gastric dilation/volvulus patients.

Cardiogenic Shock

Treatment of cardiogenic shock is directed toward improving myocardial contractility, reducing afterload and preload and controlling dysrhythmias. The clinician should examine the patient frequently to ensure that fluid therapy does not lead to decompensation because these patients are often volume intolerant. It is typically inadvisable to administer crystalloids in edematous cardiac patients. For the rare patient that must receive fluids (e.g., as a vehicle for drug administration), limited amounts of sodium should be given (e.g., 0.45% NaCl).⁷⁶ Maintenance rates or less are then carefully administered. CVP measurement can be particularly useful in monitoring these patients.

Distributive Shock

Distributive shock is principally seen in animals with SIRS. In SIRS release of various inflammatory mediators causes abnormal blood flow regulation with subsequent tissue hypoxia, even when there is normal to increased cardiac output (hence the term *hyperdynamic shock*). Increased vascular permeability may cause plasma volume to leak into interstitial tissues, further reducing tissue perfusion.⁷⁷⁻⁸⁰

It can be difficult to effectively treat some patients with SIRS. Blood volume should be maintained as for hypovolemic shock. Either isotonic or hypertonic crystalloids may be used. The clinician must also identify and eliminate the cause of the inflammation, which usually includes broad-spectrum antibiotic therapy. Pharmacologic therapies directed at specific inflammatory pathways have been investigated, but none have been found to be effective to date.⁸¹ There is limited evidence supporting the administration of nonsteroidal antiinflammatory agents and corticosteroids, and their use is generally discouraged. A syndrome of relative adrenal insufficiency (RAI) is described in critically ill humans and animals, and patients with RAI may benefit from low (i.e., physiologic) doses of corticosteroids. Criteria for the diagnosis of RAI in animals and humans have been published, but at present the syndrome is not widely recognized.⁸²

Hypoglycemia is relatively common in critical illness, and intravenous glucose supplementation may be needed. Most patients require fluid support, and adding hypertonic glucose to balanced isotonic fluids to create a fluid with a final glucose concentration of 5% is recommended. Although intermittent boluses of hypertonic glucose may be administered (0.5 gm/kg of 10% to 25% dextrose solution), continuous infusion of hypertonic solutions through a peripheral vein may cause thrombophlebitis. The addition of hypotonic glucose– containing fluids (e.g., D5W) at maintenance rates can usually maintain blood glucose concentrations of more than 100 mg/ dL in volume-sensitive patients.

Renal Disease

Fluid therapy for patients with renal disease should first correct significant fluid, electrolyte, and acid-base abnormalities and subsequently produce a diuresis to eliminate normally excreted substances that have been retained. It is important to distinguish patients with oliguric renal disease from those with polyuric renal disease and also to determine if pets have chronic kidney disease or acute on chronic kidney injury. Severely hypoalbuminemic patients with proteinuric nephropathy present special challenges. Oliguria describes a patient that is producing less than 1 to 2 mL urine/kg per hour, although some clinicians define *oliguria* as less than 0.25 mL/kg per hour.⁸³ Anuria is a more severe situation indicating negligible urine production. Polyuria means that greater than normal amounts of urine being produced. Most patients with chronic kidney disease are polyuric until they are preterminal, when they may become oliguric. Patients with acute renal injury similarly may be polyuric or oliguric-anuric.

Polyuric Renal Failure

The first goal of fluid therapy for patients with polyuric renal failure is to correct dehydration (which is commonly present with decompensated renal failure) and severe electrolyte or acid–base abnormalities. If the patient is seriously ill, intravenous fluids are usually preferred to prevent delayed uptake from subcutaneous depots or vomiting of orally administered fluids. The next step is to provide sufficient fluids to match urinary losses. Occasionally, pharmacologic attempts are made to further augment renal function and urine production with diuretics (e.g., furosemide). This should not be done unless the patient is euhydrated and on intravenous fluids or is overhydrated. The use of appropriate and aggressive crystalloid therapy is generally adequate, and although this makes sense intuitively, there is limited evidence to support the use of diuretics in this setting.

As much fluid as possible should be administered without overhydrating the patient. The amount of fluid administered is slowly increased as damaged kidneys recover and adapt to the increased demand placed on them. As a general rule of thumb, therapy is begun by replacing deficits and weighing the patient. Fluids are then administered at 1.5 to 2 times the calculated maintenance rate or more, if necessary to keep up with renal losses. If the patient does not gain weight inappropriately and does not have signs of fluid overload (i.e., gallop rhythm, murmur, pulmonary crackles), the clinician can slowly increase the amount of fluids administered each day, usually by 15% to 30%. Although loop diuretics (e.g., furosemide) are sometimes also required, vigilant therapy with balanced crystalloids often produces an adequate diuresis. When fluid-induced diuresis is brisk, the rate of intravenous fluid administered is slowly decreased (e.g., 10% to 25%) each day, and the body weight is closely monitored to prevent the patient from becoming dehydrated.⁸⁴ Recording the volume of urine produced over a given time (e.g., 24 hours) is advisable. Measurement of CVP is not useful in this setting.

Oliguric and Anuric Renal Failure

Oligoanuric renal failure is more difficult to manage than polyuric renal failure. Oligoanuria is observed with severe acute renal injury and occasionally in preterminal chronic renal disease.⁸³ In the latter situation there is usually little that can be offered to help the patient besides renal replacement therapy or transplantation. In the former situation, it is important to try to quickly convert the oliguria to polyuria by replacement of the fluid deficit and then administration of furosemide, osmotic diuretics, or dopamine, although none of these drugs has been proved to benefit or alter the prognosis of anuric renal failure patients. Furosemide, administered either as a bolus or as a constant-rate infusion, is typically the first way that the clinician attempts to convert an oliguric patient to a polyuric state. Although once highly regarded, dopamine is generally of dubious value in patients with established oliguric, acute renal failure.

If furosemide therapy fails to convert an oliguric patient to a polyuric state, osmotic diuresis may be attempted by administering a bolus of mannitol (1 gm/kg intravenous bolus) followed by additional boluses or a constant-rate infusion (1 to 2 mg/kg/minute). Alternatively, 10% to 20% dextrose may be administered. The use of dextrose is favored by some clinicians because it may be metabolized if it cannot be excreted. The clinical significance of this is uncertain. However, if this is the case, the clinician should be able to detect glucose in newly formed urine, with the recognition that some patients with acute renal failure already have glucosuria as a result of proximal renal tubular damage. The body weight should be monitored closely to prevent excessive overhydration. Serum electrolytes should also be monitored. It is important that maintenance fluids be initiated immediately after infusing dextrose or mannitol to prevent renal hypoperfusion. If urine production is not increased by these measures, infusions should be discontinued before overhydration, pulmonary edema, and hypertonicity occur (i.e., before half of the total calculated volume is administered).83

Great care must be taken not to volume overload oliguric patients. If life-threatening overhydration occurs, all intravenous therapies are discontinued. Diuretics may be administered, but these patients may not improve without hemodialysis or hemofiltration. CVP should be monitored. CVP values consistently greater than 10 to 12 cm H₂O are *compatible with* but not diagnostic for fluid overload. CVP values between 5 and 10 cm H₂O suggest that the patient may tolerate additional fluid challenge. ⁸⁵ Another technique is to measure urine output and administer fluids accordingly, using a technique sometimes called "ins and outs."⁸⁴ The patient is initially rehydrated over 6 to 8 hours. The clinician next divides the day into six 4-hour intervals. The amount of urine produced over each interval is given back to the patient over the subsequent interval.

Oligoanuric renal failure patients are predisposed to hyperkalemia and severe acidosis, Serum magnesium abnormalities are also common. If the patient is well hydrated and remains oliguric or anuric, all intravenous fluids are discontinued. Alternatively, the clinician may elect to replace only insensible losses with intravenous fluids at this time, but this has inherent risks. Body weight is assessed several times daily. Consideration of referral for hemodialysis is appropriate in persistently (i.e., duration longer than 24 hours) oliogoanuric patients.

The healing phase of acute renal failure may be accompanied by an intense diuresis that can require administration of several times the calculated daily maintenance volume. If an oliguric or anuric patient becomes polyuric, it is necessary to guard against dehydration. The rate of fluid administration must be slowly decreased when the patient is being weaned off intravenous fluids.⁸³ Excessive losses of potassium may occur during the healing, polyuric phase.

Urethral Obstruction

The clinical condition of dogs and cats with urethral obstruction depends on the duration and severity of the obstruction. Less commonly, bilateral ureteral obstruction will result in oligoanuria; in this situation the bladder is small or empty. When urethral obstruction is diagnosed, intravenous fluids should be instituted immediately, with the rate based on the degree of hypoperfusion and dehydration present. Hyperkalemia, if severe and associated with bradydysrhythmias, should be treated aggressively before relieving the obstruction. If acidosis is present and hyperkalemia is not associated with life-threatening signs, fluid resuscitation alone will often be sufficient to correct these values. A balanced isotonic electrolyte solution is recommended for initial therapy in most cases.⁸⁶ These patients often develop severe polyuria after the obstruction is relieved (e.g., postobstructive diuresis), the severity of which generally depends on the degree of renal tubular damage or loss of urine-concentrating ability. It is common for severely affected patients to have daily fluid needs that exceed their calculated maintenance values during this healing period.⁸⁶

Proteinuric Nephropathies

Glomerular diseases that have progressed in duration or severity to cause hypoalbuminemia are recognized in companion animals. Some patients with severe proteinuria will have clinical and clinicopathologic features of nephrotic syndrome. By definition, nephrotic syndrome implies glomerular protein loss sufficient to cause hypoalbuminemia, in addition to edema (or ascites) and hypercholesterolemia. Although it is postulated that patients with nephrotic syndrome have more severe glomerular lesions and a less favorable prognosis than patients that do not fulfill these criteria, this is not the case for dogs.

When choosing fluid therapy, the clinician must consider both the need for diuresis and the effects of further dilution of serum albumin concentrations by aggressive administration of crystalloids in addition to effects on blood pressure.⁸⁷ The patient may already have edema, ascites, or pleural effusion resulting in part from the hypoalbuminemia. Further dilution of plasma albumin concentrations with intravenous fluids may unmask or exacerbate fluid retention. Uncommonly, cavitary effusions will be of sufficient severity to require removal by paracentesis. Judicious administration of a loop diuretic can be used at this time; the diuretic causes fluid loss from the vascular compartment that is ideally replaced by fluid from the third space. If too much fluid is removed from the vascular compartment, renal hypoxia and damage may result.⁸⁷ Removal of cavitary effusions is generally discouraged. Such withdrawal, especially if repeated, will further lower the body albumin concentration and make fluid reaccumulation more likely.

If the patient's cardiovascular status is rapidly deteriorating because of severe hypoalbuminemia or if it is necessary to perform a procedure (especially one requiring anesthesia) in a patient with marginal cardiovascular status, a synthetic colloid (e.g., hetastarch, dextrans) can ge given. Alternatively, plasma may be administered. However, synthetic colloids are more effective in maintaining osmotic pressure in the vascular space. Moreover, the amount of plasma required to replace the deficit in albumin is relatively large, and the ability of administered albumin to maintain vascular expansion is usually gone within 24 to 72 hours (as it is with artificial colloids). Plasma is indicated only for patients with clinically significant coagulopathies that require invasive procedures. Many patients with glomerular disease are hypertensive, and blood pressure must be monitored carefully lest fluid therapy cause worsening of the hypertension with subsequent retinal or central nervous system injury.

Cardiac Disease

Most animals with cardiac failure do not need parenteral fluid therapy. Animals that are eating and drinking can usually be managed by offering distilled water and using diuretics as needed. However, if the patient is severely dehydrated, is anorexic, or has concurrent renal failure or other organ failure, fluid therapy may be needed. Treatment of such animals in severe cardiac failure is similar to the treatment of those with oliguric renal failure; the clinician must be careful not to overhydrate the patient. Measurement of CVP is useful; however, pulmonary artery catheters (i.e., Swan-Ganz) provide information (e.g., pulmonary wedge pressure) that is not available from CVP catheters. It is important to note that pulmonary artery catheters are most useful for monitoring cardiovascular status but not fluid balance in critically ill patients. Fluid administration is controversial with many cardiac diseases. Because of their lower sodium content, hypotonic solutions may be more appropriate when fluids are deemed necessary because patients with heart disease are often unable to appropriately excrete sodium. However, it is not the sodium concentration of the fluid, per se, but the volume of fluid that contributes to this situation. Similarly, sodium bicarbonate administration is often discouraged because of the relatively high sodium load.⁸⁸

Electrolyte abnormalities in patients with cardiac disease must be treated carefully. Oral potassium supplementation is best for hypokalemic animals that are not vomiting. Hypokalemic patients are more prone to digitalis toxicity and supraventricular arrhythmias.⁸ Marked repeatable hyponatremia is usually an indication that cardiac disease is advanced. Cautious sodium administration is appropriate only for patients with severe, symptomatic hyponatremia (rare). Even then, only enough sodium to alleviate or prevent central nervous system signs should be administered.

Patients with simultaneous cardiac and renal failure are among the most difficult to manage. The clinician must identify the cause of the renal and cardiac diseases and treat each. If the underlying causes cannot be determined or treated, it is best to monitor CVP and "ins and outs" while giving small amounts of fluids with minimal amounts of sodium.⁸⁸ In general, fluids are administered as rapidly as possible without excessively increasing the CVP (e.g., >10 to 12 cm H_2O).

Gastrointestinal Disorders

Acute Vomiting

Acute vomiting commonly causes fluid deficits.⁸⁹ The severity of the deficit will depend on the severity and cause of the vomiting and on whether the animal will eat or drink. Although vomiting is considered an alimentary tract disorder, vomiting is often caused by extragastrointestinal disorders (e.g., renal failure, adrenal failure, hepatic failure, hypercalcemia, pancreatitis, diabetic ketoacidosis). The therapy for most animals with moderate to severe acute vomiting includes not being fed or watered until the vomiting diminishes, which means that the patient has ongoing losses (both insensible and from vomiting) and no intake. Therefore, even if such an animal is not dehydrated at the time of examination, it will usually become so shortly.

If mild dehydration is present or anticipated, subcutaneous fluids are often adequate. If the dehydration is or will probably become severe or if the animal appears to be going into shock, intravenous fluids are indicated. Until the electrolyte and acid-base status are known, 0.9% saline, Normosol-R, or LRS are generally acceptable choices. Although hypokalemia is common in animals with acute vomiting, supplemental potassium should not be administered until it is known that the patient is not hyperkalemic as a result of adrenal or renal dysfunction. One of the most common causes of severe vomiting in young animals is parvoviral enteritis, which will be discussed later with acute diarrhea.

Chronic Vomiting

Most patients with chronic vomiting (i.e., that lasting 2 weeks or longer) are not overtly dehydrated when presented to the veterinarian. The fact that the animals have had the disease for so long usually means they were able to compensate for their fluid losses. If unable to compensate, they typically would have been been brought in earlier as emergencies (e.g., in hypovolemic shock). Some of these patients will be dehydrated because of a recent worsening of their disease. Even when the animal's fluid status is acceptable, however, there may be significant electrolyte and acid-base abnormalities.

Fluid therapy must be tailored for each individual. Hypokalemia is common if the patient does not have adrenal insufficiency or severe renal failure, both of which can cause chronic vomiting. It is not possible to predict with accuracy what a given patient's acid–base status is, even when the cause of the vomiting is known. Animals with high intestinal obstruction occasionally have a hypokalemic, hypochloremic, metabolic alkalosis that is thought to reflect gastric outflow obstruction, whereas some animals with seemingly pure gastric fluid losses can have a normal pH or are acidemic. If therapy must begin before the electrolyte and acid–base status are known (i.e., the patient is severely dehydrated), then balanced isotonic solutions (e.g., Normosol-R, PSS, LRS) are usually acceptable. Potassium supplementation is not recommended until a potassium deficit is confirmed. If renal failure and hypoadrenocorticism have been eliminated and hypokalemia is present, it is appropriate and generally safe to add 14 to 20 mEq/L of potassium chloride to crystalloid solutions and administer it at a maintenance rate.⁸

Acute Diarrhea

Many animals with acute diarrhea are not dehydrated unless the diarrhea is profuse, vomiting is present, or the patient is anorexic. Acute parvoviral enteritis is an important cause of acute diarrhea, vomiting, and anorexia. In severe cases intravenous fluid therapy is indicated regardless of the cause.⁸⁹ Treatment initially should correct hypovolemia and hydration deficits. Subsequently, when the serum potassium is determined, 20 mEq/L of potassium chloride may be added to isotonic crystalloids. If hyperkalemia is marked, up to 40 mEq/L may be added to intravenous fluids. With parvoviral enteritis, the clinician must also be concerned with hypoglycemia (discussed later), which may result from sepsis or diminished capacity for glycogenolysis and gluconeogenesis in a sick puppy.⁹⁰

Chronic Diarrhea

Most patients that are brought to the veterinarian because of chronic diarrhea are not overtly dehydrated. The fact that the animals have had diarrhea for so long and are just now being examined suggests that they are able to compensate for their fluid losses. If they had been unable to maintain hydration during the previous 2 or more weeks, they probably would have been brought in earlier in hypovolemic crisis. A recent worsening of the disease may cause dehydration, in which case it is reasonable to start fluids (usually a balanced isotonic crystalloid supplemented with 20 mEq/L potassium chloride). Hypokalemia is the most common electrolyte problem in these patients, but acute renal failure and hypoadrenocorticism, two of the most common causes of noniatrogenic hyperkalemia, occasionally cause disease characterized predominantly by diarrhea. The acid-base status cannot be predicted, and the clinician should not administer alkalinizing or acidifying solutions until at least the TCO₂ (and ideally the blood pH) is known.

Another major concern for animals (especially dogs) with chronic diarrhea is hypoalbuminemia. Protein-losing enteropathies may produce serum albumin concentrations of less than 1.5 g/dL. Not all such dogs have ascites or edema.⁸⁹ The clinician should avoid excessively diluting the remaining albumin in severely hypoalbuminemic patients because it can cause further pooling of fluid in third spaces and depletion of effective circulating volume. If the animal needs increased oncotic pressure, synthetic or natural colloids may be administered. However, albumin that has been administered intravenously can be lost rapidly into the intestines of animals with protein-losing enteropathies. Synthetic colloids (e.g., hetastarch) are typically more effective for management of these patients, unless they are simultaneously coagulopathic.

Pancreatic Disease

Acute Pancreatitis

Acute pancreatitis is a potentially fatal disease that usually has no specific therapy, although cats can have pancreatitis caused by bacterial, viral, or protozoal infections. Affected dogs usually are anorexic and yet vomit gastrointestinal secretions, leading to severe dehydration. The primary therapies available are fluid therapy (to enhance pancreatic perfusion) and initially withholding oral intake in patients that are vomiting.⁸⁹ If an inflamed pancreas is poorly perfused, the inflammatory state may progress from a relatively mild, edematous one to a severe hemorrhage or necrotic condition with a poorer prognosis.

The most common mistakes in treating dogs with pancreatitis are thought to be premature oral feeding and inadequate administration of fluids.⁹¹ The former concern is now being debated. Not only must the fluid deficit be replaced, but a normal effective circulating volume also must be attained so that visceral perfusion is improved. Severe abdominal inflammation may cause fluid to pool in the abdomen or peripancreatic tissues and thus be unavailable for organ perfusion. Furthermore, there may be pooling of fluid in the intestines because of poor motility and serosal peritoneal inflammation.

It is important to monitor the serum albumin concentration. If the albumin concentration drops and the patient is judged to be inadequately perfused, plasma or hetastarch may be useful.⁹² Although contentious, there is some thought that administration of plasma may replenish circulating proteases, thus offering some protection against enzymes released from the diseased pancreas,⁸⁹ as well as supply antithrombin, which may be helpful in treating disseminated intravascular coagulation.

Diabetic Ketoacidosis

Animals with diabetic ketoacidosis are often, but not invariably, severely dehydrated and acidotic when first examined. Fluid administration and judicious use of insulin generally produce favorable outcomes if the patient does not have severe pancreatitis or other severe concurrent illness.⁴¹ Most dogs and cats with severe diabetic ketoacidosis are treated initially with fluids until dehydration and electrolyte/acid-base abnormalities are at least partially corrected before beginning therapy with insulin, but this is not a universally accepted tenet of therapy. A balanced isotonic replacement solution is used. It is generally not necessary to administer NaHCO₃ to these patients, and clinicians are discouraged from its use unless it is determined that a profound metabolic acidosis exists after fluid deficits have been replaced. Many ketoacidotic patients will become hypokalemic once therapy is begun; therefore it is reasonable to start supplementing potassium with the initial fluids once it is determined that the patient is not hyperkalemic.⁴¹ Hypophosphatemia is a potential problem of aggressive insulin therapy, and serum phosphate concentrations must be monitored, especially if anemia is developing. If the patient becomes severely hypophosphatemic, the intravenous fluids should be supplemented with potassium phosphate

(see previous discussion on phosphorus). The patient must be monitored to prevent hypocalcemia and hyperphosphatemia.⁶⁶ Hypomagnesemia should be anticipated in ketoacidotic diabetic patients.

Hepatic Disease

The main concerns regarding administration of fluids to a patient with hepatic disease are hypoalbuminemia, hypoglycemia, fluid and salt retention, and electrolyte abnormalities. Fluids restricted in sodium (e.g., half-strength PSS plus 2.5% or 5% dextrose) should be used to help avoid fluid retention in dogs with chronic hepatic disease prone to ascites (e.g., cirrhosis). Addition of glucose to the fluids (i.e., 2.5% to 5%) guards against hypoglycemia. If hypoalbuminemia is severe, administration of colloids in addition to crystalloids should be considered. Large volumes of plasma often are required to significantly increase plasma albumin concentrations, and hypoalbuminemia is not necessarily an indication for plasma administration. Plasma is primarily administered to patients that are coagulopathic. The administration of human albumin may effectively increase serum albumin, but its use is controversial because some patients have died after using it. Hypokalemia predisposes the patient to hepatic encephalopathy; supplemental potassium chloride in the intravenous fluids prevents this occurrence. Acid-base abnormalities are difficult to predict and must be assessed in each patient. In general, the clinician should prevent alkalemia because it predisposes the patient to hepatic encephalopathy.93

Hypoglycemia

Hypoglycemia may be caused by various diseases (e.g., septicemia, hypoadrenocorticism, hepatic insufficiency, insulinoma, starvation of a neonate, iatrogenic overdose of insulin). Regardless of its cause, symptomatic hypoglycemia that is causing weakness, coma, or convulsion should be treated.⁹⁴ For emergencies 1 mL/kg of 50% dextrose/kg is drawn up, diluted 1:1 with PSS, and administered intravenously, slowly to effect. For a more prolonged effect, dextrose may be added to maintenance fluids. In most cases 2.5% dextrose given at maintenance rates will maintain the blood glucose concentration in a safe range (i.e., >80 mg/dL). In rare cases it may be necessary to administer 5% instead of 2.5% dextrose to achieve this goal.

Hypocalcemia

Symptomatic hypocalcemia is usually caused by puerperal tetany, hypoparathyroidism, resection of parathyroid tumors, ethylene glycol intoxication, or inappropriate administration of a hypertonic phosphate enema. Regardless of its cause, hypocalcemia causing clinical signs (i.e., tetany, convulsions) should be treated.⁹⁵ While calcium gluconate 10% and calcium chloride 10% may be obtained, calcium chloride is thought to be more potent (10% calcium gluconate has 0.46 mEq Ca/mL, whereas 10% calcium chloride has 1.36 mEq Ca/mL); therefore there is potential for overdosage and cardiotoxicity may, in addition to the phlebitis and perivascular tissue injury observed if extravastion occurs. Similar

tissue injury is observed if calcium chloride is given by the subcutaneous route. Calcium gluconate is therefore selected over calcium chloride for treating hypocalcemia, except in extremely rare circumstances (i.e., hepatic disease impairing metabolism of gluconate). Approximately 0.5 to 1.5 mL of 10% calcium gluconate is administered per kilogram, or 5 to 15 mg/kg may be administered slowly to effect over 10 to 30 minutes. Such a treatment usually lasts a few hours, although some animals will need additional therapy within 1 to 3 hours. Once the crisis is over, calcium may be added to the intravenous fluids to provide constant infusion. In general, 10 mL of 10% calcium gluconate is added to 500 mL of 0.9% NaCl and administered at maintenance rates. Then the serum calcium level and clinical signs are monitored, and the amount of calcium in the intravenous fluids is increased if necessary. Alternatively, the clinician may administer 1 to 2 mL calcium gluconate/kg (diluted 1:1 in sterile PSS) subcutaneously.96

Hypercalcemia

Symptomatic hypercalcemia in dogs is usually due to hypercalcemia of malignancy, vitamin D intoxication, primary hyperparathyroidism, hypoadrenocorticism, granulomatous disease, or chronic renal disease causing tertiary hyperparathyroidism.97 In the first two conditions, it is important to rapidly decrease the plasma concentration of calcium to prevent renal injury. This is ultimately best accomplished by elimination of the cause (e.g., removing or treating the malignancy causing hypercalcemia of malignancy, removing the parathyroid adenoma). While searching for the cause, however, the clinician may administer 0.9% NaCl to promote diuresis and enhance urinary calcium excretion. However, potassium concentrations must be monitored to prevent hypokalemia.98 Furosemide promotes natriuresis and calciuresis if the patient is adequately hydrated. Administration of 1 mg prednisolone/kg daily may enhance calcium excretion and reduce bone resorption as well as intestinal calcium absorption. However, steroid administration may make it more difficult to diagnose the cause of the hypercalcemia if it is due to a lymphoid malignancy. Severe cases may be treated with salmon calcitonin, pamidronate, or clodronate. Saline diuresis and furosemide are successful in controlling hypercalcemia in the short term in most patients. Prognosis depends on the underlying disease.

SURGERY

Dehydration should be corrected before surgery and anesthesia, if possible. Even after deficits have been corrected, animals undergoing prolonged general anesthesia usually benefit from intravenous fluid support. Unless the patient has cardiac disease or is hypoproteinemic or anemic, isotonic crystalloids (e.g., PSS, LRS) are usually administered at 4 to 5 mL/kg per hour. Severe hypoproteinemia or anemia should be corrected with blood products or synthetic colloids before the patient is anesthetized.

If the clinician anticipates significant loss of blood during the procedure, he or she may need to increase the basal rate by 5 to 10 mL/kg per hour. If there is substantial blood loss or the hematocrit falls to less than 20% to 25% during the procedure, strong consideration should be given to administering red blood cells (either as packed red cells or whole blood) or administering purified hemoglobin. If one is attempting to correct for blood loss during the procedure with crystalloids, approximately three times the estimated volume of blood lost should be given.

Drugs Affecting Urine Formation

Dawn Merton Boothe

Chapter Outline

RENAL PHYSIOLOGY AND DRUG THERAPY	Aldosterone Antagonists
Extracellular Fluid	High-Ceiling Diuretics
Renal Transport of Fluids and Electrolytes	Pressor Agents
Atrial Natriuretic Hormone	THE USE OF DIURETICS IN SELECTED CLINICAL
DIURETIC THERAPY	CONDITIONS
Therapeutic Use of Diuretics	Congestive Heart Failure
Targets of Diuretic Therapy	Cirrhosis
Principles of Diuretic Therapy Use	Nephrotic Syndrome
Factors Limiting Response to Diuretics	DRUGS THAT ALTER RENAL CONSERVATION OF
DIURETICS	WATER: ANTIDIURETIC HORMONE
Osmotic Diuretics	DRUGS THAT ALTER URINARY pH
Carbonic Anhydrase Inhibitors	Urinary Acidifiers
Thiazide Diuretics	Cysteine Urolithiasis
Drugs That Interfere with Renal Epithelial Sodium	Calcium Oxalate Urolithiasis
Transport	Urate Urolithiasis

RENAL PHYSIOLOGY AND DRUG THERAPY

Extracellular Fluid

The physiology of body fluids and the role of the kidney are also addressed in Chapters 16 and 18 The volume of extracellular fluid (ECF) is determined primarily by total body sodium content for two reasons: First, sodium is the major constituent of ECF; secondly, active transport mechanisms control sodium in intracellular and extracellular compartments.¹ Control of ECF involves cardiovascular, renal, and central nervous systems. Because these systems are closely integrated, one system can compensate for the failure of another system, thus ensuring that salt and water excretion remain appropriate even with changes in blood pressure. Among the compensatory mechanisms is autoregulation of renal blood flow through efferent arteriolar resistance. Because regulatory mechanisms adjust both short- and long-term sodium and water transport rates, small increases in mean arterial blood pressure can cause a marked increase in sodium excretion, ultimately changing total body sodium.¹ However, a check-and-balance system exists whereby if sodium balance becomes negative, as sodium concentration in the ECF decreases, causing thirst and water intake to decrease accordingly until ECF sodium concentration normalizes. A positive balance does the opposite, resulting in an increase in water intake. These integrated systems

maintain a sodium and water excretion that equals that of intake minus any lost through nonrenal mechanisms (e.g., feces, sweat).

Renal Transport of Fluids and Electrolytes

The proximal tubules are responsible for 66% of the sodium and glomerular filtrate reabsorbed by the kidney. The primary pathway of fluid and electrolyte reabsorption in the renal tubule begins in the lumen and progresses through the cell and the interstitial fluid and into the capillary. Two waterpermeable cell membranes are traversed during reabsorption. In the proximal tubule, active sodium ion reabsorption from the lumen into the cell generates an osmotic gradient in the lumen that leads to an almost simultaneous movement of water into the cell. Sodium reabsorption that begins with entry across the luminal membrane continues with movement across the basolateral membrane into the interstitial space (Figure 17-1). Basolateral movement is the energy-dependent process, fueled by a Na/K-dependent ATPase located on the basolateral membrane. The exchange rate of two K⁺ for each three Na⁺ entering the interstitial fluid provides an electrochemical gradient that favors passive entry of Na⁺ from the lumen into the cell. The concentration gradient generated by the basolateral movement determines the rate of sodium movement from the lumen. Chloride (and to a lesser degree, other anions) follows sodium, maintaining electroneutrality of the reabsorbate and

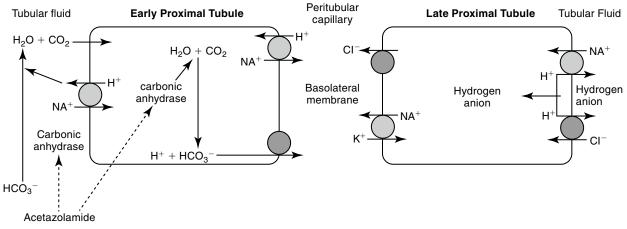

Figure 17-1 Movement of fluids and electrolytes into the proximal tubule and predominant sites of action of selected diuretics. The proximal tubule is the primary site of fluid resorption. Sodium enters the renal tubular cell by several mechanisms, including concentration-dependent passive diffusion, concentration-independent active transport, and countertransport with hydrogen. This latter mechanism yields bicarbonate and, although it occurs spontaneously, is also catalyzed by carbonic anhydrase. As sodium, chloride, and water are resorbed, the concentration of the remaining solute in the urine increases, causing an osmotic draw of fluid back into the tubule. Consequently, resorption of fluids is self-limiting to some degree. *Dashed lines* reflect inhibited actions, and *solid lines* reflect stimulation.

a slight electronegativity of the cell compared with the luminal contents. The concentration gradient also favors passive movement of potassium from the interstitium into the cell, where it is used to continue the Na-K exchange. Although movement of sodium from the lumen into the cell is passive (albeit at the cost of an active basolateral efflux), sodium reabsorption into the cell is facilitated by three additional entry mechanisms: diffusion with chloride (quantitatively the most important), co-transport with uncharged or acidic anions, and countertransport with hydrogen ions (important to acidbase regulation and the site of carbonic anhydrase action). Although transport of sodium, water, and other electrolytes raises interstitial pressure, movement into peritubular capillaries facilitates continued reabsorption. Bicarbonate processing also occurs in the proximal tubule.

Unlike the proximal tubule, cells of the descending limb of the loop of Henle do not appear to be equipped with specialized transporting systems. The cells are relatively impermeable to sodium, chloride, and potassium but are permeable to water. Water moves from the lumen into the interstitium, causing electrolyte concentrations to progressively increase in the lumen until a maximum is reached at the bend. Diuretic drugs do not appear to be active in the descending portion of the tubule. In the ascending limb of the loop, chloride is transported "uphill," achieving intracellular concentrations that are higher than predicted (based on the Nernst equation).² Chloride movement occurs by a Na (downhill), K+-2Cl-(uphill) co-transport system, with Na⁺, K⁺-ATPase in the peritubular membrane providing the energy source. High intracellular chloride concentration facilitates chloride movement into the interstitium. The ion transports in the ascending loop of Henle are critical for proper function of the countercurrent mechanism in the renal medulla. The ascending loop of Henle tubule is not permeable to water, and fluid in the lumen becomes progressively diluted (Figure 17-2). About

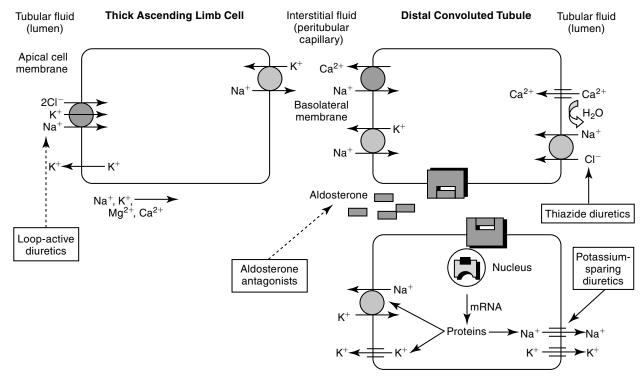

25% of sodium-chloride reabsorption and 40% of potassium reabsorption occurs in the ascending loop of Henle, although only about 15% of the filtrate is reabsorbed in this region.² In contrast to the proximal tubules, Na⁺-H⁺ exchange does not appear to occur in the loop of Henle, and little if any bicarbonate is processed.

Reabsorption of water and electrolytes in the distal tubule and collecting ducts is variable. Sodium and chloride are reabsorbed against a concentration gradient. Because the early distal tubule is impermeable to water, an unfavorable concentration gradient is generated that limits the effectiveness of a sodium pump. Sodium and potassium contents in the urine are closely regulated by an aldosterone-sensitive mechanism in the distal late tubule (see Figure 17-2). Aldosterone signals the synthesis of a protein that increases the sodium and potassium permeability of the luminal membrane. As sodium moves in, potassium simultaneously moves from the interstitium into the cell. Electrogenic movement of sodium into the cell causes an electronegativity in the lumen that attracts potassium from the cell. Whether potassium is reabsorbed or excreted is determined primarily by plasma potassium, which in turn tends to depend on dietary intake.²

In the medullary collecting ducts, only small amounts of sodium chloride and potassium are reabsorbed. Antidiuretic hormone increases permeability of the cell membrane to water, which moves from the lumen, following the previously established medullary osmotic gradient. Less than 5% of filtered sodium is reabsorbed in the distal tubule and medullary collecting system under normal conditions.²

Atrial Natriuretic Hormone

Atrial natriuretic hormone (ANH), a "natriuretic factor" first described in 1984, is involved in the control of ECF. It is synthesized from a prohormone and stored as a peptide in granules in atrial myocardial cells. Concentrations increase

Collecting tubule

Figure 17-2 Movement of fluids and electrolytes in the thick ascending loop of Henle, the distal tubule, and the collecting ducts. Sites of action of selected diuretics also are indicated *(dashed lines* reflect inhibited actions, and *solid lines* reflect stimulation). In the ascending loop of Henle, electrolytes, but not water, are able to pass from the lumen into the cells. Up to 25% of the sodium and 40% of potassium is resorbed by way of a countertransport mechanism across a concentration gradient. In addition, chloride is actively transported into the cell. In the distal tubule, aldosterone plays a major role in fluid and electrolyte transport. Aldosterone mediates uptake of luminal sodium; sodium is exchanged for potassium, which is excreted into the lumen. Because of its location distal to most diuretics, efficacy of diurectics may be markedly decreased in high aldosterone states (e.g., congestive heart failure, liver disease). Aldosterone acts through steroid receptors. Like most steroidal compounds, the effects of aldosterone depend on nuclear transcription of effector proteins.

above baseline when either the ECF expands, blood pressure increases, or dietary salt intake increases. Renal blood flow and glomerular filtration are subsequently increased. Sodium excretion also increases, presumably by a direct tubular action. Peripheral vasodilation can result in decreased blood pressure. Effects occur rapidly but are not sustained, suggesting that ANH is a mechanism that can restore equilibrium rapidly.²

Reduction of ECF is beneficial in conditions associated with inappropriate fluid retention such as in certain cardiac, renal, and liver diseases. Although the cause of ECF expansion differs in each disease, the commonality is salt and water retention. Because sodium is the primary cationic constituent of ECF, sufficient renal excretion of sodium ultimately reduces ECF.

DIURETIC THERAPY

Therapeutic Use of Diuretics

Three strategies exist for movement of inappropriate fluid accumulation (edema): correction of the underlying disease (often not possible), restriction of dietary or other sodium intake, and administration of diuretics. Of these, diuretics remain the cornerstone for treatment of edema or volume overload, particularly that which is life threatening.¹ Although diuretics increase the rate of urine formation, their therapeutic indications include maintenance of urine flow; mobilization and reduction of inappropriate ECF stores, such as that manifested as edema or ascites; correction of specific ion imbalances; reduction in the rate of intraocular fluid formation; reduction of blood pressure; and reduction of pulmonary capillary wedge pressure.²

Targets of Diuretic Therapy

Diuretics are classified by their mechanism of action and include the loop diuretics, carbonic anhydrase inhibitors, thiazides, osmotic diuretics, and potassium-sparing diuretics (Figure 17-3, Table 17-1). Rational selection of diuretics relies on an appreciation of their mechanisms of action. With the exception of the osmotic diuretics and carbonic anhydrase inhibitors (the latter targets sodium bicarbonate), each class targets sodium or chloride reabsorption of tubular cells, effectively preventing the establishment of the normal ion gradient by renal tubular cells.¹⁻³ Diuretics that increase net urinary excretion of sodium chloride or sodium bicarbonate also are referred to as *natriuretic*. The efficacy and use of each class of diuretics varies with their site of action and the

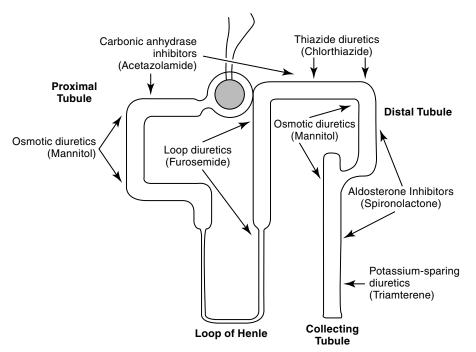

Figure 17-3 Site of action of selected diuretic classes within the nephron.

mechanism by which sodium reabsorption is inhibited. The mechanisms of sodium resorption that are targeted by diuretic therapy vary in location within the renal tubule and include electrogenic passive diffusion (proximal and late distal tubule and collecting system); exchange with hydrogen (generated by the actions of carbonic anhydrase and bicarbonate reabsorption); co-transport with glucose, organic acids, and phosphate (proximal tubule); reabsorption along with chloride reabsorption (late proximal tubule); and co-transport with chloride and potassium (by way of the thick ascending limb of the loop of Henle, which results in formation of medullary interstitial hyperosmolarity).

KEY POINT 17-1 Rational selection of a diuretic should be based on the underlying pathophysiology and the mechanism of action of the drug. Differences in patient disposition and response may require increased dosing or shorter intervals.

Principles of Diuretic Therapy Use

Several principles can guide diuretic therapy⁴: (1) The pattern of electrolyte excretion varies with the class of diuretic. (2) Maximal response to each drug class is limited by the site of action of the diuretic; as such, assuming drug delivery to the site of action has been appropriate, diuretic failure will occur to all members of the same drug class. class. (3) The combination of two (or more) diuretics with different mechanisms of action should cause additive and may cause synergistic effects.²

When used to reduce ECF volume, the selection of the most appropriate diuretic should be based on the cause of ECF volume retention. Diuretic selection for the patient with acute renal failure also should take into account the ability of the diuretic to reach the target tissue despite reduction in renal blood flow. The impact of the direct or indirect actions of the diuretic on systemic sequelae beyond decreased ECF volume (e.g., metabolic acidosis, hypokalemia) should be considered. Several diuretics also influence renal physiology by virtue of their effects on renal vasculature and may be preferred during states of reduced renal blood flow. Finally, several diuretics target physiologic processes that are not unique to the kidney (i.e., carbonic anhydrase inhibitors) and thus may be used therapeutically for reasons other than diuresis.

Factors Limiting Response to Diuretics

Two types of tolerance to diuretic therapy have been described in human patients. Short-term tolerance, or "braking," occurs after the first dose and probably reflects a response to protect intravascular volume. Restoration of diuretic-induced loss of volume will resolve this type of tolerance. Long-term administration of loop diuretics can cause tolerance that reflects hypertrophy of the distal nephron in response to prolonged exposure to increased solute concentration. Sodium reabsorption increases accordingly, decreasing diuresis. Because thiazides target regions of the nephron that hypertrophy, a combination of thiazides with loop-acting diuretics results in a synergistic diuretic response in some human patients.

Several other factors may negatively affect response to diuretic therapy. Most diuretics are present at physiologic pH as uncharged molecules or organic ions and reach the renal tubular cell by active tubular secretion. The degree of ionization can affect the rapidity with which drugs are transported to renal receptors. Declining renal blood flow can preclude drug delivery to the site of diuretic action. For drugs that must reach distal sites (e.g., thiazides), it may be necessary to double doses to achieve a clinical response. For each diuretic a threshold (in drug concentration) must be reached before diuresis will occur. Lack of response may reflect simply an underdose for that patient, and dose titration is indicated. With renal disease characterized by proteinuria, many diuretics will remain bound to plasma proteins present in the tubular lumen and thus will remain inactive. Administration of the diuretic with albumin appears to facilitate response to diuretics in human patients with edema associated with the nephrotic syndrome. Resistance to diuretic therapy also may reflect the presence of another drug that decreases response. For example, nonsteroidal antiinflammatory drugs (NSAIDs) can alter intrarenal prostaglandin regulatory mechanisms, and a number of drugs compete for active tubular secretion of the diuretic into the tubular lumen.

In addition to their direct tubular effects, all diuretics indirectly influence renal tubular function. Accommodation to the effects of a diuretic in a normal animal may result in the

Drug	Indication	Dose	Route	Interval (hrs)
Chlorothiazide	Diuretic	10-40 mg/kg	РО	12
	Partial antidiuretic hormone (ADH) deficiency/diabetes insipidus	20-40 mg/kg	РО	12
Chlorpropamide	Partial antidiuretic hormone (ADH) deficiency/diabetes insipidus	10-40 mg/kg (D)	РО	24
Demeclocycline	Inappropriate antidiuretic hormone (ADH) secretion	3-12 mg/kg	РО	6-12
Dopamine hydrochloride	Renal vasodilator: (acute renal failure)	2-5 μg/kg (low dose) in 5% D/W	IV CRI	
Ethacrynic acid	Diuretic, pulmonary edema	0.2-0.4 mg/kg	IM, IV	4-12
Furosemide	Diuresis with acute renal failure	5-20 mg/kg	IM, IV, PO	8-12 or as needed. Adjust to lowest dose possible
	Hypertension	1-2 mg/kg; maximum of 8 mg/kg for acute renal failure	РО	12
	Hydrocephalus, brain edema	0.5-2 mg/kg	РО	12
	Ascites from hepatic failure	1-2 mg/kg	PO, SC	12-24
	Hypercalcemia	1-2 mg/kg	IM, IV, PO, SC	8-12
		5 mg/kg	IV	As needed
		2-5 mg/kg	IV	To effect
		0.1-1 mg/kg	IV CRI	
Hydrochlororthiazide	Diuretic	2-4 mg/kg (D)	РО	24
	Antihypertensive agent	0.5-2 mg/kg	РО	12-24
	Nephrogenic diabetes insipidus	0.5-5 mg/kg	РО	12
	Hypoglycemia	2-4 mg/kg (D)	РО	12 (with diazoxide)
		2-4 mg/kg	РО	12
Mannitol 20%	Oliguric renal failure	0.25-0.5 g/kg of a 15% to 25% solution	IV (over 15-60 min)	Repeat every 4-6 hr if necessary
	Glaucoma	1-3 g/kg	IV (over 15-20 min)	Repeat every 4-8 hrs if necessary
	Central nervous system edema	1.5 g/kg	IV	Once
Spironolactone	Ascites	1-2 mg/kg (D); maximum of 4 mg/kg	РО	12
	Diuretic, heart failure	2-4 mg/kg	РО	24
		1-2 mg/kg (D)	РО	12
	Primary hyperaldosteronism, hepatic insufficiency	1 mg/kg (C)	РО	12
		12.5 mg (C)	РО	24
Spironolactone/ hydrochlorothiazide	Diuretic, antihypertensive agent	2 mg/kg	РО	12-24
Triamterene	Diuretic	1-2 mg/kg (D)	РО	12

loss of any pharmacologic effect several days after the start of diuretic therapy. Response to any diuretic will be modulated by internal homeostatic mechanisms that normally direct body fluid volumes and osmolar concentrations. For example, if a diuretic fails to cause a net sodium excretion (such as occurs with mannitol), ECF contraction will increase the concentration of electrolytes, stimulating water intake and replenishment of the lost volume.² Refractoriness to thiazides can develop rapidly as a result of salt-retaining mechanisms being activated. Edema (ascites) associated with liver disease

ECF.² Finally, refractoriness to diuretic therapy may reflect pharmacokinetic changes. The oral bioavailability of some diuretics (e.g., furosemide) is quite variable in human patients and unpredictable in the individual patient. It may be necessary to try several doses before the most effective one is found. Some diuretics (spironolactone, amiloride) are more effective after metabolism by the liver, although this also may be species dependent. Although the elimination half-life of several diuretics is sufficiently long to allow twice-daily elimination (in human patients), several of the loop diuretics are characterized by an elimination half-life of 2 to 3 hours. For such drugs the pharmacologic effect is decreased once the drug is no longer present. Rebound reabsorption of sodium by the nephrons has been described in such cases, suggesting that constant-rate intravenous infusion may provide better response. In addition, in patients that are not responding well, small increases in diuresis in the presence of the drug potentially will be magnified to clinically significant increases if the response is continuous.

may not respond to diuretic therapy because signals from the

cirrhotic liver indicate a depleted rather than an exaggerated

Refractoriness to diuretic therapy can be approached by cage rest (which may improve renal circulation), an increase in the dose of the diuretic, intravenous administration, the use of a more effective diuretic (such as a loop-active diuretic), or a decrease in interval such that the drug is present at the site for a longer period of time (constant infusion). For constantrate intravenous infusion, a loading dose (full to double dose) should be given, followed by a maintenance dose given each hour. Continued refractoriness should lead to the addition of a second diuretic that works through a different yet complementary mechanism of action (e.g., thiazides with a loop-acting drug).

DIURETICS

Osmotic Diuretics

Osmotic diuretics increase the osmolality of extracellular fluid, enhancing flow of water from tissues to interstitial fluid and plasma. For a solute to act as an osmotic diuretic, it must be freely filtered at the glomerulus, not reabsorbed by the renal tubule, and be pharmacologically and metabolically inert. Mannitol (Figure 17-4) is the most commonly used osmotic diuretic; others include urea, glycerol, and isosorbide. As the concentration of an osmotic diuretic increases in the renal tubular lumen, osmotic forces overcome the movement of water with sodium into the renal tubular cell. Eventually, as water retention in the urine increases, sodium concentration decreases and passive sodium reabsorption is reduced. Sodium loss is, however, relatively small. Although mannitol appears to work throughout the renal tubule, the principal site of action appears to be the loop of Henle (see Figure 17-3).¹ Mannitol is distributed to ECF and thus extracts water

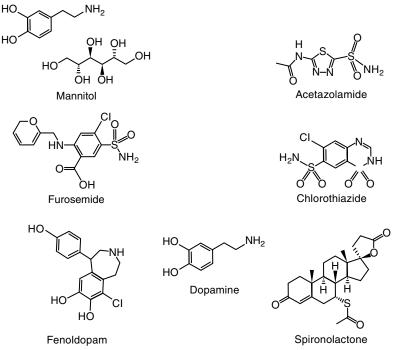

Figure 17-4 Chemical structures of selected diuretics.

from intracellular compartments, increasing ECF, decreasing blood viscosity, and inhibiting renin release.¹ The impact on intracellular compartments is therapeutically beneficial in patients with cerebral edema and glaucoma.¹ Renal blood flow increases, removing NaCl and urea from the renal medulla and decreasing renal medullary tonicity. Medullary tonicity also may be reduced further by a prostaglandin-mediated increase in renal medullary blood flow. Mannitol is not absorbed after oral administration. In humans it is characterized by an elimination half-life of approximately 1 hour.

KEY POINT 17-2 Osmotic diuretics will be useful for reducing intracellular edema only if they surround but do not enter the target cell.

The major adverse effect of osmotic diuretics is increased ECF, which can be detrimental in patients with pulmonary edema or cardiac failure. Hyponatremia resulting from water extraction causes headaches, nausea, and vomiting in human patients.¹ In contrast, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics generally are contraindicated in anuria of severe renal disease or in patients that are not responsive to test doses. Mannitol and urea also are contraindicated for patients with active cranial bleeding. Glycerin (but not mannitol) can be metabolized, causing hyperglycemia.

Mannitol is most commonly used to treat acute renal failure resulting from an acute reduction in glomerular filtration or acute changes in renal tubular permeability. Mannitol provides protection to the tubules in that it attenuates reduction in glomerular filtration rate (GFR) associated with acute tubular nephrosis if the drug is administered before an ischemic insult.1 Efficacy (experimentally) for treatment of nephrotoxicity, however, is documented only when administered before the toxin; clinical efficacy is even less obvious. Mannitol is particularly indicated for treatment of toxic nephrosis because the concentration of the toxin in the urine will be reduced by the osmotic draw of water by the solute. In contrast to diuretics that act on tubular segments, osmotic diuretics usually maintain their effect in the oliguric state that accompanies acute renal failure because they will continue to be filtered by the glomerulus. If the tubular cell becomes permeable, however, as may occur with certain toxins or prolonged tubular ischemia, the osmotic diuretics may lose their efficacy. Yet in patients with acute tubular nephrosis, mannitol may convert an oliguric patient to a nonoliguric state.1

Mannitol is distributed to ECF and thus is not effective in movement of fluids from interstitial tissues. ECF volume will initially increase and may prove detrimental to the patient with decompensated cardiac function. Plasma osmolality increases after treatment with mannitol. Cerebrospinal fluid (CSF) and aqueous humor formation subsequently decrease. Whether mannitol will cross the blood-brain barrier is unclear. However, because mannitol is distributed into interstitial fluids but does not penetrate cell membranes, intracellular edema will also be reduced. As such, mannitol is used to treat selected causes of cerebral edema associated with increased intracellular fluid volume. The use of mannitol for treatment of acute brain injury is discussed in Chapter 27. A Cochrane review failed to find conclusive evidence regarding its efficacy, although the number of eligible clinical trials for review was limited.⁵ Mannitol can be used to decrease brain mass before neurosurgery. The use of mannitol to facilitate diagnosis of ureteral obstruction has been described.⁶

Carbonic Anhydrase Inhibitors

Two types of carbonic anhydrase are located in the proximal tubule, both targeted by carbonic anhydrase inhibitors: type II, located in the cytoplasm; and type IV, located in the luminal and basolateral membranes (see Figure 17-1). In the lumen, H+ (generated from the Na⁺-H⁺ transporter) reacts with HCO₃⁻ to form H₂CO₃, which, in the presence of brush border carbonic anhydrase, rapidly decomposes to water and CO₂. The CO_2 rapidly diffuses into the tubular cell, where it reacts with water to form H₂CO₃. This reaction normally proceeds slowly but is markedly accelerated by carbonic anhydrase in the cytoplasm. Because intracellular H⁺ is low (because of Na⁺-H⁺ co-transport), H₂CO₃ spontaneously ionizes to form H⁺ and HCO₃⁻. An electrochemical gradient moves Na⁺HCO₃⁻ into the interstitial space, with water following. Chloride becomes concentrated in the lumen and diffuses down its gradient into the interstitium (see Figure 17-1).¹ Carbonic anhydrase inhibitors target both the cytoplasmic and membrane-bound carbonic anhydrase, completely impairing NaHCO₃ reabsorption in the proximal tubule (see Figure 17-3). The collecting tubule is a secondary target. As a result, urine concentrations of bicarbonate increase, and up to 35% of the filtered load is excreted. Because hydrogen ions are not generated by the conversion of bicarbonate to CO₂ and H₂O, they are not available for exchange with sodium. Thus the amount of acid and ammonia excreted in urine also decreases. The loss of titratable acid and ammonia secretion in the collecting duct results in an increase in urinary pH to approximately 8 and the potential development of metabolic acidosis.¹ At least 65% of sodium bicarbonate is reabsorbed through carbonic anhydrase-independent mechanisms. Sodium and chloride not reabsorbed in the proximal tubule are delivered to the loop of Henle, where most of the chloride and sodium subsequently are absorbed. Up to 70% of potassium is excreted because of the increased sodium load. Bicarbonate remains in the urine, contributing to alkalinity. Ultimately, however, much of the bicarbonate that remains in the proximal tubular lumen is resorbed distally in the nephron by mechanisms that are not well understood.

Several sequelae result from the diuretic mechanism of carbonic anhydrase inhibitors. First, metabolic acidosis develops as bicarbonate is lost in the proximal tubules. Second, the filtered load of HCO_3^- decreases to the point that the uncatalyzed (spontaneous) reaction between CO_2 and water leads to HCO_3 reabsorption. This in turn decreases the response of the renal tubule to carbonic anhydrase inhibitors. Thus the diuretic effect of these drugs is self-limiting. However, in patients refractory to alternative diuretic therapy, the combination of acetazolamide with diuretics that block sodium resorption distally may result in marked naturiesis. Thus carbonic anhydrase inhibitors may be useful for combination therapy.¹ In the distal tubule, as sodium is reabsorbed, potassium excretion markedly increases. Carbonic anhydrase is located in other tissues. Aqueous humor and CSF formation are both decreased by carbonic anhydrase inhibitors. Accordingly, the major indication for their use is glaucoma. The effect in the eye is direct and is not influenced by metabolic acidosis. The effect of carbonic anhydrase inhibition in the brain is not as well understood and may result from both the direct effects and the development of metabolic acidosis. Although carbonic anhydrase also is located in the gastric mucosa, only large doses of inhibitors reduce gastric acid secretion. Carbonic anhydrase activity in red blood cells will be impaired, causing an increase in CO₂ levels in peripheral tissues and decreased levels in expired air. Carbonic anhydrase can increase delivery of solutes to the macula densa. Tubuloglomerular feedback may be triggered, increasing afferent arteriolar resistance and reducing renal blood flow and GFR.

Side effects of carbonic anhydrase inhibitors are not common. Large doses may cause drowsiness. Side effects can also result from urinary alkalinization or metabolic acidosis. Hepatic encephalopathy can be induced as renal ammonia is diverted from the urine. Precipitation of calcium phosphate may cause calculus formation. Respiratory or metabolic acidosis can be worsened. Carbonic anhydrase inhibitors are contraindicated in patients with cirrhosis or other causes of hepatic encephalopathy or conditions associated with acidosis. The impact of carbonic anhydrase inhibitors on urinary pH can reduce the rate of excretion of weak bases.¹

Acetazolamide (Figure 17-4) is a potent, reversible inhibitor of carbonic anhydrase. Its primary indication in veterinary medicine is for the treatment of glaucoma with the intent to decrease aqueous humor formation. It is used less commonly to control CSF formation in patients with hydrocephalus or other causes of increased cerebral fluid pressure. Acetazolamide is characterized by some antiepileptic activity, although tolerance rapidly develops to this effect. Occasionally, acetazolamide might be used to alkalinize the urine. Indications might be for selected causes of crystalluria and to facilitate excretion of weakly acidic drugs, such as phenobarbital, and salicylate. Because its efficacy is self-limiting, combination with sodium bicarbonate may be indicated if persistent urinary alkalinization is desired.

Acetazolamide is orally bioavailable, with peak concentrations occurring within 2 hours after administration. The drug is eliminated by active tubular secretion with some passive reabsorption. In humans the drug is totally eliminated in 24 hours. The drug is relatively safe, although metabolic acidosis may occur (is is usually self-limiting). In patients with hepatic encephalopathy, alkaline urine may increase the amount of urinary ammonia reabsorbed because a greater proportion will be un-ionized. This may result in exacerbation of neurologic dysfunction, and this drug should not be used in patients with severe hepatic dysfunction. Acetazolamide decreases iodide uptake by the thyroid gland (perhaps similar to other sulfonamide antibiotics) and should be avoided in hypothyroid patients or patients undergoing thyroid testing. Whether the drugs can render a euthyroid patient hypothyroid is not known. Drugs that depend on urine acidity are less effective when used with acetazolamide. This includes urinary antiseptics such as methenamine, which is rarely if ever indicated in veterinary medicine; efficacy of weakly acidic antibiotics might also be impaired, whereas that of weak bases will be enhanced.

Methazolamide is among the orally administered carbonic anydrase inhibitors used to treat glaucoma in dogs. Its impact on intraocular pressure and aqueous humor flow rate was described in Beagles receiving a single dose of 25 or 50 mg (10 dogs per group; 5 control) followed by multiple twice-daily dosing for 9 days.⁷ A diurnal difference in intraocular pressure was measured in all animals, being highest in the morning. At 25 and 50 mg, intraocular pressure decreased in the morning but increased in the evening compared with baseline. Compared with baseline, aqueous humor flow rate increased in both groups. Although response to 50 mg (compared with 25) was greater for both intraocular pressure and aqueous humor flow rate, the difference was not significant, perhaps reflecting a small sample size.

Thiazide Diuretics

The thiazide diuretics, represented by chlorothiazide (see Figure 17-4), were developed to enhance the potency of carbonic anhydrase inhibitors.¹ Although most do inhibit carbonic anhydrase to some degree, their efficacy as diuretics reflects their ability to directly inhibit sodium chloride co-transport in the distal tubule, perhaps by competing with chloride for binding (see Figure 17-2).¹ Newer diuretics have been developed that act at the same site as the thiazides but are not thiazides; the term thiazide-like diuretics is applied to these latter drugs. The primary site of action of these drugs also is the distal tubule (see Figure 17-3), a site characterized by avid binding for thiazide diuretics. Although some action has also been described in the proximal tubule, this may reflect the weak carbonic anhydrase action of these drugs. Compared with other diuretics, the thiazide diuretics are less effective in causing sodium excretion because close to 90% of reabsorption of sodium from the urine has occurred by the time passage through the distal and collecting tubules is complete. Because the tubular site of potassium secretion is distal to the site of thiazide action, potassium excretion is increased and more sodium is reabsorbed. Thiazides have variable effects on calcium excretion, with excretion decreasing with chronic administration. Thiazides cause magnesium excretion, and the potential advent of hypomagnesia is being recognized in humans receiving thiazides long term.¹

The thiazides vary in their oral bioavailability, with that of chlorothiazide being the poorest (10% bioavailable in humans). The degree of protein binding varies among the drugs, and thus delivery to the kidneys via glomerular filtration may be limited. Active tubular secretion of the drugs can be antagonized by probenecid. Likewise, the elimination halflife of the drugs is also variable, with that of chlorothiazide being very short (1.5 hours in humans). For hydrochlorothiazide bioavailability (in humans) is 65%, whereas the elimination half-life is 2.5 hours. Thus the duration of diuretic effect is quite variable. The potency also is variable, with chlorothiazide 10 times more potent than hydrochlorothiazide. Thus doses also are quite variable.

The thiazide diuretics are characterized by a wide safety margin, and clinical toxicity is rare. As with the loop diuretics, most serious toxicities reflect overzealous use. Volume depletion, hypotension, hyponatremia, hypochloremia, hypomagnesemia, and hypercalcemia have been reported. Potassium depletion can be clinically significant, particularly in patients with primary or secondary hyperaldosteronism. Oral potassium supplementation is indicated for patients that become hypokalemic; this is particularly important for patients receiving digoxin because the risk of digoxin toxicity is enhanced in the hypokalemic patient. Alternatively, the thiazides can be used in combination with a potassium-sparing diuretic. Like the carbonic anhydrase inhibitors, thiazides may exacerbate neurologic dysfunctions associated with cirrhotic liver disease. Thiazides appear to diminish the effects of insulin, particularly in the hypokalemic patient, and should not be given to patients with diabetes mellitus.

Thiazides are involved in a number of drug interactions. They can diminish the effectiveness of anticoagulants, uricosuric drugs (for treatment of gout), and insulin and may increase the effects of anesthetics, digitalis glycosides, lithium, and vitamin D. Thiazides do provide additive or synergistic effects when combined with loop diuretics. Efficacy of the thiazides is decreased by NSAIDs and methenamines (because of alkalinization of urine). Hypokalemia induced by the thiazides may be worsened by amphotericin B or corticosteroids. Quinidine has reportedly caused lethal drug interactions with thiazides by causing ventricular tachycardia; however, this may reflect thiazide-induced hypokalemia.¹

Thiazides are used primarily in the treatment of early congestive heart failure. Although they may be less effective as diuretics, thiazides, in contrast to most other diuretics, minimally affect the composition of ECF. Thiazides may directly decrease glomerular filtration, particularly after intravenous administration. Thus they should not be given to patients with compromised renal function. Thiazides decrease renal excretion of calcium and are contraindicated in patients with hypercalcemia. In contrast, bromide excretion may be facilitated, and thiazides may be useful for treatment of bromide toxicity.

Drugs That Interfere with Renal Epithelial Sodium Transport

Potassium-Sparing Diuretics

Diuretics that are not associated with kaliuresis include the aldosterone antagonists (see later discussion), triamterene, and amiloride.¹ The primary indication for the latter drugs is their ability to spare potassium wasting. Because they cause only a small amount of sodium wasting, however, they usually are combined with another diuretic. Both triamterene and amiloride impair electrogenic sodium reabsorption in the late distal tubule and the collecting systems, after much

sodium reabsorption has already occurred. Because the normal electrical potential across the tubular epithelium is lost, the driving force for potassium secretion is reduced. The potassium-sparing effects of these drugs are most effective in the patient whose potassium excretion has markedly increased (i.e., by hyperaldosteronism or therapy with potassium-wasting diuretics). Like the thiazides, amiloride decreases calcium excretion into the urine. The impact of either triamterene or amiloride on renal hemodynamics is minimal.

The drugs are orally bioavailable (50% to 60% in human patients). Both triamterene and amiloride are actively secreted into the proximal tubule (the route by which they reach their site of action), although a portion of triamterene undergoes hepatic metabolism to a metabolite that is active in humans. Both liver disease and hepatic disease can increase the risk of adverse reactions to triamterene. The most serious toxicity is hyperkalemia that is more likely to occur in a patient receiving angiotensin-converting enzyme inhibitors or aldosterone inhibitors. As such, the drugs are contraindicated in patients at risk for or already have developed hyperkalemia. NSAIDs and dietary potassium intake increase the risk of hyperkalemia. As a pteridine derivative, triamterene is a weak folic acid antagonist. Folic acid deficiency leading to megaloblastic anemia has been reported in human patients with cirrhosis.¹ Triamterene also can reduce glucose tolerance. Amiloride, like triamterene, can cause gastrointestinal upset (vomiting, diarrhea). In general, these drugs are not effective diuretics unless combined with another diuretic and, usually, thiazides.

Aldosterone Antagonists

Aldosterone and mineralocorticoid agonists cause sodium and water retention in exchange for potassium and hydrogen excretion.¹ Spironolactone (see Figure 17-2) competitively antagonizes the actions of aldosterone and other mineralocorticoids by binding to the receptor such that it is not active. The site of action is limited to the late distal tubule and the collecting duct (see Figure 17-3). Aldosterone causes sodium and water retention by interacting with mineralocorticoid receptors. Interaction with specific DNA sequences results in the expression of multiple gene products called aldosteroneinduced proteins. The proteins appear to activate or increase the expression of preexisting yet "silent" sodium channels and pumps in the cell membrane. Sodium moves into the cell from the luminal membrane, causing an electronegative lumen that is conducive to potassium excretion. As such, spironolactone (see Figure 17-4) is effective as a diuretic only in the presence of aldosterone, and efficacy will be impaired in the presence of high concentrations of aldosterone. In addition to several segments of the nephron, aldosterone receptors occur in the colon and salivary glands. Unlike the thiazides and carbonic anhydrase inhibitors, spironolactone causes calcium excretion in the urine. Spironolactone has no effect on renal hemodynamics. However, it has a variety of effects on the diseased myocardium. The recently discovered beneficial effects of spironolactone on both acute myocardial damage⁸ and chronic cardiac remodeling⁹ are briefly discussed in Chapter 14 Spironolactone conceivably should be the drug of choice in high aldosterone states such as congestive heart failure or portal hypertension, but its efficacy is less than that of the loop-acting diuretics. Consequently, sole therapy with spironolactone occurs early in the respective syndrome or in combination with other diuretics. Supporting its early use in patients with congestive heart failure is the recognition that, in these patients, spironolactone promotes magnesium and potassium retention, increases uptake of myocardial norepinephrine, attenuates formation of myocardial fibrosis, and decreases mortality associated with both progressive ventricular dysfunction and malignant ventricular arrhythmias.^{10,11} Indeed, its apparent positive effects of decreasing mobidity and mortality rates led to early termination of a clinical trial examining these effects in humans.¹⁰

KEY POINT 17-3 Because of its site of action, spironolactone might enhance the efficacy of any naturietic that acts proximal to its site of action in the distal tubule (see Figure 17-3).

Spironolactone is 60% to 70% bioavailable (in humans), is highly protein bound, and undergoes extensive first-pass metabolism and enterohepatic circulation.¹ In humans spironolactone is characterized by a short half-life (1.4 hours). Its active metabolite (canrenone, which is available outside of the United States as canrenoate, a prodrug of canrenone); however, has an elimination half-life that is much longer (16.5 hours). It is not clear what proportion of the drug is metabolized to the active metabolite in dogs and cats. Spironolactone (or other mineralocorticoid receptors) are the only diuretics that do not require access to the tubular lumen in order to cause diuresis (although the active metabolite apparently does).¹

The most serious toxicity of spironolactone, like other potassium-sparing diuretics, is hyperkalemia, which is more likely to occur when the drug is given in combination with potassium-wasting diuretics and oral potassium supplementation. The contraindications and side effects that characterize the potassium-sparing diuretics also pertain to spironolactone. In addition, spironolactone has induced metabolic acidosis in patients with cirrhosis. Diarrhea, gastritis, gastric bleeding, and peptic ulceration have been reported in human patients receiving the drug; consequently, it is contraindicated in patients with gastric ulceration. Central nervous system adverse effects such as drowsiness, lethargy, ataxia, and confusion have been reported in human patients. Androgen side effects (e.g., gynecomastia impotence) have been reported in human patients. Finally, the ability of spironolactone to induce malignancy has been raised.¹ Aspirin (salicylates) reduce the efficacy of spironolactone by competing for active tubular secretion. Spironolactone alters the elimination of digitalis glycosides.

Spironolactone is most commonly used to control edema associated with hyperaldosteronism. It is generally, however, combined with either a thiazide or a loop-acting diuretic. Edema associated with hypertension and liver disease are among the more common indications. Spironolactone is the drug of choice for treatment of edema associated with chronic liver disease (secondary to hyperaldosteronism) in human patients.¹ Rarer indications include syndromes associated with potassium depletion.

High-Ceiling Diuretics

The efficacy of diuretics acting on the proximal tubule is limited by the marked reabsorptive capacity of the thick ascending limb of the loop of Henle. Diuretics that act beyond the loop of Henle also are limited in efficacy because only a small percentage of the filtrate reaches that area. In contrast, drugs that act at the loop of Henle tend to be very effective.¹ The term high ceiling refers to the peak diuretic effect of these drugs, which far surpasses that of other diuretics. The primary site of action is the thick ascending limb of the loop of Henle, where the drugs bind to and impair the luminally located Na+K+2Clco-transport mechanism (see Figure 17-2). Because of their site of action, these drugs also are referred to as loop diuretics.¹ Two isoforms of the Na⁺K⁺Cl⁻ co-transport enzyme exist with the second isoform located in the apical membrane of the thick ascending loop. The second is located in many body tissues.¹² The efficacy of high-ceiling loop diuretics reflects the large amount of filtrate that reaches this region of the kidney and the lack of a very efficient reabsorptive region beyond the loop. Ethacrynic acid is a phenoxyacetate derivative, and furosemide is a sulfonamide derivative (see Figure 17-4). Furosemide is the member of this class used in small animal patients. Abbott and Kovacic12 reviewed the use of furosemide in veterinary medicine.

Furosemide causes a profound increase in Na⁺ and Cl⁻ urinary excretion. Ultimately, as ECF decreases in response to furosemide, glomerular filtration decreases and proximal tubular reabsorption of sodium is enhanced. Species differences should be expected in response to furosemide. Dogs respond across a broad therapeutic range. Cats respond in a narrower range, but with a more rapid and intense saluresis and diuresis compared with dogs.¹² Doses in cats greater than 10 mg/kg, administered intramuscularly, may be associated with lethargy and decreased appetite that may last 24 to 48 hours after dosing. In dogs the dose above which intolerance occurs is 50 mg/kg, administered intramuscularly. Blood pressure will decline in both species at these doses, with hypotension more profound in cats.¹² Morbidity at higher doses may reflect volume contraction, hypotension, electrolyte abnormalities, and activation of neurohumoral endocrine responses. At massive doses furosemide inhibits carbonic anhydrase activity in the proximal tubule, but this minimally affects diuretic actions at normal doses. Like the thiazides, the mechanism of action of furosemide is proximal to the site of Na⁺ and K⁺ exchange; thus potassium excretion is increased. Furosemide also markedly enhances the excretion of calcium and magnesium but does not increase calcium reabsorption in the distal tubule, as do the thiazides. Thus furosemide is indicated for treatment of hypercalcemia, although care must be taken to replace sodium and chloride losses. Because furosemide increases the excretion of acid and ammonia in the distal nephron, diuretic-induced metabolic alkalosis may develop. This can be exacerbated if ECF is rapidly mobilized such that

its volume contracts. The kidney's ability to excrete a concentrated urine during hydropenia or a dilute urine during states of water diuresis is impaired by furosemide.

KEY POINT 17-4 In addition to its loop-diuretic effects, furosemide is useful for a variety of other physiologic effects, particularly in the vasculature

Furosemide will increase renal blood flow if volume depletion is avoided. The effect is, however, variable. NSAIDs attenuate the diuretic response to loop diuretics, perhaps by altering prostaglandin-mediated increases in blood flow. Loop diuretics block tubuloglomerular feedback, presumably by inhibiting transport of NaCl to the macula densa.¹ Because of this effect, they also are powerful stimulants of renin release; prostaglandin (prostacyclin) release may be involved in this response. During states of volume depletion, renin activation also may reflect stimulation of the sympathetic nervous system and of intrarenal baroreceptor mechanisms.

Loop diuretics, particularly furosemide, increase venous capacity, possibly because of prostaglandin release. Although this effect is short lived, it enhances the initial diuretic response. This effect is likely to be blunted or inhibited by NSAIDs, including newer drugs that are more potent toward COX-2 compared with COX-1. Decreased peripheral vascular resistance also has been reported.¹² The hemodynamic effects of furosemide may be of particular benefit in the patient with pulmonary edema: The capacity of veins increases, and left ventricular filling pressures subsequently decrease. Impaired electrolyte transport in other tissues generally is clinically irrelevant, with the exception of the endolymph, which may contribute to the ototoxicity characteristic of this group of diuretics. The pulmonary effects may contribute to potential efficacy in the treatment of the acute respiratory distress syndrome or acute lung injury (the latter when combined with albumin). In the dog furosemide dilates gastrointestinal vascular beds.12

Furosemide appears to be renoprotective in states of ischemic damage; this may reflect a reduction in oxygen consumption in response to inhibition of co-transport. However, it also has antioxidant effects and protects against free radicals at low doses (0.1 mg/kg/day in rats).¹² Nonetheless, the use of furosemide in acute renal failure has not been consistently demonstrated to reduce patient mortality rates in humans.¹²

Furosemide has a variety of actions other than vascular in the lungs. It attenuates bronchospasm in response to a number of stimuli and stimulates bronchodilation. Furosemide inhibits laryngeal irritant receptors in anesthetized dogs. Clinical signs of dyspnea may be relieved with inhaled furosemide.¹²

Interestingly, furosemide appears to have anticonvulsant properties. Its mechanism may reflect an increase in threshold and decreased seizure propagation. Intraneuronal chloride may be maintained; this may reflect interaction with potassium chloride co-transport enzymes. Interaction may impart neuroprotection. Seizure-induced cellular swelling may be reduced.¹² Furosemide may reduce production of CSF. The target enzymes are present in the choriod plexus. A 50% reduction in CSF has been reported in cats treated with 50 mg/ kg intravenously. However, furosemide should not be used to reduce CSF or intracerebral pressure in the presence of or at a dose sufficient to induced hypotension.¹² Furosemide has been associated with a decrease in intracranial pressure but is more effective if it follows a dose of mannitol.¹² In contrast to thoracic lymph flow, furosemide appears to decrease ascitic transudate from selected neoplasms.

Furosemide is rapidly absorbed from the gastrointestinal tract. Bioavailability is only about 60%, however, ranging from 10% to 100% in the individual patient. Thus several different oral doses must be given before therapeutic failure can be assumed. Intravenous administration is indicated in patients for whom lack of response due to oral absorption must be avoided. Alternatively, a drug that is 100% bioavailable after oral administration (e.g., bumetanide or torsemide in human patients) should be given. Furosemide is highly protein bound, which limits delivery through the glomerulus, but it is able to reach its site of action by active tubular secretion.

The most common toxicity associated with furosemide therapy generally reflects overzealous administration, resulting in altered electrolyte and fluid balance. Depletion of body sodium can cause hypotension, reduced GFR, circulatory collapse, and thromboembolic episodes. In the patient with liver disease characterized by activation of the renin-angiotensinaldosterone system, furosemide can induce hepatic encephalopathy. Continued Na⁺ delivery results in continued exchange for H⁺ and K⁺, causing hypochloremic alkalosis. Hypokalemia likewise can occur, particularly in patients with insufficient dietary intake or patients receiving digoxin therapy. Hypomagnesemia and hypocalcemia are less common, albeit possible, consequences of overzealous furosemide therapy.1 Furosemide depletes total body iodide, which may be of benefit in states of hyperiodism.¹² Because of its impact in the developing fetus, furosemide is not recommended in pregnant or lactating animals. Furosemide increases lymph flow through the thoracic duct in dogs at 8 to 10 mg/kg. Accordingly, it might be avoided in animals with pleural effusion. Ototoxicity can lead to tinnitus (in human patients), deafness, vertigo, and (described in humans) "a sense of fullness in the ears." Ototoxicity most commonly occurs with rapid intravenous administration, more with ethacrynic acid than with furosemide, and generally is reversible. Contraindications for furosemide therapy include severe Na⁺ or volume depletion, hypersensitivity to sulfonamides, and anuria that has not responded to a test dose of furosemide. In human patients furosemide should not be used during pregnancy. Chronic use of furosemide may result in renal hypertophy.12 The impact of furosemide on mucociliary transport rates is controversial, with some studies showing a detrimental effect.¹² Avoidance of furosemide in patients with inflammatory lung disease, particularly that which is associated with airway secretions, is prudent. Although it contains a sulfur moiety, furosemide does not contain an aryl amine (see Chapters 4 and 7), and patients that are allergic to sulfonamides are not likely to show a cross-reactivity to furosemide. However, cross-allergy has been reported, albeit rarely, in humans. The sulfur moiety may play a role in pancreatitis,

which has been reported rarely in humans.¹² Furosemide may directly inhibit insulin secretion; however, this effect is species specific, occurring in dogs and humans but not mice.

Drug interactions involving furosemide may become clinically important. Furosemide is chemically incompatible with a number of drugs (demonstrated for diazepam, dopamine, dobutamine, metoclopramide, and morphine). As such, its use as a constant-rate infusion should be through its own line and not "piggybacked" onto lines containing other drugs. When administered as a constant-rate infusion, furosemide will likely have to be diluted. Stability has been demonstrated for at least 8 hours when diluted fivefold (to a concentration of 10 mg/mL) in either 5% dextrose, lactated Ringer's solution, 0.9% saline, or sterile water.¹³ Dilution to 5 mg/mL with water or 5% dextrose is also apparently safe, but 0.9% saline or lactated Ringer's solution may result in cloudiness. Presumed precipitation with the latter probably reflects decreased solution pH.

Because it is highly protein bound (in humans), furosemide may compete with other drugs for protein-binding sites; clinically relevant interactions have been attributed to competition. For example, anticoagulant activity may be enhanced in the presence of furosemide. Other drugs known to interact with furosemide, perhaps because of competition for protein binding, include propranolol and lithium (both characterized by higher plasma drug concentrations). Competitive binding may affect thyroid function tests; initial displacement of thyroxine, causing higher free concentrations, may negatively inhibit thyroid-stimulating hormone.¹² The freed thyroxine will be cleared more rapidly and thus may not be interpreted as high. It is possible that total thyroxine will decrease; the low thyroidstimulating hormone may be interpreted as hypothyroid.

Potential ototoxicity induced by furosemide is enhanced by aminoglycosides (synergistic) and cisplatin. The risk of cardiac arrhythmias induced by digoxin also are increased by furosemide. Both NSAIDs and probenecid block diuretic response to furosemide, the former perhaps resulting from attenuation of response to renal prostaglandins and the latter from competition for active tubular secretion. In contrast, the thiazides act synergistically with furosemide to induce diuresis. The nephrotoxic potential of other drugs (e.g., cephalosporins, aminoglycosides) is enhanced by furosemide.

Furosemide is used for a variety of indications (see Table 17-1). Treatment of hypertension is limited to animals that have not responded to other therapies. Among the most common indications is edema of a variety of causes that reflect increased hydrostatic pressure and potentially decreased oncotic draw. However, edema associated with vascular permeability generally is not an indication; fluid loss in such cases generally is at the cost of decreases in total body water.

Furosemide is the drug of choice for the management of acute pulmonary edema. Its use in the long-term management of sodium retention might be postponed until other, less effective diuretics become ineffective. Edema associated with the nephrotic syndrome appears to respond only to loop diuretics. For the patient with refractory edema, furosemide can be combined with other diuretics, preferably potassium sparing, such as the thiazides or spironolactone. Doses much higher than normal may be necessary to induce diuresis in patients with renal disease for two reasons. First, renal tubular function is abnormal, and response to furosemide may be impaired. Second, drug delivery to the site of action may be decreased. Administration as a constant-rate infusion (0.66 mg/kg load followed by 0.66 mg/kg/hr) will induce more diuresis, natriuresis, and calciuresis but less kaliuresis compared with intermittent bolus administration.¹⁴ An advantage of constant-rate infusion is avoidance of toxic concentrations that have been associated with ototoxicy in humans. Because of its effects on iodine depletion, it may be useful in the cat with hyperthyroidism before radioiodine treatment, facilitating uptake, as has been demonstrated in humans receiving 40 mg/kg/day for 5 days. Its use as an adjunct to surgery or to control thyroid storm in hyperthyroid cats warrants consideration.

Proteinuria caused by glomerular nephritis may also reduce the efficacy of furosemide because it binds to protein in the urine. The massive doses necessary for acute renal failure may cause hepatotoxicity. Once oliguria has been definitively established, furosemide therapy should be discontinued. Because loop diuretics interfere with the kidney's ability to produce a concentrated urine, when combined with hypertonic saline, furosemide can be used to treat life-threatening hyponatremia. The use of furosemide to facilitate diagnosis of ureteral obstruction also has been described.⁶

Pressor Agents

Drugs that increase cardiac output should, by virtue of increased renal blood flow and glomerular filtration, increase urine output. Among the pressors used to support myocardial depression and hypotension is the positive inotrope dopamine (see Chapter 14). Dopamine receptors in the renal vasculature of several species induce renal vasodilation, with the effect accomplished at low doses of dopamine. Higher doses cause release of epinephrine and subsequent renal arterial vasoconstriction. Dobutamine does not have a similar effect in the renal vasculature. Consequently, dopamine may be the preferred inotropic drug in the face of hypotension that threatens renal function. However, Sigrist¹⁵ has retrospectively reviewed the role of dopamine in acute renal failure, including meta-analyses assessment in humans. In humans many of the studies cited for use have been implemented in animal models or healthy individuals. Because mortality does not change, the incidence of side effects no longer justifies its use. The lack of consistent response in the presence of disease may reflect receptor desensitization; further, profoundly ill patients are likely to realize changes in pharmacokinetics and pharmacodynamics that increase the risk of adversity. Finally, it is not clear if increase urine production stimulated through hemodynamic changes is in fact a positive response or if urine production is an indicator of improvement. Effects in animals are more likely to be realized in animal models of acute renal failure when administered in advance of the insult.

KEY POINT 17-5 Dopamine receptor activity of the feline kidney is different from that of the canine kidney and accordingly is less responsive to dopamine. Species differences exist in the renal response to dopamine. Although dopamine receptors are present in the feline renal cortex, their numbers are lower compared with those of other species.¹⁶ The cat is among the species for which diuretic doses of dopamine do not cause renal arterial vasodilation, perhaps because of fewer dopamine receptors in the renal vasculature. Higher doses of dopamine do increase diuresis and natriuresis.¹⁷

Fenoldopam (see Figure 17-4) is a dopamine DA-1 agonist with no α or β adrenergic receptor effects used for treatment of emergency hypertension in humans. It also stimulates systemic vasodilation, natriuresis, and diuresis in human patients with renal disease.¹⁸ Renoprotection has been described, supporting its use in acute renal failure.^{19,20} In a dog exsanguination²¹ or aortic clamp (n = 8 Labrador Retrievers)¹⁹ models, fenoldopam (0.1 µg/kg/min) maintained renal blood flow before, during, and after induction of acute hypovolemia.²¹ Zimmerman-Pope and coworkers²² attempted to study the impact of fenoldopam on renal function after nephrotomy but found that the model insufficiently affected renal function. Unlike dopamine, feline kidneys respond to fenoldopam. It exhibited a 300-fold greater affinity for feline dopamine receptor, compared with dopamine, suggesting that feline vasculature contains the receptors but lacks dopamine.¹⁷ Wohl and colleagues²³ found no effect of low-dose (3 µg/kg/min) dopamine on indices of renal diuresis (urine output, renal blood flow, sodium excretion, fractional excretion, or creatinine clearance) in anesthetized healthy cats (n = 12). Arterial blood pressure did transiently decrease. In contrast, Simmons and coworkers²⁰ found that feline kidneys responded to fenaldopam. Ketamine and diazepam were used to induce anesthesia for instrumentation purposes only; healthy awake cats were studied (n = 6). A 12-hour pretreatment assessment of baseline (an infusion of 2.2 mL/kg/hr of saline) was followed by fenoldopam infusion over 2 hours $(0.5 \ \mu g/kg/min)$. Parameters were then studied for 12 hours. Fenoldopam increased urine output, sodium excretion, and fractional excretion (with comparable changes in urine specific gravity); creatinine clearance also increased after a transient decrease. The effects were delayed: GFR was increased at 6 hours after fenoldopam administration, coinciding with increases in urine output. Central venous pressure simultaneously decreased. Studies in humans thus far have not clearly demonstrated a beneficial effect of fenoldopam in patients with acute renal failure; further studies are indicated.

THE USE OF DIURETICS IN SELECTED CLINICAL CONDITIONS

Congestive Heart Failure

The intial diuretic selection for human patients with mild congestive heart failure is a thiazide; however, most patients will require a loop diuretic. In human patients the rate of oral absorption of diuretics is slowed, requiring longer to maximal response. Delivery of loop diuretics to their site of action is normal, and doses do not necessarily need to be increased unless there is evidence of renal insufficiency. Renal response to diuretic therapy may be decreased, however, requiring more exposure to drugs. Although a dose increase may be indicated, a decrease in interval may be more likely to cause a response. A thiazide diuretic should be added to therapy if dietary salt retention coupled with a loop diuretic have not been effective. Attention should be paid to ensure that hypokalemia and volume depletion do not occur with this combination. The use of spironolactone may increase as its effects on cardiac remodeling are further described.

KEY POINT 17-6 In patients with congestive heart failure, care must be taken with diuretics to avoid overzealous therapy that may stimulate neurohumoral endocrine responses.

Cirrhosis

Ascites that accompanies cirrhotic liver disease generally reflects a state of hyperaldosteronism and subsequent sodium and water retention. Therefore spironolactone is the diuretic of choice for human patients. Although the amount of diuresis can be expected to be only moderate, this is desirable because greater diuresis may negatively affect intravascular volume. In human patients repeated large-volume paracentesis minimizes the need for more potent diuretics. The active metabolites of spironolactone allow once-daily dosing, although 3 to 4 days must elapse before full pharmacologic effects are realized. Insufficient response to spironolactone indicates the need for an additional diuretic; spironolactone should be continued. For human patients a thiazide is used initially, and a loop diuretic is used in place of the thiazide only if response has been inadequate. The decreased response to a loop diuretic in a patient with cirrhosis is not understood but does not reflect decreased drug delivery. Rather, the tubular cells do not respond maximally. Although higher doses may be of benefit, decreasing the interval may be more likely to increase response.

Nephrotic Syndrome

Response to diuretics in patients with the nephrotic syndrome may be less than ideal if hypoalbuminemia is sufficient to decrease binding of the diuretic (e.g., <2 g/dL). Unbound drug will diffuse into tissues (i.e., volume of distribution will increase), removing the drug from the site of action in the renal tubule. In such patients addition of albumin to the therapeutic regimen will increase response. Binding to albumin in tubular fluid also decreases response and is more likely to occur when urine albumin concentrations exceed 4 g/dL. Dose increases (twofold to threefold) may help compensate for increased tubular binding of the diuretic. Because tubules in patients with nephrotic syndrome may not respond to drugs in general as well as those in the normal patient, decreasing the interval (such that the duration of exposure is longer) also may increase response.

DRUGS THAT ALTER RENAL CONSERVATION OF WATER: ANTIDIURETIC HORMONE

Antidiuretic hormone (ADH) is released by the posterior pituitary in response to increased plasma osmolality (as little as 2%, or 280 mOsm/kg) and depleted ECF volume. The latter might occur, for example, resulting from acute causes such as hypovolemia, sodium depletion, and hemorrhage or chronic causes such as cardiac failure, hepatic cirrhosis with ascites, hypothyroidism, and excessive use of diuretics.. Antidiuresis involves the hypothalamus, neurohypophysis, posterior pituitary, and kidney. Neurons of osmoreceptors, baroreceptors, and higher cerebral centers stimulate the hypothalamus. Calcium-mediated degranulation results in the release of ADH as well as oxytocin and other mediators. A number of chemical mediators are also associated with the release of ADH, including angiotensin II, prostaglandins, and acetylcholine. Inhibitors of release include opioids, atrial natriuretic peptide, and γ -aminobutyric acid.

The actions of ADH are receptor mediated. At least two receptors have been identified. Both receptors are located in the kidney, although the specific tissue site varies. Glomerular, vasa recta, and interstitial medullary receptors (V1) participate in the control of the GFR, medullary blood flow, and prostaglandin synthesis, respectively. The predominant effect of ADH occurs in the collecting duct and is mediated by V2 receptors. In the presence of ADH, the collecting ducts of the cortex and medulla become permeable to water, which follows the osmotic drag.

A number of therapeutic drugs can alter ADH secretion either directly or indirectly. Drugs that alter the osmolality of urine may indirectly alter the secretion of ADH. Drugs that stimulate ADH secretion include the vinca alkaloids, cyclophosphamide, tricyclic antidepressants, and isoproterenol. Inhibitors of ADH secretion include ethanol, mineralocorticoids, and glucocorticoids. The effect of mineralocorticoids results from volume depletion that accompanies sodium loss. Inhibition by glucocorticoids, on the other hand, probably results from both a central effect and cardiac effects. Drugs that inhibit prostaglandin synthesis also will facilitate the action of ADH. Lithium is an example of a drug that inhibits the effects of ADH.

DRUGS THAT ALTER URINARY pH

Urinary acidification or alkalinization depends on normal renal function. Changes in urine pH are at best modest, and the effect on systemic acid-base status is equally modest. In the face of renal deficiency, the use of acidifying salts may be harmful. Changes in urinary pH are implemented to enhance efficacy of a drug in the urine, to enhance solubility of a drug or other solute in the urine, to facilitate urinary excretion of a toxin, or to promote an unfavorable environment for microbial growth. Excretion of an acidic compound is likely to be enhanced if the pK_a of the compound is within the range of 3 to 7.5; for a basic compound a pk_a 7.5 to 10.5 is necessary.

Urinary Acidifiers

Ammonium chloride is a urinary acidifier. Ammonium ion (NH_4^+) serves as a proton donor. Ammonia (NH_3) formed by the kidney is excreted in an acid urine as the ammonium ion. In states of acidosis, renal production of ammonia is stimulated, increasing the concentration of a proton acceptor, thus

buffering urinary acid by allowing secretion of protons in tubular fluid. The ammonium of orally administered ammonium chloride is converted by the liver to urea, freeing hydrogen ion, which subsequently decreases bicarbonate. Thus efficacy depends on hepatic conversion of ammonia to urea. Of the urinary acidifiers, ammonium chloride probably provides the most consistent changes in pH. The use of ammonium chloride is contraindicated in hepatic insufficiency.

Acetohydroxamic acid (5 mg/kg every 8 hr orally) is structurally similar to urea that acts as a potent and irreversible inhibitor of bacterial urease. It has been used in humans as adjuvant therapy to treat urinary tract infections associated with urease-producing bacteria (e.g, *Staphylococcus, Klebsiella, Corynebacterium urealyticum,Pseudomonas*, and *Providencia*). Approximately 15% of patients have had laboratory findings characteristic of a hemolytic anemia; accordingly, care might be particularly taken in cats.

Other urinary acidifiers include DL-methionine, ethylenediamine dihydrochloride, and sodium acid phosphate. Methemoglobinemia has been reported in cats receiving phosphate-containing urinary acidifiers.

Cysteine Urolithiasis

Cystinuria also is generally accompanied by increased urinary excretion of lysine, arginine, and ornithine in the urine. Cystine is a non-esssential amino acid composed of two cysteine amino acids joined at their sulfur atoms. It can be synthesized in the body from the essential amino acid, methionine. Cystine solubility in urine decreases as pH increases, predisposing to urolith formation. Cysteine urolithiasis represents a small proportion of uroliths in the dog (1% to 22%).²⁴ Cystinuria appears to decline with age in dogs with uroliths.²⁴ Therapies have been variable in choice and effect. Dietary management has included low methionine or sodium diets, the latter reducing the transport of cysteine into the urine in return for sodium.²⁴ Pharmacologic management has included conversion of cysteine to a more soluble compound with the heavy metal chelator D-penicillamine or tioproinin. However, side effects limit the successful use of D-penicillamine. The use of tioproinin has been reported in an open study of 88 dogs with cystinuria and uroliths.²⁴ Dogs in which uroliths had been removed were treated with 30 mg/kg, and dogs with uroliths present received 40 mg/kg orally every 12 hours. Treatment duration ranged from 1 month to 13 years (mean 2.8 years), with the median less than 1 year. Stones resolved in 63% of dogs receiving tioproinin, with the mean time to dissolution being 1.6 months. However, uroliths re-formed in 12 of the dogs (between 3 to 36 months) receiving tioproinin prophylactically at 30 mg/kg, with dissolution occurring in five of those when the dose was increased to 40 mg/kg. Side effects occurred in 12% of animals, with the most common being myopathy related to chewing or swallowing and aggression. Disconcertingly, proteinuria (n = 3) and thrombocytopenia (n = 4)also were reported. The authors emphasized the potential importance of lifelong therapy.

Because the potential for cysteine crystal formation is enhanced in an acidic urinary pH, one strategy for prevention of cysteine uroliths has been an increase in urinary pH. Urine pH should be sustained at or above 7.5 to dissolve or prevent the formation of cystine uroliths. Although sodium bicarbonate can be used to maintain an alkaline urine pH, dietary sodium may enhance cystinuria in humans. Further, alkalinization was not a successful treatment in six cysteinuric dogs also receiving tioproinin.²⁴ Thus potassium citrate may be the preferred urinary alkalinizer in patients with cystine uroliths.

Calcium Oxalate Urolithiasis

Close to 50% of urinary calculi in cats are calcium oxylate rather than struvite, with cats older than 7 years of age more commonly afflicted.²⁵ Uroliths composed of calcium are difficult to dissolve with diet or medications.²⁶⁻³⁰ Medications that alter urine concentrations of calcium are likely to detrimentally alter normal calcium homeostasis. Thiazide diuretics decrease renal excretion of calcium by virtue of their effect on the Na-Cl transporter: decreased intracellular sodium results in increases calcium reasorption via the Na⁺/Ca2⁺ countertransporter. Volume contraction results in both sodium and calcium reabsorption. Potentiation of the effects of parathyroid hormone on tubular reabsorption of calcium may also be beneficial. Although human patients suffering from normocalcemic hypercalciuria benefit from thiazide therapy, efficacy in comparable small animal patients has not been established. Thiazides may prove useful for patients whose hypercalciuria is associated with normocalcemia but are contraindicated for hypercalcemic patients. Hypokalemia is a potential undesirable side effect of thiazide therapy and can be prevented by oral administration of potassium citrate.

Potassium citrate therapy may also benefit the patient with calcium oxalate urolithiasis. Citrates complex with calcium to form salts that are more soluble than oxalate salts. Citrate also is metabolized to bicarbonate, which may alkalinize the urine, and in dogs, may increase citrate excretion in the urine. Low concentrations of citrate occur in up to 63% of patients with calcium oxalate urolithiasis, but a similar role has not been identified in dogs or cats. Potassium citrate is available in a wax matrix, slow-release preparation. Delayed absorption results in prolonged maintenance of urine citrate concentrations. Potassium citrate is more likely to be effective in dogs with calcium oxalate urolithiasis if hypocitraturia can be documented. Dosing regimens may be guided by measuring urinary pH, which should be maintained at or above 7. Vitamin B_6 (2 to 10 mg/kg every 24 hours) and B_{12} (1 mg/kg every 24 hours) has been recommended to decrease oxalate urolithiasis although clinical trials supporting this use are controversial. Supplementation may be indicated in cases of potential vitamin B deficiency (e,g., senior cats with bowel disease). Dietary management and encouragement of fluid intake (including slightly salting the diet) also are recommended.

Anaerobic microbial oxalate degradation in the gastrointestinal tract appears to be an important mechanism by which the incidence of hyperoxaluria occurs. Deficiency of *Oxalobacter formigenes* may be associated with calcium oxalate. Supplementation of gastrointestinal flora with the organism in human volunteers was associated with a reduction in urinary oxylate excretion, which suggests that this may be an alternative therapy.³¹

Urate Urolithiasis

In addition to low-protein diets, dissolution of urate stones can be facilitated by urine alkalinization and administration of allopurinol.²⁶⁻³⁰ Urinary pH should be maintained at 7 to 7.5 with oral sodium bicarbonate or potassium citrate. Allopurinol competitively inhibits xanthine oxidase, the enzyme that forms uric acid from xanthines. Plasma and thus urinary concentrations of uric acid are decreased. Because serum concentrations of xanthine increase with allopurinol therapy, urinary alkalinization is recommended with allopurinol therapy in human patients suffering from gout to prevent the formation of xanthine stones. Although allopurinol is recommended for treatment of Dalmatian urate urolithiasis, its use for patients with urate stones associated with portosystemic shunting should be implemented cautiously because the efficacy of allopurinol depends, in part, on hepatic metabolism. Alkalinization also is not recommended for these patients because of the potential for hepatic encephalopathy. The disposition of allopurinol has been described in Dalmations.³² After oral administration of 10 mg/kg, peak plasma concentrations (C_{max}) was 6.43 ± 0.18 µg/mL at 3 hours, and the elimination half-life approximated 2.5 to 3 hours. A dosing regimen was not recommended by the authors because of the variability of hyperuricosuria in dogs and the lack of determination of a dose-response relationship to identify a target therapeutic concentration.

Although generally safe, allopurinol is associated with several adverse effects in humans. Included are cutaneous reactions; fever and malaise; and sequelae of drug interactions. Sequential urine urate: creatinine ratios have been advocated for monitoring response to dietary and medical management of urate urolithiasis. A controlled study in healthy dogs, however, found no relationship between random urine samples and 24-hour quantitation of uric acid excretion.³³ Thus 24-hour uric acid measurements probably provide the best means for evaluating response to therapy. Note, however, that urates are easily crystallized and may be difficult to measure in urine. Medications should be continued at least 4 weeks after radiographic evidence of stone dissolution. If dissolution is not evident by 6 to 8 weeks, it is possible that the stones are composed of materials other than urate.

MANAGEMENT OF ACUTE RENAL FAILURE

Pathophysiology

Acute renal failure results from a sudden, severe decline in renal function, which may be initiated by prerenal, renal, or postrenal causes. Although several specific renal diseases can cause acute renal decompensation, in veterinary medicine acute intrinsic renal failure is most commonly caused by a nephrotoxicant or an infectious or ischemic injury. The proportionately high blood flow and large capillary surface area in the kidney increase the organ's sensitivity to blood-borne toxicants. Additionally, the sophisticated transport mechanisms, intensive metabolic activity, and refined concentrating mechanisms found in renal tubules increase the likelihood of toxic injury. Glomeruli, too, are susceptible to direct destruction and immunologic injury. The most common nephrotoxicants encountered in veterinary medicine are ethylene glycol and therapeutic agents such as aminoglycosides, amphotericin B, cisplatin, radiographic contrast agents, and analgesics.

Additional nephrotoxins include lilies, which are toxic in cats only, and raisins and grapes, which are toxic in dogs.¹

Ischemic injury may result from any insult that compromises perfusion of afferent arteriolar blood flow. Hypoperfusion from shock, dehydration, or hypotension is the most common mechanism of renal ischemia. Trauma, anesthesia, cardiac output failure, and persistent vomiting or diarrhea are potential ischemic events encountered in small animals. Thrombosis, hyperviscosity, and polycythemia are additional, less common disorders that interfere with renal blood flow. Angiotensinconverting enzyme (ACE) inhibitors, widely used in the management of congestive heart failure in dogs and proteinuric disorders, inhibit production of the vasopressor angiotensin II. In the glomerulus angiotensin II blockade preferentially dilates efferent arterioles, which may lead to loss of glomerular capillary pressure and reduction in glomerular filtration (see Chapter 14). The vasodilatory effect is most prominent in diseased or poorly perfused kidneys and can lead to progressive azotemia or overt acute renal failure in treated patients.^{2,3}

The administration of nonsteroidal antiinflammatory drugs (NSAIDs) may inhibit vasodilatory prostaglandin production in the kidneys. The effect of NSAIDs is minimal in healthy kidneys but can be devastating when superimposed on marginally functioning kidneys, hypovolemia, or other vasoconstrictive states (anesthesia, surgery, sepsis, heart failure, liver failure, nephrotic syndrome).⁴ In these disorders renal blood flow and glomerular filtration rate become increasingly dependent on prostaglandin synthesis; administration of NSAIDs can precipitate renal ischemia and failure. Many systemic diseases increase the risk of acute renal failure by ischemic or vascular mechanisms. These disorders include pancreatitis, hepatic failure, immune-mediated hemolytic anemia, heat stroke, disseminated intravascular coagulopathy, rickettsial disease, babesiosis, and bacterial endocarditis.^{5,6}

Both toxicant and ischemic insults to nephrons lead to impairment of cellular transport mechanisms, cellular swelling, and death. Cellular hypoxia and intracellular calcium overload lead to additional membrane damage and oxygen free radical formation. Vascular congestion and tubular obstruction result from cellular swelling and act as common mechanisms perpetuating renal ischemia and renal failure.⁷ Therapeutic measures employed in acute renal failure attempt to support renal excretory function, attenuate cellular damage, and favor renal recovery.

General Considerations in Management

Goals of management of established acute renal failure are to (1) treat or minimize underlying disease processes; (2) correct fluid, electrolyte, and acid–base disorders; (3) initiate a diuresis; (4) manage systemic complications; and (5) establish a prognosis. The first principle in managing any disease process is to "treat the treatable." In acute renal failure "treatable" problems may include dehydration or hypovolemia, postrenal obstruction, cardiac or hepatic disease, leptospirosis, rickettsial disease, bacterial endocarditis, pyelonephritis, hypercalcemia, renal lymphoma, and hemoglobinuria. Early recognition of potential toxicant-induced renal failure allows for treatment with specific antidotes (e.g., 4-methylpyrazole or ethanol for ethylene glycol) or with nonspecific measures such as gastric lavage, fluid therapy, and cathartics. Administration of any potentially nephrotoxic agents should be stopped.

KEY POINT 18-1 Early recognition and treatment of reversible disease, appropriate fluid therapy, and maintaining urine production are the keys to medical management of acute renal failure.

Fluid Therapy

After identification of underlying disorders, the management of acute renal failure relies largely on management of fluid, electrolyte, and acid–base imbalances. Fluid deficits are estimated (estimated percentage dehydration × body weight in kilograms = liters required) and replaced rapidly, within 4 to 6 hours. Initial fluid choices include 0.9% saline or other replacement solutions. Low-sodium fluids such as 0.45% saline/2.5% dextrose or half-strength lactated Ringer's solution in 2.5% dextrose may be used for patients with cardiac insufficiency or hypernatremia. Fluids for maintenance requirements (40 to 60 mL/kg per day) and ongoing losses (polyuria, vomiting, diarrhea) should be added to the daily fluid total. In most cases rehydration fluid requirements will equal two to three times maintenance requirements; careful calculation of deficits and ongoing needs is recommended to prevent underestimation of fluid needs (Table 18-1).

Urine output should be measured during the rehydration phase to document appropriate diuresis and to calculate future fluid requirements. After adequate volume replacement, urine output should reach at least 1 to 2 mL/kg per hour. Oliguric patients, in which urine output is less than 1 mL/kg per hour, require additional treatment. If the animal is not overhydrated, mild volume expansion may be considered. Administration of an additional 3% to 5% of the animal's body weight in fluid should eliminate any remaining, undetected volume deficits and enhance renal perfusion and glomerular filtration rate (GFR).⁸ If volume expansion is attempted, the patient must be carefully monitored for signs of overhydration, including inappropriate weight gain, systemic hypertension, increased bronchovesicular sounds, tachypnea, tachycardia, restlessness, chemosis, and serous nasal discharge. Note that dry mucous membranes can be a consequence of uremia and are not good indicators of hydration status in acute renal failure.9 Appropriate volume expansion is documented by a modest increase in body weight and modest reductions in the hematocrit and plasma protein concentrations. Volume overload is a common complication of fluid therapy in oligoanuric renal failure patients. Roughly two thirds of dogs and cats referred for hemodialysis management of uremic crises are hypervolemic. Without dialytic support this complication can be difficult to reverse unless urine production increases.9

KEY POINT 18-2 Fluid therapy must be tailored to the individual patient, based on variable urine production and ongoing losses. If urine production is poor, significant adjustments in fluid rate and pharmacologic treatments are usually necessary.

Methods to Enhance Urine Production

If urine production remains poor after rehydration and volume expansion, pharmacologic manipulation of oliguria is warranted. Furosemide, dopamine, and osmotic diuretics have been standard options for management of oliguric and anuric renal failure despite a lack of clinical studies confirming efficacy (see Chapter 17 and for dopamine, see Chapter 14). Despite the lack of proven clinical efficacy, furosemide (2 to 3 mg/kg intravenously every 6 to 8 hours) is often chosen as an initial treatment for oliguria because it is readily available and easy to administer. A constant-rate infusion (CRI) of furosemide (1 mg/kg per hour) has also been recommended.^{8,10}

As a loop diuretic, furosemide helps increase tubular flow and improve renal blood flow but does not significantly affect GFR.⁷ It is also speculated that the activity of furosemide may

Agent	Actions	Dosage	Adverse Effects	Contraindications
Agents Used to Enha	ance Urine Production			
Furosemide	Loop diuretic ↑ RBF	2-3 mg/kg IV q 6-8h 2-6 mg/kg IV q 30-60 min 0.25-1 mg/kg/h IV CRI	Volume depletion, hypoka- lemia	Gentamicin, nephro- toxicity

Table **18-1** Drugs Used in the Management of Acute Renal Failure

RBF, Renal blood flow; IV, intravenous; GFR, glomerular filtration rate; CRI, constant-rate infusion; GI, gastrointestinal; ECF; extracellular fluid; CNS, central nervous system.

protect cells of the thick ascending loop of Henle by reducing active transport at this site. Furosemide may be useful in managing overhydration and hyperkalemia and enhancing toxin elimination in acute renal failure.⁹ Furosemide has been shown to exacerbate gentamicin toxicity and should be avoided in patients recently treated with aminoglycosides.¹¹ If urine output does not increase in 30 to 60 minutes, furosemide may be repeated at 4 to 6 mg/kg intravenously at 30- to 60-minute intervals; concurrent dopamine administration should also be considered. The efficacy of furosemide in reversing oliguria appears to be improved with the concurrent administration of dopamine.¹² Dopamine in this instance may improve delivery of furosemide to sites of activity. If diuresis is established with furosemide administration, intravenous bolus doses may be repeated every 6-8 hours or a CRI can be maintained at 0.25 to 1 mg/kg/hr.⁹ In healthy Greyhounds a furosemide infusion resulted in more diuresis, natriuresis, and calciuresis and less kaliuresis than bolus doses.¹³ High-dose furosemide did not increase survival rates in people with acute renal failure in a prospective, double-blinded, randomized placebo-controlled trial.¹⁴ An influence on survival in cats and dogs has not been established. Extracellular fluid volume and potassium requirements should be carefully addressed during furosemide treatment.

Dopamine is a catecholamine (a norepinephrine precursor) that in low doses causes increases in renal blood flow. In dogs dopamine acts at specific splanchnic and renal receptors to cause efferent arteriolar vasodilation, enhancing renal blood flow and sodium excretion. Dilation of mesenteric, coronary, and intracerebral vascular beds also is expected. Effects on GFR are modest.¹⁵ In cats dopamine appears to stimulate α -adrenergic receptors, leading to increased blood pressure and natriuresis.¹⁶ Dopamine must be administered as a CRI, ideally with an automated fluid infusion pump. Dopamine is administered diluted in nonalkaline fluids, usually normal saline or dextrose solutions. Infusion rates of 1 to 5 µg/kg per minute are recommended. Infusion is usually started at 1 to 2 $\mu g/kg$ per minute while the patient is monitored for changes in heart rate or rhythm. Tachycardia, ectopic or premature ventricular beats, nausea, vomiting, and hypertension are adverse effects, predominantly seen at higher doses. The pressor effects of dopamine are variable and can be detrimental to renal function; monitoring of urine output and degree of azotemia is imperative in individual patients. The half-life of dopamine is approximately 2 minutes; effects are withdrawn within 10 minutes after the infusion is discontinued. The drug is metabolized to inactive compounds by monoamine oxidase and catechol-O-methyltransferase in the kidney, liver, and plasma.¹⁷ Recent prospective, randomized, double-blinded, placebo-controlled trials in humans have failed to show efficacy of low-dose dopamine in management of acute renal failure. Dopamine may also cause detrimental gastrointestinal, respiratory, endocrine, and immunologic effects.¹⁸ Use of dopamine for management of acute renal failure has fallen out of favor, except as needed for pressor response.

Fenoldopam and other new selective dopamine subtype DA-1 receptor agonists may more effectively increase renal blood flow in dogs⁸ and possibly in cats. Results of these selective dopaminergic compounds have not been reported in clinically affected patients in acute renal failure.

KEY POINT 18-3 The primary benefit of diuretic administration is to increase urine production and simplify management. Minimal, if any, benefits on glomerular filtration rate or survival are likely.

Osmotic diuretics currently represent the optimal pharmacologic option for enhancing urine flow. Osmotic agents such as mannitol enhance urine production by increasing both intravascular volume and tubular fluid flow. Mannitol is freely filtered at the glomerulus and poorly reabsorbed in renal tubules, creating an osmotic effect such that water is not reabsorbed from the tubular lumen. Osmotic agents also prevent tubular and vascular obstruction by minimizing cellular swelling. Mannitol also possesses weak renal vasodilatory and cellular free radical scavenging actions.¹⁹ Adverse effects of mannitol infusion include volume overload and pulmonary edema, gastrointestinal upset, and central nervous system effects (usually at high doses). The drug is contraindicated for overhydrated or dehydrated patients and for patients with preexisting cardiac disease or suspected intracranial hemorrhage. Mannitol (20% to 25% solution) may be administered at a dosage of 0.5 to 1.0 g/kg intravenously as a slow bolus (over 15 to 20 minutes).²⁰ Another protocol entails administration of partial dosages (0.5 mg/kg each) every 15 minutes for three treatments.²¹ Urine output should improve within 1 hour.

A second bolus may be attempted if the agent is unsuccessful, but the potential for volume overexpansion and edema formation increases. When mannitol is beneficial, intermittent bolus injections (0.5 to 1 g/kg intravenously every 6 to 8 hours) or CRI of a 5% to 10% solution (2 to 5 mL/min) may be given up to 2 g/kg per day.¹³ Lower doses given more frequently (0.25 to 0.5 g/kg intravenously every 4 hours) or a CRI of 1 to 2 mg/kg/ min also have been recommended.⁹ One author recommends maintaining diuresis with an infusion of mannitol diluted in lactated Ringer's solution.⁸

Hypertonic dextrose solutions have been useful as an alternative osmotic agent. Once the renal threshold for glucose transport has been exceeded, dextrose solutions create effects similar to those of mannitol on tubular flow and urine output. Solutions of 10% or 20% dextrose are formulated and administered as intermittent slow boluses of 25 to 50 mL/kg (over 1 to 2 hours) two or three times per day. The initial infusion rate may be as high as 2 to 10 mL/min in order to rapidly create hyperglycemia. The infusion rate may subsequently be dropped to 1 to 5 mL/min.^{21,22} Advantages of dextrose solutions include low cost, availability, and relative safety. Dextrose solutions also provide nominal caloric supplementation. Urine glucose is easily monitored to ensure that sufficient hyperglycemia and filtration of glucose are continuing; urine volume still must be quantitated because glycosuria can occur without significant increases in urine production. Dextrose solutions may be inferior to mannitol in other respects, however, because the osmotic effects on cellular swelling and tubular obstruction will be minimized by intracellular equilibration of glucose across cell membranes, an effect that does not occur with mannitol.8 Hypertonic glucose also lacks the vasodilatory and free radical scavenging effects of mannitol. The rapid movement of glucose intracellularly does, however, minimize the potential development of vascular overload and pulmonary edema.

For patients who become fluid overloaded and have decreased renal output, fluid removal is an essential part of management. Standard treatment in human medicine that is also available for veterinary patients includes peritoneal dialysis and hemodialysis. A promising new treatment is cross-linked polyelectrolyte sorbents. This oral solution can absorb as much as 50 times its weight in gastrointestinal water (up to a liter of fluid in a 30 kg dog) as well as urea, creatinine, and potassium, allowing an alternative to renal excretion of excessive fluid and solutes.²³

The choice of initial treatment protocol for oliguria varies with clinician preference, experience, available technical support, and patient variables. Furosemide or dopamine (or both) historically were employed initially, but this practice must be critically assessed because dopamine may actually cause detrimental effects. Mannitol is probably, however, the preferred agent for treatment of nephrotoxic and ischemic renal failure in patients that are not overhydrated. If one protocol is ineffective, another protocol may be attempted. Polyuric renal failure generally is easier to manage and has a better prognosis than oliguric renal failure. The effects of all measures to reverse oliguria appear to diminish as the duration of oliguria is prolonged.

Management of Hyperkalemia and Metabolic Acidosis

Patients with acute renal failure may be hypokalemic, normokalemic, or hyperkalemic. Hyperkalemia is most likely observed with oliguric or anuric renal failure. Management of hyperkalemia and other electrolyte disturbances is ideally based on serum electrolyte determinations; however, an estimate of potassium status can often be made on the basis of an electrocardiogram. Administration of potassium-free fluids and initiation of a diuresis is usually sufficient to correct mild to moderate hyperkalemia. Longer-term control of mild hyperkalemia may be gained with exchange resins. Sodium polystyrene sulfonate (Kayexalate) is given as a suspension in 20% sorbitol (2 g/kg/day by mouth or by rectum in 3 to 4 divided doses). Nausea, constipation, and gastrointestinal ulceration or erosion are possible complications of this product and have limited its tolerance in veterinary patients.⁹

Peaked T waves, bradycardia, prolonged PR intervals, flattened P waves, and widened QRS complexes may be seen with moderate elevations in serum potassium. Severe hyperkalemia may result in a loss of P waves, idioventricular rhythms, atrial standstill, or ventricular fibrillation and represents a life-threatening emergency. With severe electrocardiographic changes, administration of calcium gluconate (0.5 to 1 mL/kg of a 10% solution given intravenously over 10 to 15 minutes) offers cardioprotective actions. Calcium ions counteract potassium without lowering serum potassium; other measures must be initiated to prevent subsequent cardiac toxicity.²⁴

Bicarbonate administration facilitates an intracellular shift of potassium ions and is another useful initial treatment for moderate hyperkalemia. Sodium bicarbonate is administered as a slow intravenous injection of 0.5 to 2 mEq/kg.²⁴ Alternatively, bicarbonate deficits can be determined on the basis of serum bicarbonate, total CO₂, or base deficit measurement. The deficit is calculated by the formula: $0.3 \times \text{body}$ weight (kg) × base deficit or $(20 - \text{serum bicarbonate or total CO}_2$ concentration). A portion of the deficit (usually one fourth or one half) is given as a slow bolus or in fluids, and the acidbase status is reassessed. An advantage of sodium bicarbonate administration is concurrent correction of coexisting metabolic acidosis. In the absence of hyperkalemia, bicarbonate administration is reserved for severe acidosis (blood pH <7.2 or total CO₂ <12 to 15 mEq/L). Overzealous bicarbonate administration may have serious detrimental results, including hypernatremia, hyperosmolality, ionized calcium deficits, reduced plasma potassium concentrations, metabolic alkalosis, and paradoxical acidosis of the cerebrospinal fluid.

An alternative method of therapy for acute hyperkalemia includes the administration of glucose (dextrose 0.1 to 0.5 g/kg as a 20% solution *or* 1 to 2 mL/kg 50% dextrose diluted to 25%).²⁰ Administration of glucose triggers endogenous insulin secretion; both glucose and insulin facilitate intracellular movement of potassium. Protocols utilizing insulin and glucose (0.25 to 0.5 U/kg insulin followed by 1 to 2 g glucose per unit of insulin administered) have also been recommended. Exogenous insulin administration can promote hypoglycemia; blood glucose monitoring is required. Disorders of calcium are occasionally found in acute renal failure. Hypercalcemia may be a cause of acute renal damage. Calcium levels usually drop with fluid or diuretic administration; investigation into the etiology of hypercalcemia should proceed, however. Severe hypocalcemia is rare except in ethylene glycol intoxication. Alkalinizing therapy may further reduce ionized calcium levels, resulting in symptomatic hypocalcemia. Calcium administration may be necessary in some cases.

Maintenance Fluid Therapy

Once a diuresis has been established, and in cases of nonoliguric acute renal failure, fluid therapy should be tailored to match urine volume and other sensible and insensible losses. Insensible losses (e.g., water lost from respiration) are estimated at 13 to 22 mL/kg per day. Urine output (the most variable sensible loss in patients with renal failure) is quantitated during 6- or 8-hour intervals; the amount lost is replaced during an equivalent period. Ongoing gastrointestinal losses also are estimated and replaced. Some clinicians factor in a 3% to 5% estimate to provide for subclinical dehydration each day, regardless of physical examination findings (except for signs of overhydration). Intervals can be extended as the animal is stabilized.

Fluid composition during maintenance therapy should be tailored to the individual. Polyionic replacement solutions that provide buffering activity and electrolyte replacement (e.g., lactated Ringer's solution, Normosol-R, Plasma-Lyte 56) may be administered during the first few days of treatment, especially if gastrointestinal or electrolyte losses are great. For longer-term therapy, lower sodium solutions designed to meet maintenance fluid needs (e.g., half-strength lactated Ringer's solution or 0.45% saline in 2.5% dextrose, Normosol-M, or Plasma-Lyte 56) are preferred, insofar as most ongoing losses will consist of free water losses in polyuria.⁸ Alternating administration of 5% dextrose solutions with high-sodium replacement solutions may also be effective in preventing hypernatremia in patients requiring long-term fluid therapy.²¹ Potassium supplementation in excess of amounts supplied in commercial fluids is usually required during the maintenance phase of treatment; a total of 20 to 30 mEq KCl per liter of fluid administered is typically sufficient.

Other Considerations

Multiple complications may be encountered during the course of treatment of acute renal failure. Complications are usually a result of uremia and include oral ulceration, vomiting, diarrhea, malnutrition, infection, hemorrhage, anemia, hypertension, and neurologic deterioration. Most of these complications are best ameliorated by minimizing azotemia. Anorexia and vomiting are typically due to activation of the chemoreceptor trigger zone, uremic gastritis, and mucosal intestinal ulceration. Management of gastrointestinal complications of uremia is described in the later discussion of chronic renal failure. Note that metoclopramide and histamine-2 receptor blockers such as ranitidine and famotidine are renally excreted; doses should be modified for severely uremic animals. Aggressive nutritional support may be required in patients with acute renal failure undergoing long periods of treatment. A diet providing 2 to 3 g protein/kg per day and 70 to 110 kcal/kg per day is optimal for critically ill patients with renal failure. A reduced protein diet is designed to minimize uremia and acidosis associated with acute renal failure. In recovering, mildly azotemic patients, a high-protein diet may enhance renal recovery.²⁵

Although often considered a hallmark of chronic disease, anemia may become severe in the course of acute renal failure because of depressed erythropoiesis and hemorrhage. Transfusion support and attention to gastrointestinal or generalized hemorrhage may be needed. Careful attention to aseptic care of intravenous catheters, urinary catheters, and wounds is important to prevent infection in patients with acute renal failure. Neurologic disturbances, including ataxia, stupor, tremors, head bobbing, and seizures, may be observed in animals with severe anemia. Neurologic symptoms may be attributed to hypocalcemia, uremic encephalopathy, cerebral edema, dialysis, or an underlying toxicant (e.g., ethylene glycol). Resolution of uremia, control of hypocalcemia, or administration of low-dose diazepam may be required for management.

Cellular Protectants

Many agents have been investigated as potential cellular protectants or stimulants of cellular regeneration in acute renal failure. Agents such as magnesium, adenosine triphosphate (ATP), thyroxine, and glycine have been considered for their potential to restore intracellular energy stores. Atrial natriuetic peptide (ANP), brain natriuetic peptide (BNP), and other similar peptides increase GFR and have renoprotective effects in ischemic renal injury. ANP has caused severe hypotension in patients with renal failure, but BNP appears to increase GFR without causing systemic hypotension.²⁶ Oxygen free radical scavengers and calcium channel blockers have been investigated as methods of alleviating reperfusion injury in renal epithelial cells. Growth factors may promote cellular repair and regeneration. Most of these agents remain in the experimental stages, however, and have found limited clinical application in human or veterinary medicine. Manipulation of the cell biology of acute renal failure is likely to provide therapeutic options in the future, however.^{27,28}

MANAGEMENT OF CHRONIC KIDNEY DISEASE

Many varied insults can lead to progressive renal dysfunction in small animals. Infectious diseases, obstructive disorders, hypercalcemia, glomerular disease, and some neoplastic disorders may be identified and specific treatment pursued. In many cases, however, a specific etiology is not determined, and management is directed toward alleviation of clinical signs; correction of metabolic consequences; and, ideally, slowed progression of the disease process. Principles of medical management are to (1) stage the disease and pursue appropriate diagnostic strategies, (2) consider renoprotective maneuvers that may retard progression of renal damage, (3) identify and manage sequelae of renal failure (hypertension, anemia, metabolic acidosis, and gastrointestinal ulceration), (4) intervene as necessary in crises, and (5) plan and initiate appropriate monitoring and follow-up evaluations. Excellent reviews of staging criteria and management considerations are available,²⁹ and updated guidelines are available from the International Renal Interest Society (IRIS) at iriskidney.org. In general, dietary and other therapeutic maneuvers should be instituted in a stepwise approach, with serial monitoring implemented to tailor management (Figure 18-1).

Pathophysiology

The clinical and pathophysiologic consequences of renal disease result from complex events set into motion as excretory, homeostatic, and other renal functions are lost. When approximately 66% of total nephron mass is lost, fluid excretion per nephron is increased to facilitate waste excretion. Solute diuresis in remaining nephrons and developing tubular dysfunction lead to polyuria and compensatory polydipsia. As nephron loss progresses to 75% or greater, excretory function is compromised and azotemia develops. With progressive reduction in GFR, excretion of phosphorus and endogenous acids is impaired, leading to hyperphosphatemia, hypocalcemia, metabolic acidosis, and secondary hyperparathyroidism. Diseased kidneys also fail to produce or regulate other important metabolic and endocrine compounds, leading to systemic hypertension, anemia, and a catabolic state. Widespread polysystemic effects of uremia are possible as well, affecting gastrointestinal mucosa, neuromuscular function, cardiopulmonary function, and immunologic function. Management strategies are designed to blunt these effects of progressive renal dysfunction (Table 18-2).

Dietary Strategies

Protein

Reduction in protein intake (compared with protein content of maintenance commercial dog foods) has been advocated for dogs and cats with renal disease. Dietary protein restriction has been advocated on the basis of the hyperfiltration theory of progressive renal disease.³⁰ In rats with induced renal disease, the compensatory response of remaining nephrons includes increases in single nephron blood flow, single nephron filtration rate, and elevated glomerular capillary pressure.³¹ These responses are ultimately detrimental in rodent models, leading to progressive renal injury,³⁰ an effect that can be blunted by reduced protein diets that minimize glomerular hypertension.

Although glomerular hypertension and hypertrophy occur in dogs with experimental renal disease,³² a significant effect of protein restriction alone on the course of renal failure in dogs or cats has not yet been demonstrated.³³⁻³⁶ Reduction in protein intake is undeniably beneficial in moderately to severely affected patients by reducing the production of nitrogenous wastes and acid by-products that contribute to uremia and metabolic acidosis. In such patients (usually with blood urea nitrogen >60 to 75 mg/dL or mmol/L), moderate restriction of protein intake can be expected to reduce blood urea concentrations, alleviate metabolic acidosis, and indirectly minimize phosphorus intake.³⁷ Recommended dietary

Patient Monitoring Flowsheet: Chronic Renal Failure

Figure 18-1 Example of a flowsheet for monitoring the clinical and clinicopathologic features of chronic renal failure. *Minimal components of frequent serial monitoring.

protein intake for initial management is 2 to 3.5g/kg per day in dogs. This level is generally provided by diets containing high biologic value protein at approximately 13% of gross energy when fed at maintenance caloric requirements.³⁷ The protein requirement for dogs in renal failure is higher than the minimum protein requirements for healthy dogs; however, most commercial maintenance diets are 20% to 30% protein. In cats protein requirements are 3.5 to 4.0 g/kcal per day and may be provided by diets containing approximately 21% of gross energy as protein.³⁷ Products that provide high-quality protein in homemade diets include eggs, liver, cottage cheese, and lean meats.

Further reduction in protein intake should be reserved for refractory patients in which signs of uremia persist on the previously described diet. Excessive protein restriction may lead to protein malnutrition, hypoalbuminemia, and anemia. Protein or other nutrient deficiencies can inadvertently develop if adequate quantities of a moderately restricted diet are not consumed; intake of adequate energy should take precedence in dietary formulations. Protein depletion also may adversely affect renal function by contributing to alterations in renal hemodynamics and accentuating muscle catabolism, anemia, and acidosis. Animals with protein malnutrition exhibit weight loss, poor hair coats, and muscle wasting. Although reduced protein intake may improve clinical signs of renal disease, this dietary maneuver is unlikely to prevent renal disease in normal animals, dramatically slow progression of renal disease, or enhance renal function. Thus the role of reduced protein intake in animals with early renal disease is less clear. Again, moderate restriction of protein may be appropriate in these individuals, with regular monitoring for evidence of protein malnutrition and for progression of azotemia.

KEY POINT 18-4 Progressive reduction in phosphorus and protein intake is justified in chronic kidney disease in an effort to reduce nitrogenous wastes, acid by-products, and mineral deposition in the kidneys and other soft tissues.

Table 18-2 D	rugs Used in the Manag	gement of Chronic Renal Fai	lure	
Agent	Action	Dosage	Adverse Effects	Contraindications
Agents Used to Treat	t Hyperphosphatemia/Hyperp	arathyroidism		
Aluminum hydroxide	e Phosphorus binder	30-100 mg/kg/day PO	GI upset, constipation, aluminum toxicity

Phosphorus

Restriction of dietary phosphorus is advocated for patients with renal failure to minimize hyperphosphatemia, secondary hyperparathyroidism, and dystrophic mineralization. Feeding to maintain a calcium × phosphorus solubility product below 60 to 70 is recommended to minimize soft tissue and renal mineralization. In experimental studies in dogs with induced renal disease, phosphorus and calcium restriction improved survival times but did not prevent renal mineralization.³⁸ In a prospective clinical study in cats, feeding a phosphorus- and protein-restricted diet, and administering phosphorus binders if needed, improved survival times from a mean of 383 days to 616 days.³⁹ Cats fed the renal diet also had reduced plasma urea and phosphorus concentrations when compared with cats fed other diets.

Although phosphorus restriction can be advocated more reliably and earlier than protein restriction, most diets formulated for renal disease are restricted in both protein and phosphorus content because meat proteins are the primary source of phosphorus in the diet. Appropriate canine diets are 0.13% to 0.28% phosphorus on a dry weight basis, providing 0.3 to 0.5 mg phosphorus/kcal, whereas feline diets are approximately 0.5% phosphorus, providing 0.9 mg phosphorus/kcal.⁴⁰ Supplemental phosphate-binding agents may be required if dietary restriction is inadequate to minimize hyperphosphatemia and normalize the calcium × phosphorus solubility product (see later discussions of dietary supplements and secondary hyperparathyroidism).

Sodium

Moderate sodium restriction is beneficial for dogs with renal disease, particularly those with systemic hypertension. Although single nephron adaptive responses are remarkably efficient for maintaining solute and water balance in renal disease, handling of large fluid and solute loads is limited, and conservation of water and solute is impaired. Sodium excretion increases with declining GFRs to maintain homeostasis; however, response to a sodium challenge may be impaired, and excess sodium intake could lead to volume expansion. Conversely, sodium cannot be maximally conserved in the presence of acute restriction in intake or volume depletion. Diets should provide 15 to 50 mg/kg per day, usually 0.1% to 0.3% on a dry matter basis.⁴¹ Changes in sodium intake should be made gradually if possible to prevent rapid changes in fluid homeostasis and extracellular fluid volume. A recent study of the effects of dietary sodium intake on renal function in normal cats and cats with experimentally induced renal disease indicated that low sodium intake may actually contribute to hypokalemic nephropathy and progressive renal injury in cats.⁴² More research must be done to determine the optimal level of sodium intake for cats with renal insufficiency or failure.

Lipids

Abnormalities of lipid metabolism in renal disease may lead to hypercholesterolemia, hypertriglyceridemia, and elevated lowdensity lipoprotein concentrations. High saturated fatty acid intake has been shown to accelerate glomerulosclerosis and progressive renal injury in rat models. Dietary lipid composition may be manipulated to minimize hypercholesterolemia, minimize inflammation, and protect renal hemodynamic function. In one study of dogs with induced renal failure, dogs fed a diet supplemented with omega-3 polyunsaturated fatty acids (provided by menhaden fish oil) had reduced intraglomerular pressure, reduced proteinuria, and better indices of renal function than dogs supplemented with omega-6 polyunsaturated fatty acids.43 Supplementation of omega-3 polyunsaturated fatty acids may be expected to favor vasodilatory eicosanoid production, inhibit intrarenal platelet aggregation, and minimize systemic and glomerular hypertension. Whether any appreciable effect of dietary lipid manipulation will be seen over the longterm course of chronic renal failure remains unknown.^{43,44}

Energy

Appropriate caloric intake is a frequently overlooked goal of dietary management of renal failure patients. A catabolic state may be perpetuated despite the best manipulations of dietary content if sufficient calories for body energy requirements are not ingested. Energy depletion and protein malnutrition in turn exacerbate azotemia and hamper renal compensatory or regenerative responses. Energy requirements for patients with chronic renal failure have been estimated at 60 to 110 kcal/kg per day; a reasonable starting point is 75 kcal/kg per day.³¹ Frequent monitoring of body weight and body condition is imperative to ensure that appropriate weight is maintained.

As renal failure progresses, intake of appropriate calories becomes more important than the composition of the diet. Caloric supplements composed of fat and carbohydrate sources may be offered to provide additional energy. Occasionally, obese patients with renal disease are encountered. Because obesity may contribute to systemic hypertension and impair other organ system functions, weight reduction is desirable in these patients. Adjustments in weight must be gradual, however, and excessive restriction of calories and protein intake should be avoided.

Dietary Supplements

Intestinal Phosphate-Binding Agents

If dietary phosphorus reduction is ineffective in maintaining a serum phosphorus level of less than 6 mg/dL and a calcium \times phosphorus solubility product less than 70, phosphorousbinding agents may be administered.45 These agents are generally ineffective if dietary phosphorus is not restricted concurrently and are most effective when given just before or with a meal. Liquid or encapsulated preparations are preferable to tablet forms because they more readily mix with ingesta in the intestinal tract. These agents prevent absorption of ingested phophorus or phosphorus secreted in saliva, bile, or intestinal fluid. Tablet forms can be crushed and given with food. Aluminum-based products (aluminum hydroxide, aluminum carbonate) are widely available and are administered at daily dosages of 30 to 100 mg/kg divided into two or three feedings.⁴⁶ Magnesium-based products should be avoided in patients with renal failure.45

Calcium-based products (calcium acetate, 60 to 90 mg/kg per day; calcium carbonate, 90 to 150 mg/kg per day) are alternative phosphorus-binding agents with additional alkalinizing effects. Calcium-based products can also be used to minimize or correct hypocalcemia. Calcium acetate is recommended in normocalcemic to mildly hypercalcemic patients, insofar as calcium carbonate is more likely to lead to hypercalcemia. Calcium-based products and aluminum-based agents also may be administered concurrently for added phosphorus-binding effects.^{37,45} Serum calcium and phosphorus concentrations should be monitored every 2 weeks initially, then monthly or as needed during chronic therapy. Adverse effects of phosphorus-binding agents include nausea, gastrointestinal upset, constipation, and hypophosphatemia. Toxic effects of aluminum are theoretically possible with long-term administration, including anemia, encephalopathy, and osteomalacia.47 Aluminum toxicity appears to be unlikely in dogs and cats.

Alkalinizers

Although dietary protein restriction helps reduce acid metabolites and metabolic acidosis, alkalinization therapy may be required in animals with moderate to severe metabolic acidosis. Chronic untreated metabolic acidosis may accelerate protein catabolism and azotemia, promote renal ammoniagenesis contributing to progressive renal tissue damage, and lead to increased calcium and potassium losses. Acid–base derangements also likely contribute to the clinical manifestations of renal failure, including anorexia, vomiting, and weight loss.^{48,49} Alkalinizing therapy is ideally planned on the basis of serial blood gas analyses. Serum total CO_2 (TCO₂) measurement is a reasonable guide to management in most patients. Oral alkalinization is recommended when bicarbonate or TCO₂ measurements fall below 15 to 17 mmol/L, whereas parenteral supplementation may be needed if the TCO₂ falls below 10 to 12 mmol/L.

Alkalinizing agents include potassium citrate (35 mg/kg orally every 8 hours or 0.3 to 0.5 mEq potassium/kg orally every 12 hours) and calcium carbonate or calcium acetate (100 mg/kg daily).^{31,50} These agents are particularly valuable when hypokalemia (potassium citrate), hyperphosphatemia, or hypocalcemia (calcium-based agents) is a concurrent problem (discussed elsewhere). Oral sodium bicarbonate may be administered at 8 to 12 mg/kg every 8 to 12 hours (1 mEq/cat every 8 to 12 hours for cats). Household baking soda supplies approximately 4000 mg bicarbonate per teaspoon (or 12 mEq bicarbonate/g); 5- and 10-grain tablet preparations are also available. Alternatively, a 1 mEq/mL solution of bicarbonate can be prepared by adding 5 or 6 tablespoons of baking soda to 1 L of water (or one third of an 8 ounce box is added to 1 quart of water).48 Because of the added sodium intake, sodium bicarbonate may be inadvisable in hypertensive patients, and some clinicians prefer to use alternative alkalinizing agents in all renal failure patients. It is questionable, however, whether the sodium salt in sodium bicarbonate contributes to hypertensive disease in dogs and cats.

Dosages of all alkalinizing agents may be titrated to effect. The goal of treatment is to modify bicarbonate concentrations to approximately 18 to 24 mmol/L. Overcorrection of acidosis can lead to metabolic alkalosis, hypokalemia, or ionized calcium deficits.

Potassium

Renal failure and metabolic acidosis have been identified as risk factors for hypokalemic myopathy in cats.^{51,52} Increased fractional excretion of potassium is observed, although 24-hour potassium loss is variable. Hypokalemia may be exacerbated by chronic metabolic acidosis, especially in cats fed acidifying diets. Potassium depletion in turn induces acidosis and depresses GFR, intensifying renal disease and potassium loss.⁵²⁻⁵⁴ From these observations it has been hypothesized that supplementation of potassium in cats with renal insufficiency may stabilize or improve renal function. A beneficial effect on renal function and overall outcome in chronic kidney disease has not yet been proven; however, potassium supplementation can increase total body potassium somewhat and appears to be well tolerated.

Most commercial renal diets have been adjusted to provide potassium beyond requirements for healthy animals, but cats with mild to moderate hypokalemia (K 3.5 to 4.5 mEq/L) will benefit from potassium supplementation at 2 to 5 mEq/day. Low-dose supplementation (2 mEq/cat per day) may be justified in normokalemic cats to prevent potassium depletion.⁵² Cats with severe hypokalemia may require intensive replacement with intravenous potassium chloride or increased supplementation (5 to 10 mEq/day). Potassium supplementation may be initiated at 1 to 6 mEq/kg per day if other dietary measures do not correct the hypokalemia.³¹ Potassium concentration should be carefully monitored in cats and in dogs undergoing fluid diuresis for renal disease. Chronically, dogs with polyuric renal failure also may become hypokalemic but seem more resistant to this sequela of renal disease. Some renal failure diets may in fact oversupply potassium for canine needs.

Potassium supplements are available in powder or liquid form for long-term oral administration. Potassium gluconate powder mixed in food appears to be the most palatable and best-tolerated product; flavored potassium gluconate elixirs also are available. A relatively new flavored gel preparation also may be acceptable to cats. Potassium citrate solution or diluted potassium chloride for injection (dilute 1:1 with water) also may be given orally. Gastrointestinal ulceration, nausea, vomiting, and food aversion may develop with liquid preparations.

Summary of Dietary Recommendations

On the basis of current information, the ideal diet for small animals in mild to moderate chronic renal failure should be moderately reduced in protein, phosphorous, and sodium content; contain high-quality protein sources; be highly digestible; and provide adequate potassium, nutrient, and caloric density. In a recent study, feeding a diet appropriately modified in protein, phosphorus, lipids, and sodium was associated with stable renal function and delayed onset of uremia in dogs with moderate chronic renal failure.55 These dogs had a better perceived quality of life, lower risk of death, and prolonged survival (>13 months) compared with dogs fed a maintenance diet. In these studies other treatments appropriate to the stage and consequences of renal failure were initiated as needed, lending support to the long-term benefits of a carefully crafted and monitored treatment regimen for chronic renal diseases. Similarly, in 45 cats with mild to moderate renal failure followed for up to 2 years, cats fed a renal diet had significantly lower all-cause mortality rates and no uremic crises or renal mortality compared to cats fed a maintenance diet. Cats fed the diet formulated for renal disease also had reduced azotemia and acidosis during the study period.56 The composition and nutrient profiles for commercial renal diets are available in manufacturers' product information and summarized in a review by Bartges and Brown.⁵⁷Dietary supplements or homemade diets may be required to meet the needs of individual patients.

KEY POINT 18-5 The overall effects of feeding a diet formulated for renal disease include enhanced quality and length of life.

Management of Anorexia and Vomiting

The best dietary strategy is ineffective if the patient becomes anorectic, cannot consume adequate calories for energy needs, or is vomiting and intolerant of enteral feeding. Many metabolic consequences of renal failure may affect appetite, including hydration status, severity of uremia, degree of anemia, acidosis, secondary hyperparathyroidism, gastrointestinal complications, and electrolyte imbalances. In the sick, uremic animal, correction of dehydration, acidosis, electrolyte abnormalities, and gastrointestinal complications should be accomplished before attempting to introduce a therapeutic renal diet⁵⁸ Supplementation of water-soluble vitamins and correction of anemia also may improve appetite. ACE inhibitors, some antimicrobials, and many other therapeutic agents can contribute to anorexia, and their potential benefit should be reviewed critically in intolerant patients.

In anorectic patients with chronic renal failure, a review of previous diets, dietary habits, and drug therapy is advised. As with all dietary changes, new diets should be introduced gradually, and small, more frequent meals may be preferable for many patients. Owners and nursing staff can tailor the feeding schedule and feeding environment to enhance appetite by avoiding hurried, noisy feeding or feeding in close association with painful or stressful procedures. Some animals respond to hand feeding or feeding during petting and socialization, especially in a quiet ward or outside the hospital area. Warming of food, moistening food, and ensuring easy access to food are practical methods of improving acceptance.58 Flavoring agents can also be added, including animal fat, bouillon, clam juice, tuna broth, brewer's yeast, garlic, butter, or cottage cheese.³⁷ An added benefit of flavored liquids is enhanced fluid intake, although broths high in sodium and phosphorus should be avoided. Supplementation of vegetable oils, margarine, cream, or complex sugars may be used to increase caloric intake.³¹ If oral ulcers that limit food intake are observed, application of xylocaine gels or cool tea flushes may be used to alleviate pain. Enteral feeding using esophagostomy or gastrostomy tubes are another option for managing chronic renal failure in dogs and cats. They allow easy administration of medications and fluids in addition to providing adequate nutrition to an anorectic or hyporexic patient.

Gastrointestinal effects of uremia include mucosal irritation from nitrogenous waste products, impaired gastrointestinal mucosal barriers, and hypergastrinemia. Central receptors for appetite and nausea also are affected by retained substances and increased parathyroid hormone (PTH) concentrations. Anorexia, vomiting, and diarrhea are common complications of advanced renal failure. In patients with chronic renal failure, sporadic vomiting, nausea, and anorexia may be alleviated by the administration of histamine blockers such as cimetidine (5 mg/kg orally, intramuscularly, or intravenously every 6 to 8 hours), famotidine (0.5 to 1 mg/kg orally every 12 to 24 hours), or ranitidine (0.5 to 2 mg/kg orally every 12 hours). Cimetidine inhibits hepatic metabolism of many drugs, including β -blockers and calcium channel blockers, and should be avoided in patients receiving these drugs. Alternately, administration of a proton pump inhibitor (omeprazole 0.7 to 1.5 mg/kg orally every 12 to 24 hours in cats or 0.5-1 mg/kg orally every 24 hours) may be effective in cases refractory to histamine blockers. The addition of sucralfate, a gastrointestinal mucosal protectant, may be useful for patients with severe gastritis or suspected gastrointestinal hemorrhage. Because sucralfate is most effective in an acidic stomach environment, other antiemetics or antacid medications should be given at least 30 minutes after administration of sucralfate when used concurrently. For refractory vomiting metoclopramide (0.2 to 0.4 mg/kg subcutaneously, intramuscularly, or orally every 8 hours) may be administered to improve gastric emptying and reduce centrally mediated nausea. Dolasetron is a serotonin receptor antagonist that has been used extensively in people to decrease nausea and vomiting associated with chemotherapy and anesthesia. Little published information is available about the efficacy and pharmacokinetics of this drug in dogs or cats, but its use in veterinary medicine is growing. It has potential use in managing nausea and vomiting in dogs and cats caused by chemotherapy; anesthesia; enteritis; and metabolic diseases, including renal failure. A dose of 0.6 mg/kg intravenously or orally every 24 hours is recommended to prevent nausea and vomiting, whereas a higher dose of 1 mg/kg intravenously or orally every 24 hours is recommended for treatment of clinical emesis and nausea. It can be used in combination with other antiemetics, including metoclopramide.⁵⁹ Ondasetron, another serotonin receptor antagonist, was shown to be about twice as effective as metoclopramide in alleviating nausea and vomiting in uremic human patients.⁶⁰ Maropitant, a novel synthetic nonpeptide neurokinin type 1 (NK1) selective receptor antagonist, prevents and treats emesis and is licensed for use in dogs. The dose of 1 mg/kg orally or subcutaneously every 24 hours for up to 5 days is recommended for dogs to manage nausea and vomiting caused by a variety of factors, whereas a higher dose is recommend for prevention of motion sickness.⁶¹ Maropitant has not been approved for use in cats. One published study concerning its use in cats demonstrated that it is safe and effective in reducing the incidence of vomiting induced in laboratory cats by xylazine administration or motion sickness.62

Misoprostol, a synthetic prostaglandin analog, inhibits gastric acid and pepsin secretion and has a cytoprotective effect on gastric mucosa. The drug may be useful in renal failure– induced gastritis at a dosage of 1 to 5 μ g/kg orally every 6 to 8 hours. Transient gastrointestinal upset is a possible adverse effect of misoprostol administration that may be managed by adjusting the drug dosage and giving the drug with food.¹⁷ Anorexia or gastrointestinal complications of drug administration must be addressed quickly in patients with renal failure, however, because dehydration and renal decompensation can occur.

Pharmacologic manipulation of appetite also has been attempted in anorectic patients. In the short term, intravenous administration of low-dose diazepam (0.05 to 0.15 mg/kg intravenously) may be successful in reviving appetite or stimulating food intake. Oral administration of benzodiazepines, such as oxazepam, may result in unacceptable sedation. Oral diazepam also has been associated with behavior changes and incidences of hepatic failure in cats. The metabolism of benzodiazepines may be reduced with concurrent administration of cimetidine. Cyproheptadine, dosed at 2 to 4 mg/cat orally every 12 to 24 hours, is an additional appetite stimulant. Other agents, such as anabolic steroids, glucocorticoids, and progestins, are of questionable benefit in stimulating appetite. Glucocorticoids are not recommended for most patients with renal failure because they may promote tissue catabolism, contribute to gastrointestinal ulceration, and result in fluid and sodium retention and glomerular hyperfiltration. Mirtazapine is a noradrenergic and specific serotonergic antidepressant that has been used in dogs and cats for management of nausea and vomiting, although no published data confirm its efficacy and safety.

KEY POINT 18-6 Pharmacologic management plays an important role in ameliorating the effects of systemic hypertension and proteinuria, two key risk factors for progression of chronic kidney disease in dogs and cats.

Management of Systemic Hypertension

In animals with chronic kidney disease, the afferent arteriole dilates, which leads to increased intraglomerular pressure. The kidney is susceptible to hypertensive damage, on account of both elevated systemic arterial blood pressure and intraglomerular pressure. In dogs there is a close association between elevated intraglomerular pressure and progressive renal injury. Systemic hypertension is observed in more than 60% of dogs and cats with renal disease, particularly in animals with glomerular disorders, renal vascular disease, and renal neoplasia.⁴¹ Multiple mechanisms may contribute to the development of hypertension in renal failure, including decreased glomerular filtration, impaired sodium and water handling, local activation of the renin-angiotensin-aldosterone system, and impaired production of renal vasodilatory substances. High systolic blood pressure (>163 mm Hg) in dogs at the time of diagnosis of chronic renal failure was associated with increased risk of developing a uremic crisis and dying, compared with dogs that had lower blood pressure.63 Controlling hypertension may decrease the rate of progression of chronic renal failure. Clinical signs of hypertension in small animals are usually manifestations of ocular complications, including blindness, retinal hemorrhages, retinal detachment, and glaucoma, but they may include cardiac failure, neurologic signs, hemorrhage, and effusions. Overt signs are often inapparent, however, and blood pressure recordings should be routinely monitored in patients with renal disease.

Moderate restriction of sodium intake is one step in management of mild systemic hypertension. Dietary sodium content of 0.1% to 0.3% sodium by dry matter is recommended for initial management.^{41,64} Most commercial "renal" diets provide appropriate sodium content, limiting sodium intake to 10 to 40 mg/kg per day. Sodium restriction should be gradual so as not to precipitate volume depletion. If necessary, additional sodium restriction may be accomplished by feeding homemade diets or diets formulated for cardiac disease.

Pharmacologic manipulation of blood pressure may be indicated in animals with moderate to severe hypertension (systolic blood pressure >180-200 mm Hg), clinical signs attributable to hypertension, or persistent hypertension despite sodium restriction. There is evidence that dogs with renal failure have great variability in blood pressure, and it may be appropriate to initiate antihypertension drugs in dogs with intermittently elevated blood pressure (>160/100 mm Hg).⁴⁶ The choice of agent must be based on the potential risks and benefits in the individual animal and the clinician's experience and preference. A variety of agents have been proposed for use in hypertension, including ACE inhibitors and calcium channel blockers, diuretics and β -blockers.

In dogs ACE inhibitors are the first choice for management of hypertension. Inhibition of angiotensin II production leads to decreased aldosterone secretion, decreased blood pressure, efferent arteriolar dilation, and reduced intraglomerular capillary pressure. In glomerular disease ACE inhibitors are helpful in controlling hypertension and minimizing proteinuria. In dogs with experimentally induced chronic renal insufficiency, enalapril was shown to decrease proteinuria and glomerular capillary pressure after 3 and 6 months of therapy, respectively. Dogs receiving enalapril had fewer glomerular and tubulointerstitial lesions than the placebo-treated group.⁶⁵

KEY POINT 18-7 Angiotensin-converting enzyme inhibitors are the first choice antihypertensive agent for dogs. They are administered at low doses initially and titrated to achieve ideal effect without worsening azotemia or electrolyte disturbances.

Potential risks of ACE inhibitor administration include hypotension; decreased renal perfusion; hyperkalemia; gastrointestinal upset; and, rarely, myelosuppression or seizures. Excessive reductions in renal perfusion and GFR are most worrisome because they may lead to acute decompensation of renal failure. To prevent this complication, administration of ACE inhibitors is initiated at a low dosage while blood pressure, blood urea nitrogen, and creatinine concentration are measured. The drug may be slowly increased to an effective dosage. Starting dosages of enalapril and benazepril are 0.25 to 0.5 mg/kg orally per day. Benazepril is less likely to cause renal damage than enalapril and has been shown to decrease systolic blood pressure in dogs and cats. A dose of 0.5 to 1 mg/kg orally every 24 hours successfully decreased blood pressure in cats with experimentally induced renal disease, without decreasing GFR.⁶⁶ Irbesartan (5 mg/kg orally every 12 to 24 hours) is an angiotensin II-receptor blocker that will also lower blood pressure in dogs.⁶⁷ Further research is needed to determine whether all cats and dogs with chronic renal failure or renal insufficiency would benefit from ACE inhibitor therapy. This class of drugs may be renoprotective without lowering systemic blood pressure.

Calcium channel blockers such as diltiazem or amlodipine also are attractive agents for the management of hypertension in patients with renal failure. Amlodipine (0.625 to 1.25 mg/cat daily by mouth) has become the preferred agent for cats.⁶⁸ In dogs that are nonresponsive to ACE inhibitors or in which the drugs are contraindicated, amlodipine (0.05 to 0.25 mg/kg orally every 24 hours) can be administered. Calcium channel blockers reduce blood pressure by peripheral vasodilatory effects; potency varies with the preparation. Calcium channel blockers increase peripheral resistance, leading to a decrease in blood pressure, but they also dilate afferent renal arteriole, which can be detrimental. There are some concerns about possible detrimental effects of calcium channel blockers, which were associated with exacerbation of renal injury, proteinuria, or both in studies of people and diabetic dogs. Newer classes of calcium channel blockers may offer increased renoprotective effects by dilating both the efferent and afferent renal arterioles.⁶⁷ Calcium channel blockers also possess cytoprotective qualities that may be helpful in acute or chronic renal damage. Calcium channel blockers are negative inotropes and may cause hypotension, cardiac arrhythmias, and gastrointestinal upset in some patients.

KEY POINT 18-8 The calcium channel blocker amlodipine is the first-line antihypertensive agent for cats.

Diuretics are the mainstay of treatment of early volumedependent hypertension in human patients; however, they may contribute to dehydration and potassium loss and may be inadvisable for patients with chronic renal failure. The diuretic spironolactone acts by inhibiting aldosterone. Aldosterone has hemodynamic effects that preferentially dilate the afferent arteriole, raising intraglomerular pressure; thus spironolactone and eplerenone (another aldosterone antagonist) may be useful drugs in the management of patients with renal failure.⁶⁷ Further studies are necessary.

Beta-blockers such as propranolol and atenolol are agents with negative inotropic and vasodilatory actions. Atenolol (2 mg/kg daily for cats, 0.25 to 2 mg/kg daily for dogs) may be preferred over propranolol because of its duration of action and β_1 -receptor specificity. Atenolol is less likely to cause bronchoconstrictive side effects than propranolol.⁶⁴ Both diuretics and β -blocking agents appear to be minimally effective in dogs with hypertension of renal failure, although β -blockers may be effective in cats.⁶⁹ Clinical application now is limited.

Serial monitoring of blood pressure, hydration status, and renal and cardiac function is imperative for the appropriate management of hypertensive disease (reduction to approximately 150 to 170 mm Hg). Weekly blood pressure recordings should be made initially as dietary and then pharmacologic management is initiated. Biweekly or monthly recordings can be continued during maintenance treatment. Refractory hypertension may respond to combination therapy or addition of a direct vasodilator such as hydralazine. Administration of a calcium channel blocker with a β -blocking agent is not recommended because of additive negative inotropic effects. Control of hypertension in patients with renal failure may slow the progression of disease and minimize the ocular, cardiovascular, and neurologic complications that can develop with uncontrolled hypertension.

Management of Secondary Hyperparathyroidism

Hyperphosphatemia, hypocalcemia, and impaired activation of vitamin D metabolites contribute to the development of secondary hyperparathyroidism in animals with renal failure. PTH plays an important role in regulating plasma calcium and phosphorous concentrations through effects on the gastrointestinal tract, kidney, and bone. The primary stimulus for PTH release is a drop in plasma calcium concentration; in renal failure phosphorous retention and hyperphosphatemia may lead to hypocalcemia. Additionally, and perhaps more important, impaired conversion of 25-hydroxycholecalciferol (25-hydroxyvitamin D) to the active 1,25-hydroxycholecalciferol (1,25-hydroxyvitamin D, or calcitriol) by 1- α -hydroxylase impairs gastrointestinal absorption of calcium. Calcitriol also plays an important role in the regulation of PTH by exerting an inhibitory (negative feedback) effect on PTH production and release.

The classic effect of secondary hyperparathyroidism in animals with renal failure is the development of renal osteodystrophy, usually seen as "rubber jaw," which results from excessive calcium and phosphorous removal from bone. This complication appears to be rare in dogs and cats but may develop with long-standing disease or juvenile renal disease. Secondary hyperparathyroidism has, however, been implicated as a contributor to many other manifestations of uremia in human patients, including anemia, glucose intolerance, hyperlipidemia, encephalopathies, neuropathies, cardiac damage, muscle damage, and immunologic dysfunction. Furthermore, soft tissue mineralization associated with hyperparathyroidism may contribute to the progression of renal failure.

Dietary restriction of phosphorus, administration of phosphorus-binding agents, and calcium supplementation may be sufficient to minimize secondary hyperparathyroidism in early chronic renal failure (see earlier discussions of phosphorus binders and alkalinizers). Supplementation of the active vitamin D metabolite calcitriol may be valuable in further management of hyperparathyroidism and renal failure. Calcitriol acts to enhance calcium absorption in the intestines, enhance reabsorption of calcium from bone, and directly inhibit PTH secretion.^{70,71} Calcitriol supplementation should help normalize plasma calcium and phosphorous concentrations and minimize the clinical and clinicopathologic effects of secondary hyperparathyroidism.

Calcitriol supplementation has been recommended in lowdose (2.5 to 3.5 ng/kg per day)⁷⁰ and high-dose (6.6 ng/kg per day)⁷¹ protocols. Formulations of 250- and 500-ng capsules are available; other doses may be prepared by special order from compounding pharmacies. Serum calcium concentrations should be normal, and serum phosphorus concentrations should be maintained at less than 6 mg/dL before initiation of calcitriol supplementation. Frequent monitoring of calcium and phosphorus concentrations is required during administration. The first assessment should be completed 7 to 14 days after initiation of treatment, followed by monthly rechecks. Ideally, efficacy of treatment should be assessed by PTH measurements on pooled blood samples obtained before and during the first 6 months of treatment. The major complication of calcitriol supplementation is the development of hypercalcemia. Hypercalcemia can be managed by adjusting calcium-based phosphorus-binding agents used concurrently, reducing the dosage of calcitriol, or discontinuing administration of calcitriol temporarily and reinstituting the drug at a lower dosage when calcium concentrations return to normal.⁷⁰ If phosphorus-binding agents are required to help normalize serum phosphorus, calcium acetate or aluminum-based binding agents may be preferable to calcium carbonate to minimize the propensity for hypercalcemia.

KEY POINT 18-9 When administered and monitored appropriately, calcitriol appears to improve quality and length of life in dogs with moderate-stage chronic kidney disease.

Calcitriol administration reportedly results in rapid reduction of serum PTH levels, normalization of serum calcium concentrations, and subjective improvement in the general well-being of treated dogs.⁷⁰ Some investigators advocate its use early in renal failure as a method of improving quality of life in patients with renal failure and as a method of potentially slowing progression of renal disease. However, other investigators reserve calcitriol supplementation for animals in which hyperparathyroidism has been documented.⁷¹ Preliminary results from a double-blind randomized controlled clinical trial of calcitriol administration in dogs with spontaneous mild to moderate chronic kidney disease indicate prolonged survival and reduced mortality in dogs receiving calcitriol. PTH measurements and ionized calcium measurements were conducted frequently so that the dosage could be tailored appropriately; effective doses ranged from 0.75 to 5.0 ng/kg/day.⁷² As with other medical manipulations in patients with renal failure, careful monitoring of treatment is essential, with the potential benefits and possible risks weighed for each individual patient.

Management of Anemia

Progressive, nonregenerative anemia is a common complication of chronic renal dysfunction. Moderate to severe anemia is responsible for many of the clinical signs of renal disease, including apathy, lethargy, weakness, poor appetite, and poor body condition. A number of pathophysiologic mechanisms probably contribute to the anemia observed in renal failure, including depressed erythrocyte production, shortened red blood cell life spans, concurrent chronic inflammatory disease, and blood loss caused by gastrointestinal bleeding.⁷³ Gastrointestinal blood loss and erythropoietin lack appear to be the most important mechanisms of anemia. Dramatic responses to erythropoietin supplementation are seen in some cases.

Recombinant human erythropoietinrh (EPO), a genetically engineered replica of human erythropoietin, became available in the late 1980s and has been used in dogs and cats with anemia of renal failure. Erythropoietin is administered at an initial dosage of 100 U/kg subcutaneously three times weekly until the hematocrit is normalized. A rapid loading phase of 150 U/kg/day for the first week has been recommended for severely anemic (<14% packed cell volume) patients.⁴⁶ Target hematocrits are 0.37 to 0.45 L/L in dogs and 0.30 to 0.40 L/L in cats. Initial monitoring includes reevaluation of packed cell

volume or hematocrit measurements at 7- to 14-day intervals. In most cases rapid, progressive increases in red blood cell count, hemoglobin concentration, and hematocrit are observed, along with improvement in clinical parameters such as appetite, body condition, alertness, and activity.^{74,75} Lower initial dosages (50 to 75 U/kg) may be used if a slower response is desired, in hypertensive patients, or if the drug is cost prohibitive. If a response is not observed in 3 to 4 weeks, the dosage may be increased incrementally to 125 to 150 U/kg three times weekly. If a poor response is seen, the animal should be evaluated for untreated blood loss, iron deficiency, concurrent inflammatory disease. As target hematocrits are reached, the dosage and frequency of administration are tapered, with required maintenance dosages usually at 75 to 100 U/kg every 4 to 7 days. Follow-up monitoring can then be performed at monthly intervals if a stable clinical course has been observed.

Unfortunately, resistance to rhEPO is observed in some dogs and cats after several weeks of treatment. Anti-rhEPO antibodies are formed in 25% to 50%74 of treated patients, blocking the erythropoietin effect. A rapid decline in hematocrit, red blood cell count, and hemoglobin concentration, along with erythroid hypoplasia of the bone marrow, is observed 4 to 16 weeks after initiation of therapy. AntirhEPO antibodies may also interfere with remaining endogenous erythropoietin and result in life-threatening anemia or a transfusion-dependent anemia. Because of the potential development of cross-reacting antibodies, rhEPO treatment is generally reserved for dogs and cats with symptomatic severe anemia, usually when the hematocrit drops below 20% to 25% in dogs or 17% to 20% in cats. Anecdotal evidence suggests that darbepoetin, a second-generation erythropoietin analog with a longer duration of action, may be less antigenic in dogs and cats than rhEPO.

A suboptimal response to rhEPO treatment also may be attributed to depleted iron stores. Iron status, including serum iron concentration and total iron-binding capacity, should be evaluated before initiating treatment and reevaluated monthly or if apparent resistance to treatment is observed. Some authors recommend iron supplementation for all animals treated with rhEPO.74 Ferrous sulfate is given orally at a dosage of 100 to 300 mg/day (dogs) or 50 to 100 mg/day (cats). Gastrointestinal side effects may be minimized by dividing the dose into smaller doses. Iron dextran can be given intramuscularly to ensure administration; however, anaphylaxis and iron overload are possible. Systemic and intrarenal hypertension are additional consequences of rhEPO administration that may develop as a result of the increased red cell volume and adaptive increased peripheral vascular resistance. Initiation of rhEPO treatment is contraindicated for patients with uncontrolled hypertensive disease. Other adverse effects uncommonly observed with rhEPO administration include allergic reactions, fevers, seizures, vomiting, and polycythemia.76

Ideally, recombinant feline and canine EPO would be used in anemic patients with chronic renal failure, but these products are not available commercially. Recombinant canine EPO (rcEPO) was shown to be effective in stimulating erythropoiesis in 19 dogs with anemia caused by chronic renal failure but had less efficacy in dogs with red cell aplasia caused by previous therapy with rhEPO.⁷⁷

The androgenic effects of anabolic steroids also may stimulate red blood cell production in renal failure patients. Androgens increase renal and extrarenal erythropoietin secretion, stimulate erythroid precursors in the bone marrow, and may stimulate heme synthesis. Testosterone esters, nandrolone decanoate, and stanozol are readily available and inexpensive agents, but they may be controlled substances in some areas. These agents have been recommended for their nonspecific effects on appetite, strength, body condition, and general well-being, effects that are largely anecdotal. Administration of anabolic steroids may promote sodium and fluid retention and cause hepatotoxicity, so their use in animals with renal or cardiac dysfunction is not entirely innocuous. For the most part, rhEPO has replaced anabolic steroids in the management of renal failure.⁴⁶

MANAGEMENT OF GLOMERULAR DISEASE

Pathophysiology and General Considerations

Glomerular disease is a common cause of proteinuria and progressive renal disease in dogs and is encountered occasionally in cats. In glomerulonephritis (GN) the deposition of immune complexes in glomerular capillary walls initiates a local inflammatory response, including complement activation, activation of the membrane attack complex, chemotaxis of neutrophils and macrophages, and production of oxygen free radicals. Immune complexes may form in circulation in response to numerous antigens or when antibodies react with endogenous or planted glomerular antigens in situ. GN in dogs has been associated with numerous systemic infectious and inflammatory diseases, including canine adenovirus, bacterial endocarditis, brucellosis, dirofilariasis, ehrlichiosis, borreliosis, neoplasia, pancreatitis, systemic lupus erythematosus, and other immune-mediated and chronic inflammatory disorders (including neoplastic disease). In cats feline leukemia virus, feline infectious peritonitis, polyarthritis, pancreatitis, and other immune-mediated diseases are implicated. Many of these are treatable diseases; however, a source of antigen is not identified in many cases of GN; familial and idiopathic glomerulopathies are recognized.78

Proteinuria is a typical sequela of glomerular damage and may be the earliest detectable laboratory abnormality. Leakage of protein across the glomerulus can lead to tubulointerstitial injury and progression of renal damage. In humans, dogs, and cats, proteinuria is linked to progression of renal disease. Two studies have shown that higher urine protein:creatinine ratios in cats are inversely related to survival in cats with chronic renal failure and proteinuria. Benazepril has been shown to decrease proteinuria in cats.⁷⁹

In renal amyloidosis deposition of amyloid A, derived from the acute phase reactant serum amyloid A, predominates. In dogs and cats, renal amyloidosis is usually a component of reactive systemic amyloidosis triggered by chronic inflammatory disease.⁸⁰ Familial forms of systemic amyloidosis are observed in the Abyssinian cat and Chinese Shar-Pei dog. In both GN and renal amyloidosis, glomerular surface area, function, and permeability are affected, leading to proteinuria and glomerular hyperfiltration. Ultimately, the nephron becomes nonfunctional; azotemia and renal failure ensue.⁸¹

Other sequelae of progressive glomerular disease include systemic hypertension, hypercoagulability, hyperlipidemia, and nephrotic syndrome.^{41,82} Systemic hypertension develops commonly in glomerular disease as a result of sodium retention and complex intrarenal mechanisms leading to depressed vasodilatory and enhanced vasoconstrictive responses. A hypercoagulable state is favored not only by loss of antithrombin III but also by increased concentrations of fibrinogen; factors V, VIII, and X; and enhanced platelet aggregability in glomerular disease.⁸² Dogs with antithrombin III concentrations less than 70% of normal and with fibrinogen concentrations of more than 300 mg/dL are at high risk for thromboembolic events.

Goals of management of glomerular disease are (1) to identify and treat the underlying disease process if possible, (2) to minimize proteinuria, and (3) to manage the consequences of glomerular disease and renal failure as they occur. Additional information about the disease and improved management strategies can be expected if renal lesions are appropriately characterized in biopsy specimens.⁷⁸

KEY POINT 18-10 Pharmacologic treatment should be initiated in dogs and cats with persistent proteinuria (urine protein creatinine > 2.0 or >0.5, respectively). Medical management is most effective when initiated early in the disease process (before azotemia) and when a treatable underlying disease can be identified.

Glomerulonephritis

If an underlying disease process is not found or is not reversible, adjunctive treatments are initiated. Intervention is recommended early in the disease process and should be instigated before the development of renal azotemia when possible. Once a dog or cat is diagnosed with persistent proteinuria (urine protein:creatinine ratio >2 or >0.5, respectively), medical intervention should be considered.⁸³

ACE inhibitor therapy should be initiated at the time of diagnosis of GN. Enalapril (0.5 mg/kg orally every 12 to 24 hours) has been shown to decrease proteinuria, serum creatinine, and blood pressure, compared with a placebo, in dogs with idiopathic membranous and membranoproliferative GN.⁸⁴ Enalapril is used in proteinuric, normotensive dogs as well as hypertensive dogs with GN. Benazepril has not been objectively assessed for treatment of GN in dogs but may be as efficacious. Dosages should be started low and titrated to effect while renal function and blood pressure are monitored carefully because administration of ACE inhibitors can cause acute decompensation of renal function, especially if volume status is poor.

Immunosuppressive therapy is often considered to counter the immunologic components of glomerular diseases. Corticosteroids, although often potent immunosuppressive and antiinflammatory agents, have potential disadvantages in the treatment of glomerular disease. Steroids may increase glomerular permeability and worsen proteinuria. Steroid treatment may accelerate muscle catabolism, worsen azotemia, contribute to hypercoagulability and thromboembolism, exacerbate hypertension, and immunosuppress already-debilitated patients.85 Because of these effects and the lack of convincing evidence of the efficacy of steroids in glomerular disease, steroid treatment is generally reserved for patients in which the underlying disease process is steroid responsive, such as systemic lupus erythematosus.⁸¹ One histologic variant of glomerular disease in humans, minimal change disease, is responsive to corticosteroids; if lesions are consistent with this diagnosis in a dog, corticosteroid treatment should be more strongly considered.⁷⁸ Other cytotoxic agents such as azathioprine, cyclophosphamide, and chlorambucil may be chosen for immunosuppressive effects in cases of rapidly progressive GN. Human patients with membranous nephropathy respond best to a combination of corticosteroid and alkylating agent.⁷⁸ However, efficacy of many of these agents as single agents or in combination has not been adequately determined in dogs. Cyclosporine was not beneficial for dogs with idiopathic GN in one study.86

Inflammation may be modified by other means. Thromboxane synthetase inhibitors are effective in decreasing proteinuria, platelet aggregation, and thromboxane generation in experimental models of GN and can prevent histologic development of GN if administered at the time of the glomerular insult.87 The drug may decrease proteinuria even when administered after the insult.88 The NSAID aspirin is advocated in glomerular disease for its antithrombotic effects, but it may also influence glomerular inflammation by inhibiting platelet activation and aggregation. Low-dose aspirin administration (0.5 to 5 mg/kg every 12 hours) is designed to allow inhibition of platelet cyclooxygenase without affecting prostacyclin formation, an important vasodilatory compound and an antagonist of platelet aggregation.⁸⁹ Low-dose aspirin administration also may reduce the risk of thromboembolic complications in dogs with glomerular disease.78

Dietary lipid composition has been shown to affect glomerular hypertrophy, glomerular capillary pressure, and renal function in dogs with experimentally reduced renal mass (15/16 nephrectomy).⁹⁰ In humans with nephrotic syndrome, omega-3 fatty acid supplementation has been effective in reducing triglyceride concentration and platelet aggregation.⁹¹ These effects may be important because hypercholesterolemia may contribute to progressive glomerular damage and increased proteinuria.

Dietary protein is also manipulated in glomerular disease. Although protein supplementation may appear logical in patients with urinary protein loss and hypoalbuminemia, moderate restriction of protein has been more effective in minimizing proteinuria and effective protein loss. Recommendations are similar to those for other types of chronic renal failure. Certainly, protein synthesis is affected by dietary protein intake, however, and appropriate dietary protein levels must be determined for individual patients. Sodium restriction also is implemented, as for chronic renal failure, and is particularly important in glomerular disease to prevent or minimize hypertension and edema.

Diuretics may be required for management of the edematous patient with nephrotic syndrome. Furosemide (2.2 mg/kg orally every 12 to 24 hours) is reasonably effective. Patients should be monitored for volume depletion or hypokalemia associated with furosemide administration.

A logical overall approach to the patient with GN is as follows. Baseline measurements of renal function, albumin, blood pressure, antithrombin III levels, and urinary protein loss are measured. Dietary manipulation, ACE inhibitor therapy, fatty acid supplementation and aspirin administration are initiated, and the patient is reevaluated in 1 to 2 weeks. Reductions in the urine protein:creatinine ratio, along with stable renal function, indicate good response. Ancillary treatment for renal failure or nephrotic syndrome may be initiated as needed in individual cases. Although some cases resolve with treatment of underlying disease or spontaneous remission, many cases are steadily progressive. Patients with nephrotic syndrome or established azotemia have a poor prognosis.

KEY POINT 18-11 Dietary management, angiotensinconverting enzyme inhibitor administration, fatty acid supplementation, and aspirin provide the cornerstones for management of glomerular disease. Goals of treatment include a reduction in urine protein creatinine, avoidance of complications, and stable renal function.

Renal Amyloidosis

Renal amyloidosis carries a poor prognosis, especially if renal failure and uremia are evident. Underlying inflammatory and neoplastic diseases should be identified and managed if possible; however, few interventions will affect established amyloid deposits. Dimethylsulfoxide (DMSO) has been suggested in the treatment of amyloidosis. The drug may enhance solubilization of amyloid fibrils, reduce serum amyloid A protein concentrations, and reduce associated interstitial inflammation and fibrosis. The latter effect is most likely to be beneficial in improving renal function and reducing proteinuria. Longterm management of a few dogs with DMSO injections has been described.^{81,92} DMSO (90% solution) may be diluted 1:4 with sterile water and administered subcutaneously at a dosage of 90 mg/kg three times weekly.⁸¹ Adverse effects of DMSO include nausea, a garliclike odor, and pain on injection. Oral daily dosages have been described, ranging from 250 to 300 mg/kg per day.93,94

Colchicine is another agent that impairs the release of serum amyloid A from hepatocytes and may prevent the production of amyloid-enhancing factor.⁷⁸ The agent is used to prevent development and progression of amyloidosis in human patients with familial Mediterranean fever. Like DMSO, the agent is unlikely to be helpful after the development of renal failure. Low doses of colchicine (0.01 to 0.03 mg/kg daily) may be considered prophylactically for Chinese Shar-Pei dogs with recurrent fevers and joint disease, which may be precursors to systemic or renal amyloid deposition.^{78,81} Both colchicine and DMSO are most effective in the early phases of amyloid deposition; colchicine may reduce proteinuria as well. As with other types of glomerular disease, metabolic complications such as hypertension and hypercoagulability must be identified and addressed.

DIALYTIC THERAPY

Dialytic therapy is available to remove excess water or solutes from plasma using osmotic gradients across a semipermeable membrane. In hemodialysis the membrane is an extracorporeal synthetic membrane, whereas in peritoneal dialysis the peritoneum serves as the membrane for exchange. By these methods urea, creatinine, and other retained molecules can be eliminated in the patient with renal failure. Although peritoneal and hemodialysis techniques have been described in many animal models, their clinical application in small animal veterinary medicine has been limited by the extensive technical, equipment, and financial requirements involved.95-102 Dialytic therapy is generally considered most appropriate as a temporary, short-term measure in reversible renal and postrenal disorders. It can, however, be an effective means of supplementing medical management in refractory end-stage chronic renal failure. It is also used to manage feline transplant recipients and cats with ureteral obstruction before surgical intervention. Intermittent hemodialysis has been successful in reducing the average urea concentration in dogs and cats with chronic renal disease and moderate azotemia.^{100,101,103} Indications for dialytic therapy in acute renal failure include failure of conservative therapy; refractory oliguria or anuric, life-threatening fluid overload; or life-threatening electrolyte or acid-base disturbances. Hemodialysis also is useful in the early management of toxicoses, especially ethylene glycol intoxication, as well as adjunctive treatment of refractory leptospirosis. In chronic renal failure, dialysis is considered when uremic signs are unresponsive to therapy, usually when azotemia is advanced. The procedure requires reliable vascular access, an appropriate hemodialyzer and dialysis delivery system, and dedicated technical team.^{101,103} Currently, hemodialysis is available at the University of California-Davis Companion Animal Dialysis Unit, Davis, California, and San Diego, California; and the Animal Medical Center, New York, New York. Continuous renal replacement may be available at additional specialty centers or veterinary teaching hospitals. The development of additional centers for intermittent dialysis in dogs may increase the application of the technique for improved management and prolonged survival in selected cases. Peritoneal dialysis may be initiated in the practice or referral center setting after placement of an intraabdominal dialysis catheter.98 Straight, acute peritoneal dialysis catheters are available for emergency dialysis, whereas column disk or T-fluted catheters are preferred for long-term dialysis. Dialysate solutions of 1.5% to 4.25% dextrose are infused to create an osmotic gradient within the abdomen. Substances such as urea, creatinine, phosphorus, electrolytes, and other uremia molecules can pass through intercellular channels of the peritoneum into the dialysate for removal. A dedicated technical

RENAL TRANSPLANTATION

Renal transplantation is the definitive mode of management of chronic renal diseases in human patients and has become a viable option in veterinary medicine in selected circumstances. A successful clinical renal transplantation program has been developed for cats at the Veterinary Medical Teaching Hospital, University of California, Davis, 104-106 and is now available at several veterinary referral hospitals in the United States and Canada. With transplantation of a healthy donor kidney and appropriate immunosuppressive therapy, uncomplicated cases can expect good-quality posttransplant survival times of 1 to 3 years. Of 61 cats receiving renal transplants between 1996 and 1999 at the University of Davis, approximately 60% survived 6 months after the operation, whereas the 3-year survival rate was about 40%.107 Cats 10 to 14 years of age had a higher risk of death, especially during the 6-month postoperative period.¹⁰⁷ The best candidates for renal transplantation are cats in early renal failure, with less than 20% weight loss and no other disease conditions. Candidates are screened for cardiac disease, neoplasia, concurrent metabolic disease, urinary tract infection, feline leukemia virus, and feline immunodeficiency virus.

Immunosuppressive therapy with cyclosporine and prednisolone is initiated perioperatively and continued indefinitely. Treatment is monitored by frequent measurements of trough blood levels of cyclosporine. Potential complications of transplantation include anesthetic and surgical complications, obstruction of the transplanted ureter, infections caused by immunosuppression, pyelonephritis, postoperative hypertension, central nervous system disease, hypercalcemia, and acute or chronic graft rejection.^{107,108} De novo malignant neoplasia was diagnosed in 9.5% of 95 feline transplant recipients 2 to 28 months after transplantation and may be associated with immunosuppressive therapy.¹⁰⁹Transplantation cannot be regarded as a cure for renal disease or an option for emergency treatment of renal failure, but it can be expected to provide an improved quality of life and enhanced survival in some cats with renal failure. Details of the program, surgical procedure, and criteria for case selection are available.^{105,106} Canine transplantation remains problematic, although newer immunosuppressive strategies have been developed.¹¹⁰

MANAGEMENT OF MICTURITION DISORDERS

Physiology of Micturition

The storage phase of micturition is characterized by sympathetic dominance, with sympathetic innervation to the bladder and urethra supplied by the hypogastric nerve. Activation of β -adrenergic receptors in the urinary bladder facilitates relaxation of the detrusor muscle, whereas stimulation of α -adrenergic receptors in the bladder neck and urethra facilitates smooth muscle contraction and closure of the outlet. Additional urethral resistance is supplied by the striated muscle of the external urethral sphincter. As bladder volume and pressure increase with filling, afferent information is transmitted to the central nervous system by way of the pelvic nerve and spinal afferent pathways. Voiding is initiated by voluntary control centers in the cerebral cortex and midbrain. Efferent impulses are transmitted by spinal pathways and the pelvic nerve in the parasympathetic system, initiating contraction by stimulating cholinergic receptors in the detrusor muscle of the urinary bladder. The sympathetic input to the bladder and urethra is inhibited, allowing outlet resistance to drop appropriately. After complete voiding, the system is reset for storage.¹¹¹

Disorders of urine storage usually result in urine leakage, whereas disorders of voiding result in urine retention, incomplete voiding, or incontinence. Most disorders of micturition can be classified and managed according to the status of urinary bladder (hypocontractile or hypercontractile) and urethral (hypotonic or hypertonic) function.^{112,113} Diagnosis is usually based on evaluation of historical, physical, and observational findings, although specialized urodynamic testing is required in some instances. Pharmacologic agents are valuable in the management of functional micturition disorders; manipulation of urinary bladder or urethral smooth muscle tone can aid in facilitating normal micturition. Because pharmacologic activity is directed at the end organ (postganglionic receptors in the urinary bladder or urethra), agents are applied similarly in both neurogenic and non-neurogenic disorders (Table 18-3). Practical reviews regarding the management of major micturition disorders are available.114,115

KEY POINT 18-12 Pharmacologic manipulation of micturition is aimed at the target end-organ receptors (in the urinary bladder or urethral muscle), so treatments are applied similarly regardless of the cause of the dysfunction.

The Hypocontractile Urinary Bladder

Problems resulting in hypocontractile urinary bladders include sacral or suprasacral neurologic lesions, acute or chronic overdistention of the urinary bladder, disorders causing general muscle weakness, or dysautonomia. Urinary bladder contraction is primarily controlled by parasympathetic (cholinergic) input. Cholinergic agents have been used to promote bladder emptying in atonic bladders, although the success of orally administered agents is unreliable.¹¹⁶ Bethanechol chloride is administered at starting dosages of 1.25 to 2.5 mg (cats), 5 mg (small dogs), and 10 mg (larger dogs) every 8 to 12 hours. Full effects of the drug should be apparent within 1 to 2 days. When effective, voiding is usually observed within 2 hours. The dosage may be increased by 2.5- to 5-mg increments up to 25 mg every 8 hours in dogs and 7.5 mg every 8 hours in cats if ineffective.¹¹³ Parenteral administration of bethanechol (2.5 to 10 mg given subcutaneously every 8 hours) may be effective in refractory dogs with bladder atony; however, the likelihood of adverse effects is increased with this route.^{117,118}

Agent	Actions	Dosages	Adverse Effects	Contraindications
Agents Used to Increase B	Bladder Contractility			
Bethanechol (Urecholine)	Parasympathomimetic	Dog: 5-25 mg PO three times daily Cat: 1.25-5.0 mg PO three time daily	Vomiting, cramping Ptyalism, anorexia	Urethral obstruction, GI disease, hyper- thyroidism
Cisapride	Smooth muscle prokinetic			
Agents Used to Decrease I	Bladder Contractility			
Oxybutynin (Ditropan)	Anticholinergic, antispasmodic	Dog: 1.25-5 mg PO two to three times daily Cat: 0.5-1.25 mg PO two to three times daily	Vomiting, diarrhea, urine retention, sedation	Glaucoma, car- diac disease, GI obstruction
Propantheline (Pro-Banthine)	Anticholinergic	Dog: 7.5-15 mg PO three times daily Cat: 5-7.5 mg/cat PO three times daily or as needed	As for oxybutynin	As for oxybutynin
Dicyclomine (Bentyl)	Anticholinergic, smooth muscle relaxant	Dog: 10 mg/dog PO three times daily Cat: not determined	As for oxybutynin	As for oxybutynin
Imipramine (Tofranil)	Tricyclic antidepressant, anticholinergic and adrenergic effects	Dog: 5-15 mg PO twice daily Cat: 2.5-5 mg PO three times daily	Tremors, seizures, tachycardia, excitability	
Agents Used to Increase U	Jrethral Resistance			
Diethylstilbestrol (DES)	Reproductive hormone (female)	Dog: 0.1-1.0 mg/dog PO daily for 5 days, followed by 0.1-1.0 mg q 5-14 days as needed	Signs of estrus, bone marrow suppression, pyometra	Immune-mediated disease, pregnancy
Stilbestrol	Reproductive hormone (female)	Dog: As for DES, <i>or</i> 0.01-0.02 daily (see text)	As for DES	As for DES
Estriol	Reproductive hormone (female)	Dog: 0.5-2 mg/dog PO q 24-48 hr	As for DES, GI upset	As for DES
Premarin (conjugated estrogen)	Reproductive hormone (female)	Dog: 0.02 mg/kg PO q 48-72 hr or as needed	As for DES	As for DES
Testosterone proprionate	Reproductive hormone (male)	Dog: 2.2 mg/kg SC or IM q 2-3 days Cat: 5-10 mg IM as needed	Aggression, prostatic disease, perianal disease	Prostate disorders
Testosterone cypionate	Reproductive hormone (male)	Dog: 2.2 mg/kg IM or 200 mg/dog IM q 30-60 days	As for testosterone propionate	Prostatic disease
Phenylpropanolamine	Alpha-agonist	Dog: 1.5 mg/kg PO two to three times daily Cat: 1.5-2.2 mg/kg PO two to three times daily	Tachycardia, hyperten- sion, restlessness, anorexia	Cardiac disease, glau- coma, hyperten- sive disease
Ephedrine (Pseudoephedrine)	Alpha-agonist	Dog: 1.2 mg/kg PO two to three times daily Cat: 2-4 mg/cat PO two to three times daily	As for phenylpropanol- amine	
Deslorelin	GnRH analog	Dog: 5-10 mg depot injection once or twice (see reference for details)		
Agents Used to Decrease	Urethral Resistance			
Phenoxybenzamine (Dibenzyline)	Alpha-antagonist, urethral smooth muscle relaxation	Dog: 0.25 mg/kg PO twice daily Cat: 1.25-7.5 mg/cat PO once to twice daily	Hypotension, GI upset, tachycardia	Cardiac disease, glaucoma, diabetes mellitus, renal failure
Prazosin (Minipress)	Alpha-antagonist, urethral smooth muscle relaxation	Dog: 1 mg/15 kg PO three times daily Cat: 0.5 mg PO three times daily or 0.03 mg/kg IV	As for phenoxybenza- mine	As for phenoxyben- zamine

Agent	Actions	Dosages	Adverse Effects	Contraindications
Baclofen (Lioresal)	Skeletal muscle relaxant	Dog: 5-10 mg PO three times daily Cat: Not recommended	Weakness, pruritus, GI upset	
Dantrolene (Dantrium)	Skeletal muscle relaxant	Dog: 1-5 mg PO two to three times daily Cat: 0.5-2 mg/kg PO three times daily, 1.0 mg/kg IV	Weakness, GI upset, sedation, hepatotox- icity	Cardiopulmonary disease
Diazepam (Valium)	Benzodiazepine, skeletal muscle relaxant	Dog: 2-10 mg/dog PO three times daily Cat: 1-2.5 mg/cat PO three time daily (<i>or</i> 0.5 mg/kg IV)	Sedation, polyphagia, paradoxical excite- ment, hepatotoxicity	Hepatic disease, pregnancy

Table 18-3	harmacologic Agents Used in the Management of Micturition Disorders-Con
	narnacologic Agents osca in the Management of Mictantion Disorders of

PO, By mouth; Gl, gastrointestinal; SC, subcutaneous; IM, intramuscular; IV, intravenous.

Adverse effects of cholinergic agents include muscarinic effects such as salivation, defecation, and abdominal cramping. Vomiting, diarrhea, and anorexia also are possible complications. Overdosage or parenteral administration can (rarely) result in a cholinergic crisis and death; atropine is useful as an antidote. Parasympathomimetic agents are contraindicated in the face of urinary or gastrointestinal obstruction and should be used with caution in animals with bronchial disease or ulcerative gastrointestinal disease. Bethanechol administration may increase smooth muscle tone at the bladder neck and outlet;¹¹⁹ ure thral resistance must be minimized with α -antagonists, striated muscle relaxants, or both before bethanechol treatment is initiated. Intermittent urinary catheterization or indwelling urinary catheterization may be necessary during early therapy to ensure a patent outlet and to maintain a small urinary bladder, facilitating recovery of smooth muscle function.

Recovery of urinary contractile function is most likely in animals with acute overdistention of urinary bladder or with reversible neurologic lesions creating detrusor atony. Alternative pharmacologic agents enhancing bladder motility are lacking; cholinesterase inhibitors, β -antagonists, dopamine antagonists, and prostaglandin treatments have been investigated in human beings but have not received much attention in veterinary patients. Increased urinary frequency and enhanced contractile indices have been observed with cisapride administration in human patients.^{120,121} This prokinetic agent increases acetylcholine release at neuromuscular junctions and may ultimately be valuable in stimulating bladder smooth muscle in dogs and cats, but urinary effects remain unproved and availability is limited to veterinary compounding pharmacies.115,122

The Hypercontractile Urinary Bladder

Accommodation, or compliance, of the urinary bladder may be affected by congenital disorders, chronic inflammation, infiltrative masses, neurologic disorders, or idiopathic causes. In cats bladder hypercontractility (detrusor instability) has been described in feline leukemia-associated urinary incontinence.¹²³ Filling of the bladder is impaired, and involuntary bladder contractions occur at low bladder pressures and volumes. Clinically, disorders of bladder accommodation are manifested by urinary incontinence and pollakiuria.

Management of urinary bladder storage dysfunction may include treatment of urinary tract infections, correction of neurologic disorders, or pharmacologic intervention.

KEY POINT 18-13 Urinary bladder overactivity is rare in small animals but responds well to pharmacologic treatment. Treatment of urinary tract infection and inflammation and consideration of behavioral disorders should precede trial treatment.

Agents with anticholinergic properties may be used to alleviate the signs associated with bladder contractility or reduced bladder storage function. These agents appear to be quite effective in dogs and cats with idiopathic and feline leukemiaassociated urinary incontinence but may be less effective in bladders with severe inflammatory disease, neoplastic diseases, or fibrotic changes. Oxybutynin, with anticholinergic, antispasmodic, and local anesthetic actions on the urinary bladder, has been used in veterinary patients and is available in tablet form (5-mg tablets) and in a liquid syrup. In dogs dosages of approximately 0.2 mg/kg have been effective.¹²³ Small dogs usually respond to 0.75 to 1.25 mg oxybutynin every 8 to 12 hours, whereas larger dogs may require 2.5 to 5 mg every 8 to 12 hours. In cats a dosage of 0.5 to 1.25 every 8 to 12 hours is recommended.¹²⁴ Long-acting formulations have recently become available. Tolterodine is a competitive, pure muscarinic receptor antagonist that is the drug of choice in humans for treating destrusor instability in human beings, which results in a hyperactive or hyperreflexive bladder. It has fewer side effects than oxybutynin, which was previously the drug of first choice.¹²⁵ At this time there is not information on appropriate doses in veterinary patients.

Other agents with anticholinergic or antispasmodic activity include dicyclomine, tricyclic antidepressants, propantheline, and tolterodine. Dicyclomine is a similar, less expensive agent that has been as effective as oxybutynin in preliminary studies in dogs. Dosages of 5 to 10 mg every 8 hours are recommended in dogs.¹²⁶ Use of this drug in cats has not been reported.

The tricyclic antidepressant imipramine is another agent with anticholinergic properties. Imipramine also has mild stimulatory effects on α - and β -receptors in the bladder and urethra, which serve to further facilitate urine storage.

Recommended dosages of imipramine are 5 to 15 mg orally every 8 to 12 hours in dogs and 2.5 to 5 mg orally every 12 hours in cats.¹¹² Propantheline is an alternative anticholinergic agent. Recommended dosages of propantheline range from 5 to 7.5 mg as needed in cats (frequency varies from every 8 hours to every 2 or 3 days)^{112,127,128} and 7.5 to 30 mg every 12 hours in dogs.¹¹³ Starting doses of 5 mg/day in cats and 7.5 to 15 mg every 12 hours in dogs are reasonable.

Ptyalism is a common complication of anticholinergic administration in cats that can be minimized by placing the product in gelatin capsules. Other adverse effects of anticholinergic agents include drowsiness, ileus and vomiting, constipation, and urine retention. Dry mouth, dry eyes, and mydriasis have been reported in humans. Anticholinergic agents are contraindicated in animals with glaucoma. Many alternative agents have been employed for detrusor instability in people, including tolterodine, β -agonists, calcium channel blockers, and other smooth muscle relaxants. Success rates have varied, and these agents have not been investigated in veterinary medicine.

The Hypotonic Urethra

Reproductive Hormones

Poor outlet resistance (urethral incompetence) is a common disorder of middle-aged, neutered, medium- to large-breed dogs, and predisposing factors include caudal bladder position, a short urethra, poor urethral tone, neutering, breed, and obesity. German Shepherd Dogs, Doberman Pinschers, Old English Sheepdogs, Springer Spaniels, Boxers, Rottweilers, Weimaraners, and Irish Setters are overrepresented.¹²⁹ Urethral incompetence can also be attributed to congenital, inflammatory, and neurogenic disorders. Because of the prevalence of this problem in older, neutered animals, reproductive hormone supplementation has been used extensively with good results. Affected animals do not appear to be deficient in reproductive hormones; improved continence observed with reproductive hormone administration is likely due to a variety of effects on the urethra. The major action of reproductive hormones in the lower urinary tract may be sensitization and upregulation of α -adrenergic receptors in the bladder neck and urethra. Mucosal integrity, collagen content, and capillary vascularity in the urethra also are enhanced by estrogens, contributing to a more effective urethral mucosal "seal."130

KEY POINT 18-14 Urethral sphincter mechanism incompetence is the most common cause of urinary incontinence in dogs. Most affected dogs leak urine intermittently at rest and respond well to alpha-adrenergic agents, reproductive hormones, or a combination of the two.

Diethylstilbestrol and stilbestrol are effective and reasonably safe choices for female dogs with urethral incompetence. Diethylstilbestrol is initially administered at a total dosage of 0.1 to 1 mg (approximate 0.02 mg/kg) orally each day for 5 to 7 days, followed by a similar dosage administered every 5 to 14 days.¹¹² Daily estrogen treatment, using minimal dosages of stilbestrol, also has been recommended. The protocol includes starting dosages of 0.04 to 0.06 mg orally administered daily for 1 week and then reduced at weekly intervals to 0.01 mg daily. After 4 weeks the treatment is discontinued. A prolonged residual effect may be observed. If incontinence recurs, the protocol may be repeated or the drug may be administered indefinitely at 0.01 to 0.02 mg/dog daily.¹³¹ Commercially available alternative estrogens include conjugated estrogens (Premarin, 0.02 mg/kg orally every 2 to 4 days and estriol, 0.5 to 2.0 mg/dog every 2 to 3 days). As for diethylstilbesterol, daily loading doses are advised for the first 5 to 7 days. More frequent dosing (two to three times per week) are usually necessary with these preparations.

Response to estriol was studied in a group of 129 incontinent adult spayed female dogs in an open label trial. Dogs were given 2 mg of estriol daily for 1 week, then the dose was reduced at weekly intervals to the minimal effective dose (0.5 to 2 mg/dog every 24 to 48 hours). Veterinarians reported continence in 61% and improvement in an additional 22% of the dogs; owner-reported responses were slightly less favorable.¹³² Favorable experience with natural, conjugated estrogen (similar to Premarin) has been described in nine incontinent large-breed dogs followed in a prospective manner. All dogs responded well to estrogen administration; daily administration was continued until 2 weeks of continence had been achieved. In seven of nine dogs in which dose information was reported, maintenance dosages ranged from 0.625 mg to 1.25 mg per dog, administered orally every 12 to 72 hours. In the remaining two dogs, administration every 4 to 7 days was effective.¹³³ No hematologic effects of estrogen were observed in estrogen-treated dogs in either study.^{132,133}

Significant inter-animal variation in accumulation and recirculation of the drug was noted in pharmacokinetic studies.¹³⁴ Potential adverse effects of estrogen administration include bone marrow suppression, alopecia, behavioral changes, and signs of estrus, although the risks are minimal when the drug is used properly. Periodic monitoring of complete blood counts is advised for dogs receiving long-term estrogen administration. In addition to toxic effects, estrogens frequently cause signs of estrus in cats and are not recommended in that species.¹¹²

Many spayed female dogs respond well to estrogen administration. A response rate of 60% to 70% can be expected.¹³¹ A residual effect may be observed in some dogs such that the drug can be discontinued intermittently; however, most dogs require constant treatment and ultimately become refractory to the drug. Dosage and frequency adjustments can be attempted when treatment failure occurs; however, switching to or combining with an alternative agent may be more effective.

Testosterone administration may be used similarly for the treatment of urethral incompetence in male dogs and cats. The potential for adverse effects is significant; effects include aggression, other behavioral changes, prostatic disease, and aggravation of disorders such as perianal adenomas and perineal hernias. Other disadvantages of the drug include the ineffectiveness of oral preparations and its classification as a controlled drug. Testosterone proprionate may be administered parenterally at dosages of 2.2 mg/kg subcutaneously or intramuscularly (dogs) or 5 to 10 mg/cat every 2 to 3 days. Testosterone cypionate or testosterone enanate may be administered every 30 to 60 days at a similar dosage. Some dogs require higher doses; a dosage of 200 mg/dog administered intramuscularly has been effective.¹³⁵ Experiences with oral preparations (methytestosterone) for urinary incontinence have not been reported. The many disadvantages of this drug limit its application in the treatment of urinary incontinence, although it may be useful in some neutered male dogs with acquired urethral incompetence. If the product is minimally effective or frequent injections are required, alternative agents should be used.

KEY POINT 18-15 When used at appropriate dose and frequency of administration, estrogen treatment of urinary incontinence is safe in dogs and highly unlikely to cause bone marrow suppression.

α-Adrenergic Agonists

Sympathomomimetic agents (Alpha-agonists) are effective agents for the treatment of urethral incompetence. α -adrenergic agents probably enhance ure thral closure through release of endogenous norepinephrine and direct stimulation of α -receptors in the bladder neck and urethra. The agents are usually well tolerated and may be used in animals of either sex. Phenylpropanolamine preparations are effective and available from veterinary suppliers. The agent is no longer found in overthe-counter decongestant preparations. Approximate dosages of 1.5 to 3 mg/kg orally every 8 to 12 hours are recommended. The best responses appear to be gained by starting at a dosage of at least 1.5 mg/kg every 8 hours and then adjusting the dosing frequency after a few weeks. Many dogs can be maintained with once- or twice-daily administration of phenylpropanolamine, especially in timed-release formulations. Ephedrine (ephedrine, pseudoephedrine) is an alternative α -agonist also available in over-the-counter preparations. However, many of these preparations are also under pharmacist control at this time and cannot be purchased in bulk amounts. Dosages are similar to phenylpropanolamine (1.2 mg/kg orally every 8 to 12 hours).¹¹² Dogs usually receive 12.5 to 50 mg orally two to three times daily. Efficacy of ephedrine compounds is slightly less predictable than that of phenylpropanolamine.

KEY POINT 18-16 Phenylpropanolamine remains the most reliable pharmacologic treatment for urethral incompetence in dogs. Adjustments in dose, frequency, and type of product may improve response in the small percentage of affected dogs with refractory incontinence.

In cats the administration of α -agonists is somewhat problematic. One-half of a 25-mg phenylpropanolamine tablet may be given orally every 8 to 12 hours. Some experts recommend sprinkling $\frac{1}{12}$ of a 75-mg capsule onto food twice daily.¹³⁶ The effectiveness of α -agonists in cats is questionable, however. Only small portions of the urethra are composed predominantly of smooth muscle and expected to respond to α -agonists. Fortunately, pure urethral incompetence is rare in cats.

Adverse effects of α -agonists include anorexia, weight loss, hyperexcitability, and tachycardia. The author has observed occasional instances of gastrointestinal upset and skin eruption with phenylpropanolamine administration. Systemic hypertension is a serious theoretical complication, although it has not yet been reported with clinical use.^{137,138} The drug should be avoided or used cautiously in dogs with cardiac or hypertensive disorders, including renal disease and diabetes mellitus. In human patients the drug is contraindicated in the face of prostatic hypertrophy, hyperthyroidism, and glaucoma.

Response to appropriate dosages of phenylpropanolamine are usually good. Excellent clinical responses or "cures" can be expected in 75% to 90% of dogs,^{131,137,139,140} with significant improvement noted in almost all patients treated with the drug. In a large (n = 50) prospective, blinded, placebocontrolled study, Scott et al.¹⁴¹ found 55% of treated dogs (phenylpropanolamine 1 mg/kg orally every 8 hours) became continent after 7 days of treatment, as opposed to 26% of placebo-treated dogs. After 28 days the percentage of continent dogs rose to 85.7% in the phenylpropanolamine group, as opposed to 33% of placebo-treated dogs.¹⁴¹ In another randomized, double-blinded study, female dogs responded well to phenylpropanolamine (1.5 mg/kg every 12 hours); 21 of 24 dogs were continent and another 2 improved.¹⁴²

Although most resources recommend administration of phenylpropanolamine two or three times daily for best effect, the dose is adjusted to the minimal amount needed to achieve continence. As with reproductive hormones, it is usually beneficial to start with the optimal dose until continence is achieved. However, a recent investigation in healthy intact Beagles challenges this assumption. Dogs were treated with phenylpropanolamine at once-, twice-, or thrice-daily intervals. Urodynamic changes (increased urethral pressure) were similar for all dosing frequencies, leading the authors to recommend once-daily treatment for incontinent dogs.¹⁴³ Desensitization of receptors was suspected with thrice-daily administration. Responses in intact Beagles may not parallel those in incontinent spayed dogs; however, reduced frequency of administration may be effective in some dogs and may prevent development of tolerance during long-term treatment.

Although over-the-counter availability of ephedrine and pseudoephedrine makes their use convenient, outcomes are slightly less favorable with these agents. With ephedrine compounds, 82.4%¹⁴⁴ and 74%¹³⁹ continence rates are reported. In another group of nine female dogs studied in a crossover design, improvement in continence score, maximal urethral closure pressure, and functional area of the urethral pressure profile was observed after pseudoephedrine (1.5 mg/kg every 8 hours) administration.¹³⁸

Although most dogs exhibit excellent response to alpha agonists, refractory incontinence does occur. Patients that do not respond tend to be younger dogs with congenital urethral incompetence or dogs in which incontinence develops before or soon after ovariohysterectomy. These patients may respond to an increased therapeutic dosage; combination treatment with reproductive hormones; or other treatment modalities, such as urethral injection of collagen.

Alternative agents currently under investigation include gonadotropin-releasing hormone (GnRH) analogs and duloxetine. Reichler¹⁴⁵ reported their experience with luprolide, buserelin, and deslorelin, GnRH analogs that suppress the release of sex hormone. Their use in incontinence is based on the theory that chronically unsuppressed follicle-stimulating hormone (FSH) and luteinizing hormone (LH) release (due to lack of negative feedback) in ovariectomized dogs may contribute to urinary incontinence. Administration of analogs paradoxically results in reduced FSH and LH over time. In 12 of 13 dogs with refractory incontinence, the drug appeared useful, either alone or in combination with alpha agonists. Deslorelin (5 to 10 mg depot injection) became the preferred treatment in this study. In a subsequent trial, 9 of 23 incontinent dogs treated with long-acting leuprolide were continent for prolonged periods (70 to 575 days); another 10 of the dogs had partial response. These 23 dogs, however, also responded to phenylpropanolamine, with 92% overall reduction in urine leakage.¹⁴⁶ Urethral closure pressures did not increase in these dogs, however. The only urodynamic parameter that changed after depot leuprolide injection in spayed Beagles was cystometric threshold volume (an indicator of capacity and accommodation).147 There were no apparent adverse effects of GnRH treatment reported in this study, but long-term use of these drugs in dogs has not been evaluated. GnRH analogs may prove to be a valuable long-acting treatment that would alleviate the need for daily or weekly medication; however, availability and cost of GnRH analogs limit their use in the United States.

Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has proven useful in women with stress incontinence and may improve striated muscle resistance as well as bladder capacity.¹⁴⁸ Adverse effects included nausea, fatigue, insomnia, constipation, diarrhea, and headache, but these symptoms were infrequent and mild. Experience is limited in small animals at this time.

For incontinent dogs that fail to respond to appropriate pharmacologic treatment, a search for underlying urinary tract infection, neurologic abnormalities, and other causes of incontinence is indicated. For refractory female dogs, a bulking agent such as collagen can be injected into the urethral submucosa to generate increased urethral resistance. This minimally invasive, endoscopic-assisted procedure provides significant improvement for up to several years and can be repeated when effectiveness wanes.¹⁴⁹⁻¹⁵¹ Alternatively, surgical options, including episioplasty, colposuspension, or urethropexy, are reasonable for some dogs that fail to respond to medical management.^{152,153} Many dogs undergoing urethral injections or surgical procedures require phenylpropanolamine treatment after surgery to achieve the best outcome.

The Hypertonic Urethra (Functional Urethral Obstruction)

Inappropriate urethral resistance may lead to functional urethral obstruction and urine retention. Urethral inflammation or spasm can develop after urethral obstruction with uroliths or urethral plugs. Urethral resistance also may be uncoordinated with bladder contraction as a result of neurologic disorders or idiopathic causes. Urethral resistance also may increase when bethanechol is administered for hypocontractile urinary bladders; the drug also stimulates contractions of musculature at the bladder neck. In these situations pharmacologic manipulation may be instituted to decrease smooth or striated muscle contractility in the urethra and reduce outlet resistance.

Alpha-Adrenergic Antagonists

Alpha-adrenergic antagonists are the preferred agents for decreasing urethral smooth muscle tone and are experimentally effective in reducing overall urethral resistance in dogs.¹⁵⁴Their activity is less predictable in cats, in which striated muscle predominates in the urethra. Phenoxybenzamine has been a commonly used α -antagonist in both dogs and cats.^{155,156} Phenoxybenzamine irreversibly inactivates α-receptors and may have a central effect on striated musculature.¹⁵⁷ The drug is available in 10-mg capsules and is dosed at approximately 0.25 mg/kg orally every 12 to 24 hours.¹¹² Total dosages usually range from 5 to 20 mg (dogs) and 2.5 to 5 mg (cats). Efficacy may be discerned by judging the quality of urine stream produced. Phenoxybenzamine is expensive and unavailable in some areas. The drug's availability may be further limited because of the discovery of its carcinogenic potential in rats157 as well as its obsolescence relative to newer alpha antagonists used in human beings.

An alternative, and more selective, α_1 -antagonist is prazosin, a drug that has been recommended in the management of heart failure and systemic hypertension in dogs. Extrapolated dosages are 1 mg per 15 kg body weight orally every 8 to 12 hours in dogs; dosages of 0.25 to 0.5 mg every 12 to 24 hours seem reasonable for cats. Because total dosages of 1.5 to 3 mg orally every 8 hours are used for functional urethral obstruction in humans, however, lower dosages may be effective in small animals. Prazosin was shown to produce superior urethral pressure reduction compared with phenoxybenzamine, although prazosin therapy was associated with a significant drop in blood pressure.¹⁵⁸ Additional α-blocking agents have included terazosin and doxazosin.^{157,159} No reports are available regarding their use in small animals, although a starting dose of 0.125 to 0.25 mg/dog orally every 24 hours can be extrapolated from human dose recommendations.

Tamsulosin is a newer antagonist that exhibits strong selectivity for urinary α_1 receptors (α_{1A}) over vascular α_1 receptors (α_{1B}), minimizing the risk of hypotension.^{160,161} Because glucuronidation is probably required for metabolism, tamsulosin cannot currently be recommended for use in cats. In experimental studies in dogs, doses of 1 to 100 µg/kg intravenously and orally have been used to evaluate the effect of tamsulosin on urethral pressure and arterial blood pressure.^{160,162,163} Oral tamsulosin doses of 1 to 10 µg/kg produced dose-dependent blockade of phenylephrine-induced urethral pressure.¹⁶³ For clinical application in dogs, 10 µg/kg orally every 24 hours is recommended on the basis of anecdotal evidence.

Silodosin is another commercially available α_1 antagonist that shows even greater α_{1A} receptor selectivity in canine

tissues than does tamsulosin and may prove to be a useful therapy, but veterinary clinical data and experience with silo-dosin are lacking at this point.¹⁶⁴

Adverse effects of α -antagonists include hypotension, reflex tachycardia, and gastrointestinal irritation. Nausea can be minimized by administration of the drug with food. The drug may be dangerous to animals with cardiac disease receiving other vasodilators or diuretics and to animals with renal disease, in which drops in perfusion pressure could precipitate an acute crisis. Any evidence of weakness should prompt withdrawal of the drug or adjustment of the dosage.

Striated Muscle Relaxants

If manipulation of urethral smooth muscle does not sufficiently improve voiding, addition of a striated muscle relaxant may be considered. Striated muscle relaxants are particularly useful in dysuric patients with upper motor neuron lesions and in cats with functional urethral obstruction. In this species striated muscle predominates in the distal urethra and likely contributes most to functional obstruction. The most common muscle relaxant used for urethral resistance is the benzodiazepine diazepam. The drug serves as a short-acting muscle relaxant by centrally mediated actions, and its effect on urethral striated muscle is variable.

Diazepam (0.2 to 0.5 mg/kg orally) is recommended as a temporary agent to facilitate bladder expression or to augment weak voiding; the agent is given 15 to 30 minutes before expression.¹⁵⁶ Dosages for cats range from 1.25 to 2.5 mg/cat every 8 to 12 hours; sedation is common with higher dosages.^{155,156} In dogs total dosages of 2 to 10 mg/dog are given.^{117,118} Adverse effects of diazepam administration include sedation, weakness, and paradoxical excitement. In cats behavior changes and idiosyncratic hepatotoxicity are additional concerns. Alprazolam is a reasonable alternative if chronic administration is needed.

Dantrolene is an alternative striated muscle relaxant that has been investigated in cats. Dantrolene acts as a direct muscle relaxant by inhibiting calcium movement from the sarcoplasmic reticulum in muscle cells. The agent (1 mg/kg, administered intravenously) was effective in reducing segmental urethral pressures in healthy male cats¹⁶⁵ and in moderately reducing urethral pressures in a small group of recently obstructed cats.¹⁶⁶ The effect on urethral musculature was enhanced by the concurrent administration of prazosin.¹⁶⁶ Recommended oral dosages are 1 to 5 mg/kg orally every 8 hours in dogs and 0.5 to 2 mg/kg orally every 8 hours in cats.¹⁶⁷ Potential adverse effects include sedation, dizziness, weakness, and gastrointestinal upset; the drug is contraindicated in patients with cardiopulmonary disease. Hepatotoxicity is a worrisome adverse effect of dantrolene administration in humans, usually after longterm treatment at high dosages.¹⁷ Although oral dantrolene has been recommended for several years, clinical reports regarding its use in small animals are lacking. Other striated muscle relaxants include baclofen, cyclobenzaprine, and botulinum toxin injections.¹⁵⁹ On the basis of anecdotal reports relayed to the authors, baclofen cannot be recommended because of poor tolerance of the drug in dogs and cats.

Treatment of detrusor–urethral dyssynergia has been unrewarding in reported cases.^{155,168-170} In the authors' experience, dogs with dysfunctional voiding in the absence of compressive neurologic disease are often responsive to manipulation of smooth muscle resistance.¹⁷¹ Pharmacologic manipulation of urethral tone in cats with dyssynergia or functional obstruction and dogs with suspected striated urethral dyssynergia is less rewarding. Recovery is also related to the degree of detrusor damage sustained by the time of diagnosis. In chronic cases circumvention of urethral resistance using intermittent urinary catheterization or urethral stents may be necessary for temporary or prolonged relief of obstruction.¹⁵⁹

PHARMACOLOGIC AGENTS THAT TARGET URETERAL MOTILITY

With an increase in obstructive ureteroliths observed in small animal practice, interest in pharmacologic strategies to promote passage of ureteroliths through the urethra has increased. Fluid therapy and diuretics may be useful in increasing urine flow and hydrostatic pressure proximal to a ureterolith, but this approach must be done with caution so that affected animals, especially those with complete obstruction, are not overhydrated. Alleviating ureteral spasm can be attempted. Alpha antagonists, calcium channel blocking agents, and antiinflammatory agents can facilitate ureteral relaxation.¹⁷² These drugs do appear to facilitate ureterolith passage in humans but have not been well studied in dogs or cats. Glucagon appears to reduce ureteral contractions in dogs and has been used in cats with ureteral obstruction. In cats, however, the drug did not appear overly efficacious and can lead to acute adverse reactions, characterized by tachypnea, dyspnea, and gastrointestinal signs.¹⁷³ Amitriptyline, a tricyclic antidepressant, reduced smooth muscle activity in human and pig ureteral segments in ex vivo studies. Further study of the effects of amitriptyline on feline ureters is warranted. Tamsulosin (see the discussion of the hypertonic urethra in this chapter) has become the agent of choice for medical management of small ureteroliths in humans.

DRUGS USED IN THE MANAGEMENT OF FELINE LOWER URINARY TRACT DISEASE

Idiopathic hematuria, dysuria, and urethral obstruction represent a common clinical problem encountered in cats. *Feline urologic syndrome, idiopathic feline lower urinary tract disease (iFLUTD), idiopathic feline cystitis*, and *feline interstitial cystitis* all are terms that have been used to describe this combination of clinical signs when urinary tract infection, urolithiasis, neoplasia, and other causes have been ruled out. Many pharmacologic agents and treatment strategies have been proposed to manage this disorder and prevent its recurrence. The apparent efficacy of any treatment for cats with idiopathic disease should be considered in light of the usual self-limiting nature of this disorder, and pharmacologic agents should be administered only after assessment of the likely benefits and possible risks of each treatment.^{127,174} Recent publications suggest a relationship among stress, alterations in the feline nervous system, and the development of iFLUTD, with an increased emphasis on environmental and behavioral influences.¹⁷⁵⁻¹⁷⁷ Moisture intake and environmental modifications appear to be the most effective treatments in cats with recurrent idiopathic disease; however, pharmacologic agents have a place in short-term symptomatic relief and in reducing discomfort and recurrence in refractory cases.

KEY POINT 18-17 Idiopathic lower urinary tract signs in cats are usually self-limiting. Pharmacologic agents are reserved for cats with refractory idiopathic cystitis, after dietary, water intake, and environmental modifications have failed to sufficiently alleviate recurrences.

HISTORICAL TREATMENT STRAGEGIES

Urinary Acidifiers

Manipulation of urine pH, usually by dietary means, has been a long-standing strategy for management of feline lower urinary tract disease (FLUTD). The strategy is most likely to be helpful in cats in which struvite crystalluria is a significant component of obstructive FLUTD and does not eliminate recurrence in all cats with idiopathic disease.^{127,178} Most urologic diets are designed to promote acid to neutral urine in fed cats; additional acidification is rarely necessary or wise.

Overacidification is another possible complication of urine acidification in cats; young cats and cats with renal insufficiency are most susceptible. Long-term administration of urinary acidifiers may contribute to metabolic acidosis, hypokalemia, bone and mineral imbalances, renal failure, and calcium oxalate urolithiasis.¹⁷⁹⁻¹⁸¹ Heinz body anemia and methemoglobinemia have been observed in kittens treated with DL-methionine as well as in adult cats treated with high dosages.¹⁸² Arrhythmias and central nervous system depression are serious complications of highdose ammonium chloride administration. Both agents are contraindicated in patients with hepatic disease because the administration of an ammonium load may potentiate hepatoencephalopathy. Serial monitoring of clinical status, complete blood counts, acid-base, and electrolytes is recommended during therapy.

Urinary Antiseptics

Urinary antiseptic agents have been considered as adjunctive treatment in FLUTD because of their antiviral activity.¹²⁷ Viruses including herpesvirus, feline syncytia-forming virus, and feline calicivirus have been implicated in the etiopathogenesis of FLUTD, although a consistent cause-and-effect relationship has been difficult to establish. The agents are more commonly used for antibacterial and antifungal properties, but these are uncommon causes of urinary disease in cats. The most commonly suggested antiseptic for small animal usage is methenamine, a cyclic hydrocarbon administered in combination with either mandelic acid (methenamine mandelate) or hippuric acid (methenamine hippurate). Mandelic acid and hippuric acid serve to acidify the urine and may exhibit some additional antimicrobial activity. With sufficient contact time in acidic urine, methenamine is converted to formaldehyde, a potent antimicrobial agent. Methenamine is contraindicated for patients with renal or hepatic insufficiency, and its use may contribute to overacidification like other urinary acidifiers. Use of other antiseptics or analgesics containing methylene blue or azodyes is discouraged in cats because of the potential for development of Heinz body hemolytic anemia.

Glucocorticoids

Glucocorticoids have been recommended to alleviate urinary bladder or urethral inflammation in cats with iFLUTD. Antiinflammatory effects of glucocorticoids on leukocyte migration, vascular permeability, and arachidonic acid metabolism would be expected to suppress the inflammatory symptomatology and hematuria associated with this disorder. Treatment is based on the assumption that persistent inflammation leads to hematuria. Although it appears that glucocorticoids do little to alter the course of typical iFLUTD,¹⁸³ some clinicians recommend glucocorticoid administration (prednisone or prednisolone 1 to 2 mg/kg every 24 hours) in cats exhibiting chronic, recurrent, or refractory idiopathic hematuria and dysuria.¹⁸⁴ No convincing evidence has been presented to establish that glucocorticoids alter the natural course of iFLUTD or prevent recurrence, however.

Glucocorticoid administration also presents certain risks. Refractory urinary tract infection and pyelonephritis may develop, especially when glucocorticoids are administered to cats with indwelling urinary catheters.¹⁸⁵ Prophylactic antimicrobial treatment does not appear to reduce the risk of catheter-induced infection. Glucocorticoids must be considered contraindicated for cats with urinary catheters in place or with evidence of bacteriuria. The catabolic effects of glucocorticoids also may be hazardous in debilitated, azotemic, or dehydrated cats.¹²⁷

CONTEMPORARY TREATMENT STRATEGIES

Antispasmodic Agents

Agents that relax smooth or striated muscle of the urinary tract have been advocated for symptomatic relief of pollakiuria, dysuria, and stranguria in cats with FLUTD.^{128,184,186} The anticholinergic agents propantheline and oxybutynin have been recommended for their antispasmodic effects on the urinary bladder. In one small controlled study, propantheline administration did not affect resolution of clinical signs at 5 days after treatment compared with placebo administration;¹⁸⁷ however, this agent has little direct smooth muscle relaxant properties. If antispasmodic agents are administered, cats should be monitored for urine retention; the loss of a frequent mechanical washout of urine theoretically could delay resolution of inflammation or predispose cats to urinary tract infection.

Agents acting on urethral musculature also have been recommended to facilitate urination in dysuric cats and to

alleviate functional urethral obstruction in postobstructed cats. Phenoxybenzamine and prazosin are α -adrenergic antagonists that serve to inhibit urethral smooth muscle contracture. These agents may be helpful in minimizing resistance in the preprostatic and prostatic portions of the urethra in cats;¹⁸⁸⁻¹⁸⁹ striated muscle components of the urethra are not affected. Diazepam or dantrolene may be more effective in relaxing skeletal muscle in the postprostatic urethra.^{165,166,189} Phenothiazine derivatives, such as acepromazine¹⁸⁸ and aminopropazine, may also be effective as direct smooth and striated muscle relaxants and can be particularly useful in minimizing anxiety of acutely affected cats.

Analgesia

For acute flare-ups of lower urinary tract signs, short-term analgesic treatments may be useful to reduce the discomfort associated with bladder and urethral inflammation. Butor-phanol (0.5 to 1.25 mg/cat orally every 4 to 6 hours) has been recommended;¹⁹⁰ longer-acting buprenorphine can be considered as well. Both agents can be given as subcutaneous injections if this is less stressful to the cat.¹⁸⁶ NSAIDs have also been recommended for analgesic and antiinflammatory effects. No controlled studies are available to demonstrate a response from any of these agents.

Anxiolytic Agents

A variety of other agents have been considered for treatment of nonseptic, idiopathic inflammatory cystitis (interstitial cystitis [IC]) in human patients, and many have been suggested for similar usage in cats. In some ways the disease in cats does appear to mimic IC in women, a disorder characterized by dysuria, pollakiuria, and painful urination without demonstrable cause. Pathophysiologic mechanisms identified in women with IC have been documented in affected cats,^{178,191-193} including increased mast cell numbers in the urinary bladder, decreased urinary glycosaminoglycan excretion,¹⁹¹ and altered urinary bladder permeability.¹⁹³Additional investigations have focused on the influence of neurogenic mediators of inflammation in IC, in which sensory input from afferent neurons in the urinary bladder may trigger inflammatory and pain responses.¹⁹²

A variety of anxiolytic and antidepressant agents have been investigated in IC, including antihistamines, doxepin, and amitriptyline (Elavil). Amitriptyline is a tricyclic antidepressant with multiple actions, including (1) potentiation of neurotransmitter activity in the central nervous system, (2) inhibition of histamine release, (3) potent antihistaminic properties, and (4) anticholinergic activity.¹⁹⁴ As an antidepressant and antianxiety agent, amitriptyline has been used in small animals for behavioral modification, elimination disorders, chronic pruritus, and self-mutilation.^{195,196} The agent has shown promise for the treatment of IC in women and has been recommended for alleviation of anxiety and pain associated with iFLUTD.¹⁹² Eleven of fifteen cats treated with amitriptyline were free of chronic iFLUTD signs for 6 months in one study, and nine were asymptomatic for 12 months or longer.197

Amitriptyline may be less effective for treating acute than chronic episodes of iFLUTD. Amitriptyline administration (5 mg/day orally) had no beneficial effect in treating 31 cats with acute, nonobstructive iFLUTD, and they were significantly more likely to have recurrence of hematuria and pollakiuria within 7 days of discontinuation of amitriptyline, compared with cats administered a placebo. Clinical signs usually resolved within 7 days, regardless of whether a placebo or amitriptyline was administered.¹⁹⁸ A second placebo-controlled study of 24 cats with iFLUTD did not show a benefit of daily amitriptyline (10 mg/cat) administered for 1 week.¹⁹⁹

For cats in which amitriptyline is indicated, a starting dosage of 5 mg/cat every 24 hours is empirically recommended; the dose is adjusted to effect a mild calming behavior in the cat, which is usually achieved with dosages of 2.5 to 12.5 mg/cat per day.¹⁹² Long-term treatment is recommended, along with elimination of environmental stresses, in cats affected by severe, recurrent idiopathic disease. Adverse effects of amitriptyline administration in human patients include anticholinergic effects (dry mouth, blurred vision, constipation), hypotension, drowsiness, and cardiac arrhythmias.¹⁹⁴ Sedation, vomiting, and disorientation have been reported in dogs treated with the drug,¹⁹⁵ whereas transient sedation has been the most common adverse effect observed in cats. Amitriptyline may also predispose to bacterial cystitis by causing urinary retention and decreased frequency of urination.¹⁹⁸ Clomipramine (0.5 mg/kg/day) is a good alternative anxiolytic agent that seems to be more tolerable for cats.

Behavioral-modification drugs have been used in treatment of iFLUTD, but results are only anecdotal. Fluoxetine and paroxetine, two selective serotonin reuptake inhibitors, have been used with some success to treat compulsive disorders in cats and dogs. They are dosed at 0.5 to 1 mg/kg orally every 24 hours. Although considered safe, sedation, anxiety, poor appetite, constipation, lowered seizure threshold, and difficulty in controlling diabetic patients are possible side effects. These drugs should not be used concurrently with monoamine oxidase inhibitors, selegiline, or L-tryptophan.²⁰⁰ In a recent prospective clinical trial involving 12 cats, feline facial pheromone was compared with a placebo as treatment for iFLUTD. Although there was no statistical differences between the two groups, more of the pheromone-treated cats had less severe and fewer episodes of iFLUTD,²⁰¹ and further studies are warranted. Modification of environment and attention to behavioral issues must be done concurrently to minimize the neuroendocrine influences on the disease. Environmental enrichment, reduction in intercat conflict or aggression, change of feeding method, and litter box management are included in the potential modifications.¹⁷⁶

Glycosaminoglycans

Pentosan polysulfate (PPS; Elmiron) is a synthetic polysaccharide that augments the protective glycosaminoglycan layer of the urinary bladder. Orally administered PPS has resulted in good long-term responses (>6 to 12 months) in some women with IC²⁰² and may be effective in reducing clinical episodes in cats with recurrent or chronic idiopathic disease. The currently recommended dosage for cats is 8 mg/kg orally every 12 hours.¹⁹⁰ Oral glucosamine has been suggested as an alternative glycosaminoglycan. In a controlled study of 40 cats treated for 6 months, there was no difference in owner assessments of each cat's health and number of days with lower urinary tract signs between glucosamine-treated cats and placebo-treated cats.²⁰¹ Cats in both groups were somewhat improved owing to the introduction of canned cat food; however, recurrences were still frequent.

INTRAVESICULAR AGENTS USED IN LOWER URINARY TRACT DISEASE

Infusion of antimicrobial and antiinflammatory agents into the urinary bladder has been attempted as a form of local therapy in dogs and cats with lower urinary tract disease. The idea of directly applying antiseptic, antiinflammatory, or analgesic agents to diseased mucosa is enticing. Even saline infusion may provide symptomatic relief of lower urinary tract symptoms. Simple urohydrodistention provides temporary relief of symptoms in some women with IC.²⁰³ Presumably, extreme distention of the urinary bladder may stimulate and exhaust mast cell degranulation, induce urinary glycosaminoglycan production, and cause ischemic degeneration of bladder sensory nerve endings. Released inflammatory mediators also can be flushed with the infused solution. Instillation of solutions into the urinary bladder requires placement of a urinary catheter, however, and urohydrodistention requires general or regional anesthesia. Furthermore, agents instilled into the urinary bladder often are rapidly voided and may be altered with inflammation; enhanced permeability to salicylate infusion has been documented in cats with idiopathic cystitis.¹⁹³ Thus the risk of significant systemic absorption of intravesicular agents is difficult to predict.

Antifungal Agents

Primary fungal infections of the lower urinary tract are rare, and *Candida* spp. are the most common cause of funguria in dogs and cats. *Candida* spp. are normal florae of the gastrointestinal system, upper respiratory tract, and genital mucosa. Infections in dogs and cats are usually due to *Candida albicans*, although other species have been reported. Candiduria in humans occurs when predisposing factors are present, such as indwelling urinary catheters, diabetes mellitus, drug therapy (antibiotic, steroids, cancer chemotherapeutic), and lower urinary disease. In dogs and cats, these same factors are likely to be relevant. In a report of 31 cases of candiduria in dogs and cats, 35% of the patients had diabetes mellitus.²⁰⁴

Unlike management of funguria in humans, in which correction of the underlying condition often resolves the infection, treatment of all cases of funguria in dogs and cats is recommended. The drug of first choice in humans with a persistent infection is fluconazole, and this is likely true for dogs and cats. The condition should be managed as a complicated urinary tract infection, and treatment should be continued for at least 2 to 4 weeks, with resolution confirmed by negative urine culture. If the infection persists beyond 4 weeks of therapy, then antifungal susceptibility testing should be done because *Candida* organisms can develop resistance to azole drugs.²⁰⁴ Previously reported doses of fluconazole are 2.5 to 5 mg/kg orally every 24 hours in dogs and 2.5 to 10 mg/kg orally every 12 hours in cats.¹⁷ An alternative treatment to oral or injectable antifungals is intravesicular infusions of 1% clotrimazole into the urinary bladder, using a Foley catheter. A dose of 9 mL/kg infused by a urinary catheter weekly for 3 weeks was successful in treating a diabetic cat. A diabetic dog was successfully treated with 7 mL/kg injected into the bladder, with ultrasound assistance, for four treatments. This treatment may be a useful alternative to oral fluconazole, although further studies are needed to prove efficacy and safety.²⁰⁴

Dimethylsulfoxide

The free radical scavenging agent DMSO has been applied intravesicularly as a local antiinflammatory and analgesic agent. The drug and its metabolites neutralize free radical hydroxides and free radical oxygen, modulate platelet aggregation and prostaglandin metabolism, decrease fibroplasia, and provide local analgesia. In high concentrations DMSO may have antibacterial activity, but it also creates mucosal edema and hemorrhage.²⁰⁵ The agent has been used in the management of interstitial and radiation-induced cystitis in human patients, cyclophosphamide-induced cystitis in dogs, and idiopathic cystitis in cats.^{184,203,206} DMSO infusion may be considered for cats with chronic, refractory idiopathic disease, especially those with thickened urinary bladder walls.

The treatment regimen for cats involves instillation of 10 to 20 mL of 10% medical grade DMSO (Rimso-50) into the urinary bladder with the cat under general anesthesia. The solution is left in the urinary bladder for 10 minutes and then removed. The process can be repeated 2 weeks after the initial application if needed.¹⁸⁴ Up to 25 mL of 25% to 50% intravesicular DMSO is empirically recommended for dogs. In cats instillation of 45% veterinary grade DMSO for 3 days after induction of salicylate/ethanol bladder wall injury did not alter the subsequent inflammatory response or infection rate.¹⁸⁵ The drug also may have contributed to renal lesions observed in these cats and appeared to be locally irritating.¹⁸⁵ Intravascular hemolysis and hemoglobinuria may result if significant quantities of DMSO are absorbed.

Bacillus Calmette–Guérin Therapeutic

Bacillus Calmette–Guérin (BCG) Therapeutic is a bacterial product of attenuated *Mycobacterium bovis*, with muramyl dipeptide as the predominant active compound. Intravesicular BCG cell wall infusion is used as an alternative to radical surgery in human patients with carcinoma of the urinary bladder. The agent promotes a local inflammatory reaction that appears to suppress superficial cancerous lesions by incompletely understood mechanisms.²⁰⁷ Effects of T cells and natural killer cells also lead to its use as an immunostimulant. The agent must be administered by way of nontraumatic urethral catheterization and handled as hazardous infectious material. Local irritation and hematuria are commonly observed after infusion; systemic adverse effects are rare but may include fever, nausea,

diarrhea, anemia, leukopenia, ureteral obstruction, shock, and death. The agent is contraindicated for patients with urinary tract infections or fevers and those receiving immunosuppressive therapy. In dogs injection of intralesional BCG has been variably helpful during surgical resection of transitional cell carcinomas. Severe granulomatous reactions are possible.

Infusion of other chemotherapeutic agents (doxorubicin, thiotepa) is rarely attempted in veterinary medicine because of the advanced stage of disease usually present at diagnosis. Local infusions are not expected to penetrate beyond the submucosa, whereas most neoplasms have infiltrated the muscularis or serosa in small animals.²⁰⁸

Piroxicam

Piroxicam (Feldene), a potent NSAID, appears to have antitumor activity in some animals with urinary tract neoplasia.²⁰⁹ In dogs with transitional cell carcinoma, sustained remissions are possible in selected individuals, whereas maintenance of stable disease may be obtained in many. For neoplastic disease, piroxicam is administered daily at 0.3 mg/kg/day. Piroxicam (administered daily or every other day) also has been considered for the treatment of chronic inflammatory bladder disorders. Clinical experience supports this practice; the safety and efficacy of the drug have not been critically evaluated, however.¹⁷⁴ Gastrointestinal ulceration is common; concurrent administration of gastrointestinal protectants is recommended.

DRUGS THAT TARGET APPETITE OR CALORIC BALANCE

Drugs that alter body weight play can be important in the the prevention or treatment of disease in dogs and cats. Targets of pharmacologic management of weight include decreased energy intake (e.g., appetite, caloric absorption), altered energy partitioning, and increased energy expenditure.

Appetite is controlled primarily, but not exclusively, by the ventral and lateral nuclei of the hypothalamus. The nuclei respond to both short- and long-term signals.¹ Hypothalamic directives are influenced by energy, which in turn is influenced by ingestion, absorption, metabolism, and storage. Chemical signals mediating these directives act locally or distantly, often balancing one another. Signals include hormones, neuropeptides, cytokines and neurotransmitters, several of which are pharmacologic targets. Although a discussion of energy utilization is too com-

plex and extensive for this text, understanding of the role of body fat in appetitic control and body weight has been markedly advanced in the last decade and warrants review of those aspects relevant to drug therapy. In the arcuate nucleus, primary neurons detect concentrations of metabolites and secondary neurons synchronize signals and coordinate vagally mediated responses. Among these neurons are two distinct populations of primary neurons and neuropeptides that control food intake and energy expenditure. Orexigenic peptides increase food intake and include neuropeptide Y (NPY) and agouti-related protein (AgRP); gamma amino butyric acid (GABA) is also released as an orexigenic signal. The NPY/ AgRP neurons direct the effects of leptin and ghrelin and stimulate feeding during states of fasting. They also influence the anorexigenic peptides, which decrease food intake. Anorexigenic peptids include the pro-opiomelanocortin (POMC) neurons which produce alpha-melanocyte hormone (α -MSH), a powerful appetite suppressant, and the β -endorphins. The POMC extensively communicates with hypothalamic neurons as well as other regions that regulate energy. Both orexigenic and anorexigenic neurons have receptors for balancing signaling molecules, which often cause opposing effects by interacting at the same ligand. NPY and α -MSH ,located in the ventromedial nucleus of the appetite

center, are considered balancing hormones. Other stimulatory mediators include norepinephrine (α_2 -receptors), dopamine (possibly D₁ receptors), and opiate and pancreatic polypeptides. Although GABA also stimulates appetite, its effect may vary with route of administration.¹ Other inhibitory mediators include serotonin (5-hydroxytryptamine [5-HT]), calcitonin, cholecystokinin, and corticotrophin-releasing factor. In addition to their central roles, several of these mediators influence energy metabolism peripherally.

Among the major target tissues for signals modulating energy metabolism is adipose tissue, which is now a recognized endocrine organ (Figure 19-1). Hormones play a critical role in energy homeostasis, insulin sensitivity, and lipid and carbohydrate metabolism. The system appears to be more sensitive to preventing starvation rather than obesity. Leptin and insulin appear to be the predominant mediators that signal adiposity: both circulate in proportion to body fat, enter the central nervous system (CNS) in proportion to plasma

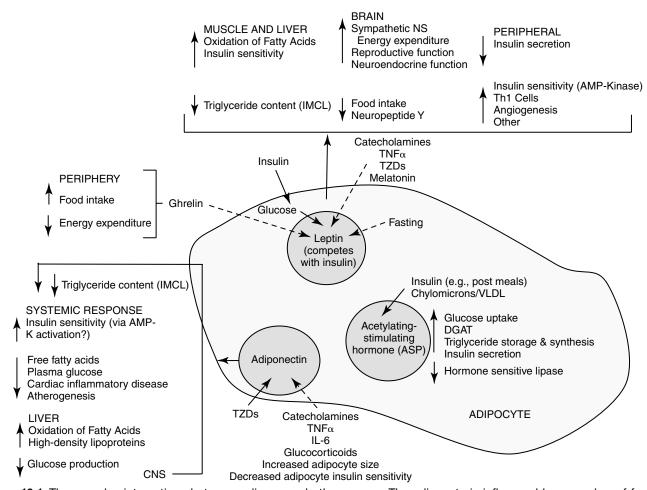

Figure 19-1 The complex interactions between adipose and other organs. The adipocyte is influenced by a number of factors and responds with paracrine, autocrine, and endocrine responses. Leptin is produced by many tissues, but particularly white adipose tissue. It inhibits food intake and increases energy expenditure while increasing insulin sensitivity (by way of activation of AMP kinase). Central influences include reproductive and neuroendocrine functions. In the adipocyte leptin is influenced by changes in adipocyte glucose metabolism as insulin secretion responds to food intake. Adiponectin also increases insulin sensitivity (through activation of AMP kinase), resulting in increased fatty acid oxidation in the muscle and liver and decreased hepatic triglycerides. Acetylation-stimulating protein also reduces hepatic glucose production. *Solid arrows,* stimulate; *dashed arrows,* inhibit; *DGAT,* diglycerol acyltransferase; *TZD,* thiazolidinediones.

concentrations, and interact with CNS receptors that influence energy regulation, as reviewed by Havel.² Other important peripheral mediators include acetylation-stimulating protein (ASP) and adiponectin, each being principally regulated by host nutritional status.

KEY POINT 19-1 Adipose tissue has emerged as one of the biggest endocrine organs, affecting appetite and energy homeostasis.

Leptin was discovered in obese mice that randomly emerged as mutants among normal populations. At least six leptin receptors ("LepR", *a* through *f*) are associated with the *ob* gene (Ob-R) (obesity gene), suggesting a complex role for this hormone. ³ Leptin receptors are similar to class I cytokine receptors, perhaps linking cytokines to diseases associated with obesity disorders.³

Currently, little information appears to be available regarding leptin content in dogs or cats and information must be drawn from other species. Although most organs produce leptin, white adipose tissue is the primary source, with the amount produced varying among species: more leptin is produced in subcutaneous compared with omental fat in humans, but the opposite is true in rats.³ In humans, leptin content is greatest in the heart, liver, small intestine, prostate, and ovaries versus the lung and kidney in mice. Each tissue may have a particular receptor isoform, allowing differential roles among tissues. Leptin plays an important, albeit complex, role in the peripheral regulation of adipose tissues. Its primary function is as a lipostat, communicating to other tissues the current status of body fat reserves. As such, leptin mediates fuel movement and use (see Figure 19-1) and energy expenditure.³ It is more effective in signaling deficient rather than excessive energy reserves.² Activated leptin receptors induce satiety in the appetite center (inhibition of NPY, stimulation of alpha-MSH neurons). Leptin also appears to influence thermogenesis. Peripherally, leptin appears to increase hematopoiesis, angiogenesis, wound repair, and puberty; its role in reproduction is particularly complex. Leptin is primarily regulated by food-induced responses to insulin, with influences being more dramatic during fasting and characterized by diurnal variation.² In normal animals, insulin appears to directly regulate leptin gene expression and excretion in adipose tissue; it also indirectly influences it through adipocyte glucose use and oxidative metabolism. Both hormones increase in concert.³ Both leptin and insulin share inhibitory signal transduction pathways in response to food.² Leptin, in turn, appears to inhibit insulin secretion, and, peripherally competes with insulin; however conflicting results also suggest that leptin has no effect on insulin.^{2,3} Glucocorticoids appear to stimulate leptin gene expression, although it is not clear if this effect is direct (gene expression) or indirect (altered food intake or insulin concentrations). Leptin is downregulated by melatonin at night; accordingly, humans with short sleep cycles may be predisposed to obesity. Depletion of body stores is not detected in hypoleptimemic animals, and as such, is more dangerous than hyperleptinemia. In

humans, hypoleptinemia is associated with neuroendocrine, reproductive, metabolic, and immunologic imbalances,and in rodents, marked insulin reistance and hyperlipidemia.² Leptin concentrations in persons with eating disorders characterized by anorexia are similar to or lower than concentrations in persons without eating disorders.³ . Its role in chronic liver disease increasingly is being recognized.⁴ Many of these abnormalities can be normalized in humans with recombinant human leptin. Differences in genes (including mutations) regulating leptin also are linked to human obesity with hyperleptinemia indicating leptin resistance.

KEY POINT 19-2 Leptin acts as a lipostat, communicating to the tissue the status of fat reserves.

The second major hormone influencing energy metabolism, ASP, is produced from complement factor C. Locally, ASP paracrine actions in adipose tissue include increased glucose uptake and diacylglycerol acyltransferase activity and decreased hormone-sensitive lipase (see Figure 19-1). As such, adipocyte triglyceride synthesis and storage increase after eating, resulting in increased free fatty acids and triglyceride clearance. Serum ASP concentrations are increased by lipids, and increase in proportion to body fat in obese human patients; they decrease during states of fasting. Insulin may control ASP in reponse to eating or fasting; ASP in turn may directly stimulate insulin secretion.

Adiponectin, a large protein secreted by adiopocytes, is a third hormone influencing energy metabolism. Its biological effect varies with its state of diamerization.² Adiponectin appears to influence lipid and carbohydrate metabolism both directly and indirectly (see Figure 19-1). Adiponectin appears to be necessary for normal insulin actions. Concentrations are reduced in patients with type 2 diabetes compared with nondiabetic humans.² The effect of adiponectin on decreased circulating glucose are independent of fat content and occurs without influencing insulin secretion. Mechanisms may include decreased hepatic glucose formation and increased tissue glucose use by decreasing insulin resistance. Circulating adiponectin is negatively correlated with the content of body fat, particularly visceral (e.g., omental) rather than subcutaneous in humans.² Adiponectin may reduce ectopic fat in the liver and muscle through increased fat oxidation. Thus, low visceral fat may reduce adiponectin production, contributing to insulin resistance associated with obesity.² The impact of insulin on adiponectin is not clear. Among the emerging effects of adiponectin is protection against inflammatory cardiovascular disease (including atherosclerosis), which may explains the relationship between body fat and cardiac disease. Cytokines, catecholamines, and glucocorticoids decrease adiponectin production, which may contribute to their characteristic incease in insulin resistance.

KEY POINT 19-3 Adiponectin influences lipid and carbohydrate metabolism and is necessary for normal insulin action. A final signal able to centrally influence energy metabolism is ghrelin. Located in peripheral tissues, ghrelin is released by an empty stomach, appears to oppose leptin in the hypothalamus, and has been shown to increase food intake and decrease energy expenditure.

Control of appetite through pharmacologic manipulation of orixogenic and anorexigenic signals has proven difficult. Obvious targets which might suppress appetite (e.g., α -MSH) have profound impacts in multiple body systems, increasing the risk of adverse reactions. The complexties of regulation contribute to the risk of adversity. For example, alternate pathways of synthesis or response tend to emerge with blockade of a target signal.

APPETITE STIMULANTS

Studies regarding the pharmacologic control of appetite have traditionally focused on decreased, rather than increased, food intake, particularly in humans. However, the role of cachexia associated with weight loss and anorexia in human patients with cancer has stimulated a renewed interest in appetite stimulants.⁵ Drugs that inhibit gluconeogenesis, such as hydrazine sulfate, or promote gastric emptying, such as metoclopramide, have been used successfully to stimulate food intake in some human patients.⁵ The use of steroids, including megestrol acetate, in treatment of cachexia is discussed later in this chapter.⁵ Both glucocorticoids and B vitamins have been used to nonspecifically stimulate appetite in animals. Drugs used to treat depression and psychosis in human patients are associated with appetite increase and weight gain.⁶ They antagonize a variety of receptors, although their clinical potency is often related to increased serotonin, which may, in fact, decrease appetite in some patients.

Mirtazapine is a piperazino-azepine antidepressant characterized by serotonergic activity as a result of 5-HT-₁ agonistic activity and inhibition of serotonin reuptake.⁷ Sympathetic (norepinephrine) actions reflect antagonism of α -₂ autoreceptors as well as influences by other receptors. As a behavior-modifying drug, mirtazapine is discussed in greater depth in Chapter 26. Anecdotally, mirtazapine has been used to stimulate appetite in either dogs or cats, the latter at 3 mg/cat every 72 hours.

The benzodiazepines diazepam (Valium) and oxazepam, a metabolite of diazepam (Serax), have successfully induced appetite in cats, probably through gabaminergic effects and central inhibition of the satiety center in the hypothalamus (Table 19-1).⁸ Diazepam is administered intravenously or orally, whereas oxazepam is administered orally. Of the two drugs, diazepam may be more effective, although sedation is greater. The benzodiazepines do not stimulate appetite in the dog as effectively as in the cat. Hepatotoxicity associated with diazepam therapy when used as an appetite stimulant has been reported in cats^{9,10} and is discussed in more depth in Chapter 27. Toxicity appears to be idiosyncratic and thus may not be predictable; it is not likely to happen in a large percentage of animals receiving the drug.

Cyproheptadine, an antihistamine with antiserotonin properties, has caused weight gain in geriatric human patients

and in adults and younger patients afflicted with eating disorders. Its mechanism probably reflects inhibition of serotonergic receptors that control appetite. Serotonin antagonists also increase food intake in cats,¹ and cyproheptadine has been used clinically to stimulate the appetite of some anorexic cats. Cyproheptadine kinetics have been reported in the cat. Oral bioavailability of the tablet is 100%, and the elimination half-life approximates 13 hours.¹¹ Cats tolerated a dose of 8 mg orally with no adverse effects, although impact on appetite was not described. Based on this study, once- to twice-daily dosing of 8 mg appears to be safe.

Cachexia

Cachexia is an involuntary state characterized by loss of more than 5% of body weight. In humans it occurs over a defined period, generally of 2 to 6 months. Ultimately, it is a condition of starvation characterized by depletion of body mass, particularly muscle, but to a lesser degree, adipose tissue.¹² Cachexia develops in 50% of human patients with cancer, contributing to substantially shortened survival times. Cachexia also is a manifestation of other chronic diseases, including (in humans), acquired immune-deficiency syndrome (AIDS), heart failure, rheumatoid arthritis, Crohn's disease, chronic obstructive pulmonary disease, and chronic renal disease.¹² It appears to be a cytokine-driven process, with key components including anorexia and a state of hypercatabolism. The principle cytokines appear to include TNF-alpha, interleukins 1 and 6, and interferon- γ Of these, TNF-alpha is presumed to stimulate mechanisms that lead to severe cachexia.¹² Muscle wasting may reflect inhibition of myogenic differentiation; an energy sink may result from increased concentrations of mitochondrial uncoupling proteins. Lipoproteinase activity is inhibited by TNF-alpha. Interleukins contribute to CNSmediated anorexia and decreased albumin synthesis in the liver. Megestrol acetate is the only treatment approved by the Food and Drug Administration for cancer or AIDS-related cachexia syndromes in humans.12 Other less commonly used drugs are glucocorticoids, anabolic steroids, antiseratonergic drugs, dronabinol, and prokinetic drugs.

Megestrol is a synthetic derivative of progesterone.¹² As such, megestrol acetate targets cachexia by directly and indirectly stimulating appetite and antagonizing the catabolic metabolic effects of cytokines. As with other steroidal hormones, the effects of megestrol (and progesterone) involve passive diffusion into the cell and binding to specific intracellular progesterone receptors A or B (PR-A or -B) and heat shock proteins. The drugs move into the nucleus, bind to progesterone response elements on target genes, and influence transcription through inhibition (PR-A) or stimulation (PR-B) of other steroid response elements. Although the majority of progesterone effects are genomic, nongenomic actions also occur. Metabolic effects of progesterone include increased basal insulin concentration and increased response to carbohydrate load; increased lipoprotein lipase with altered fat deposition, plasma lipid, and lipoprotein concentrations; and modulation of body temperature.12 In humans and animal models of cancer, megestrol stimulates appetite, increases caloric intake, induces a sense

Drug	Indication	Dose	Route	Interval (hr)
6-aminosalicylic acid	See Mesalamine			
Activated charcoal	Gastrointestinal adsorbent	1 g/5-10 mL water. Administer 6-12 mL of slurry/kg; follow with 0.9% saline cathartic	PO PO	6 hr for several days
Aluminum hydroxido	Phosphate binder	1-8 g/kg (granules)	PO (with food)	6 hr for several days 8-24
Aluminum hydroxide Aluminum magnesium hydroxide	Laxative	30-90 mg/kg 2-10 mL	PO	2-4
7		3 mg/kg (C)	PO	24
Aminopentamide	Antidiarrheal	0.1-0.4 mg	IM, PO, SC	8-12
		0.01-0.03 mg/kg	IM, PO, SC	8-12
		0.1 mg/cat	IM, PO, SC	8-12
Ammonium chloride	Ammonium tolerance test	0.1 mg/kg of 5% solution	Rectally	Once
		100 mg/kg. Maximum of 3 g	PO	Once
Apomorphine	Emesis	0.02-0.04 mg/kg (D)	IM, IV	Efficacy lost with subse- quent doses
		0.08-0.1 mg/kg (D)	IM, SC	Efficacy lost with subse- quent doses
		0.25 mg	Topical (conjunctival sac)	Flush once emesis begins; efficacy lost with subse- quent doses
Aprotinin	Pancreatitis (protease inhibitor)	5000 kallikrein inhibitor units (KUI)/kg	IP (preferred), IV	6-8
Ascorbic acid	Copper-induced hepatotoxicity	500-1000 mg/day (D)	РО	24
	Feline infectious peritonitis	25 mg/kg or 125 mg (C)	PO	24
	Acetaminophen toxicosis	30 mg/kg (C)	PO, SC	$6 \text{ hr} \times 7 \text{ treatments}$
	Urinary acidifier	100-500 mg (D) 100 mg (C)	PO PO	8-24 8-24
Atracurium besylate	Hypersialism	0.02 mg/kg	SC	As needed
Atropine	Hypersialism	0.02 mg/kg	SC	As needed
	Cholinergic toxins	0.2-2 mg/kg	Administer 0.25 of the total dose IV and the remaining dose SC, IM	lo effect
Azathioprine	Myasthenia gravis	2 mg/kg (D)	PO	24×7 days then every 48
	Chronic atrophic gastritis	0.5 mg/kg (D)	PO	24-48
	Lymphocytic or eosinophilic enteritis		РО	24-48
		0.2-0.3 mg/kg(C)	PO	24-48
D: 11	Chronic active hepatitis	2-2.5 mg/kg (D)	PO	24
Bisacodyl	Stool softener	5-20 mg/dog	PO PO	24 or as needed 24 or as needed
		2-5 mg/cat 1-3 suppositories	Rectally	24 or as needed 24 or as needed
		1-2 mL enema	Rectally	24 or as needed
Bismuth subcarbonate	Gastrointestinal tract protectant	0.3-3 g	PO	4
Bismuth subsalicylate	Gastrointestinal tract protectant	175-524 mg/dog	РО	4-6
	1	4.4-52 mg/kg (D)	РО	6-8
		4.4 mg/kg (C)	PO	4-6
		18-52 mg/cat	PO	4-6
Bran	Bulk laxative	Approximately 15-30 mL (1-2 tbsp)/400 g food	РО	As needed

Drug	Indication	Dose	Route	Interval (hr)
Budesonide	Inflammatory bowel disease	1 mg/small dog or cat	РО	24
		2 mg/large dog	РО	24
Calcium acetate (contains 0.235 mg elemental calcium)	Phosphate binder	60-100 mg/kg	РО	24
Calcium carbonate (con- tains 0.4 mg elemental calcium)		0.5-5 g/dog	РО	As needed
Cascara sagrada	Laxative, stool softener	1-4 mL/dog 0.5-1.5 mL/cat	PO PO	12 to effect 12 to effect
Castor oil	Cathartic, stool softener	8-30 mL/dog PO 12 to effect		
Castor on	Cathartic, stoor softener	4-10 mL/cat	PO	12 to effect
Chlordiazepoxide– clidinium	Irritable colon syndrome	0.1-0.25 mg/kg (D). Based on clidinium dose	PO	8-12
Chlorpromazine hydro- chloride	Antiemetic	0.5 mg/kg	IM, IV, SC	6-8
		0.05-0.5 mg/kg (D)	IM, SC	6-24
		1 mg/kg (D)	Rectally	8
		3.3 mg/kg (D)	PO	6-24
		1.1-6.6 mg/kg (D)	IM	6-24
	Irritable colon syndrome	0.5 mg/kg (D)	IM	8-24
		2 mg/kg (D)	PO	8-24
Cholestyramine	Short bowel syndrome	200-300 mg/kg	РО	12
		1-2 g/dog	PO	12
Cimetidine	Esophagitis, gastric ulceration, antiemetic, chronic gastritis, GI tract ulceration		IM, IV, PO	6-12 (D), 8-12 (C)
	Gastrinemia	5-15 mg/kg	IV, PO, SC	6
	Effects of mast cell tumors	5 mg/kg (D)	IV, PO	6-8
	Immunomodulator	6-10 mg/kg	IM, IV, PO	8
Cisapride	Prokinetic	0.1-0.5 mg/kg (D)	PO	8-12
		2.5-7.5 mg (C)	РО	8-12
Clindamycin	Stomatitis, acute pancreatitis Pancreatic exocrine insuf- ficiency	5-10 mg/kg 5-10 mg/kg	IM, IV PO	8 6-8, 30 min before meals
Clonidine	Refractory diarrhea, inflam- matory bowel disease	1-10 μg/kg (C)	PO, SC	8-12
Codeine	Diarrhea	0.25-0.5 mg/kg (D)	РО	6 - 8
Colchicine	Chronic hepatic fibrosis	0.01-0.03 mg/kg (D)	РО	24
Cyanocobalamin	See Vitamin B ₁₂		РО	24
Cyclizine	Antiemetic	4 mg/kg	IM	8
Cyproheptadine hydro- chloride	Antihistamine	1.1 mg/kg (D)	РО	8-12
	Appetite stimulant	2-4 mg/cat	РО	12-24
Dexpanthenol (panto- thenic acid)	Intestinal atony	11 mg/kg	IM	4-6
Diazepam	Irritable colon syndrome	0.15 mg/kg (D)	РО	8
•	Appetite stimulant	0.05-0.4 mg/kg (C) 1 mg/cat	IM, IV, PO Po	24 or 48 24
Dicyclomine	Acute colitis, irritable colon	0.15 mg/kg (D)	РО	8
Dimenhydrinate	Motion sickness	25-50 mg/dog	PO	8-24
2 memyarman	THOUGH SIGKINGS	12.5 mg/cat	PO	8
		4-8 mg/kg	PO	8

Drug	Indication	Dose	Route	Interval (hr)
Dicyclomine	Detrusor hyperspasticity or urge incontinence	5-10 mg	РО	6-8
	Acute colitis, irritable colon	0.15 mg/kg (D)	РО	8
Dioctyl sulfosuccinate	Stool softener	25 mg/small dog or cat 50-100 mg/medium or large dog	PO PO	12-24 12-24
Diphenhydramine	Antihistamine	2-4 mg/kg	РО	6-8
	Mast cell disease, antiemetic	2 mg/kg	IM, IV (slowly)	12 or as needed
	Anaphylaxis, urticaria	2 mg/kg	IM, IV (slowly)	12 or as needed
	Angioneurotic edema	2 mg/kg	IM, IV (slowly)	12 or as needed
	Antipruritic, allergic skin disease	1-2 mg/kg (D)	РО	8-12
		5-50 mg	IM	12
Diphenoxylate (contains atropine)	Acute colitis, irritable colon syndrome	0.1-0.2 mg/kg (D)	РО	8
		0.05-0.2 mg/kg (C)	PO	12
	Antidiarrheal	2.5-10 mg (D)	PO	8
		0.6-1.2 mg (C)	РО	8-12
Dirlotapide	Weight loss	0.1 ml/kg (D)	РО	24×14 days
		0.2 ml/kg (D)	РО	24 × 14 days, then base on current weight (see pack- age insert)
Docusate calcium, sodium	Stool softener	25-200 mg (D)	РО	12
		50 mg/cat	PO	12-24
Dolasetron mesylate	Antiemetic	0.6 mg/kg	IV, PO, SC	24
Domperidone	Prokinetic agent, antiemetic	2 mg/kg	РО	12-24
	C	0.1-0.3 mg/kg	IM, IV, PO	12
D-Penicillamine	Copper hepatopathy	10-15 mg/kg	PO (on an empty stomach)	12
		125 -250 mg/dog	PO (on an empty stomach)	12
Edrophonium	Tensilon test	0.11-0.22 mg/kg (D). IV Maximum of 5 mg		Once
		0.1-0.5 mg/puppy	IV	Once
		0.25-0.5 mg/cat	IV	Once
Emetine	Emesis	1-2.5 mL/kg (D). Maximim of 6.6 mL/kg	РО	Once
		3.3 mL/kg, dilute 50:50 with water (C)	РО	Once
Famotidine	Gastric ulcers, esophagitis	0.5-1 mg/kg (D)	IM, IV, PO, SC	12-24
Flumazenil	Hepatic encephalopathy	0.01-0.02 mg	IV	As needed
Flurazepam	Appetite stimulant	0.5 mg/kg (D). Maximum of 30 mg/day	РО	4-7 days
Folic acid	Nutritional supplement	0.25-0.5 mg/kg (C)	РО	24
	Supplement to pyrimeth- amine	2.5 mg/cat	РО	24
Glucosamine sulfate	Gastrointestinal inflammation	0.5 g/kg	РО	24
Glycerin, enema	Constipation/obstipation	250 mg or 12 mL glycerin	Rectally	1; repeat once only
Glyceryl monoacetate	Hypersialism	0.01 mg/kg	SC	As needed
Grycer yr monoacetate		0.0		
Glycopyrrolate	Hypersialism	0.01 mg/kg	SC	As needed

Drug	Indication	Dose	Route	Interval (hr)	
Hydrogen peroxide 3%	Emetic	5-10 mL	РО	Repeat in 20-30 minutes on time only	
Ipecac syrup	Emetic	1-2.5 mL/kg (D). Maximum of 15 mL	РО	Repeat once in 20 min	
Isopropamide/prochlor- perazine	Antiemetic, antidiarrheal	0.14-0.22 mg/kg (D)	SC	12	
		0.5-0.8 mg/kg (C)	IM, SC	12	
Kaolin/pectin	Gastrointestinal tract protectant	3-6 g/kg	РО	2-6	
Lactitol	Stool softener, hepatic encephalopathy	250 mg	РО	12	
Lactulose	Stool softener, hepatic encephalopathy	0.5 mL/kg (D)	РО	8 or to achieve 2-3 soft stools per day	
		5-45 mL/dog	PO	8	
		2.5-5 mL/cat	PO	8	
		0.25-1 mL/cat	PO	12-24	
		5-10 mL/cat (diluted 1:3 with water)	Rectally	To effect	
	Constipation	1 mL/4.5 kg (D)	PO	8, to effect	
Levodopa	Hepatic encephalopathy	6.8 mg/kg initially, then 1.4 mg/kg	РО	6	
Lime water	Alkaline gastric lavage	5 mL/kg	РО	Once	
Loperamide	Antidiarrheal, acute colitis	0.06-0.20 mg/kg (D)	РО	8-12	
1		0.1-0.3 mg/kg (C)	PO	12-24	
		0.08-1.16 mg/kg (C)	РО	12	
Magnesium citrate	Laxative	2-4 mL/kg	РО	12-24 or to effect	
Magnesium hydroxide	Antacid	5-30 mL/dog	РО	12-24	
		5-10 mL/cat	PO	8-24	
	Cathartic	15-50 mL/dog	РО	24 or to effect	
		2-6 mL/cat	PO	24	
Magnesium oxide	Antacid, laxative	1-2 mEq/kg	РО	24	
Magnesium salts	Cathartic, stool softener	0.75-1 mEq Mg ²⁺ /kg	IV	Over 24 hrs; CRI thereafter	
		0.3-0.5 mEq/kg	IV	24	
Magnesium sulfate 25%	Hypomagnesemia	5-15 mL	IM, IV over 1-2 hr	Repeat as needed	
Maropitant	Acute vomiting	1-2 mg /kg (D)	PO, SC	24	
	Motion sickness	8 mg/kg (D)	PO	24×2 days	
	Acute vomiting, motion sickness	1 mg/kg (C)	PO, SC	24	
Meclizine	Antiemetic, motion sickness	25 mg/dog	РО	24, beginning 1 hr before riding in car	
		4 mg/kg	PO	24	
		12.5 mg/cat	РО	24, beginning 1 hr before riding in car	
Megestrol acetate	Appetite stimulant/ anticachexia	0.25-5 mg/kg (C)	РО	24 × 3-5 days then every 48 to 72 hr	
Mesalamine	Inflammatory bowel disease	10-20 mg/kg (D)	РО	6-8	
Metamucil (psyllium)	Laxative	2-10 g/dog	PO (in moistened food)) 12-24	
	Билинте	2-10 g/dog	PO (in moistened food)		
	A				
Methscopolamine bro- mide	Antiemetic, decongestant	0.3-1 mg/kg	РО	8. Use cautiously in cats	
Methylcellulose	Laxative	0.5-5 g/dog	PO	As needed	
		1-1.5 g/cat	PO	As needed	

Continued

Drug	Indication	Dose	Route	Interval (hr)
Metoclopramide	Gastric motility disorders, antiemetic	0.2-0.5 mg/kg	IM, PO, SC	6-8
		5 to 20 μg/kg (0.005 - 0.02 mg/kg)	IV CRI	
	Gastric reflux	0.2-0.4 mg/kg	PO	8. Administer 30 min before meals and at bedtime
Metronidazole	Cholangitis	7.5 mg/kg	РО	8
	Bacterial overgrowth	10 to 15 mg/kg	PO	12
	Stomatitis	10 to 15 mg/kg	PO	12
	Giardia	10-30 mg/kg	PO	12-24
Milk thistle (silymarin)	Hepatoprotection	50-250 mg	PO	12-24
		30 mg/kg (D)	PO	24
Mineral oil	Laxative	5-30 mL (D)	PO, rectally	12
		1-2 mL/kg (D)	PO, rectally	12
		5-10 mL (C)	PO, rectally	12
Mirtazapine	Appetite stimulant	3.75 mg/cat (0.25 of a 15 mg PO tablet)		As needed
Misoprostol	Gastric protectant	1-5 μg/kg (D)	РО	6-8
Nandrolone decanoate	Anabolic effects, appetite stimulant	5 mg/kg (D). Maximum of 200 mg/week	IM	2-3 weeks
	Bone marrow or appetite stimulant	1-3 mg/kg (D). Maximum of 200 mg per week	IM	Every 7 days
Neostigmine	Myasthenia gravis	<5 kg: 0.25 mg/dog	IM	6
C C		5-25 kg: 0.25-0.5 mg/dog	IM	6
		>25 kg: 0.5-0.75 mg/dog	IM	6
		40 μg/kg or 0.04 mg/kg (D)	SC	6-8
		40 µg/kg or 0.04 mg/kg (C)	SC	6-8
	Diagnostic aid for myasthenia gravis	40 μg/kg (D)	IM	Once
		20 μg/kg	IV	Once
Nizatidine	Gastric ulcers	5 mg/kg (D)	PO	24
	Prokinetic	2.5-5 mg/kg	PO	24
Omeprazole	Reflux esophagitis, gastroin- testinal ulceration	0.7-2 mg/kg (D)	PO	$24 \times 10-14$ days
		20 mg/dog	PO	24
		>20 kg: 1 capsule (20 mg)	PO	24
		<20 kg: 0.5 capsule (10 mg)	PO	24
		<5 kg: 0.25 capsule (5 mg)	PO	24
	Helicobacter (adjuvant)	0.5-1.5 mg/kg 0.7 mg/kg	PO PO	24 24
Ondansetron	•		PO	12-24
Ondansetron	Antiemetic	0.1-1 mg/kg Loading dose: 0.5 mg/kg	PO IV	Once
		Followed by: 0.5 mg/kg	IV IV	1 h infusion
	Intractable vomiting	0.11-0.176 mg/kg	IV (slowly)	6-12
Olsalazine	Inflammatory bowel disease	10-20 mg/kg (D)	PO	8-12
	•			
Opium tincture	Antidiarrheal	0.01-0.02 mg/kg	PO	12
Oxazepam	Appetite stimulant	2-2.5 mg (C)	PO	12
Pancreatic enzyme	Pancreatic exocrine insuf- ficiency	0.5- 2 tsp	PO (crush pills first)	Mix with food. If cat is intol- erant, then dose orally. Mixing 20 min in advance may not be necessary.

Drug	Indication	Dose	Route	Interval (hr)
Paregoric	Antidiarrheal	0.05-0.06 mg/kg (5 mL of paregoric corresponds to approximately 2 mg of morphine)	РО	8-12
Petrolatum, white	Laxative	1-5 mL/cat	PO	24
Phenobarbital	Irritable colon syndrome	2.2 mg/kg (D)	РО	12
Phosphate enemas	Constipation, obstipation	large D)		Once. Use cautiously
Polyethylene glycol	Colonscopic procedure	20-33 mL/kg	PO (volume may require orogastric or nasogastric tube)	In fasted (18-24 hr) animal, administer 2 doses 4-6 hr apart the day before the procedure. Follow with warm water enema before anesthesia.
		60 mL/kg	PO (volume may require orogastric or nasogastric tube)	In fasted (18-24 h) animal, administer 2 doses 4-6 h apart the day before the procedure. Follow with warm water enema before anesthesia.
	Preoperative mechanical cleansing	60 mL/kg	PO (volume may require orogastric or nasogastric tube)	The evening before surgery
Prednisolone/ Prednisone (++)	Eosinophilic ulcers, plasma cell gingivitis	1-2.2 mg/kg (D)	PO	24 × 7 days, then taper to every 48
	Eosinophillic gastritis, enteritis colitis	1-3 mg/kg (D)	РО	24, then taper to every 48
	Plasmacytic/lymphocytic enteritis	1-2 mg/kg	РО	12, then taper dose weekly
	Lymphocytic cholangitis, chronic active hepatitis, copper hepatopathy	0.25-2 mg/kg (D)	РО	12
	Myasthenia gravis	0.5 mg/kg (D)	РО	12 initially. Slowly increase to every 24 until remis- sion then every 48.
Prochlorperazine	Antiemetic	1 mg/kg (D)	РО	12
		0.13-0.5 mg/kg (D)	IM	6-8
		0.1 mg/kg	IM	6
		0.13 mg/kg(C)	IM	12
Promethazine	Antihistamine, antiemetic	0.5 mg/kg (C) 0.2-0.4 mg/kg. Maximum of	PO IM, IV, PO	6-8 6-8
hydrochloride	Acute colitis, irritable colon syndrome, antiemetic	1 mg/kg 0.22-0.5 mg/kg	РО	8. Maximum of 3 days
	Antiemetic, antidiarrheal	0.25 mg/kg	РО	8
Dropanthaling knows 1.				
Propantheline bromide	Anticholinergic	0.25-1 mg/kg (D) 7-30 mg/dog	PO PO	8 8
		0.8-1.6 mg/kg (C)	PO PO	8
		7.5 mg/cat	PO PO	8
Prucalopride	Colonic motility	0.02-1.25 mg/kg (D)	IV, PO	Frequency not established
raculopilae	Colonic motinty	0.64 mg/kg (C)	IV, PO IV, PO	Frequency not established
		3.4 g/5-10 kg (D)	· / -	1 /

of well-being, and causes weight gain, particularly of fat. Fat is the preferred weight gain because it provides more kilocalories per gram than proteins or carbohydrate and helps stabilize body temperatures.¹² Megestrol decreases the effects, sometimes by inhibiting formation of TNF-alpha, interleukin-1 (IL-1), and interleukin-6 (IL-6). Centrally, megestrol appears to modulate neurotransmitters responsible for appetite regulation such as NPY, which in turn stimulates the release of other mediators. Megestrol may also stabilize declining concentrations of β -endorphins in the cerebrospinal fluid.

KEY POINT 19-4 Megestrol acetate targets cachexia either directly and indirectly, stimulating appetite and antagonizing the catabolic metabolic effects of cytokines.

Effects of megestrol are dose and (particularly for fat gain) duration dependent. Initial weight gain requires high concentrations (>300 ng/mL) for more than 40% of a 24-hour dosing interval. In humans this requires administration of the tablet four times daily. Megestrol acetate is used rather than other progestationals, which must be given parenterally.¹² Bioavailabilty of megestrol acetate is variable, being greater with the oral solution compared to the tablet. With tablets, peak concentrations may vary 6 fold; variability is much less with the oral solution. Disposition is complex. Hepatic metabolism is necessary to free the steroid from acetate, with the steroids subsequently conjugated with glucuronic acid before elimination. Elimination also varies, with half-lives that range from 13 to 105 hours. In humans, a single daily dose of the suspension (800 mg) achieves peak concentrations between 1500 and 3000 ng/mL. Not surprisingly, the oral solution is associated with a much higher rate of response compared with the tablet. A micronized (nanocrystal) preparation is currently under investigation for human use.

Limited information is available regarding use of megestrol acetate in animals. The disposition of megestrol acetate has been described in Beagles as part of the preclinical assessment in humans. Four preparations were studied for 72 hours after administration of 10 mg/kg (by oral gavage) either in the fasted or the fed (high-fat meal) state. The preparations included two different nanocrystal oral solutions and two commercially available oral suspensions (Par Pharmaceutical and Bristol-Myers). After the high-fat meal, peak concentrations (1600 to 2200 ng/mL) and area under the curve (AUC) were higher with the nanocrystal oral suspensions compared with the commercially available oral suspensions (both approximating 300 ng/mL). Although the elimination half-life was not reported, the disappearance half-life of megestrol appeared to be between 10 and 20 hours.¹²

Megestrol acetate appears to be better tolerated in humans compared with animals. The primary adverse events in humans are thromobembolic, reflecting increased thrombin receptors in smooth muscles. Venous distention and capacitance increase, contributing to reduced blood flow and stasis. Addison's disease and glucose intolerance are sporadically reported, reflecting its intrinsic corticosteroid activities.¹²

Anecdotally, megesterol acetate has been effective in dogs to treat chemotherapy-induced nausea and inappetence. However, in humans a prospective randomized controlled clinical trial in cachectic human cancer patients compared the efficacy of an anabolic steroid (fluoxymesterone [10 mg, 0.142 mg/k] twice daily), megestrol acetate tablets (800 mg [11.4 mg/kg] once daily), and a glucocorticoid (dexamethasone, 0.75 mg [0.01 mg/kg] four times daily) as appetite stimulants. Of the three ,the anabolic steroid was least (significantly) and megestrol (nonsignificantly) most clinically effective. Glucocorticoids usually were discontinued because of side effects, although megestrol acetate was associated with the most thromboembolic events.¹³

APPETITE SUPPRESSANTS AND ANTI-OBESITY DRUGS

Obesity is a physiologic disorder of energy balance in which energy intake exceeds energy expenditures. Excessive energy is stored as fat. In rodent models and humans, leptin deficiency or leptin resistance can result in obesity caused by hyperphagia and decreased energy expenditure.³ Other characteristics of obesity in humans include non–insulin-dependent diabetes mellitus, severe insulin resistance, hypothermia and cold intolerance, infertility, and decreased lean body mass.³

Anti-obesity drugs might target mediators of appetite or satiety. However, differences in response to drugs that affect appetite limit extrapolation of studies among species. Hypoleptinemia has been associated with obesity. However, obesity appears to be accompanied by resistance to leptin or leptinlike drugs. Alternative targets for treatment of obesity might include mediators of leptin actions, including NPY, Y1 and Y5 receptor agonists, and melanocortin MC4 receptors. Central chemical targets for drugs that might influence appetite include all mediators, their receptors, or upstream regulators of mediator release. These include anorexigenic signals such as α -MSH, opioids, and serotonin (specifically the 5-HT2C receptor) or mediators of satiety that emerge after food ingestion, such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), ghrelin, peptide YY (PYY), bombesin-like peptides, enterostatin, oxyntomodulin, and apolipoprotein IV (apoAVI).

Among the drugs studied for central suppressant effects are cannabinoids, the manipulation of which may influence consumption of highly palatable foods. For example, rimonabant is a cannabinoid receptor type 1 (CB1) receptor antagonist that decreases intake of palatable foods, leading to decreased body weight in rodents. However, dogs (and other species) respond differently to cannabinoids. For example, although CB1 antagonists decrease food intake, causing weight loss in dogs, appetite suppression is attenuated after several weeks. Dogs also appear more sensitive to side effects associated with CB1 antagonists, exhibiting vomiting, diarrhea, and pruritus at doses necessary to decrease appetite. Although cats tolerate antagonists better than dogs, they respond only at doses associated with severe pruritus, panting, agitation, and CNS stimulation.¹⁴ Selective 5-HT_{2C} receptor antagonists appear to be effective in decreasing food intake in rodent models but not in dogs or cats. Higher doses that might be more effective are associated with adverse effects.¹⁴ The human pancreatic lipase inhibitor orlistat is associated with modest weight loss in dogs. However, significant increase in food intake, presumably in response to caloric loss, is accompanied by markedly increased fecal fat, leading to uncontrolled leakage and perianal and abdominal soiling.¹⁴

KEY POINT 19-5 Anti-obesity drugs target mediators of appetite or satiety or alter energy intake, expenditure, or use.

Anti-obesity drugs might target altered energy intake. Dirlotapide is a selective microsomal triglyceride transfer protein inhibitor that blocks both assembly and release of lipoprotein particles into the bloodstream (package insert [PI]). However, the mechanism by which weight gain is controlled is not clear. Appetite suppression reflects local GI effects, including decreased fat absorption. Subsequent lipid filling of enterocytes appears to stimulate a satiety signal. Fecal fat is increased. Efficacy does not appear to correlate with serum concentrations. The impact of dirlotapide on serum or gastric mucosal leptin, ASP, or adiponectin apparently has not been addressed.

In dogs, dirlotapide (Slentrol) is systemically bioavailable after oral administration, although absorption is markedly variable. Elimination of absorbed drug reflects hepatic metabolism that follows nonlinear kinetics, with concentrations increasing disproportionately with dose. Mean half-life varies between 5 to 18 hours at the clinical dose but appears to increase with dose and duration of dosing ((package insert).

Safety of dirlotapide when administered in dogs for 1 year has been established in dogs. Adverse effects, should they occur, generally emerge within the first month of therapy. According to the package insert, the incidence of vomiting and diarrhea was greater in dirlotapide-treated (25% and 12%, respectively) compared with control-treated (corn oil) animals (22% and 7%, respectively). Serum chemistry changes occurred early, including mild to moderately increased serum hepatic transaminase, although concentrations remained within the normal range and decreased over the 4-month treatment period. Mean cholesterol and high-density lipoprotein also decreased (below reference range for cholesterol during the treatment period); however, triglycerides did not change. Serum total protein, albumin, and blood urea nitrogen levels also decreased compared with those of control animals, although all were within normal ranges. Enterocytes were characterized by lipid vacuolization and the liver by mild periportal fatty changes.

Absorption of fat-soluble vitamins might be affected by dilortapide. Plasma vitamins A and E concentrations were lower in treated compared with control dogs, but concentrations appeared to increase during weight stabilization (second through sixth months), reaching control concentrations after treatment was discontinued (PI). A study in 72 obese Labrador Retrievers (n = 48) receiving dilortapide at the labeled dose for 52 weeks was reported in materials obtained through the Freedom of Information Act. Weight loss during the initial and retraining phases was 18.4% and 5% to 6%, respectively. In addition to vomiting and diarrhea, ophthalmic abnormalities were found at study end. These included focal or multifocal retinopathies or diffuse retinal degeneration in eight dogs receiving the drug for 12 months and two dogs for 6 months. Generalized progressive retinal atrophy occurred in one dog treated for 12 months and one dog treated for 6 months, respectively. Cataracts were observed in four dogs receiving the drug for 12 months and one dog receiving the drug for 6 months. Pretreatment ophthalmic exams were not available, and abnormalities were not reported in control dogs, although it is not clear if they did not occur or simply were not recorded. However, a follow-up 9-month study of 34 dogs of different breeds, in which a different formulation was used that yielded pharmacokinetics similar to the commercial preparation, found no ocular lesions, leading investigators to conclude that previous ocular abnormalities reflected breed predisposition.

Use of dilortapide in dogs must be accompanied by a weight loss program. Loss of appetite will not last more than several days after therapy is discontinued. Dosing is complex and is

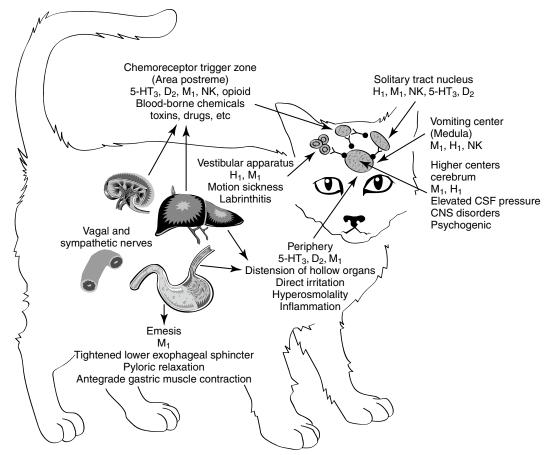

Figure 19-2 Sites that mediate the emetic reflex. The secondary neurotransmitters at each site are in parentheses. Stimuli that mediate emesis at each site are listed below the neurotransmitter. *CNS*, Central nervous system; *CTZ*, chemoreceptor trigger zone; *CSF*, cerebrospinal fluid; *LES*, lower esophageal sphincter.

based on body weight (see package insert). A total of 11% to 13% of body weight was lost in patients studied during drug approval (PI), an amount considered to contribute positively to animal health. At study end mean final dose was 0.26 to 0.56 mg/kg. Dilortapide should not be administered to humans or cats. Adverse reactions in humans include abdominal pain, distention, diarrhea, flatulence, nausea, and vomiting.

Several drugs may affect appetite secondary to their intended therapeutic effect. Propofol (1-2 mg/kg IV) was reported in a research abstract¹⁵ to be an effective appetite stimulant, presumably through stimulation of GABA-A and NYP and inhibition of serotonin receptors. Anecdotally, omega-3 fatty acids (EPA and DHA) may stimulate appetite by inhibiting cytokines responsible for anorexia.

EMETICS AND ANTIEMETICS

The Vomiting Reflex

Emesis is a complex protective reflex that is not well developed in all species but does occur in both dogs and cats.¹⁶⁻¹⁸ Although several afferent pathways may be responsible for initiating emesis, all signals are coordinated by the emetic center. Located in the lateral reticular formation in the mid brainstem, the emetic center is in close proximity to the nucleus tractus solitarius of the vagus nerve and the chemoreceptor trigger zone (CTZ), the latter of which is located adjacent to the area postrema in the bottom of the lateral ventricle. The latter coordinates vomiting associated with bloodborne chemicals (Figures 19-2 and 19-3). The emetic center coordinates vomiting associated with afferent peripheral and central (neural) signals. Among the signals coordinating vomiting is the tachykinin neuropeptid, ≥substance P. Drugs that cause or ameliorate vomiting generally do so by modifying afferent or efferent neurotransmitters responsible for transmission of the signal from various afferent sites. The emetic center is protected by the blood-brain barrier, whereas the CTZ is not; therefore, the CTZ is able to monitor the presence of emetics in the blood or cerebrospinal fluid. However, drug penetrability to each site varies, affecting both drug safety and efficacy.16-20

KEY POINT 19-6 Drugs that inhibit emetic signals at the vomition center have the potential to be the broadest in efficacy.

Several sites in the vomiting reflex are targeted by drugs. Ideally, drugs that target the emetic center would be characterized by the broadest spectrum and potentially the best efficacy. Historically, because such drugs must be able to penetrate

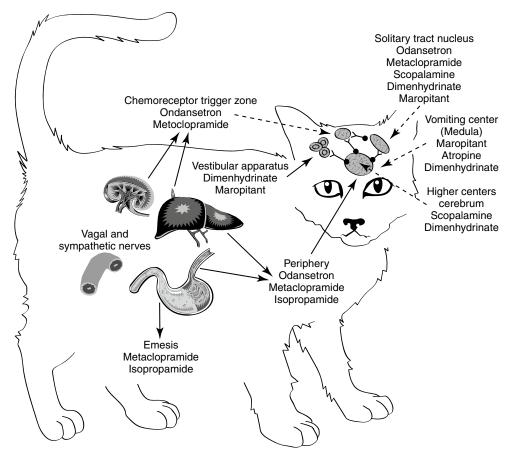

Figure 19-3 Antiemetic drugs effective at each site of the emetic reflex. CTZ, Chemoreceptor trigger zone.

the blood-brain barrier, they tend to be characterized by increased risk of side effects. This risk is minimized if the drug targets a mediator whose effects are limited to the vomiting center only. In addition to integration of the emetic reflex, impulses integrated by the center include afferent signals from higher centers such as the cerebral cortex and limbic system. For example, psychogenic vomiting, or vomiting induced by visual and olfactory stimuli, originates in the cerebral cortex, whereas head injuries and increased intracranial pressure initiate emesis by way of the limbic pathways. The solitarius nucleus contains receptors for enkephalin, histamine, serotonin (5-HT₃), and acetylcholine (ACh). ACh is a major afferent neurotransmitter in the higher centers, with histamine acting as a secondary transmitter by way of H₁ receptors.¹⁹ However, substance P, a member of the tachykinin family of neuropeptides, has recently been identified as a key neurotransmitter associated with emesis in higher centers, including the emetic center.²¹ Substance P targets neurokinin (NK₁) receptors located throughout the emetic center (as reviewed by Wu²⁰), including the nucleus tractus solitarius, the area postrema, and the dorsal motor nucleus of the vagus.²² The emetic center also involves cannabinoid receptors (also located in the CTZ), although their role is not clear.

Blood-borne chemical compounds stimulate the CTZ.^{17,19} Examples include circulating toxins associated with disease (uremia, pyometra, liver disease, endotoxemia), radiation sickness, and drugs (e.g., opioids, cardiac glycosides, anticancer chemotherapeutic agents). Signals in the CTZ are mediated by dopaminergic $(D_2)^{19}$ and serotonergic (5-hydroxytryptamine; 5-HT₃) receptors²³ and neurokinin receptors. Histamine by way of H₁ receptors acts as a secondary neurotransmitter at the CTZ. Neurokinin receptors in humans are responsible for the delayed phase of vomiting associated with cisplatin anticancer chemotherapy. Alpha-2 receptors associated with the area postrema also induce emesis in dogs, cats, and other species.²⁴⁻²⁶ The CTZ also is rich in opioid receptors. The safety of CTZ-active drugs may be increased by selectively targeting the subreceptor types for each neurotransmitter.

Emetic impulses originating from the semicircular canals of the vestibular apparatus are transmitted by the eighth cranial nerve to the vestibular nuclei and then by way of the CTZ and the uvula and nodulus of the cerebellum to the emetic center. This pathway, mediated by histaminergic (subtype H_1) receptors, is responsible for eliciting the emesis that accompanies motion sickness and labyrinthitis.²⁷

Peripheral impulses cause emesis that arises from stimulation of the pharynx and fauces; the signals are transmitted by afferent nerves in the ninth cranial nerve to the emetic center. Other peripheral afferent pathways include those arising from stimulation (i.e., irritation or distention) of various visceral organs and tissues. Impulses may be carried by sympathetic or vagal afferents from the heart, stomach, duodenum, small intestine, liver, gallbladder, peritoneum, kidneys, ureter, urinary bladder, and uterus. ACh is the primary neurotransmitter mediating the afferent limb of the emesis reflex from peripheral causes. Muscarinic receptors initiate the impulse that travels to the emetic center by way of the vagus nerve.

Efferent signals that stimulate the emetic reflex travel back to the stomach by the tenth cranial (vagus) nerve. ACh also acts as the primary efferent neurotransmitter in the vagus and in the smooth muscle of the stomach. In the stomach, dopamine receptors (D₂) appear to inhibit gastric motility, during nausea and vomiting. In addition, dopamine receptors contribute to reflexes that allow relaxation of the upper stomach and delayed gastric emptying associated with gastric distention caused by food.²⁴ Finally, serotonin (by way of 5-HT₃ receptors) contributes afferent pathways from the stomach and small intestine.²⁴

Emetics

Clinically, emesis is pharmacologically induced to empty the anterior portion of the digestive tract. Indications include preparation for induction of general anesthesia in animals that may have food in the stomach (e.g., use of hydromorphone) or treatment of ingested, noncorrosive poisons.

Peripherally Acting (Reflex) Emetics

Although their efficacy and safety vary, a number of substances induce emesis by either distending the pharynx, esophagus, stomach, or duodenum (hollow organs) or irritating the epithelium of the GI tract. Distention with warm water or saline can induce the emetic response. In addition, in the case of toxin ingestion, administration of warm water by stomach tube may help dilute poisons. Emesis can be induced in dogs by oral administration of a solution of warm saturated (strong) sodium chloride or pharyngeal placement of a small amount of plain table salt or neutral salt crystals, such as sodium carbonate. Orally administered hydrogen peroxide (3%) often induces emesis rapidly in cats and dogs, although fatal aspiration of hydrogen peroxide foam is possible. Ipecac syrup is an over-the-counter emetic commonly recommended to induce emesis in human pediatric patients. It contains the alkaloid emetine, which increases lacrimation, salivation, and bronchial secretions. Emesis usually, but not consistently, occurs as a result of both peripheral and central stimulation. If repeated use fails to induce emesis, however, gastric lavage may be indicated to remove potentially toxic doses of the drug. Although ipecac syrup or powder has been used as an emetic for many years for cats, adverse effects include death, and its use in cats is discouraged.

Centrally Acting Emetics

The central effects of ipecac were discussed in the previous section. Although a number of drugs are capable of stimulating the CTZ centrally, certain opiates, particularly apomorphine, are indicated for their emetic effect. Apomorphine hydrochloride is a synthetic derivative of morphine but is characterized with only marginal depressant activity. Its emetic activity reflects stimulation of dopamine receptors and more readily than other morphinelike actions. Emesis will occur regardless of the route of administration, although oral doses are higher than those by other routes to compensate for reduced oral bioavailability. Emesis generally occurs in 2 to 10 minutes after subcutaneous or conjunctival administration. Although apomorphine stimulates vomiting at the CTZ, it also directly depresses the emetic center, and subsequent doses are not likely to induce emesis if the first dose was not successful. Excessive doses of apomorphine can depress the CNS, particularly the respiratory center, and are contraindicated in the presence of existing central depression. Apomorphine is currently available as an injectable preparation.

Xylazine is an α_2 -agonist historically used for sedative analgesia. Emesis in dogs is not as consistent as in cats. Emesis mediated by α_2 stimulation occurs in cats at doses lower than that recommended for sedation (0.05 mg/kg).²⁶ Emetogens were evaluated in cats in anticipation of an antiemetic clinical trial.²² Three emetogens were tested, with xylazine (0.44 mg/kg intramuscularly) reliably causing emesis. In contrast, neither apomorphine (0.04 mg/kg intravenously) nor syrup of ipecac (0.5 mL/kg) predictably caused emesis. Syrup of ipecac causes anorexia for several days. The use of medetomidine to induce emesis has not been reported, although its actions are similar to those of xylazine.

Antiemetics

Antiemetics control emesis by either a central or a peripheral action (see Figures 19-2 and 19-3). Both actions depend on and can be correlated with blockade of neurotransmission at receptor sites.^{27,28} Centrally acting antiemetics block impulses at higher centers and at the emetic center and include muscarinic anticholinergics and drugs that target neurokinin receptors; antidopaminergics and antiserotonergics, which block dopaminergic receptors at the CTZ; and antihistaminergics, which primarily block H₁ receptors at the vestibular apparatus but secondarily at multiple central centers. Antiemetic agents possess either a limited or a broad effect, depending on which signals and centers are inhibited.

Centrally Acting Antiemetics

Vomiting center. Maropitant (Cerenia) is a neurokinin (NK_1) receptor antagonist that blocks the actions of substance P in the area postrema and nucleus solatarius; Aprepitant is a human drug in the same classused as rescue anti-emetic therapy in cancer patients nonresponsive to $5HT_3$ -dexamethasone combinations.²⁹ Approved as an oral or subcutaneous preparation for dogs for the prevention of acute vomiting and motion sickness, maropitant has proved efficacious in the control of vomiting associated with many central and peripheral causes (Table 19-2).

In dogs bioavailability is greater after subcutaneous (91%) compared with oral (24%) administration, probably because of first-pass metabolism (PI). Relevant pharmacokinetic parameters include C_{max} (ng/mL) of 92 and 81 ng/mL at 0.75 and 2 hours, respectively, after administration of 1 mg/kg subcutaneously and 2 mg/kg orally, respectively. It is highly (99.5%) bound to plasma proteins. Maropitant is metabolized in dogs by CYP2D15 and CYP3A12. Elimination half-life in

Table 19-2 Antiemetic Drug–Receptor Interactions						
		Dopamine D ₂	Histamine H ₁	Muscarinic M ₁	Neurokinin NK-1	Serotonin 5-HT ₃
Chlorpromazine	Phenothiazine	4+	4+	2+	4+	1+

dogs approximates 9 hours after subcutaneous administration and 4 to 5 hours after oral administration. However, saturation of drug-metabolizing enzymes (probably CYP2D15) results in nonproportional increases in drug concentrations as the dose is increased up to 16 mg/kg orally; proportionality returns at 20 to 50 mg/kg orally. The injectable product remains potent for 28 days when prepared and stored according to labeled directions (amber vial at room temperature). Pain on injection may be common. Side effects delineated on the package insert include bone marrow hypoplasia in puppies younger than 11 (but not greater than 15) weeks of age.

KEY POINT 19-7 As a neurokinin antagonist, the specificity of maropitant results in safe and effective control of motion sickness and vomiting associated with both central and peripheral causes of vomiting.

Maropitant kinetics have been described in the cat after single subcutaneous and oral dosing and multiple subcutaneous dosing.²² The drug was well tolerated in cats (n = 6)during 15 days of subcutaneous administration at doses ranging from 0.5 to 5 mg/kg; one cat developed tremors at the 5 mg/kg dose. No changes occurred in clinical laboratory tests. Plasma maropitant concentrations increased proportionately with dose. After single intravenous dosing, the volume of distribution of maropitant in cats was 6.2 L/kg. Maximum drug concentration after oral and subcutaneous administration of 1 mg/kg in cats were 156 ng/mL and 269 ng/mL (with 50% coefficient of variabilility), respectively. The elimination half-life in cats was 13 to 17 hours; oral bioavailability varied from 50% to 117%. A dose of 1 mg/kg administered intravenously, orally, or subcutaneously prevented emesis induced by xylazine (0.44 mg/kg intramuscularly) and experimentally induced motion sickness.

Maropitant was approved for use in animals in Europe before the United States. It has proved effective for control of vomiting associated with drugs such as cisplatin, apomorphine, and morphine derivatives. Maropitant has been compared with

metoclopramide (0.33 mg/kg every 8 hours subcutaneously in study one, 0.5 to 1 mg/kg/day in study two) in two multicenter, prospective, randomized, positively controlled clinical trials.³⁰ Dogs (n = 64 in study one, 77 in study two) were at least 8 weeks of age and had been vomiting for at least 24 hours. Maropitant as studied at 1 mg/kg once daily subcutaneously in study one, and 0.5 to 1 mg/kg subcutaneously in study two with oral dosing of either maropitant or metoclopramide continued in study two until vomiting stopped or for up to 5 days. Vomiting caused by toxin ingestion or in patients with clinical signs indicating the need for acute surgical treatment were excluded. Causes of vomiting were multiple, including metabolic disorders, neoplasia, drug-induced reactions, food intolerance, and parvovirus. In both studies, maropitant was associated with a greater antiemetic response (discontinuation of vomiting) compared with metoclopramide.³¹

The comparative efficacy and safety of maropitant have been recently described for dogs on the basis of manufacturersponsored studies. It was compared (1 mg/kg) to placebo, metoclopramide (0.5 mg/kg subcutaneously), chlorpromazine (0.5 mg/kg subcutaneously), or ondansetron (0.5 mg/kg intravenously) in prevention of apomorphine-induced (0.1 mg/kg intravenously) vomiting. Efficacy in controlling vomiting either central or peripheral in origin was superior to that of chlorpromazine or metoclopramide but did not differ from ondansetron.³² Both safety and efficacy for prevention of emesis associated with motion sickness were assessed in dogs (n = 198)16 weeks or older. Dogs received approximately 8 mg/kg orally. Data were collected from 26 different clinics in two different crossover randomized, placebo-controlled double-blinded trials with a 14-day washout period between trials. Vomiting was prevented in 86% or 77% of dogs dosed at 2 or 10 hours before a 60-minute car ride. No adverse events were described.

Vestibular Apparatus

Vomiting caused by motion sickness or inner ear disease is mediated by the vestibular apparatus (see Table 19-2). Motion sickness in dogs and cats can be controlled for several (8 to 12) hours by administration of antihistamines such as cyclizine hydrochloride, meclizine hydrochloride, or diphenhydramine hydrochloride (Figure 19-4; see also Figure 19-3). Effects may reflect, in part, sedative effects. In addition to direct effects on neural pathways arising in the vestibular apparatus, actions may also be independent of antihistaminic effects. These may include anticholinergic effects. Those drugs able to penetrate the blood-brain barrier may thus have effects at the vomiting center but generally only at higher doses. Drowsiness and xerostomia (dry mouth) are typical side effects that occur with use of this group of drugs in humans. Although phenothiazine antiemetics may be used to treat motion sickness (e.g., acepromazine), efficacy may reflect sedative rather than direct effects. Centrally active maropitant is approved for use in dogs to treat motion sickness (see preceding discussion) and has been used successfully in cats as well.

Drugs Active at the Chemoreceptor Trigger Zone

Phenothiazines. Phenothiazines are broad-spectrum antiemetics that control emesis induced by most central causes other than labyrinthine stimulation (see Figure 19-4). Their classification as broad reflects the variety of signals that serve as primary, secondary, and tertiary mediators. Phenothiazines block emesis mediated by the CTZ at low doses because of their antidopaminergic (D₂) and, secondarily, antihistaminergic effects. Several phenothiazines are also characterized by weak antiserotinergic activity (see Table 19-2).²⁴ At higher (perhaps nonpharmacologic) doses, their anticholinergic effects may also act at other central sites, including the vomiting center. A variety of phenothiazine derivatives (e.g., chlorpromazine, prochlorperazine, triflupromazine, perphenazine, trifluoperazine, and mepazine) are used in small animals as antiemetics. The primary adverse effects associated with their use as antiemetics are sedation (which contributes to their efficacy for motion sickness) and hypotension due to peripheral α -blockade. Selection of a particular phenothiazine may be based on avoidance of adverse reactions. Fluid replacement therapy should be instituted if necessary before use of a phenothiazine. The impact of phenothiazine derivatives on the seizure threshold and in epileptic dogs is discussed in more depth in see Chapter 27. In general, their use in epileptic animals may require caution but do not appear to be contraindicated.

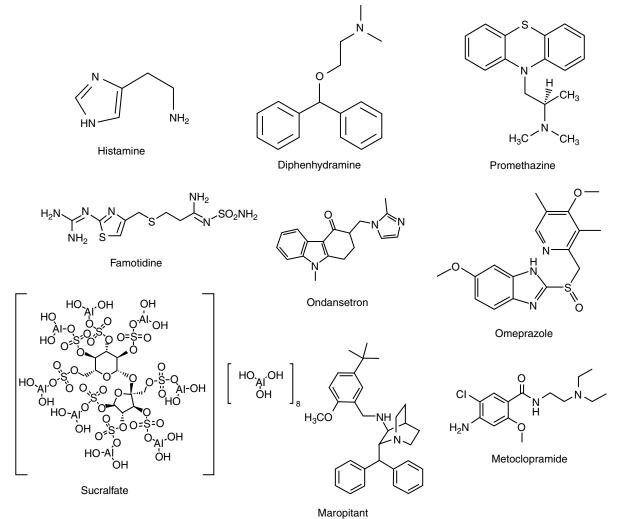

Figure 19-4 Chemical structures of selected gastrointestinal drugs.

691

KEY POINT 19-8 Drugs active at the CTZ are most effective for control of vomiting associated with drugs, toxins, and metabolic diseases.

Butyrophenone derivatives. Haloperidol (Haldol) and droperidol (Inapsine), which are also used as major tranquilizers, are potent antiemetics because of their antidopaminergic activity. These drugs are rarely used as antiemetics because of their side effects (similar to those encountered with the phenothiazine group but perhaps more profound).

Metoclopramide. Metoclopramide (see Figure 19-4) effectively blocks emesis mediated by the CTZ. Although its potent antagonism of dopamine was thought to be solely responsible for inhibition at the CTZ, metoclopramide is also a mixed 5-HT₃ receptor antagonist/5-HT₄ receptor agonist; emesis at high doses probably reflects 5-HT₃ receptor antagonism.³³ Metoclopramide effectively antagonizes apomorphine-induced emesis³⁴ and is 20 times as potent as phenothiazines (although differences in efficacy have not been documented).³⁵ The peripheral effects of metoclopramide on emesis resulting from prokinesis are discussed with the prokinetic drugs. Metoclopramide is indicated for control of emesis induced by a wide variety of blood-borne and peripheral causes.^{36,37} High doses of metoclopramide, particularly when combined with dexamethasone, have been used to treat emesis associated with cancer chemotherapy in human patients.38-40

Serotonin antagonists. Serotonin antagonists are useful for their antiemetic effects mediated at the CTZ, particularly those induced by chemotherapeutic agents (see Table 19-2).⁴¹ Unlike most other antiemetic drugs, antiserotonergics have no effects at other receptors, thus increasing the safety of those drugs selective for serotonin receptors. Ondansetron is a potent antiemetic and affects human cancer patients undergoing chemotherapy.^{23,33,42} It has also been used in small animals suffering from refractory vomiting that have not responded to other antiemetics. The efficacy of ondansetron reflects, in part, its active metabolite dolasetron, which is also available as an orally administered as well as an intravenous product. Dolasetron also is metabolized (reduced) to a metabolite characterized by greater activity for 5-HT₃receptors compared with dolasetron.43 The pharmacokinetics have been reported for dolasetron and its reduced metabolite in dogs (n = 3).⁴³ After intravenous administration of 2 mg/kg, clearance of the parent compound was $109 \pm 41 \text{ mL/min/kg}$ and volume of distribution was 0.83 \pm 0.23 L/kg. After an oral dose of 5 mg/kg, C_{max} of the parent compound was 219 ± 149 ng/mL at 0.17 hours. The elimination half-life was 0.15 ± 0.11 hour. The active metabolite appears to potentially double the AUC of active compound. Although oral bioavailability of the parent compound is less than 10%, it is probable that first-pass metabolism results in formation of the active, reduced metabolite: oral administration of 5 mg/kg radioactive dolasetron results in a C_{max} of 700 ng/mL radioactivity (i.e., a combination of both radioactive parent and metabolite). Example uses of ondasetron include presurgical preparation, chemotherapy,

and treatment of parvovirus infection; vomiting induced by hepatic lipidosis or GI irritation is less likely to respond. Ogil-vie⁴⁴ has reviewed the use of dolasetron in dogs.

KEY POINT 19-9 Side effects of antiserotinergic antiemetics active at the CTZ are limited by their selectivity at the site.

Cyproheptadine is an anthistaminergic antiserotoninergic drug that has been used to control vomiting and diarrhea (the latter associated with spasticity) in humans. Its use in animals might be limited to more chronic control of vomiting when combined with other compounds or as part of combination therapy to treat vomiting and diarrhea associated with inflammatory bowel disease (IBD).

Miscellaneous Antiemetics

Sedatives such as the barbiturates (phenobarbital) and the benzodiazepines have been used to control psychogenic and behavioral vomiting. Glucocorticoids and in particular dexamethasone are characterized by antiemetic effects, although the antiemetic mechanism of action is not understood.²⁴ An antiinflammatory mechanism has been proposed. Glucocorticoids also appear to act in an additive or synergistic fashion when combined with other antiemetics. Both dexamethasone and methylprednisolone have been used in human patients to control vomiting associated with chemotherapy.

Natural extractions or synthesis of *Cannabis sativa* cannaboids inhibit vomiting, probably through stimulation of CB1 receptors. Dronabinol is an example of an antiemetic used in humans prophylactically to prevent chemotherapyinduced vomiting. It is characterized by complex kinetics that include high protein binding, extensive first pass metabolism to active and inactive metabolites. Side effects are similar to sympathomimetic drugs. Because dogs and cats respond differently to drugs which target cannanboid receptors, use should be based only on scientific evidence in the target species.

Peripherally Acting Antiemetics

Protectants. Drugs that locally protect the GI epithelium from further irritation may help prevent vomiting. Drugs that modulate gastric acid secretion might also provide antiemetic effects; these drugs are discussed later with the antiulcer drugs. Demulcents, antacids, and protectants such as kaolin, pectin, and bismuth salts are of limited benefit in the control of emesis that is gastric in origin. Distention or initial irritation of the stomach by these agents may exacerbate emesis. Antacids may be effective in certain cases. Other peripherally acting antiemetics include drugs that affect gastric motility, including anticholinergic drugs, and prokinetic drugs such as metoclopramide and domperidone (discussed later with modulators of GI motility).

Anticholinergics. Anticholinergic drugs that block muscarinic receptors in the emetic center also inhibit peripheral cholinergic transmission. Those anticholinergic drugs that do not cross the blood-brain barrier well are essentially peripheral in action and include glycopyrrolate, propantheline, isopropamide, and methscopolamine (which should not be used for cats). The ability of anticholinergics to suppress emesis is probably related to inhibition of afferent vagal impulses, relief of GI smooth muscle spasms, and inhibition of gastroenteric secretions. Delayed gastric emptying caused by these drugs may itself cause emesis, and anticholinergics should not be used for more than 3 days by the vomiting patient. Because of their anticholinergic properties, these drugs should not be used in combination with drugs whose actions depend on cholinergic activity in ganglion or smooth muscle. These include metoclopramide, cisapride, and the opioids.

KEY POINT 19-10 Centrally acting anticholinergic antiemetics are less ideal than other centrally acting drugs because they simultaneously act peripherally, increasing the risk of side effects.

Prokinetics. Prokinetics, and specifically metoclopramide, are peripherally acting antiemetics because of their prokinetic effects on the GI tract. Metoclopramide physiologically antagonizes emesis by virtue of its actions on the upper gastroduodenal area: increased esophageal sphincter tone, duodenal pyloric relaxation, and antegrade contraction of the gastric antrum. The prokinetic effects of metoclopramide are discussed later with other drugs that modify GI motility.

ANTIULCER DRUGS

Pathophysiology of Gastrointestinal Ulceration

Gastroduodenal Ulceration

The events leading to gastroduodenal ulceration are complex and reflect interactions between acid-secreting and defense mechanisms of the GI mucosa.45,46 Regardless of the cause of GI erosion or ulceration, the basic pathologic mechanism is similar. Gastric acid secretion is a prerequisite for damage to the GI mucosa^{46,47} with luminal damage not occurring unless luminal pH is less than 7. Pepsin and bile acids can contribute to mucosal damage. Even though these chemicals are inherently caustic, mucosal damage generally does not occur in the face of normal mucosal cytoprotective mechanisms. These include but are not limited to secretion of bicarbonate and mucus and rapid epithelial turnover. Deceased mucosal blood flow can have a profound effect on the ability of the injured mucosa to heal itself. Drugs used to control or treat GI erosion and ulceration include those that inhibit gastric acid secretion or provide or facilitate other cytoprotective effects. The role of Helicobacter sp. in the pathogenesis of gastroduodenal ulceration in human patients has been well established, but its role in disease in animals is less well documented (see later discussion; e.g., IBDs).

KEY POINT 19-11 Drugs that target mucosal damage either facilitate cytoprotection or decrease the effects of hydrochloric acid.

Physiology of Gastric Acid Secretion

Gastric acid secretion occurs in four phases. The first three phases-referred to as cephalic, gastric, and intestinal-are stimulated by food and mediated by gastrin, which is the most potent secretagogue.⁴⁸ Secretion is persistent during these phases, and gastric pH progressively decreases as nutrients traverse the GI tract. Gastrin secretion is inhibited as gastric pH declines to 3.5 and is completely inhibited at a pH of 1.5, to begin again only when pH approximates 3 to 3.5. The fourth phase of gastric acid secretion is basal and occurs in the absence of external stimuli. The amount of basal secretion varies among animals. In humans basal secretion follows a circadian rhythm, reaching a peak at midnight and a nadir at 7 AM.49 As a model for the study of antisecretory drugs, information can be found regarding basal and responsive gastric acid secretion in dogs.^{50,51} In fasted Beagle dogs (n = 8), gastric pH (collected by stomach tube) fluctuated from 2.7 to 8.3. Basal pH tended to be 7.0; treatment with a placebo (500 mg lactose) reduced pH almost the same magnitude as pentagastrin (3 and 2, respectively) at 1-2 hrs post treatment.50

Gastric acid secretion at the cellular level involves the generation and subsequent secretion of hydrogen ions by the parietal (oxyntic) cells of the gastric mucosa. Responses are controlled through chemical signals interacting with corresponding receptors located on the basolateral membrane of parietal cells. Central and peripheral signals stimulating gastric acid secretion include endocrine (gastrin: CCK), paracrine (histamine: H₂), and neuronal (ACh: M₃) (Figure 19-5).⁴⁹ In addition to its direct effects, acetycholine indirectly increases release of gastrin from G cells and histamine from enterochromaffin cells. Of the mediators increasing gastric acid secretion, gastrin is the most potent, although its effects are mediated indirectly through stimulation of histamine receptors, particularly on enterochromaffin cells.48 Somatostatin, which inhibits gastric acid secretion, is released from D cells when gastric pH is less than 3. In humans the effects of Helicobacter spp. may reflect, in part, the ability of these organisms to decrease D cells. The hydrogen ion pump, located at the apical membrane and associated with the smooth endoplasmic reticulum, is unique in that it is a hydrogen-potassium ATPase exchange system. Three distinct pathways are capable of stimulating gastric acid. Each acts through chemical mediators that in turn interact with receptors on the parietal cell membrane.⁴⁹ H₂ receptors are linked to adenylyl cyclase and cyclic AMP.48 Of these, the ACh pathway appears to be less important in small animals.

KEY POINT 19-12 Prevention and treatment of gastrointestinal ulceration focuses on prevention of hydrochloric acid secretion and promotion of cytoprotection.

Intracellular messengers mediating gastric acid secretion vary with the receptor stimulated. Histamine increases cAMP production, which subsequently activates the adenylyl cyclase cAMP-dependent protein kinases. Gastrin and muscarinic stimulation by cholinergic drugs increased cytosolic calcium, through inositol phosphate pathways. Both pathways activate

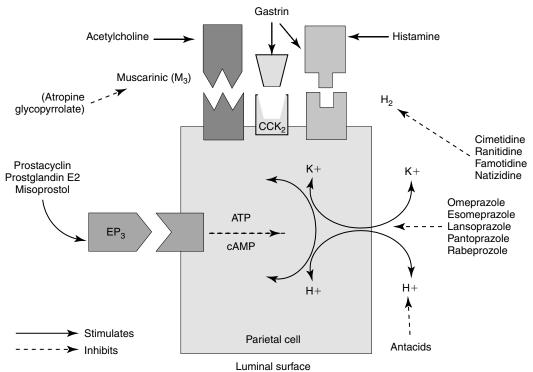

Figure 19-5 Receptor interactions that mediate gastric acid secretion by the parietal cell include acetylcholine with muscarinic receptors and histamine with H₂ receptors. Gastrin may interact with either receptor. Receptor stimulation activates the K⁺, H⁺-ATPase pump and exchange of potassium for hydrogen into the lumen. Prostaglandin E1 (PGE) modulates gastric acid secretion by inhibiting cyclic adenosine monophosphate (cAMP). ATP, Adenosine triphosphate.

an H+, K+-ATPase proton pump that exchanges hydrogen and potassium across the parietal cell membrane. Prostaglandins of the E series serve to modulate these effects, inhibiting gastric acid secretion by blocking cAMP production through EP3 receptors, also on parietal cells.^{48,49} The impact of opioid receptors on gastric acid secretion is discussed with drugs targeting intestinal secretion.

Mucosal Defenses

The primary mucosal defense of the esophagus reflects increased lower esophageal sphincter tone. Defenses of the GI mucosa require sufficient mucosal blood flow and act to prevent or repair GI ulceration (Figure 19-6).⁵²⁻⁵⁴ These include (1) secretion of bicarbonate into the lumen and neutralization of hydrochloric acid in the lumen; (2) secretion of a thick, insoluble, alkaline mucus that traps and neutralizes inwardmoving hydrogen ions and protects against macromolecules such as pepsin; (3) a gastric epithelial barrier composed of active phospholipids, a lipoprotein cell membrane, and tight junctional complexes, all of which prevent hydrogen ion back diffusion; (4) mucosal blood flow, which first provides nutrients and oxygen to mucosal cells and second removes hydrogen ions that have penetrated the gastric barrier; (5) rapid replication of mucosal epithelial cells; and (6) production of cytoprotective agents. Many of these effects reflect local secretion of prostaglandin E₂ and I₂, important defense mechanisms. They modulate hydrochloric acid secretion, increase bicarbonate and mucus production, and enhance mucosal blood flow and

epithelialization.55,56 Sulfhydryls also produced locally may act as scavengers of oxygen and other tissue-damaging radicals.⁵⁷

Gastric Antisecretory Drugs

Drugs used to prevent or modulate gastric acid secretion include anticholinergics, H2-receptor antagonists, proton pump inhibitors, and prostaglandin E2.49,55,58,59 Despite the role of muscarinic receptors in gastric acid secretion, anticholinergics have not proved effective for the control of GI ulceration in animals and are not discussed. Drugs that modify gastric acid (e.g., antisecretory drugs or antacids) are discussed with cytoprotectants. All drugs that modify gastric pH can cause complications of achlorhydria when used chronically. Although both gastric acid and pepsin are required for hydrolysis of proteins and other foods, achlorhydria is rarely accompanied by malabsorption unless bacterial overgrowth occurs. Achlorhydria can lead to malabsorption of certain nutrients, among them vitamin B₁₂ and iron, as well as decreased absorption of some (weakly acidic) drugs. Although the advent of antihistaminergic antisecretory drugs represented a landmark change in the approach to medical management of GI ulcers in humans, their use is increasingly being replaced with proton pump inhibitors.

 H_2 -Receptor antagonists. H_2 -receptor antagonists are reversible, competitive inhibitors that reduce both the amount and the hydrogen ion content of gastric secretion and the amount of pepsin⁶⁰ induced by a variety of secretagogues.⁶¹ Secretion of intrinsic factor also is reduced, although this

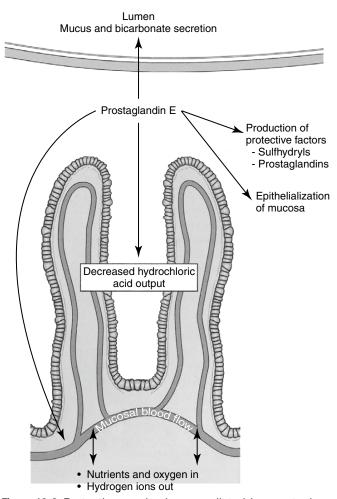

Figure 19-6 Protective mechanisms mediated by prostaglandin E against gastroduodenal ulceration provide targets for drug therapy. Bicarbonate secretion acts to neutralize gastric acid; mucus protects against hydrochloric and bile acids. The rapid turnover of epithelial cells is paramount for rapid healing if damage occurs. Mucosal blood flow not only provides critical oxygen and nutrients necessary for epithelialization but also removes H⁺ ions that have penetrated the protective barrier. Other protective factors include mechanisms to control gastric hydrochloric acid secretion and the production of protective factors that scavenge mediators capable of cell damage.

effect does not appear to be clinically relevant.^{24,48} Each antagonist is a congener of histamine, containing a bulky side chain (see Figure 19-4).^{24,48} Cimetidine; ranitidine; and, to a lesser degree, famotidine have been used to control gastric acid secretion in animals. Nizatidine is the most recent of the approved drugs and has been used least in dogs and cats. Each drug varies in potency, duration of action, disposition, and drug interactions.⁶² Ranitidine is 5 to 12 times more potent as an inhibitor of gastric acid secretion than cimetidine, whereas famotidine is nine times more potent than ranitidine and 32 times more potent than cimetidine. Famotidine (see Figure 19-4) has the longest duration of action.⁴⁰ In a cat model, famotidine was 4.5 times as potent as ranitidine; effects of famotidine were reversible at the highest dose studied (0.01-0.32 μmol kg/hr) supporting the need for higher doses or twice-daily dosing for conditions in which histamine-mediated high gastric acid output is mediated.⁶³ In animal models, including dogs, nizatidine is more potent than cimetidine.⁶⁴ In a Beagle model, ranitidine (50 mg IV) reduced resulted in a mean gastric pH of 7.8 by 1 hr; however, basal gastric pH was high as well. The pH was maintained for the 4-hour duration of the study.⁵⁰ Although the H₂-receptor antagonists have variable prokinetic actions, they appear to have inconsistent effects on the rate of gastric emptying or lower esophageal sphincter pressure.⁴⁸

KEY POINT 19-13 Antihistaminergic antisecretory drugs are competitive inhibitors whose dose may need to increase as signals causing gastric acid secretion increase.

Disposition. The disposition of antisecretory antihistamines has not been well studied in animals, with information drawn largely from human data. Cimetidine, the oldest of the clinically used H_2 -receptor antagonists, is rapidly absorbed from the GI tract, although food will delay the process. The drug undergoes hepatic metabolism and is about 70% bioavailable after oral administration. It is excreted in the urine in both the unchanged and conjugated forms. The plasma half-life is about 1 hour but may be prolonged in the presence of liver or kidney disease.

Ranitidine is less bioavailable (50%) than cimetidine after oral administration. Its elimination half-life is approximately 2.5 hours. Absorption is not impaired by food as with cimetidine. It is minimally protein bound (15%). Hepatic elimination is responsible for 30% of an intravenous dose and 73% of an oral dose.⁶⁵

Famotidine is only 37% bioavailable after oral administration reflecting decreased oral absorption; however, this is compensated for somewhat by increased potency. In contrast, nizatidine is rapidly and completely absorbed.⁶⁰ Both drugs are largely eliminated unchanged in urine.⁶⁰ Nizatidine is almost exclusively eliminated by renal excretion, which suggests that it might be the preferred H₂-receptor antagonist for patients with hepatic disease. Its efficacy apparently has not been studied clinically in animals, although its safety has been established in healthy dogs.⁶² Famotidine renal clearance appears to be saturable in the dog, albeit at suprapharmacologic doses.⁶⁶

Drug interactions. The antisecretory antihistamines can be involved in a number of drug interactions, with cimetidine being best characterized.^{48,67} Cimetidine, like all antisecretory drugs, impairs the oral absorption of a number of drugs (generally weak acids) through the alteration of GI pH. Cimetidine also directly impairs the absorption of many drugs by directly binding to the drugs. These effects might be balanced by competition for P-glycoprotein, for which cimetidine is a substrate. Cimetidine is a potent microsomal enzyme inhibitor and will decrease the hepatic metabolism of concurrently administered drugs.^{68,69} Enzymes targeted in humans include CYP1A2, CYP2C9, and CYP2D6. Occasionally, this effect may be clinically useful, as in the prevention of acetaminophen intoxication in cases of accidental overdose.⁷⁰ However, impaired

metabolism of other drugs can also lead to clinically relevant toxicity of other drugs metabolized by the liver. The impact of cimetidine on cyclosporine elimination has been studied in dogs. Although one study indicated a longer half-life, several other studies have demonstrated "no effect" of cimetidine on the disposition of cyclosporine (see Chapter 31). It is likely that the impact varies among animals, indicating a need to monitor. Cimetidine also reduces hepatic blood flow by about 20% and has been shown to reduce the clearance of flow-limited drugs such as propranolol and lidocaine.⁷¹ Unlike cimetidine, the other antihistamines have limited to no effects on hepatic blood flow. Although ranitidine also inhibits CYP, its affinity for the enzymes is only about 10% of that for cimetidine. Famotidine and nizatidine have limited to no effect on the metabolism of other drugs (or endogenous compounds). Famotidine is a potent inhibitor of transport of cationic drugs, although the clinical relevance of this is not clear.

KEY POINT 19-14 Famotidine is the preferred antisecretory antihistamine because of its increased potency and fewer drug interactions

Adverse reactions. The side effects seen with any of the H_2 -receptor antagonists are generally minor even at relatively high doses. Thrombocytopenia has been reported. Although there have been a number of reported side effects for ranitidine in humans, limited experience to date in animals has not indicated any serious toxic manifestations from ranitidine. Famotidine and nizatidine are devoid of many of the side effects of cimetidine.⁶⁴

A clinically important disadvantage of H2-receptor antagonists described in humans is relapse of gastroduodenal ulceration during or after H₂-receptor antagonist therapy is discontinued. Although several explanations for relapse have been offered, rebound hypersecretion of gastric acid appears to be most plausible.72-74 Suppression of gastric acid by H₂-receptor antagonists results in increased plasma gastrin concentrations as early as 3 hours after a single dose. Subsequent stimulation of gastric mucosal G cells results in gastric acid hypersecretion that becomes evident when the drugs are discontinued. The likelihood of hypersecretion is compounded by increased parietal cell receptor sensitivity, which apparently characterizes (human) patients afflicted with ulcers.⁷⁵ Among the H₂ receptors studied, cimetidine seems to be the most likely and famotidine or nizatidine the least likely to cause rebound gastric acid hypersecretion.74-76 Rebound hypersecretion can be minimized by tapering the dose as the drug is discontinued. Tolerance to the antisecretory effect of antihistaminergic antisecretory drugs also occurs, being well described in humans. Tolerance appears within 3 days of therapy and may not respond to increasing doses.48

KEY POINT 19-15 Rebound hypersecrtion can be minimized by use of famotidine and gradual discontinuation of any antisecretory drug.

Clinical use. The principal therapeutic uses of H₂receptor antagonists include uremic gastritis, gastric and duodenal ulcers, stress-related erosive gastritis, and hypersecretory conditions such as gastrinoma or systemic mastocytosis. Although H₂-receptor antagonists can be used to treat drug-induced (e.g., nonsteroidal antiinflammatory drug [NSAID]) ulceration, their efficacy is controversial and other, more specific antidotes (e.g., PGE₁) or more effective antisecretory drugs (e.g., proton pump inhibitors) should first or also be administered.⁷⁷ On the other hand, the drugs have proved beneficial in providing protection against gastric ulceration induced by a number of etiologic agents, including aspirin and stress.⁴⁸ Their combination with proton-pump inhibitors is discussed in the following section. When treating drug-induced ulcers, antisecretory drugs that inhibit drug metabolizing enzymes should be avoided. H₂-receptor antagonists also appear to be effective in controlling upper GI bleeding when hemorrhage is not due to erosion of major blood vessels. H₂-receptor antagonists have also been used in gastroesophageal reflux disorders, esophagitis, and duodenal gastric reflux. In exocrine pancreatic insufficiency, cimetidine or ranitidine (and presumably famotidine), if given about 30 minutes before feeding, may decrease enzymatic and acid hydrolysis of replacement pancreatic enzymes added to food on their contact with gastric secretions, thus improving the efficacy and decreasing the cost of their use. Patients suffering from short bowel syndrome may benefit from long-term H₂receptor therapy to decrease the hyperacidity associated with this syndrome. The H₂-receptor antagonists are sufficiently safe that high doses can be given to humans to maintain pharmacologic effects with once- to twice-daily dosing.⁴⁸ A meta-analysis in humans studied the impact of renal disease on the disposition of H₂-receptor blockers. Declining renal function is associated with a concomitant reduction in the renal clearance of those drugs renally eliminated. Appropriate dose reduction was associated with decrease in cost, as well as decrease in adverse events, with the major adversity being mentation disorders.78

KEY POINT 19-16 Proton pump inhibitors generally are more effective than antihistaminergic antisecretory drugs, but the lag time to efficacy may support initial therapy with both classes of antisecretory drugs.

Proton Pump Inhibitors

The substituted benzimidazole proton pump inhibitors are the most potent antisecretory drugs, reducing gastric acid secretion by 80% to 95%.⁴⁸ Each is a potent and irreversible antagonist of the H⁺, K⁺-ATPase proton pump, the final step in gastric acid secretion stimulated by any secretagogue. No differences in antisecretory efficacy have been demonstrated among these drugs. Omeprazole will be discussed as the model drug.

Mechanism of action. Omeprazole (Prilosec) (see Figures 19-4 and 19-5), was the first of the commercially available drugs. It is sold as a racemic mixture. Other proton pump inhibitors currently approved for use in the United States include esomeprazole (Nexium), the S-isomer of omeprazole

(cleared more slowly than the R isomer in some species), lansoprazole (Prevacid), rabeprazole (Aciphex), and pantoprazole (Protonix). Omeprazole is approximately 30 times more potent as an antacid than is cimetidine.⁷⁹ Secretory volume is not as affected as is acidity.⁷⁹

Pharmacokinetics. As a weak base, omeprazole is unstable in an acid environment and thus is formulated as encapsulated enteric-coated granules.⁷⁹ Drug dissolution occurs in the more alkaline environment of the small intestine. Acidity degrades (inactivates) the drug. Consequently, the drugs are generally prepared as enteric-coated products or combined with antacids (e.g., sodium bicarbonate). Compounded products must be made with attention to formulation, including pH, to ensure pharmaceutical efficacy. Oral bioavailability increases with environmental intestinal pH, and plasma drug concentrations tend to increase the first 4 to 5 days of therapy.⁷⁹ The complicated nature of proton pump inhibitors has limited the availability of parenteral preparations; however, pantoprazole and lansoprazole (and, in Europe, esomeprazole) are available for intravenous administration.

Once absorbed, the acidic environment (pH 0.8 to 1) of the GI tract causes omeprazole to selectively partition into the secretory canniculi of parietal cells compared with other cells (pH 5). In the acidic environment, the drug is protonated, trapped, and subsequently further transformed to the active inhibitor. As such, proton pump inhibitors are prodrugs. Ideally, the drugs are administered about 30 minutes before a meal; other antisecretory drugs do not appear to affect proton pump activity.⁸⁰ Indeed, antihistaminergic antisecretory drugs might be given in combination with proton pump inhibitors for a rapid response because of the slower onset of action of the proton pump inhibitors.⁸¹ Once in the canniculi, omeprazole covalently and irreversibly binds to sulfhydryl groups of potassium-adenosine triphosphate (H⁺, K⁺-ATPase), thus inhibiting the energy source for the proton pump.^{48,79} Because the enzyme is permanently inhibited, secretion of HCl will resume only after new molecules have been formed in the luminal membrane, which generally requires 24 to 48 hours.⁴⁸ Therefore the duration of action of proton pump inhibitors is much longer than their plasma half-life. Drug accumulation in parietal cells and alternating activity of parietal cells or pumps result in a lag time of up to 3 to 5 days before maximum effect (generally 70% of pumps are inhibited at steady state) is realized.^{79,82} Consequently, alternative drugs may need to be considered if a rapid response is desired. In addition, efficacy will be maintained at low plasma drug concentrations and for some time after the drug is discontinued. Because of these characteristics, omeprazole can be administered once daily.⁸² In humans omeprazole is highly (96%) bound to serum albumin and α_1 -acid glycoprotein. Its apparent volume of distribution is 0.31 L/kg.⁷⁹ Clearance is accomplished through hepatic metabolism; in humans the major enzymes are CYP2C19, for which genetic polymorphisms have been reported (decreased activity in Asians), and CYP 3A4, an enzyme characterized by broad substrate specificity. Also in humans drug elimination depends on hepatic metabolism to inactive metabolites, and elimination half-life is short (52 minutes).79 Omeprazole

has been studied in dogs.⁸³ Oral bioavailability is reduced, although therapeutic concentrations can be achieved.

Dosing at 0.17 mg/kg orally once a day for five years was well tolereated in Beagles (n = 10). Changes in disposition were not detected across time. The AUC was similar to that measured in humans receiving 20 mg (approximately 0.28 mg/kg) daily. omeprazole daily. Mean inhibition of acid secretion by omeprazole 4-7 hours after dosing approximalted 50%.

Drug interactions. Partial inhibition of drugs eliminated by selected cytochrome P450 enzymes have been reported for omeprazole.84 However, compared with cimetidine, omeprazole may be less likely to be involved in drug interactions. All proton pump inhibitors appear to inhibit a variety of CYPS (including CYP3A4), with clinically relevant drug interactions described for warfarin, cyclosporine, and diazepam. Omeprazole (more so than other proton pump inhibitors) appears to inhibit CYP2C19 and induce CYP1A2 (metabolism of several trycyclic or other behavior-modifying drugs); its S isomer is characterized by less in hibition. Other interactions are likely to exist, indicating caution when combining proton pump inhibitors with other drugs metabolized by the liver. Lansoprazole may be involved with fewer cytochrome P450-based drug interactions. Drug interactions appear to occur at the level of P-glycoprotein; omeprazole, lansoprazole, and pantoprazole appear to be substrates.⁸⁵ Because of the delay in onset of action, the use of more rapidly acting antihistaminergic drugs might be considered as proton pump therapy has begun. That the latter does not appear to have the efficacy of the former has been demonstrated.80,81

KEY POINT 19-19 The potential for inhibition of drug metabolism because of drugs or disease may result in longer drug half-lives of other drugs.

Adverse reactions. Adverse reactions caused by omeprazole are limited because the drug is selective for the H⁺, K⁺-ATPase pump. An exception is the sequelae of achlorhydria. Diarrhea and transient fluctuations in liver enzymes have been reported. Hypergastrinemia has been documented in human patients⁷⁹ after therapy with omeprazole, and is more severe compared with that associated with use of antihistaminergic antisecretory drugs and may be associated with gastric hyperplasia or an increase in gastric tumors. Rebound hypersecretion of gastric acid as described for antihistaminergic drugs should be anticipated, and discontinuation of proton pump inhibitors should occur gradually, with tapering or substitution of alternative drugs in at-risk patients.⁴⁸ Hypertrophy of gastric mucosa has been reported. A marked increase in gastric acid secretory capacity has been detected after omeprazole treatment, presumably owing to proliferation of an enterochromaffin-like cell mass.⁸⁶ However, in contrast to H₂-receptor blockers, proton pump inhibitors may not cause tolerance because their inhibition is distal to histamine-mediated secretion targeted by increased gastrin. Chronic use may decrease absorption of vitamin B12, although clinical relevance is not clear.48

Clinical use. Proton pump inhibitors are indicated to support gastroduodenal healing, prevention or treatment of gastroesophogeal reflux, treatment of hypersecretory conditions, and other conditions that benefit from reduced hydrochloric acid secretion (e.g., IBDs). Omeprazole is the drug of choice for the treatment of the Zollinger–Ellison syndrome. Omeprazole has been used to control gastric acid secretion that has not responded to H₂-receptor antagonists, although its superiority to these and other antacid drugs has not been firmly established. Generally, however, studies support the superiority of omeprazole over cimetidine for treatment of GI ulceration, including response of pain.⁷⁹ Lansoprazole is often preferred in humans for prevention of NSAID-induced ulceration but does not appear to offer an benefit in terms of long-term efficacy.

Bersenas and coworkers⁸⁷ studied normal fasting and postprandial intragastric pH and its response to a variety of antisecretory drugs in Beagles (n = 12). Antisecretory drugs included ranitidine (2 mg/kg intravenously every 12 hours), famotidine (0.5 mg/kg intravenously every 12 hours), pantoprazole (1 mg/kg intravenously every 24 hours), and omeprazole (1 mg/kg orally every 24 hours), or saline placebo. Intragastric pH was recorded on days 0, 2, and 6. Outcome measures included median 24-hour intragastric pH, percentage of time pH was at or above 3, and percentage of time pH was at or above 4. All outcome measures were better (pH higher for longer) in the fasting compared with the postprandial state. Only famotidine, pantoprazole, and omeprazole suppressed gastric acid secretion, compared with placebo. The investigators also found that a suspension of omeprazole (1 mg/kg orally every 12 hours; n = 6) but not famotidine (0.5 mg/kg intravenously every 8 hours; n = 6) suppressed gastric acid secretion; information was not available regarding quality assurance of the suspensions. The authors concluded that only famotidine (at the doses and intervals studied), pantoprazole, and omeprazole significantly suppressed gastric acid secretion and the only suspension that was anticipated to be effective in treating gastric acid-related diseases (in normal dogs), based on outcome measures targeted in humans, was omeprazole; the power of the study may have impacted interpretation. This study suggests that ranitidine at 2 mg/kg, administered intravenously, is not an effective antisecretory drug in dogs, and famotidine is indicated at 12-hour intervals.

KEY POINT 19-20 Studies in the dog suggest that famotidine and omeprazole provide the most effective control of gastric acid secretion.

Prostaglandin Analogs

In addition to blockade of receptors that mediate secretion, gastric acid might also be modulated by prostaglandins of the E series. Their actions appear to be mediated by interaction with a basolateral membrane receptor. Intracellular concentrations of cAMP decrease, which in turn decreases protein kinase activity and hydrogen ion concentration (see Figure 19-6).⁴⁹ Misoprostol is a methyl ester analog of prostaglandin

E₁. As such, it is pharmacologically active after oral administration, with effects lasting longer than those of endogenous prostaglandins.88 Food delays its time of onset, which generally occurs within 30 minutes. Effects in humans tend to last for 3 hours, reflecting, in part, a short half-life of 20 to 40 minutes. The effects of misoprostol tend to be restricted to the local environment, with systemically absorbed drug rapidly metabolized by the liver.89 Misoprostol does not appear to alter serum gastrin levels, and rebound acid hypersecretion has not been reported.83 Basal, nocturnal, and food-induced gastric acid secretion is inhibited by misoprostol, which appears to be the primary cytoprotective effect. Although 75% to 85% of basal acid secretion may be inhibited, high doses at frequent intervals (four times daily in humans) may be necessary. The drug is not likely to be as effective as H₂-receptor or proton pump antagonists in decreasing intraluminal pH and appears less effective in controlling pain associated with hydrochloric acid secretion. Unabsorbed drug that reaches the intestine can cause intestinal secretion, smooth muscle contraction, and thus diarrhea (occurring in up to 30% of human patients), but these side effects may be resolved after several days.⁸⁸ Misoprostol can exacerbate clinical signs associated with inflammatory bowel disease and should be avoided in patients at risk.⁴⁸ Misoprostol can induce uterine contractions and is contraindicated in pregnancy; clients who are of childbearing age should be warned of this potential side effect. The primary indication for misoprostol is prevention or treatment of NSAID-induced ulceration, although more convenient drugs tend to be used for prevention. Its use might be considered in diseases associated with marked mast cell influx (e.g., mastocytosis) because of its inhibitory effect on mast cell degranulation.90

Cytoprotective Drugs

Antacids

Antacids have largely been replaced by drugs that more effectively prevent deleterious effects of gastric acid. Nonetheless, antacids continue to have a role in the treatment or prevention of mucosal disorders associated with gastric acid or other caustic agents. As with many GI-active drugs, information regarding the effects of antacids largely is extrapolated from data from studies on other species. Antacids chemically neutralize HCl present in the gastric lumen such that gastric luminal pH is increased to an acceptable level (pH of 3 or 4, at minimum) without causing systemic alkalosis.91 Inactivation of pepsin and binding of bile salts by some products (e.g., aluminum hydroxide) are also important. Finally, some products (e.g., aluminum hydroxide) also induce the local synthesis of mucosal protectants (e.g., prostaglandins and sulfhydryls).^{57,92} Some antacids are indicated for their impact on electrolyte (e.g., phosphorus) absorption. Factors influencing rational antacid therapy are rate of acid secretion, duration of time the antacid remains in the stomach, the potency of the antacid, and adverse effects.93

The relative efficacy of antacids is based on the number of milliequivalents of acid-neutralization available (the volume of 1N HCl, or milliequivalents of HCl, that can be titrated to a

pH of 3.5 within 15 minutes). The major nonsystemic antacids used in veterinary medicine are salts of aluminum, magnesium, and calcium used either alone or in combination with each other or with various protectants, adsorbents, and astringent. In general, in vitro, 1 gram of these antacid compounds generally neutralize 20 to 35 mEq of acid. Neutralization of (reaction with) HCl generates chlorides, water, and carbon dioxide48; release of CO2 from carbonates can cause abdominal distention and belching.⁴⁸ In the fasting state the action of gastric antacids is usually transient and lasts only 1 to 2 hours. In general, antacids are cleared from the stomach within 30 minutes. Neutralization of acid in the stomach antrum removes negative feedback control of gastrin release, which in turn leads to elevated gastrin levels and enhanced HCl secretion, with increased tone of the lower esophageal sphincter. In the past antacid administration was recommended at 4- to 6-hour intervals to minimize rebound hypersecretion. The presence of food, which increases gastric pH to about 5,48 will prolong the effects of antacids for up to 2 to 3 hours. In human patients, however, administration with each meal has proved more convenient yet equally efficacious. Time to onset of action is different among antacids. Calcium and sodium carbonate are considered fast acting, magnesium salts moderate to rapid acting, and aluminum salts slow acting.

KEY POINT 19-21 Antacids containing a combination of aluminum and magnesium hydroxide provide the best balance in efficacy and avoidance of side effects.

Aluminum hydroxide is a good adsorbent (of bile acids and pepsin), as well as an antacid. Although slow in action, it tends to provide prolonged antacid effects.⁴⁸ Because it is slow acting, it is often combined with more rapidly acting magnesium salts. An advantage of aluminum hydroxide compared to other antacids is its stimulatory effect on local prostaglandin production in the intestinal mucosa.92 Aluminum preparations tend to cause constipation and are often mixed with magnesium salts (laxative inaction) to prevent this side effect. However, this combination is not always effective, with emergence of constipation (because of aluminum) and diarrhea (because of magnesium) emerging in some patients. Aluminum hydroxide also decreases phosphate absorption by forming insoluble aluminum phosphates in the intestine and is used to control serum phosphorus in patients with renal disease. Note that prolonged administration with meals may cause hypophosphatemia in patients.

Magnesium-containing products can raise gastric pH higher than aluminum-containing antacids (as high as 9 versus 4).⁹¹ Magnesium hydroxide is the most commonly used form of magnesium. Magnesium salts tend to be laxative and are often found in combination with aluminum and calcium salts. Their cathartic effects result from soluble but unabsorbed magnesium salts that remain in the intestine and retain water. The neutralizing effect of magnesium hydroxide is prompt and prolonged. Up to 20% of the magnesium is absorbed in normal circumstances, and in the presence of renal dysfunction repeated administration can result in hypermagnesia.

Combination antacid products containing both aluminum and magnesium are often used to balance the adverse effects of each cation or bowel function.⁹³ Magaldrate is a hydroxymagnesium–aluminate hydroxide complex that rapidly dissociates in the gastric acid to magnesium or aluminum hydroxide, providing a sustained effect.

KEY POINT 19-22 Sucralfate must bind to damaged tissues and therefore is ineffective until damage occurs. However, prophylactic use should still be considered.

Calcium carbonate is a rapid-acting, potent antacid with a prolonged duration. Slowly developing metabolic alkalosis, gastric acid rebound, hypercalcemia, and calciuria with metastatic calcification and urolithiasis, hypophosphatemia, and constipation are, however, potential side effects that may occur after chronic administration of calcium carbonate.⁹³ In addition, interference with calcium-dependent processes may lead to excessive gastrin and HCl secretion.⁴⁸ Release of carbon dioxide may increase gastrin release owing to distention.

Antacids may be involved in a number of drug interactions, despite their largely local effects. Antacids may alkalinize the urine, generally increasing it 1 pH unit. The rate of elimination of renally eliminated weak acids will be increased (e.g., NSAIDs, phenobarbital), whereas that of weak bases is decreased.⁴⁸ Drug interactions of antisecretory drugs reflecting increased gastric pH may also occur with antacids. Oral absorption of a number of other drugs⁹⁴ may be affected as a result of changes in gastric pH. Further, magnesium and aluminum in particular are likely to chelate other drugs, precluding their absorption. Therefore antacids should be given approximately 2 hours before or after other orally administered drugs.

In addition to gastric distention (carbonates) and altered electrolytes that vary with each compound, side effects to antacids are not common. Antacids may increase the risk of food allergies based on a mouse model in which proteins extracted from caviar induced caviar-specific IgE antibodies, T-cell reactivity, and increased GI eosinophil and mast cells in mice simultaneously receiving ranitidine or sucralfate. The authors identified the aluminum hydroxide component of sucralfate as being responsible for the increased risk of allergic response. The rationale for the increased risk was incomplete protein digestion.⁹⁵

Gastric hyperacidity, peptic ulcer, gastritis, reflux esophagitis, and chronic renal failure (uremia) are the more common indications for antacid preparations in veterinary medicine. Pyloric and duodenal peptic ulcers that may be related to gastric hyperacidity have been reported in dogs. Antacids intended to treat gastroduodenal ulceration generally are administered orally 1 and 3 hours after meals and at bedtime. For severe conditions or to treat uncontrolled reflux, doses in humans are repeated as often as every 30 to 60 minutes. Suspensions have greater neutralizing capacity than do powder or tablet dosage forms; in humans tables must be thoroughly chewed for maximum effect. A number of acid products

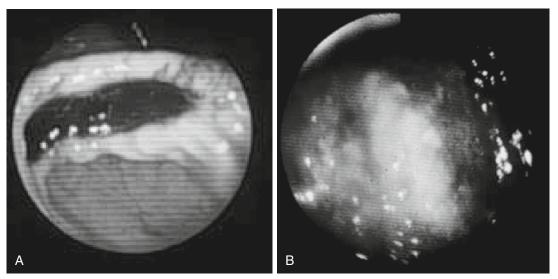

Figure 19-7 An endoscopic view of sucralfate bound to damaged gastrointestinal epithelium. Binding not only protects the damaged epithelium from further damage but also prevents loss of critical nutrients and fluids.

intended to treat "acid indigestion" in humans contain silmethicone (see the discussion of antiflatulence agents), a surfactant that decreases esophageal reflux. Whereas the choice of over-the-counter preparations containing a combination of antacids and silmethicone is reasonable, products that are combined with aspirin should be avoided.

Sucralfate

Sucralfate (see Figure 19-4) is an orally administered disaccharide (octasulfate of sucrose) aluminum hydroxide product that binds to and protects damaged epithelial cells from acid, bile, and pepsin activity.96-99 In the acid environment of the stomach, sucrose is freed from aluminum hydroxide, cross-polymerizes, and binds to exposed (damaged) anions of GI epithelial cell membranes (Figure 19-7).¹⁰⁰ The maximum protective effects of sucralfate depend on an acid environment (pH <4) for activation; therefore it should be administered at least 30 minutes before antacids¹⁰⁰ and on an empty stomach, 1 hour before feeding.⁴⁸ Binding occurs in the base of ulcer craters and is greater in duodenal than in gastric ulcers. Sucralfate also binds to and inactivates bile acids, thus promoting its use in biliary disorders, and inhibits pepsin-mediated hydrolysis of mucosal proteins.¹⁰¹ In addition to binding and protection of cells, the polymerized sucrose prevents exudation of protein and electrolytes into the gastric lumen. Effects of sucralfate may last up to 6 hours, supporting a four-times-daily dosing regimen.⁴⁸ The amount of aluminum hydroxide released from sucralfate may not effectively neutralize gastric acidity, although this may be controversial.¹⁰² Sucralfate appears to stimulate production of local mediators that protect the gastric mucosa. These include prostaglandins^{99,101,103} sulfhydryl ions or other oxygen radical scavengers, and epidermal growth factor.¹⁰⁴ Sucralfate effects on epidermal growth factor cause its accumulation in ulcerated lesions.^{99,105} Sucralfate also increases mucosal blood flow either by inducing local nitric oxide or prostaglandin production¹⁰⁶ or by directly stimulating mucosal angiogenesis.107

KEY POINT 19-23 In addition to its mechanical protection, sucralfate also increases local prostaglandin protection and promotes angiogenesis and epithelialization.

Drug interactions with sucralfate are limited to local effects. Sucralfate binds to a number of drugs, with the prototypic example being cimetidine. Because cimetidine also increases gastric pH (thus potentially reducing activation of sucralfate), these two drugs probably should be alternated (i.e., administer sucralfate 1 to 2 hours before cimetidine) in patients receiving both drugs. In addition to direct binding to drugs, sucralfate may influence drug absorption through formation of a thick mucus layer. Thus, in general, other drugs should be administered at least 2 hours before sucralfate.

Sucralfate is minimally absorbed after oral administration and is associated with few, if any, side effects. Sucralfate is recognized to be the safest drug available for treatment of gastroduodenal ulcers.¹⁰¹ Constipation occurs in up to 2% of humans. Currently, sucralfate is recommended for treatment of gastroduodenal erosion ulceration, regardless of the cause. Its prophylactic use is also recommended for illnesses associated with ulceration such as renal or liver disease, mastocytosis, and IBDs for which prolonged use of antiprostaglandin is indicated. However, sucralfate does not prevent the formation of the ulcer; rather, it protects damaged tissue once it occurs. Sucralfate appears beneficial prophylactically for stress-induced ulcers but is less effective prophylactically in patients receiving NSAID therapy.¹⁰⁰ Sucralfate is effective for treatment of acid-induced esophagitis,¹⁰⁸ although antisecretory drugs such as omeprazole or H2-receptor antagonists are probably superior.⁴⁸ In critical patients at risk for nosocomial pneumonia, sucralfate may be preferred to antisecretory drugs such that increased gastric pH might be prevented.48 Sucralfate has been administered rectally (in humans) for treatment of rectal ulcerative disease.

MODULATORS OF GASTROINTESTINAL MOTILITY

Normal Physiology

The GI tract functions to ensure the metabolic survival of the host and in doing so sorts ingested materials as to nutritional, toxic, or pathologic status. To accomplish its activities, the alimentary tract has its own enteric neurologic system (ENS) composed of vagal and sympathetic nerves (Figure 19-8). The network communicates through a large variety of chemicals, including neurotransmitters and neuropeptides. Primary signals include ACh, the tachykinins (substance P, neurokinin A), nitric oxide, adenosine triphosphate (ATP), vasoactive intestinal polypeptide, opioid peptides, neuropeptide Y, and 5-hydroxytryptamine.¹⁰⁹ Circuits of the ENS include intrinsic primary afferent neurons; interneruons; and either excitatory or inhibitory neurons that innervate effector motor, secretomotor, or vasodilator neurons. Additionally, the ENS integrates with the CNS, forming a brain-gut axis. The interactions of the integrated signals are complex and often not well characterized and thus are difficult to correct in the face of dysfunction, whether induced by disease or drugs.

Regulation of electrical and mechanical, activities of GI smooth muscle is a complex but ordered activity involving

hormonal, myogenic, and neurogenic factors and sensory, relay and effector functions.²⁴ Integration occurs at the level of the CNS at both spinal and supraspinal levels¹¹⁰ and locally through the ENS, including intrinsic and interneuronal nerves and ganglia are located between the longitudinal and smooth muscles and at least 10 different classes of receptors located on the smooth muscle cell. Intrinsic innervation includes the Auerbach (or myenteric) plexus, which forms a neural sympathetic and parasympathetic network connecting longitudinal and circular smooth muscle and the secondary Meissner (or submucosal) plexus, which parasympathetically innervates circular muscle. Both systems are secretory and motor in effect, although the Meissner plexuses predominantly modify mucosal absorption and secretion. Coordination of inhibitory and excitatory muscle movements results in two primary movements: mixing and aboral propulsion of liquefied contents. Mixing reflects rhythmic segmentations caused by simple nonprogressive contractions of circular muscle. Electrical activity for propulsion occurs initially as a "slow waves" whose crest is followed by "spike potentials." Slow waves keep the membrane potential in a constant state of fluctuation, with the frequency of contraction waves ranging between 10 to 20 times per minute, being fastest in the small intestine. Slow waves coordinate synchronous muscle contraction by releasing neurotransmitters from the myenteric plexus such

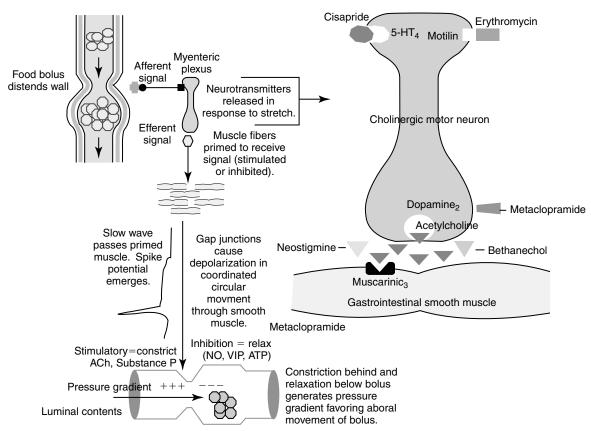

Figure 19-8 The integrated neurologic systems of the intestinal tract. See text for details. Metoclopramide antagonizes dopamine receptors, which antagonize release of acetylcholine. Cisapride is an agonist of 5-HT₄ receptors, which are excitatory in the enteric nervous system. Erythromycin acts as an agonist at excitatory motilin receptors. *Ach,* Acetylcholine, *NO,* nitric oxide; *VIP,* vasoactive intestinal peptide.

that smooth muscle fibers are "primed" to respond to the spike potential that follows. Gap junctions between circular and longitudinal fibers ensure that electrical stimuli (i.e., depolarization) spread outward in a circular fashion such that an entire ring of circular smooth muscle contracts in a coordinated fashion (Figure 19-9).

Peristalsis is the major propulsive movement, occurring principally in the esophagus and intestines, involving both longitudinal and circular smooth muscles and reflecting signals originating in the myenteric plexus without being influenced by signals peripheral to the ENS. Peristalsis reflects an ascending excitatory reflex of circular smooth muscle causing contraction on the oral side of a bolus, with ACh and substance P as the primary interneuronal mediators, and a descending inhibitory aboral reflex that causes relaxation, with nitric oxide, vasoactive intestinal peptide, and ATP as mediators.²⁴ Luminal contents follow the net pressure gradient. Contraction of longitudinal smooth muscle in the descending (aboral) phase and relaxation in the ascending oral phase facilitates peristaltic movements and aboral movement of intestinal contents.¹¹¹ Although peristaltic activity is mainly propulsive, it also ensures mixing and successful absorption. Wilson and coworkers review the physiology of the gastroesophageal sphincter.¹¹² Relaxation is mediated by noncholinergic and nonadrenergic signals. Absorption of luminal contents is facilitated as intestinal luminal contents are impeded by narrowing of the intestinal luminal diameter.

Receptors and Signals

Most smooth muscle activity ultimately reflects response to ACh through cholinergic receptors. However, activity of cholinergic receptors is modulated by a variety of other receptors (see Figure 19-8). Muscarinic (M₂) receptors regulate phasic bowel movements during fasting. Several types of muscarinic receptors have been identified pharmacologically (M_{1-4}) in the GI tract. Of these, M1 or M3 receptors interact with G protein and mobilize intracellular calcium; M₂ and M₄₁ receptors inhibit adenylyl cyclase and regulate ion channels. M1 receptors present in the myenteric plexus may inhibit motility by way of gabaminergic mechanisms. M2 receptors, located presynaptically and postsynaptically, mediate presynaptic inhibition of ACh release. M₃ receptors appear to be located on smooth muscle cells, and although less abundant than M₂ by a ratio of 4:1, they are more important because they increase intracellular calcium.24,110

KEY POINT 19-24 Regulation of gastrointestinal motility is complex, with muscarininic (M_2 and M_3 subtypes) and 5-HT₄ being the major role players.

A number of other receptor types influence GI motility. Adrenergic receptors, including α_1 , and α_2 postsynaptically and α_2 , presynaptically regulate ACh release from the myenteric plexus. Generally, cholinergic neurons stimulate and

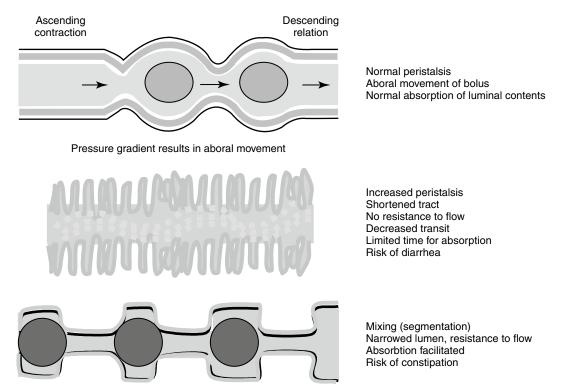

Figure 19-9 The sequelae of smooth muscle contraction in the intestines vary with the type of muscle. Longitudinal muscle contraction shortens the gastrointestinal tract; peristalsis thus forces expulsion of luminal contents. Contraction of circulatory muscle causes segmentation or resistance to outflow. This effect predominates with opioids. Anticholinergic drugs impair both types of muscle activity.

adrenergic neurons inhibit gastric motility. Both H_1 and H_2 receptors have been identified in the GI tract. They are located both prejunctionally, where they control ACh release, and postjunctionally. Stimulation of H_1 receptors induces, whereas H_2 -receptors inhibit, smooth muscle contraction.¹¹³ The role of dopamine and serotonin in gastric motility is complex and not well elucidated. Among the effects of dopamine are reduction in esophageal sphincter and intragastric pressures. Dopamine, by way of D_2 receptors, inhibits smooth muscle of the stomach, duodenum, and colon and has been implicated as a mediator of receptive relaxation in dogs (see Figure 19-8).^{24,34} Dopamine exerts its inhibitory effect through inhibition of ACh at myenteric motorneurons.³⁴

Over 90% of serotonin in the body is located in the GI tract, indicating its importance in this system. The majority of serotonin is produced by enterochromaffin cells that rapidly release serotonin in response to a variety of mechanical or chemical stimuli. Its effects generally are stimulatory by way of 5-HT₃ and 5-HT₄ receptors and inhibitory by way of 5-HT_{1P} receptors. The result is a peristaltic reflex, mediated by 5-HT_{1P} and 5-HT₄ receptors at the myenteric plexuses and 5-HT₃ receptors at extrinsic vagal and spinal sensory neurons.²⁴ Serotonin often exerts its effects through secondary chemicals. For example, the inhibitory effects of 5-HT_{1P} receptors reflect release of nitric oxide, which reduces muscle tone, whereas the stimulatory effects of 5-HT₄ receptors reflect enhanced ACh release. However, the effects of 5-HT₄ receptor stimulation appear to vary with species and origin. In the guinea pig ileum, effects are stimulatory, but in human and canine colons, 5-HT₄ receptor stimulation causes relaxation of smooth muscle.114 In the dog, 5-HT₄ receptors appear to mediate relaxation in gastric cholinergic neurons where gastric contraction facilitates gastric emptying, and jejunal and ileal mucosa and circular colonic smooth muscle cells, where activation appears to cause relaxation. Conflicting studies may reflect the different roles that 5-HT₄ receptors have in stimulating contraction and peristalsis: a positive effect may occur with mucosal stimulation but not luminal distention.¹¹⁴ 5-HT₄ receptors appear to be potent secretagogues in most species, again with effects variable among species and location. These differences among species and tissues suggest that extrapolation of therapeutic indications and doses should be based on scientific studies in the target species. The effects of serotonin are ameliorated, in part, by reuptake. However, uptake can be inhibited by CNSactive serotonin reuptake inhibitors, although the sequelae may cause diarrhea.

Other sites are targeted by motility-modifying drugs. Activation of the noncholinergic, nonadrenergic inhibitory neurons results in bowel relaxation.¹¹³ Prostanoids and specifically prostaglandin E (PgE) receptors have been identified in the gastric fundus and ileum. PgE receptors may modulate motility from the esophagus to the colon.¹¹³ Generally, PgE inhibits mechanical activity of circular smooth muscle, whereas prostaglandins of the D and F series are stimulatory. At high doses, PgE stimulates peristaltic activity, although this may represent mechanical response to excess watery fluid in the intestinal lumen stimulated by PgE.¹¹³ Motilin is a peptide hormone located in M and enterochromaffin cells of the GI

tract. Motilin appears to enhance and potentially induce phase III activity.

Smooth muscle activity in the large bowel varies from that in the small bowel. In the small bowel, slow waves generally occur continuously and propagate aborally. In the colon slow waves are sometimes absent, and propagation may be variable.¹¹⁰

Prokinetic Drugs

Prokinetics enhance the transit of intraluminal contents.³⁴ The mechanisms of action of these drugs are varied and are not completely understood. Their effects on intestinal functions generally reflect either promotion of an agonist, such as ACh by muscarinic drugs, or inhibition of an inhibitory signal, such as dopamine (see Figure 19-8).³⁴ Organ-specific and species-specific differences complicate our comprehension of these drugs.³⁴

Cholinergics

Clinically, the use of cholinergics is limited by their tendency to cause systemic effects. Bethanechol is an ester derivative of choline that acts as a cholinergic agonist almost exclusively at muscarinic (M_2) receptors.¹¹³ Bethanechol will enhance the amplitude of contractions throughout the GI tract, including the lower esophageal sphincter (Figure 19-10; see also Figure 19-8).^{34,113} Its effects on the coordination of small intestinal contraction may be minimal, however, and thus it is often not considered to be a prokinetic agent.³⁴ Adverse effects reflect direct enhanced parasympathomimetic stimulation and include abdominal cramps, diarrhea, salivation, and bradycardia.³⁴

Metoclopramide

Metoclopramide is a lipid-soluble derivative of para-aminobenzoic acid. It is structurally related to procainamide, a cardiac antiarrhythmic (see Figure 19-4).³⁴ In addition to its central antidopaminergic (antiemetic) effects, metoclopramide acts peripherally as both an antidopaminergic and as a direct and indirect stimulator of cholinergic receptors.^{34,35}

The effect of metoclopramide on canine gastromotility was described as early as 1969.¹¹⁵ Compared with saline, metoclopramide decreased transit time and volume but did not affect flow of intestinal contents. Clinically, its effects appear to be limited to the upper intestinal tract (see Figure 19-10).^{35,37,116,117} The peripheral effects of metoclopramide apparently reflect enhanced release of ACh from intrinsic cholinergic neurons. These effects are completely inhibited by pretreatment with anticholinergics such as atropine.34,37,118 The peripheral effects, however, appear to be mediated by effects on other (noncholinergic) local neurotransmitters, particularly dopamine. Serotonin receptors also may play a role.³⁴ The prokinetic activity of metoclopramide reflects muscarinic activity, D₂ receptor antagonist activity, and 5-HT₄ receptor agonist activity.³⁴ Because of its effects on the stomach, metoclopramide physiologically antagonizes emesis by increasing the tone in the lower esophageal sphincter, increasing the force and frequency of gastric antral contractions (gastrokinetic effect), relaxing the pyloric sphincter, and promoting peristalsis in the duodenum and jejunum, resulting in accelerated gastric emptying and upper intestinal transit.35

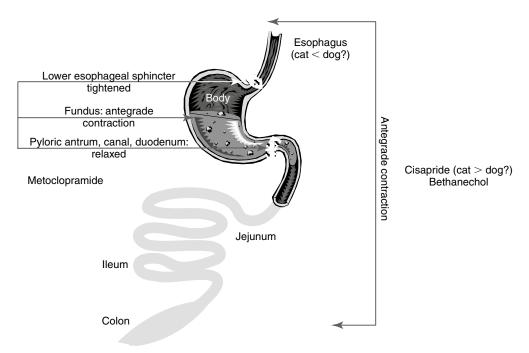

Figure 19-10 The sites of actions of two clinically useful prokinetic drugs. In vivo, at standard doses, metoclopramide's actions are limited to the lower esophagus (feline more than canine), stomach, and upper duodenum, where it physiologically antagonizes vomiting. Cisapride appears to increase motility throughout the gastrointestinal tract.

KEY POINT 19-25 Clinically, the prokinetic effect of metoclopramide is limited to the stomach, lower esophagus, and pylorus.

Metoclopramide is well absorbed orally but undergoes significant first-pass metabolism with a bioavailability in the 50% to 70% range. Tissue distribution is rapid, and excretion is both renal and hepatic. Because the plasma half-life in the dog is only 90 minutes, metoclopramide has a short duration of action.³⁵ Dose-dependent CNS side effects include nervousness, restlessness, listlessness, depression, and disorientation.^{34,35,119} Extrapyramidal antidopaminergic effects include tremors and motor restlessness. Tremors in cats, particularly after intravenous administration, are not unusual. Gynecomastia caused by enhanced release of prolactin has been reported in humans.³⁴ GI disorders may also be observed, with constipation being common with long-term use.

Metoclopramide has a demonstrated impact on the oral bioavailability of several drugs, with the effect varying with the drug. For example, co-administration with the oral hypoglycemic agent ciglitazone decreased C_{max} by 16% and AUC 8%,¹²⁰ but co-administration with cephalexin increased cephalexin C_{max} by 21% and AUC by 36%.¹²¹ It is not clear if the latter effect reflected increased gastric emptying or interference with intestinal transport proteins. As an antiemetic, the main indications for metoclopramide include severe and intractable emesis caused by chemotherapy or other blood-borne toxins as well as nausea and vomiting associated with delayed gastric emptying, gastroesophageal reflux, reflux gastritis, and peptic ulceration. As a prokinetic, metoclopramide is indicated for treatment of a variety of gastric motility disorders, including gastric dilation, volvulus, postoperative ileus, gastric

ulceration, and idiopathic gastroparesis.³⁷ Metoclopramide is contraindicated in GI obstruction or perforation, potentially in epilepsy, and for patients receiving neuroleptics. Because of their anticholinergic effects, atropine and the opioid analgesics antagonize the action of metoclopramide.

KEY POINT 19-26 Anticholinergics and opioids decrease the prokinetic efficacy of metoclopramide.

Domperidone

Domperidone is a dopamine antagonist whose prokinetic properties are similar to those of metoclopramide.¹²² However, unlike metaclopramide, it has no cholinergic activity and is not inhibited by atropine. Domperidone does not cross the blood–brain barrier as readily as metoclopramide. Like metoclopramide, however, domperidone can affect central dopamine receptors and thus modulate temperature control, prolactin secretion, and activity at the CTZ.³⁴ Extrapyramidal side effects are rare. Domperidone acts peripherally to coordinate antroduodenal contractions. Its peripheral effects accelerate small intestinal transit, but colonic activity is apparently unaffected.¹¹⁹

Cisapride

Cisapride has the broadest spectrum of action of the prokinetic agents.¹²³ It causes dose-dependent increased activity at all GI sites, including the esophagus, stomach, jejunum, ileum, small intestine, and colon³⁴ (see Figure 19-10). Because 75% of the feline esophagus is skeletal muscle, esophageal prokinetic effects are likely to be less in cats than in dogs. The prokinetic actions of cisapride appear to reflect indirect stimulation of cholinergic nerves. Serotonin appears to mediate this effect through 5-HT₄ receptors (see Figure 19-8). Stimulation of colonic contractions reflects 5-HT_{2a}. Because secretion is not enhanced, stimulation probably occurs at the level of the myenteric plexus.³⁴

Well absorbed after oral administration, cisapride undergoes first-pass metabolism, with oral bioavailability in humans being 50%. Metabolites are apparently inactive. Volume of distribution is large (2.4 L/kg) in humans, and elimination half-life is 10 hours. Cisapride kinetics have been reported in the cat.¹²⁴ Oral administration is characterized by 30% bioavailability, and the elimination half-life approximates 5 hours. A dose of 1 mg/kg every 8 hours or 1.5 mg/kg every 12 hours is recommended on the basis of these data. Elimination may be prolonged in the presence of liver disease.¹²³ Indications for use of cisapride are similar to those for metoclopramide (excluding dopaminergic effects). Indications in humans include any disorder associated with impaired gastric emptying as well as gastroesophageal reflux. Unlike metacolopramide, cisapride does not interact with central dopamine receptors, and its use is not associated with extrapyramidal side effects.¹¹³ However, stimulation of 5-HT₄ receptors by cisapride (and other drugs) causes blockade of the rapid component of potassium influx through the delayed rectifier potassium channel. Prolongation of the QT interval results in torsades de pointes and the potential for sudden cardiac death. Subsequently, cisapride has been withdrawn from the humanmedicine market, mandating the need for compounding for veterinary use. Myocardial side effects have not been reported in peer-reviewed literature but have been reported anecdotally. Further, in vitro studies have revealed a similar effect in the canine myocardium. The risk is greater when cisapride is combined with other drugs that inhibit the cytochrome P450 enzyme responsible for cisapride metabolism in humans (e.g., clarithromycin, itraconazole).125

Miscellaneous and Pending Prokinetic Drugs

Erythromycin stimulates GI motility at low doses not associated with antimicrobial effects (0.5-1 mg/kg every 8 hours). Its effects appear to mimic those of motilin (see Figure 19-8). Lower esophageal sphincter pressure will be increased. However, contraction in the stomach is not coordinated and may result in "dumping" of food from the stomach into the intestines before maceration is complete. Increased small bowel motility has led to its clinical use in humans with small bowel dysmotilities, but clinical use has not been reported in animals. Doses greater than 3 mg/kg may actually cause spastic contractions and cramps. The prokinetic effects of erythromycin may be responsible, in part, for GI disturbances that occur in up to 50% of patients receiving this drug. However, tolerance develops rapidly, probably because of downregulation of motilin receptors. Other macrolides will also stimulate motility to variable degrees.

Among the H_2 - receptor antagonists, ranitidine and nizatidine inhibit anticholinesterase activity and thus are prokinetic at antisecretory doses.¹²⁶ Comparison between cisapride and ranitidine, an H_2 -receptor antagonist, for the treatment of gastroesophageal reflux reveals both to be effective.¹²⁷ Nizatidine was demonstrated to have prokinetic effects similar to those of cisapride owing to noncompetitive inhibition of ACh at a level comparable to that of neostigmine.¹²⁸

Misoprostol, a PgE analog, also is associated with prokinetic properties in the colons of dogs and cats. At least two prokinetic agents have been in various stages of approval in human medicine: prucalopride (R093877; Janssen Pharmaceutical) and tegaserod. Both are potent, partial agonists of 5-HT₄ receptors. Prucalopride (benzamide) is void of activity at other serotonin receptors or cholinesterase enzyme activity. Although pharmacokinetics have not been reported in dogs, prucalopride causes a dose-dependent (0.01-0.16 mg/ kg [dog]) increase in gastric emptying and increased giant migrating contractions with defecation in dogs (0.02-1.25 mg/ kg) or cats (0.64 mg/kg).¹²⁹ Fecal consistency does not appear to be affected. In contrast to prucalopride, tegaserod is a nonbenzamide. In addition to effects at 5-HT₄ receptors, it acts as a weak agonist at 5-HT_{1D} receptors. Like prucalopride, tegaserod acts as a prokinetic in the canine colon, with effects apparent within 1 hour of an intravenous dose (0.03-0.3 mg/kg). Prokinesis also appears to occur in the intestine on the basis of normalization of transit time in opioid-induced bowel dysfunction in dogs (3-6 mg/kg orally). Because the colonic effects of tegaserod do not appear to be dose dependent, prokinetic effects in the colon may reflect an alternative mechanism of action. The impact of tegaserod on the canine stomach or in the cat have yet to be described. Tegaserod was approved for human use in the United States in 2002 (Zelnorm).

The Impact of Nongastrointestinal Drugs on Gastrointestinal Motility

Benzodiazepines influence gastrointestinal smooth muscle activity and secretion. In fasted dogs, the diazepam (0.5 mg/kg, IV) was associated with disruption of migrating myoelectric complexes and increased conctractility in the jejunum. In humans, diazepam (approximately 0.15 mg/kg PO) suppressed basal gastric acid secretion for 5 hours posttreatment.^{129a,b} A variety of drugs alter esophageal sphincter function. Anesthetic drugs that reduce gastroesophageal sphincter tone include acepromazine, diazepam, morphine, halothane, isoflurane, xylazine, and atropine. The effect of intravenous morphine and butorphanol on GI motility has been studied in dogs. Morphine (0.1 mg/kg) was associated with a dose-dependent increase in duodenal smooth muscle activity and a dose-dependent decrease in bile duct flow, with the effects described as spasmogenic. In contrast, butorphanol administered at a dose described as equianalgesic (0.025 mg/ kg intravenously) had little or no effect on the biliary or GI smooth muscle in dogs.¹³⁰

The effect of xylazine (1 mg/kg) or the combination of acepromazine (0.1 mg/kg) and butorphanol (0.05, 0.2, or 1 mg/kg) on GI motility as it influenced GI radiocontrast studies was studied prospectively in healthy dogs (n = 6) using a randomized crossover saline–placebo-controlled design.¹³¹ Total gastric emptying time (gastric and intestinal) was prolonged by xylazine and the combination of acepromazine and butorphanol (all doses). However, nonmanual restraint was

facilitated and the combination protocol with butorphanol at 0.05 mg/kg provided sufficient chemical restraint to allow functional morphologic examination of the GI tract (within 5 hours).¹³¹ It is unclear how this combination would affect the study in an animal with GI disease.

The impact of selected drugs on feline gastroduodenoscopy has been reported in normal cats receiving ketamine intramuscularly followed by isoflurane maintenance. Each of eight cats was studied four times, once per drug. No differences were detected in difficulty or time to pass the endoscope through the cardiac or pyloric sphincters for hydromorphone, with or without glycopyrrolate, medetomidine, or butorphanol. Passage into the stomach required only 16 seconds, and the drug took at most 2 minutes (generally 20 seconds) to pass into the duodenum. Although sample size may have precluded detection of significant differences among drugs, the authors concluded that none of the drugs impeded endoscopy.¹³²

DRUGS AFFECTING THE INTESTINAL TRACT

Physiology, Pathophysiology, and Motility

The primary clinical sign reflecting intestinal disease is diarrhea; accordingly, drugs targeting the intestinal tract frequently are intended to control diarrhea. Drug therapy for diarrhea tends to be nonspecific, preferably targets the underlying disease rather than the GI tract, but occasionally might target the physiologic (rather than pathologic) cause of diarrhea. Diarrheas can be classified as inflammatory or infectious, osmotic (including malabsorption), and secretory. The goal of antidiarrheal therapy generally is to reduce the discomfort and inconvenience of frequent bowel movements and, when indicated, to replace fluids or electrolytes lost with diarrhea. Rehydration followed by oral replacement therapy often is the preferred treatment for diarrheas associated with infectious agents.¹³³ Suitable solutions contain K⁺, HCO⁺, Na⁺, and glucose in sufficient quantities to replace stool losses.¹³³ Substantial evidence exists linking GI secretion with GI motility, with increased motility usually being accompanied by increased fluid and electrolyte secretion.¹³⁴ The physiology of intestinal motility was previously discussed.

Absorption and Secretion

Increased amounts of fecal water reflect either diminished absorption or a net secretion (accumulation) of fluid into the lumen of the intestine. In all diarrheal states, increased fecal water loss is associated with an overall secretion of electrolytes and water in selected segments of the GI tract. The absorptive capacity of the alimentary canal is overwhelmed distal to the site of secretion. Sodium-absorbing cells are present predominantly on the villi, and chloride-secreting cells are located primarily in the crypts.

Absorption in the small intestine occurs by passive sodium absorption across the luminal membrane and by active secretion of sodium across the basolateral membrane. Water follows the osmotic draw of sodium into the lateral intracellular space. The electrochemical gradient caused by sodium movement facilitates chloride diffusion into the cell.¹³³ A specific brush border carrier for NaCl co-transport accomplishes absorption. Nutrients such as glucose and other organic solutes, however, facilitate solvent drag of water and electrolytes as they enter cells.¹³³ Secretion in crypt cells of the intestinal epithelium is initiated by intracellular signaling (cAMP) or calcium. Increased chloride conductance into the lumen results in sodium recycling, first through the lateral intercellular space and second into the lumen. Although NaCl co-transport can be inhibited, NaCl movement can still occur as a result of solvent drag (i.e., that mediated by nutrients).¹³³

Increased intestinal cell cyclic adenosine monophosphate, cyclic guanosine monophosphate, and Ca²⁺ (through calmodulin) all diminish sodium absorption and increase chloride secretion, with a net efflux of water into the lumen. Cholera enterotoxin is the best-known intestinal secretagogue,¹³³ but several hormones, including vasoactive intestinal peptide, gastric inhibitory peptide, CCK, secretin, glucagon, and PGE₁, and infectious agents (e.g., *Escherichia coli, Staphylococcus* spp.) are associated with net fluid accumulation.¹³³ Several laxative agents such as bile acids and ricinoleic acid may act through this mechanism. The exact role of intestinal motility in the alteration of fluid and electrolyte movement and the role of mucosal permeability or mucosal damage in the genesis of fluid accumulation within the gut lumen remain unclear.

Modulators of Intestinal Motility and Secretions Anticholinergic Agents

Parasympatholytic or antimuscarinic agents diminish motor and secretory activity of the GI tract. Tone and propulsive movements are decreased (see Figure 19-9), and these agents will often relax spasm of visceral smooth muscle. Such antimuscarinic drugs are thus known as *antispasmodics* or *spasmolytics*. Although cholinolytic agents are commonly used as spasmolytics in antidiarrheal mixtures, the absence of segmentation may lead to severe forms of diarrhea with intestinal paralysis or ileus induced by the cholinergics. The main benefit of anticholinergic agents may be related to their ability to reduce intestinal secretions.

KEY POINT 19-27 A disadvantage of anticholinergic drugs is decreased gastrointestinal motility, loss of segmentation, and severe diarrhea.

Antimuscarinic agents used as spasmolytics include the belladonna alkaloids (atropine and hyoscine), their congeners (atropine methonitrate, homatropine methobromide, hyoscine butylbromide,), and synthetic cholinolytic drugs (aminopentamide, dicyclomine, glycopyrrolate, mepenzolate, oxyphenonium, propantheline). Many of the belladonna alkaloid derivatives are substituted tertiary amines and thus may have undesirable CNS and other systemic effects. The synthetic groups are mostly substituted quaternary amines and are devoid of CNS effects. Xerostomia, loss of lens accommodation, urinary retention, constipation, tachycardia, and CNS stimulation are potential side effects that may be encountered when parasympatholytics are administered.

Opioids

Receptors and peptides. Opiates have been used since antiquity to control diarrhea, and they remain the cornerstone of nonspecific antidiarrheal therapy for humans.48 Opioids appear to influence normal GI physiology.¹³⁵ Opioids may stimulate GI motility both locally and by central effects in the brain or spinal cord.¹¹³ Both opioid peptides and opioid receptors have been identified throughout the GI tract. The specific location of receptors has been based on the physiologic effects of opioid agonists and antagonists.¹³⁵⁻¹³⁷ Both in vitro and in vivo preparations have been studied, often with conflicting results. Confounding interpretation is the variability in number and receptor type among species. High-affinity, reversible, and saturable binding of opioid receptors has been identified in longitudinal and circular smooth muscles and the myenteric and submucosal plexuses. Binding has also been noted in the muscularis mucosae. Although multiple opioid receptors have been identified, μ -type (OP₃) and δ -type (OP₁) opioidbinding sites appear to predominate among the species. Morphine acts to stimulate µ-receptors of the myenteric plexus, thus inducing migrating motor activity in the duodenum and jejunum. The relative importance of different receptor types in the control of intestinal peristalsis has not been established.

Not surprisingly, in addition to opioid recetpors, endogenous opioids are also present in high concentrations in the intestinal wall. Biosynthesis of enkephalins has been demonstrated in the myenteric plexus of some species. In addition, antral G cells are thought to be capable of synthesis of enkephalins or endorphins. β -endorphin and dynorphin have also been demonstrated. In cats enkephalin has been detected in both myenteric and submucosal plexuses. In contrast to other species, the predominant location of enkephalin neurons in dogs is the submucosal plexus. Opioid nerve fibers have also been documented in the lower esophagus, pyloric junction, and cardiac and ileocecal regions. Specific degradative enzymes for the opioid peptides have also been identified in similar locations.¹³⁵

Impact of opioids on gastrointestinal motility. Much of the research regarding opioids and the GI tract reflects an attempt to understand the mechanisms of GI adversities resulting from opioid analgesic therapy. In vitro studies indicate that endogenous opioids in the GI tract modulate normal GI motility and gastrin release. Exogenous opioids depress the normal peristaltic reflex (see Figure 19-9), as has been repetitively demonstrated with the use of the pure antagonist naloxone, which consistently increases peristaltic activity. As such, among the side effects of opioids is constipation, associated with an inhibitory effect on smooth muscle motility. The intestinal opioid mechanism occurs in vitro throughout the intestinal tract, with function apparently increasing distally from duodenum to ileum. Endogenous opioids may thus be partially responsible for the gradient of intestine, a term that describes the oral to aboral phenomenon of decreasing frequency of peristaltic waves and decreasing sensitivity to distention stimuli.135 GI opioids appear to be subject to feedback control.¹³⁵ The widely accepted mechanism of opioid actions in the GI tract is principally presynaptic inhibition of ACh (and potentially

other mediators, such as serotonin) release.¹⁰⁹ Postsynaptic modulation of the effects of ACh already released may also be important for the effects of opioids on peristalsis. Intracellular mechanisms may involve increased calcium-dependent potassium conductance and hyperpolarization. Opioids also reduce calcium entry during the action potential and deplete neurons of calcium. In addition to inhibition of propulsion, tonic spasmogenic effects may occur in some species. The spasmogenic effect caused by opioids is antagonized by atropine. The effect of opioids on GI sphincters varies, with the effect appearing to vary with dose. For example, excitation (contraction) of the choledochoduodenal junction in dogs occurs with some drugs at low doses and inhibition at higher doses. Species differences in sites of action, receptor populations, and motility may be more quantitative than qualitative.¹³⁵

KEY POINT 19-28 Opioids enhance retention of luminal contents facilitate absorption, rendering them very effective for treating diarrheas.

Impact of opioids on intestinal secretion. As with motility, the effects of opioids on gastric acid secretion vary with the study, species, and opioid. Opioids enhance gastric acid secretion mediated by histamine using in vitro studies, but the effect on ACh-induced secretion varies among in vivo studies. Dose dependence may account for some of the variability, with excitation or enhancement of basal secretion occurring at lower doses and inhibition at higher doses. A dual effect on stimulated gastric acid secretion appears to be mediated both peripherally and centrally.¹³⁵

In contrast to gastric secretion, the effect of opioids on intestinal secretion appears to be consistent among the species.¹³⁵ Opioids stimulate the net absorption of water and electrolytes in enterocytes of both small and large intestines in a variety of species. In vitro studies indicate that these peripheral effects are mediated by δ -receptors. Receptor types may, however, vary with the site. These effects, which may reflect facilitated absorption or inhibited secretion, are largely responsible for the antidiarrheal properties of the opioids. Several mediators, acting centrally and peripherally, may mediate opioid antisecretory effects, with the impact varying with the chemical mediator. Presynaptic inhibition of ACh release and inhibition of prostaglandin-mediated adenylate cyclase activity have been implicated as the target signals, with sodium, but not chloride, the targeted ion that is negatively influenced. Opioids also centrally decrease intestinal secretions, perhaps through the sympathetic nervous system. Antisecretory effects may involve norepinephrine and its effects on vasoinhibitory peptide, PgE, or ACh.¹¹³ Decreased intracellular free calcium also has been implicated as a possibility. In contrast to water and electrolyte secretion, opioids act to increase bicarbonate secretion from the gastric and duodenal mucosa.135

Drugs

Diphenoxylate hydrochloride is a meperidine derivative used specifically to control diarrhea. It is often administered in combination with atropine-like compounds, whose bitter taste and drying effect on salivary secretions are added as a deterrent to substance abuse. The actions of diphenoxylate largely depend on a direct peripheral effect on the GI wall. Because diphenoxylate can penetrate the blood-brain barrier, systemic opiate effects may occur. The potential for drug abuse has led to its designation as a Schedule V drug. The use of opioids in cats is generally reasonable, as long as accommodation is made for the increased sensitivity that appears to characterizes their response .

Loperamide hydrochloride, a butyramide derivative, is an orally active and effective antidiarrheal agent used for symptomatic control of acute and chronic nonspecific diarrhea. Unlike diphenoxylate, systemic opiate agonist effects do not appear to occur after oral administration of loperamide, and there are few side effects. Although loperamide has some structural similarities to diphenoxylate, it does not cross the blood–brain barrier, and it differs both qualitatively and quantitatively from diphenoxylate and difenoxin in its pharmacologic actions.¹³⁸ Intestinal transit time and intestinal luminal capacity increase after treatment with loperamide.¹¹³

KEY POINT 19-29 Because loperamide does not penetrate the blood-brain barrier, it has fewer side effects than diphenoxylate.

Miscellaneous Antisecretory Drugs

There are a number of potentially useful drugs that have not been extensively studied but for which there is some evidence of clinical benefit. Glucocorticoids have been found to be beneficial in treating refractory chronic diarrheal disease as well as chronic inflammatory diseases of the intestinal tract. Glucocorticoids stimulate active sodium absorption in the jejunum, ileum, cecum, and colon. However, because of many undesirable side effects when used chronically, the glucocorticoids should not be used on a routine basis to treat diarrhea.

Adrenergic agents appear to act predominantly by increasing basal fluid absorption and do so at very low concentrations. The mechanisms involved are unclear. Clonidine and other α_2 -adrenergic agonists are potentially useful in this regard. Calcium/calmodulin antagonists may act by stimulating active absorption as well as by inhibiting intestinal secretion, but the precise mode of action of these drugs is not clear. Several drugs with this effect have been found to be useful in the control of certain forms of secretory diarrhea. Examples include chlorpromazine and trifluoperazine. NSAIDs such as aspirin, indomethacin, flunixin, and the subsalicylate of bismuth subsalicylate inhibit the cyclooxygenase pathway of arachidonic acid metabolism and thereby suppress the formation of prostaglandin mediators. The role of various prostaglandins in intestinal motility as well as in absorption and secretory processes is complex, and the inhibition of prostaglandin synthesis will not consistently influence secretory diarrheal states. The NSAIDs may, however, prove to be therapeutically beneficial in some acute and chronic diarrheal syndromes as long as care is taken regarding their gastrointestinal advesre effects.

Asulfidine (sulfasalazine) is a sulfapyridine-5-aminosalicylic acid (5-ASA; mesalazine) compound joined by a diazo bond that is broken by colonic microbes.¹³⁹ It is the 5-ASA component that is beneficial, with the sulfapyridine simply carrying the active drug to the colon.¹³⁹ This finding led to the development of 5-ASA products without the sulfonamide component. Compounds equally efficacious to sulfasalzine include osalazine, balsalazide, and mesalazine. An advantage of these products is efficacy above the colon (i.e., in the absence of microbial metabolic activation). A variety of preparations are available such that oral absorption is prevented and specific sites of delivery (e.g., jejunem versus ileum versus colon) might be targeted, with the intent of topical, rather than systemic, delivery. These include pH-dependent (e.g., Asacol) and slow continuous release (Pentasa) mesalazine (also known as mesalamine), diazo bond delivery (osalazine, a diamer of mesalazine), or balsalazide (a prodrug).¹⁴⁰ The exact mechanism of action of mesalazine is not known, but presumed activities include inhibition of cytokines, leukotrienes, and nuclear factor kappa B. Mesalazine is metabolized by both epithelial and hepatic acetylation. Although these newer 5-ASA products have not been proved to be more efficacious than sulfasalazine in treatment of IBD in humans, they are better tolerated. Because they are better tolerated than glucocorticoids, they are the cornerstone of therapy for some human IBDs.

As with all aspirin-containing compounds, caution is indicated when a sulfasalazine is used in the cat because salicylic acid released in the colon can be subsequently absorbed. For example, the aspirin component of mesalamine (and thus osalazine) may be 30% or more bioavailable (demonstrated in humans), and care should be taken to avoid aspirin toxicity, especially in cats. Mesalamine enema may contain sufficient sodium benzoate (as a preservative), which also should be used cautiously in cats (see Chapter 4).

GASTROINTESTINAL PROTECTANTS AND ABSORBENTS

Compounds that are not absorbed from the GI tract and either line the mucosal surface or adsorb toxic compounds are often incorporated into antidiarrheal mixtures. The protectants seemingly produce a coating of the GI epithelium that prevents irritation or erosion by potentially harmful substances. The adsorbents physically bind chemical compounds, which precludes their absorption, and they are then eliminated in the feces. Use of these two therapeutic classes is obviously directed at potentially harmful agents of either inorganic or organic nature. Adsorbents will also, however, bind concurrently administered drugs used for therapeutic purposes. Care must be taken with the use of over-the-counter products. Active ingredients may change under the same trade name. Although over-the-counter products often are safe, some may present a health risk to certain patients (e.g., bismuth subsalicylate and cats).

Many protectants and adsorbents possess both properties to varying degrees. Those most frequently used are magnesium trisilicate, hydrated magnesium aluminum trisilicate (activated attapulgite), kaolin (natural hydrated aluminum silicate), aluminum hydroxide and phosphate, bismuth salts, calcium carbonate, pectin (natural polygalacturonic acids), and activated charcoal.

The combination kaolin–pectin product is dissolved in 20 parts water. Described as a demulcent and adsorbent, the drug supposedly binds and removes bacteria and their metabolic products and toxins. These effects are controversial. Although stool consistency may improve, studies do not indicate that fluid and electrolyte imbalance is corrected, nor is the course of disease shortened.¹⁴¹

KEY POINT 19-30 Bismuth subsalicylate is an effective antidiarrheal because of its adsorptive capacity and effects on secretion.

The insoluble bismuth salts have been used for more than 400 years.¹⁴² Products include bismuth subcarbonate, bismuth subnitrate, and bismuth subsalicylate. Bismuth subsalicylate is a crystalline 1:1 trivalent bismuth and salicylate compound. It is chemically transformed throughout the GI tract to bismuth and salicylate. The drug has been shown to have both antisecretory and antimicrobial effects in several species.¹⁴² The subsalicylate fraction has been shown to have antiprostaglandin synthetase effects, which would enhance its action in controlling diarrheal syndromes.¹³³ In humans and cats, nearly all the salicylate is systemically available.^{142,143} Caution is recommended in order to prevent salicylate toxicity in cats receiving this drug.

Activated charcoal has primarily adsorbent properties. Because of its broad spectrum of adsorptive activity and its rapidity of action, it is one of the most valuable agents for emergency treatment of certain cases of poisoning. It forms a stable complex with many substances and permits their evacuation from the body. Charcoal preparations vary according to the source of base material, surface area, capacity for drug binding and affinity, and avidity of drug binding.¹⁴⁴ Source materials are usually lignite, wood, or peat. Activation forms more pores and enlarges the surface area. Activation time is directly correlated with the molecular size of the compounds adsorbed. Because most drugs are of an intermediate molecular weight, charcoals with pore sizes between 10 to 20 Å are most appropriate.¹⁴¹ Administration with a cathartic, such as sorbitol, is a common practice and facilitates rapid movement of the charcoal-toxin complex.144 Activated charcoal loses its efficacy as the time interval between treatment and toxin ingestion increases. The optimal dose and interval for administration of activated charcoal have not been well established,144 although a charcoal to toxicant ratio of 10:1 has been recommended.141 One source suggests treatment at 6-hour intervals.¹⁴⁴ Powders are superior to tablets.141 Food generally decreases the efficacy of these products. In the common domestic species, 20 to 120 mg/kg powered activated charcoal is usually administered as a drench after mixing with water. An activated charcoal suspension may be used for gas lavage in simple-stomached animals.

Cholestyramine is a basic anion exchange resin that binds to acidic side chains such as those occurring in bile acids. Endotoxin also is bound. To increase the number of basic binding sites, cholestyramine is attached to a polystyrene matrix that can act as a nonspecific adsorbent. As bile salts are bound in the GI tract, lipoproteins, cholesterol, and neutral fat absorption is also decreased. Although specifically indicated in humans for pruritis associated with increased bile acids (hypercholesterolemic syndromes) cholestyramine has also been used to symptomatically treat diarrhea, particularly that which is intractable. Nausea, constipation, steatorrhea, and decreased fat-soluble vitamin absorption are reported undesirable effects. The product should be administered in food or water.¹⁴¹

LAXATIVES AND CATHARTICS

Laxatives and cathartics promote defecation by increasing frequency of defecation or fecal volume or consistency.^{119,145-147} Laxatives (or aperients) promote elimination of a soft-formed stool, whereas cathartics (or purgatives) tend to produce a more fluid evacuation. The difference between these two effects may be just a matter of dose, but in some instances laxatives are only capable of increasing the hydration or softness of the fecal mass without ever inducing catharsis. The enhanced intestinal transit times that occur with use of some of these cathartics are usually due to intrinsic local myenteric reflexes within the visceral smooth muscle or to stimulation of the cholinergic receptors of the extrinsic parasympathetic nervous system. Although a traditional classification of the group is presented here, it should be noted that many cathartics alter intestinal electrolyte transport to increase fecal water excretion, so the grouping of these compounds should perhaps more logically follow their effects on intestinal electrolyte movement.

A number of deleterious effects may occur with excessive or constant use of cathartics. Severe, continuous diarrhea and abdominal colic, leading to dehydration and even shock, may follow overdosage. Other potentially harmful effects include decreased sensitivity of the intestinal mucosa, megacolon, flatulence, loss of electrolytes (especially sodium, potassium, chloride, and bicarbonate), secondary aldosteronism, melanosis coli (anthraquinones), steatorrhea, protein-losing gastroenteropathy, excessive calcium loss with resultant osteomalacia, and exacerbation of inflammatory intestinal disease. Several drugs can also distribute into milk and adversely affect suckling young.

Emollient Laxatives

The emollient laxatives (lubricant laxatives, mechanical laxatives, fecal softeners) act unchanged. They are not absorbed to any appreciable extent and simply soften and lubricate the fecal mass, which in turn facilitates expulsion. Although not always reliable, particularly in the ruminant, they are used in all species.

Mineral oil (liquid paraffin) is a commonly used lubricant laxative. It is bland and generally safe, but chronic administration may impair absorption of fat-soluble vitamins, other nutrients, and co-administered therapeutic agents. Decreased irritability of the intestinal mucosa may develop with protracted use and, paradoxically, cause chronic constipation. White or yellow soft paraffins are used most commonly for small animals as lubricant laxatives (e.g., feline hairballs). Several anionic surfactants are employed as fecal softeners. Examples include docusate sodium, previously called *dioctyl sodium sulfosuccinate* and *dioctyl calcium sulfosuccinate*.

Simple Bulk Laxatives

The simple bulk laxatives are hydrophilic and not digested. As such, they adsorb water and swell, forming an emollient gel. Increased volume or bulk causes distention and reflex contraction, leading to peristaltic activity. Feces remain soft and hydrated. Methylcellulose, carboxymethylcellulose sodium, and plantago seed (psyllium seed) are examples of simple bulk purgatives. Wheat bran, prunes, and other fruits also belong in this group. In addition to their bulk action, celluloses and hemicelluloses will be fermented in the hind gut by bacteria to produce volatile fatty acids and other products that exert an osmotic effect, which enhances their laxative action. Meteorism and a very fluid stool often result from the use of simple bulk laxatives.

KEY POINT 19-31 Bulk laxatives cause reflex bowel contraction and softening of the stool.

Osmotic Cathartics

Osmotic cathartics (saline purgatives) consist of salts or compounds that are either partially and slowly absorbed or not absorbed. Water is osmotically retained or attracted into the intestinal lumen, although enhanced mucosal secretion of fluid may also occur. Drinking water must be freely available, and use is contraindicated with dehydration. Effects are realized in monogastric animals generally in 3 to 12 hours. Magnesium salts are frequently used as saline purgatives. Magnesium ions also cause release of CCK, which increases peristaltic activity. Magnesium sulfate (Epsom salts), isotonic in a 6% solution, magnesium hydroxide, magnesium oxide (milk of magnesia), and magnesium citrate are the magnesium salts most commonly employed. The solutions need not be hypertonic to produce an effect. About 20% of the magnesium ions are absorbed when magnesium sulfate is dosed orally, and if purgation does not occur, additional amounts of magnesium may be absorbed with subsequent depression of the excitable tissues in the body. This is more likely to occur if renal function is impaired. Salts such as sodium sulfate (Glauber's salt), sodium phosphate, potassium sodium tartrate (Rochelle salt), and even large quantities of sodium chloride are effective saline purgatives. Saline purgatives are often combined with polyethylene glycol (PEG) for whole bowel irrigation implemented for bowel preparation before lower bowel procedures such as surgery or colonoscopy. The safety and efficacy of sodium phosphate has been described in healthy dogs (n = 8) when used to prepare for colonoscopy. Orogastric sodium phosphate (1 mL/ kg in 2 mL/kg water followed by 2 mL/kg) was less effective as a preparatory agent compared with PEG (66 mL/kg) and bisacodyl (10 mg/dog; dog weight not provided). Most (five

of eight) dogs receiving sodium phosphate vomited during or after administration. In contrast, dogs receiving PEG tended to regurgitate. Sodium phosphate enemas were associated with transient hyperphosphatemia and hypocalcemia that were not considered clinically relevant in these normal dogs. Other electrolyte concentrations statistically varied but remained within normal limits. The protocols for colonoscopy preparation included 20 mL/kg warm water enemas; treatments were repeated at 4 hours and enemas at 24 hours (before procedures). Enemas may have contributed to vomiting because of distention. Dogs receiving PEG were also pretreated (20 minutes) with metoclopramide (0.3 mg/kg subcutaneously). The authors concluded that sodium phosphate enemas should not be considered as preparative agents for colonoscopy.¹⁴⁸

The sugar alcohols mannitol and sorbitol will also induce an osmotic catharsis, as will the synthetic disaccharide lactulose, which is not digested in the small intestine because no specific enteric enzyme is present. It passes to the large intestine, where saccharolytic microflora ferment lactulose to produce acetic, lactic, and other organic acids, which in turn lower the pH of the colonic content and exert an osmotic effect. Water is attracted, the fecal mass softens, and colonic peristalsis ensues. Lactulose is used for chronic constipation and treatment of hepatic encephalopathy. Acidification of the contents of the large intestine favors a greater formation of the ionized and thus nonabsorbable ammonium ion rather than the readily absorbable ammonia molecule, which requires detoxification in the liver by the urea cycle. Hyperammonemia is thus decreased. Absorption of other toxic amines from the hind gut is also reduced by acidification of the contents. Some meteorism may be evident after administration of lactulose. Lactitol is an alternative osmotic cathartic. It is less sweet than lactulose and may be better tolerated.

Irritant Cathartics

Contact or irritant purgatives were thought to stimulate the mucosal lining of the GI tract and thereby initiate local myenteric reflexes that would enhance intestinal transit. However, they also activate secretion. Irritant cathartics act either directly or indirectly, depending on whether the compound must be metabolized to its active product. Some purgatives are so highly irritating that they may cause severe colic and superpurgation.

Several bland vegetable oils act as irritant purgatives. Their action is based on hydrolysis by pancreatic lipase in the small intestine and subsequent formation of sodium and potassium salts of the released fatty acids, which act as irritant soaps. They differ in potency depending on the oil used. Castor oil produces highly irritant ricinoleates; raw linseed oil leads to formation of less irritant linoleates; and olive oil leads to rather mild oliveates. The response to castor oil is prompt, and evacuation of the whole intestinal tract occurs, leading to an almost complete emptying. Moist bulky feeds are necessary after purgation with castor oil. It is used mainly in nonruminants and often employed in calves and foals. The effect occurs in 4 to 8 hours in small animals. The diphenylmethane cathartics appear to have a greater effect on the large intestine. Their precise mechanism of action is unclear. An effect is usually seen within 6 to 8 hours, and excessive catharsis may occur with overdosage. Bisacodyl also is a diphenylmethane cathartic that inhibits glucose absorption and Na⁺, K⁺ ATP activity, as well as altering motor activity of the visceral smooth muscle. Only about 5% of any dose of bisacodyl is absorbed. This agent is used both orally and by enema.

Enemas

Introduction of solutions or suppositories into the rectum to initiate the defecation reflex is a useful and simple method to correct or prevent constipation. Many preparations have successfully served as enemas, including soapy water (soft anionic soap), isotonic or hypertonic sodium chloride solutions, sorbitol, glycerol, surfactants such as sodium lauryl sulfoacetate, mineral oil, and olive oil. Enema preparations that contain phosphate should not be used indiscriminately because they can precipitate potentially fatal hyperphosphatemia, hypocalcemia, and hypernatremia in cats¹⁴⁹ or debilitated animals.

AGENTS PROMOTING GASTROINTESTINAL FUNCTIONS

Several preparations are used therapeutically to control specific GI diseases by promoting digestive or other metabolic processes. These compounds generally consist of normal microbiota or digestive enzymes or related substances that are used for replacement therapy in deficiency states.

Digestive Enzymes

Pancreatic extracts that stimulate pancreatic exocrine secretions are of therapeutic benefit in cases of chronic pancreatitis and pancreatic hypoplasia, in which glandular function is diminished or destroyed. Pancreatin (Panteric, Stamyl, Viokase) obtained from hog pancreas is the major ingredient of most commercial pancreatic enzyme preparations. Entericcoated preparations to prevent destruction of pepsin in the stomach are generally thought to be better than noncoated preparations. In a few instances, enteric-coated preparations are the most effective in dogs with pancreatic insufficiency; they are added to food and must be provided with each meal. Dosage is adjusted to obtain a normal stool. Simultaneous administration of nonsystemic alkalinizing agents to maintain an optimal pH range for enzyme activity has not proved successful clinically. However, the administration of cimetidine about half an hour before dosing with pancreatic extract does limit gastric inactivation of the enzymes. Proper dietary control is also essential for the successful management of animals suffering from pancreatic insufficiency. Premixing in food does not appear to be necessary for efficacy of these products.

Bile acids and their salts promote absorption of long-chain fatty acids and fat-soluble vitamins. They also act as choleretics (discussed previously). Examples include dehydrocholic acid (Decholin) and chenodiol (previously called *chenodeoxycholic acid*). Diastases are amylolytic enzymes obtained from malt and *Aspergillus oryzae* and are used for replacement of pancreatic α -amylase and to control flatulence caused by gas produced from soluble carbohydrates by bacterial flora.

Antiflatulence Drugs

Simethicone is an inert over-the-counter mixture of siloxane polymers stabilized with silicon dioxide.²⁴ It acts as an antifoaming agent by covering bubbles with a thin layer that facilitates bubble collapse. Reduction in foam may reduce gas volume, although therapeutic efficacy is not clear.²⁴

BIOTHERAPEUTICS: PREBIOTICS, PROBIOTICS, AND SYNBIOTICS

The concept that microbes might be beneficial rather than simply detrimental to health enjoys a long history of anecdotal evidence. Among the oldest observations is the Old Testament recording of Abraham ingesting sour milk (Genesis 18:8). The purported health benefits of microbial products are varied, but they are more often supported by testimonials than by scientific evidence. However, hypothesis-driven research is increasingly generating evidence-based examples of the therapeutic benefits of biotherapy.

KEY POINT 19-32 The normal intestinal microbiota plays an important role in nutrition, metabolism, pathogen control, and immunity.

Product Definitions

The term *probiotic* was originally coined in 1965 to refer to substances secreted by one microorganism that stimulate the growth of another.¹⁵⁰ The term has been modified at least five times and continues to vary with the author. Most recent modifications are intended to encompass nondairy products (e.g., plant-based products), recognizing the importance of organism load to ensure a therapeutic effect; to allow for transient, rather than prolonged, effects that would otherwise require transplantation (implying colonization), and to allow for multiple and diverse benefits, including those manifested beyond the GI tract.¹⁵⁰ Perhaps the easiest working definition of probiotics is that offered by the World Health Organization: live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.¹⁵⁰

In contrast to probiotics, *prebiotics* are nondigestible food ingredients (e.g., dietary fiber) that beneficially affect the bacterial population. They differ from other fermentable carbohydrates in that they interact with selective microorganisms.¹⁵¹ They presumably are most beneficial to those microbes targeted for their therapeutic benefit, thus shifting the composition of the intestinal microbiota toward the beneficial organisms. Examples include fructooligosaccharides, inulin, transgalactosylated oligosaccharides, and soybean oligosaccharides that selectively promote the growth of bifidobacteria. Metabonomics is the scientific discipline that studies compounds formed from prebiotics. *Synbiotics* contain both prebiotics and probiotics, with the prefix *syn* implying a synergistic effect of the prebiotic on the probiotic portion of the combination products. To be a symbiotic, the prebiotic portion should have demonstrated positive effects on the specific probiotic component of the combination product.¹⁵⁰ Some products sold as probiotics are actually the fermentation products produced by target microbe; presumably, the products are those imparting the therapeutic benefits of the microbes.

Normal Microbiota

Normal Flora

Understanding the impact of biotherapeutics requires an appreciation of the normal GI microflora. The total body microbiota (human and presumably dogs or cats) outnumbers other cells by approximately tenfold. Up to 30% of dry fecal matter represents microbes. The number of microbial species in the GI tract (again in humans) is estimated to be between 400 and 500 based on 16S rRNA sequencing and metagenomic. However, only a fraction (approximately 10%) are conducive to cultures.^{152,153} Whereas some of these unculturable microbes are closely related to those already identified, others represent totally new species. Therefore very little is known regarding the microbiota of the GI tract. To further complicate our understanding, the number and diversity of microbes increases with a number of factors. Differences owing to location in the GI tract reflect, in part, differences in pH and transit time. Peristalsis and low pH lower microbial counts in the stomach, duodenum, and jejunum,152 whereas numbers and diversity increase in the ileum (104-8 CFU or colony-forming units/mL) and colon. Rapid transit decreases numbers because bacteria colonizing sites with a high transit rate (e.g., lower ileum) must be able to effectively adhere to the mucosal epithelium; thus organisms such as lactobacilli must compete with pathogenic organisms for adherence receptors if they are to colonize these regions. Organisms that do not have to adhere are likely to be present in much higher numbers in the colon. Higher colonic pH (5 to 6) leads to slower epithelial turnover, which also increases bacterial counts. More rapid microbial growth results in a lower redox potential.

KEY POINT 19-33 The normal microbiota consists of close to 500 organisms, most of which have not been cultured or otherwise specifically identified.

Intestinal bacterial by-products produced under low redox conditions contribute to a higher short-chain fatty acid concentration. Even within the colon, bacterial growth and fermentation products are diverse among regions, with growth and carbohydrate fermentation greater proximally and protein fermentation greater distally. Diet has a profound impact on microbiota. Nondigestible foods are a source of energy and carbon for the microbiota and may influence metabolites that positively or negatively influence the population. Food also affects host GI function and health and thus indirectly affects the microbiota.¹⁵²

The microbiota of the human GI tract was recently reviewed and may provide insight into the complexities of microbiota in other species.¹⁵² The number of colony-forming units per mL increased from the stomach and duodenum (10³) to the colon (10¹⁴). The composition increases in complexity with age such that the microbiota is relatively simple in newborn and very old subjects. Nutritional and physical requirements are sufficiently sophisticated that the conditions for optimal growth simply are not known for up to 70% of the bacterial population.¹⁵¹ However, four microhabitats have been described: the lumen; the mucous layer of epithelial cells; the surface of epithelial cells; and the crypts of the ileum, cecum, and colon (which generally are colonized with motile, spiral-shaped organisms). In humans a central core of microbiota might be partitioned into five bacterial groups: *Clostridium leptum; Clostridium coccoides; Bacteroides;* and, in smaller part, *Bifidobacterium*.¹⁵¹

The GI flora of dogs has been described and compared to that in humans,^{154,155} (Table 19-3) and the microbiota of the cat has been described.¹⁵⁴ Selective media often do not support the growth of target microbes in dogs, contributing to the list of unculturable bacteria.¹⁵⁴ However, because the dog is a carnivore, its GI tract is shorter than that of humans. Similarities between human and dog include the proportion of gram-negative to anaerobic organisms, the makeup of gramnegative isolates, and floral behavior in response to probiotics or prebiotics.^{154,156} Genera that are numerous in both the GI tract of restricted-access dogs and humans include Lactobacillus, Bifidobacterium, Eubacterium, Bacteroides, and Peptostreptococcus. The major difference between dogs and humans appears to be the proportion of bifidobacteria;¹⁵⁴ however, a study examining floral changes in response to different housing environments demonstrated that the number of bifidobacteria dramatically increase under conditions in which exposure to the environment is controlled.¹⁵⁶ Under such conditions major differences between the two species among culturable bacteria are limited and include the following: (1) Bacteroides and Streptococcus are the most common isolates in the ileum and colon of dogs; however, these isolates, although not the predominant isolate in humans, are present in a large proportion of humans; (2) Fusobacterium is not as numerous in dogs as in humans. In the cat, bifidobacteria appear to be even less numerous than in the dog.

Gastrointestinal Microbe–Host Interactions

The sophisticated interactions among the intestinal mucosa, host immune cells, the microbiota, and food have been described,¹⁵⁷ and the impact of probiotics on host immunity has been reviewed.¹⁵⁸ It is beyond the scope of this chapter to discuss the interactions, but it is notable that the mechanisms by which commensals are recognized as such and fail to stimulate an inflammatory response by the GI tract are not yet known. Interactions are modulated in part through pattern recognition receptors (PRRs) that recognize microbial motifs referred to as pathogen-associated molecular patterns (PAMPs). The PAMPs are evolutionarily highly conserved, not varying within microbes in the same class. Consequently, mammalian cells are able to recognize all microorganisms with only a few PRRs. Receptor families that identify PAMPS include Toll-like receptors located either on the cell surface or intracellularly and nucleotide-binding oligomerization domain

CFU, Colony-forming units. *Eubacterium* and *Corynebacterium* are pleomorphic. *Data from Mentula S, Harmoinen J, Heikkilä M et al: Comparison between cultured small-intestinal and fecal microbiotas in beagle dogs, *Appl Environ Microbiol* 71(8):4169-75, 2005.

[†]Data from Rastall RA: Bacteria in the gut: friends and foes and how to alter the balance, *J Nutr* 134:2022S-2026S, 2004. (NOD) receptors. Thus far, 11 mammalian Toll-like receptors have been identified.¹⁵⁷ Whether colonization is necessary for immunomodulation to occur is not clear.¹⁵⁸ However, microbial adhesion to the epithelial cells or mucus is generally recognized to be necessary. Activation of the immune system may reflect microbial alteration of epithelial tight junctions with subsequent bacterial translocation.

KEY POINT 19-34 The relationship between microbiota and the gastrointestinal immune system represents one of the most sophisticated communication systems in the body and its inadvertent or intended or manipulation is likely to contribute to disease or control, respectively.

Impact of Normal Flora on Gastrointestinal Health and Disease

In the last decade, the role of normal microbiota in GI physiology has been recognized as critical, protecting against invasion of pathogenic strains of bacteria, facilitating maturation and maintenance of the immune system, facilitating normal bowel smooth muscle function, supporting digestion of certain foods, and contributing to nutrition through the production of vitamins (vitamin K; vitamin B in some species) and other nutrients (e.g., short-chain fatty acids). Energy salvage is facilitated through conversion of nutrients to short-chain fatty acids.^{152,159} Known effects of commensal intestinal bacteria include GI epithelial cell proliferation, energy capture, and production of metabolites; the latter, in particular, also can result in detrimental health effects.¹⁵²

By-products of microbial metabolism may be either beneficial or detrimental. When included with probiotics, byproducts are intended to support beneficial organisms or ameliorate negative effects of by-products. However, organisms themselves are chosen for their anticipated by-products. Among the organisms most commonly cited as beneficial are Lactobacillus and Bifidobacterium spp. Major sources of food for microbes include resistant starches; dietary fibers such as cellulose, hemicellulose, pectin, and inulin; and unabsorbed sugars and sugar alcohols. Substrates also include dietary protein (host or diet) and endogenous materials such as pancreatic enzymes, GI secretions, the mucoid layer, and sloughed GI epithelial cells. By-products of carbohydrates are formed primarily in the proximal colon; products include monosaccharides, disaccharides, and oligosaccharides. Further metabolism of these by-products results in short-chain fatty acids (including butyrate), as well as lactic, succinic, and formic acid. Butyrate is the major fuel source of colonic epithelial cells. However, butyrate purportedly also reduces the risk of colon cancer and inhibits proinflammatory cytokines. Intestinal microbes may metabolize other compounds into active or inactive metabolites, which may be subsequently absorbed. Examples include flavonoids, isoflavonoids and plant lignans.¹⁵² Benefits of microbial fermentation of plant products include the production of enterolignans associated with estrogenic and antioxidant effects. Oxalobacter formigenes transforms oxalates; its absence increases the risk of oxalate stones in humans.¹⁵² The production of potentially beneficial by-products often requires cooperative actions among different populations of microbes.

Bacterial by-products have a number of adverse effects. Protein by-products, produced primarily in the distal colon, include ammonia and amines resulting from deaminations; these products are associated with procarcinogenic effects (e.g., nitrosamines). Cysteine and methionine degradation yields sulfides, which inhibit colonic use of butyrate. Anaerobic colonic fermentation of aromatic amino acids tyrosine to phenols and tryptophan to indoles and their subsequent metabolism yield several procarcinogenic compounds. Many of these determinental compounds also play a role in hepatic encephalopathy. Bacterial deconjugation and dehydroxylation of bile acids contribute to their enterohepatic circulation; other compounds conjugated by compounds such as taurine, glycine, and sulfate may likewise be recycled. The general effect of recycling is longer exposure to potentially toxic compounds.

Probiotics as Therapeutic Agents

The science behind the use of probiotics is profoundly complicated by the unknown nature of the normal microbiota; the variables that influence it, including diets, diseases, and other patient factors such as breed, age, or gender; a lack of understanding of the pathophysiology of targeted disease; and issues regarding the quality of the products. Further hampering our understanding are the studies themselves. A variety of in vitro and in vivo models have been used (as reviewed by de Vrese and Schrezenmeir¹⁶⁰ and Lenoir-Wijnkoop and coworkers¹⁵¹), but poor scientific design mars the credibility of many.

KEY POINT 19-35 Evidence for the beneficial effects of probiotics will be difficult to establish because of the impact of multiple (including unknown) variables on response.

In humans probiotics have been demonstrated to have an impact on a large number of potential health problems (Table 19-4).¹⁵¹ Although the data were drawn from humans, a review of those indications relevant to dogs and cats is reasonable; this discussion is limited to those indications for which sufficient evidence exists to support potential to probable therapeutic benefit. This review summarizes human reviews of well-designed clinical trials.^{151,161, 162}

Gingival disease. Theoretically, probiotic microbes able to adhere to dental tissues occupy spaces that otherwise would be occupied by pathogens. For example, dairy products containing *Lactobacillus* or *Bifidobacerium*organisms might compete with cariogenic microbes such as salivary *Streptococcus mutans* or others. Several clinical trials have demonstrated a reduction in the number of dental caries in humans who ingest probiotics containing *Lactobacillus*.¹⁵¹

Antibiotic-induced diarrhea. Diarrhea as a side effect of selected commonly used antibiotics may reflect colonic overgrowth of *Clostridium difficile* or other organisms. Strategies for treatment (discontinuation of the inciting antibiotic, immediate retreatment with a new antibiotic) are not always successful, and one of the most commonly selected antibiotic in humans (oral vancomycin) to treat overgrowth of *Clostridium* organisms tends to be associated with adverse events. Although other antibiotics may be as effective as vancomycin, use of probiotics is a reasonable approach.

Based on a review of 10 clinical trials in close to 2000 children ranging in age from less than 1 year up to 18 years of age, probiotics were beneficial in the prevention of pediatric antibiotic-associated diarrhea.¹⁶² Probiotic strains that showed the most promise included Lactobacillus GG, Lactobacillus sporogenes, and Saccharomyces boulardii when 5 to 40 billion colony-forming units were administered daily. Other organisms studied included members of Lactobacillus spp., Bifidobacterium spp., Streptococcus spp., and S. boulardii alone or in combination, including other treatments that might prevent antibiotic-associated diarrhea. The impact of age (e.g., infants versus older children) or duration of antibiotic therapy could not be assessed. Probiotics tended to be well tolerated after 2 to 12 weeks of therapy. Although the review concluded that routine treatment of probiotics for the prevention of pediatric antibiotic-associated diarrhea could not yet be recommended, further studies are warranted.

Infectious diarrhea. Probiotics also appear to be beneficial when used as an adjunct to rehydration fluids in the treatment of acute, infectious diarrhea in adults and children, although further research is indicated to determine the most effective probiotic and dosing regimen. In contrast, the use of probiotics as an adjunct to antibiotic therapy for *C. difficile* colitis could not be supported by a review of relevant clinical trials. However, the number of studies was small.

Liver disease. A review of clinical trials studying the use of probiotics for treatment of nonalcoholic fatty liver disease and nonalcoholic steatohepatitis found insufficient evidence to support or refute treatment. However, the use of probiotics and synbiotics to support liver function or treat liver disease has been reviewed by Lenoir-Wijnkoop and coworkers¹⁵¹ and is discussed with regard to the management of liver disease.

Hyperlipidemia. Several species of *Lactobacillus* may bind to cholesterol in the presence of bile acids and low redox potential.¹⁶¹

Inflammatory bowel disease. Because of the complex relationship between the intestinal microbiota and the immune response, the use of probiotics as adjunct therapy for treatment of IBD is reasonable.¹⁶³ Probiotics have been used successfully to reduce Helicobacter pylori colonization in humans; severity of mucosal inflammation also is reduced in a mouse model. Clinical trials investigating the efficacy of probiotics in the treatment of *H. pylori* often are conflicting, ranging from ineffective as sole therapy to effective if used in conjunction with standard therapy antimicrobial and antiulcer therapy. One study in humans (n = 138) found that equal numbers of Lactobacillus acidophilus, Lactobacillus bulgaricus, Streptococcus thermophilus, and Bifidobacterium lactis (total of 10⁹ organisms/mL) combined with quadruple therapy (amoxicillin, metronidazole, bismuth subcitrate, and omeprazole) eradicated infection in 85% of humans compared with 71% receiving quadruple therapy alone (as reviewed by Lenoir-Wijnkoop and coworkers¹⁵¹).

Probiotic therapy with conventional therapy does not appear to provide any benefit compared with conventional therapy alone in patients with mild to moderate ulcerative colitis. Although limited evidence suggests that probiotics may reduce clinical signs, support was not sufficient for recommendations. Likewise, evidence was not sufficient to support a role for probiotics in the treatment of Crohn's disease.

Probiotics do not appear to be effective for prevention of allergic diseases or food hypersensitivity in pediatric patients.

Urinary tract infection. The use of probiotics in the treatment of urinary tract infections in human patients was reviewed by Lenoir-Wijnkoop.¹⁵¹ GI bacteria are a major source of urinary tract infections. As in animals, those causing UTI in humans are predominantly caused by uropathogenic *E. coli*, gramnegative organisms, and *Enterococcus faecalis*. In general, *Lactobacillus* sp. is the most common probiotic recommended for treatment of UTI. However, selected species are likely to emerge as more effective than others. A meta-analysis of 25 studies in human medicine found probiotics (lactobacilli) to be of benefit in treatment of bacterial vaginosis. However, a clear benefit could not be demonstrated for UTI (five studies); conclusions were difficult to draw because of limitations, including differences in study design and limited sample size.^{163a}

Oxalate urolithiasis. The use of probiotics in the treatment of renal oxalate stones in human patients was reviewed by Lenoir-Wijnkoop and coworkers.¹⁵¹ The absence of *O. formigenes* from fecal microbiota increases the risk of kidney stones. Both animal and human studies have documented that *O. formigenes* is able to become established in the GI tract, and establishment reduces urinary oxalate concentration. At least two studies have demonstrated a potential benefit of probiotics containing *O. formigenes* in the prevention or treatment of oxalate crystalluria.^{164,165} Weese and coworkers¹⁶⁶ demonstrated that fecal samples containing lactic acid bacteria and several bacteria isolated from dogs or cats degraded oxalate in vitro. The addition of selected prebiotics (e.g., guar gum) increased the degradation.¹⁶⁶

Allergic diseases. The use of probiotics in the treatment of allergic diseases (including atopic allergic disease and asthma in human patients) was reviewed by Lenoir-Wijnkoop and coworkers.¹⁵¹ The rationale for efficacy reflects the immuno-modulatory effects of probiotics. Based on clinical trials in humans, response has been limited to younger patients with severe disease. Similarly, probiotics have had only a limited, if any, effect on allergic rhinitis and asthma in humans.

Nosocomial infections. A meta-analysis examined the impact of probiotics on the prevention and treatment of nosocomial *C. difficile*-associated diarrhea and hospital-associated pneumonia in humans.¹⁶⁷ Although the prevention of antibiotic-induced diarrhea was a recognized beneficial effect, no evidence was found to support the theory that probiotics prevent nosocomial infection; clinical trials were recommended.

Irritable bowel syndrome. A meta-analysis¹⁶⁸ identified the limitations of drawing conclusions given differences in study design, including organisms, doses, and the definition of

irritable bowel syndrome (IBS). Clinical efficacy was reported in several studies, with improvement manifested as decreased bloating, gas, and pain. *Lactobacillus* spp. and *Bifidobacterium* were targeted treatments.

Prebiotics (as opposed to probiotics) also have been associated with therapeutic benefits in humans with effects extending beyond local (GI) sites. The list is not much different than that for probiotics. Those conditions for which scientific evidence supports the potential use of prebiotics include allergies, immunomodulation (gut-associated lymphoid tissue as well as cellular Th1/Th2 ratio) that improves resistance to infections, constipation, irritable bowl syndrome, mineral metabolism (particularly strengthening of bone), prevention of cancer, and treatment of H. pylori infections. In addition, prebiotics have been scientifically associated with weight loss, presumably as a result of increased satiety mediated through GI suppression of ghrelin. Feed conversion efficiency has been described in food production animals. Interestingly, fermentation of prebiotics purportedly increases bacterial biomass in which nitrogen is fixed, thus decreasing the ammonia load in patients with hepatic encephalopathy.

Scientific data regarding the use of biotherapeutics in dogs and cats are slowly emerging. The use of prebiotics and probiotics in dogs has been reviewed by Rastall.¹⁵⁴ *L. acidophilus* DSM 13241 fed (2×10^9 colony-forming units daily per dog) in 15 healthy dogs decreased the number of culturable *Clostridum* spp. and was associated with an increase in indices indicative of immunomodulation (increased serum IgG and monocytes and decreased plasma nitric oxide). Prebiotics that have been studied¹⁵⁴ include lactosucrose and fructooligosaccharides. In their report, the authors noted that most prebiotics are enzymatically synthesized and that the technology can be modified such that enzymes are obtained from the target microbe, thus yielding highly specific probiotics.

Feeding 1.5 g lactusucrose daily for 2 weeks to healthy dogs (n = 8) increased bifidobacteria and decreased Clostridium spp. In another study, Bifidobacterium and Lactobacillus organisms also increased, and *Clostridium* and Enterobacteriaceae organisms decreased in cats receiving 0.75 g daily. A decrease in toxin levels and odor also was described for both dogs and cats. Fructooligosaccharides fed at a rate of 4 g/day to adult health dogs (n = 20) increased Bifidobacterium and Lactobacillus organisms and decreased Clostridium spp. Although both lactate and butyrate increased, ammonia, dimethylsulfide, and hydrogen sulfide also increased. Fructooligosaccharides at a rate of 0.75% in the diet of healthy adult cats for 2 weeks decrease Clostridium spp. and E. coli. Rastall¹⁵⁴ also described the formulation of a symbiotic containing Lactobacillus organisms cultured from one dog, following the tradition of probiotics being based on microbes isolated from the target species. Among the isolates cultured, Lactobacillus mucosae, L. acidophilus, and Lactobacillus reuteri were subjected to prebiotic carbohydrates. Baillon and coworkers¹⁶⁹ prospectively studied the viability of L. acidophilus added to a dry dog food at a concentration of 10(9) colony-forming units. Dogs (n = 15) were fed control and treated diet for 2 weeks each. Supplementation of the diet resulted in fecal recovery of organisms during but not after feeding of the treated diet, indicating colonization had occurred. The number of clostridial organisms was decreased.

Probiotics might comprise wild-type microbes associated with natural microbiota or genetically mutated forms of otherwise pathogenic but normal microbiota. Different strains of probiotic bacteria are presumed to impart differential effects, with variability representing habitat preferences of the microbe, specific capabilities of the microorganism, and differential enzymes. The number of colony-forming units ingested as probiotics is minor compared with the normal microbiota.¹⁵¹ However, they travel through regions of the GI tract that are sparsely populated and therefore may transiently become the dominant microbe, potentially muting pathogens as a result of competitive exclusion. Rinkinen and coworkers¹⁷⁰ demonstrated the ability of lactic acid bacteria to competitively inhibit adhesion of selected canine pathogens (including C. perfringens) in vivo using isolated canine jejunal mucosa. However, Enterococcus faecium actually facilitated adhesion and colonization of Campylobacter jejuni, supporting the need for controlled clinical trials before assumptions are made regarding the impact of probiotics.

Probiotics and related compounds are not approved drugs and undergo no premarket approval with regard to efficacy, safety, or quality. Data, if available, represent efforts of the manufacturer or the scientific community. Consumer Laboratories (www.consumerlab.com) reviewed issues specifically related to quality assurance of a probiotic product. Many of these factors should be addressed on the label, including the following:

- All types of bacteria or yeast, including genus and species, should be listed, with their correct spelling. The number of colony-forming units should also be included on the label. The number must be sufficient to allow adequate dosing in reasonable volumes. Generally 1 to 10 billion (10⁹ to 10¹⁰) colony-forming units are recommended (in humans) per day.
- Viability of organisms, which may decrease during time that elapses from manufacture to purchase because of exposure to heat, moisture, and oxygen.
- 3. The presence of contaminating (potentially pathogenic) organisms including *E. coli, Salmonella* spp., *Staphylococcus aureus*, and *Pseudomonas aeruginosa* (according to Food and Drug Administration requirements).
- 4. The extent of enteric protection of selected organisms, including *L. bulgaricus*, *S. thermophilus*, and *Leuconostoc* and *Lactococcus* spp., varies (Table 19-4). Organisms that generally do not need protection include most *Lactobacillus*, *Bifidobacterium*, and *Streptococcus* organisms or organisms present as spores, including *Bacillus* and some *Lactobacillus* spp.

KEY POINT 19-36 Because probiotics and related compounds are not approved products, they undergo no premarket approval with regard to efficacy, safety, or quality; extra care should be taken to find a high-quality product.

Consumer Laboratories might also be solicited to identify superior products. Of 27 products (23 human, 4 pet) reviewed by Consumer Laboratories (as reviewed by the author January 2010), 10 (9 human, 1 pet) failed to contain the labeled amount of microbes and 5(2 human, 3 pet) failed to provide at least 10⁹ colony-forming units per serving (although dogs and cats may require less than 1 billion). Marked variability was found in the dose delivered among pet products. No product failed as a result of microbial contamination (with mold). Weese and coworkers¹⁶⁶ also examined the quality of probiotics, including eight veterinary products. The contents of only two of thirteen products matched labeled descriptions, with five veterinary products not providing specific content information. Some products did not contain all labeled products while some products contained additional bacteria, some of which were potentially pathogenic. Organisms in several products were not viable. These studies emphasize the importance of selecting a probiotic that meets the standards of quality assurance reviews.

DRUGS AFFECTING THE LIVER

Cholagogues and Choleretics

Substances that cause contraction of the gallbladder are called *cholagogues*. The resistance of the sphincter of Oddi decreases as bile flows freely into the duodenum. Dietary fat and concentrated magnesium sulfate introduced directly into the duodenum through a tube exert a cholagogue effect through release of CCK/pancreozymin from the upper small intestine. Vagus stimulation also promotes contraction of the gallbladder.

Substances that increase secretion of bile by the hepatocytes are known as *choleretics*. A drug that stimulates the liver to increase output of bile of low specific gravity is called a *hydrocholeretic*.

Bile acids are synthesized from cholesterol and secreted into bile. Their production is increased by stimulation of the vagus nerves and by the hormone secretin, which increases the water and bicarbonate content of bile. Physiologically, however, bile acids are mainly responsible for the "bile saltdependent" component of bile secretion and flow. Bile salts secreted with bile are almost complete (95%) resorbed, undergoing enterohepatic circulation. Reabsorption occurs principally in the terminal ileum. The primary bile acids are cholic and chenodeoxycholic acids; secondary acids include deoxycholic and lithocholic acid; lithocholic acid and ursodeoxycholic acid (UDCA) represent less than 5% of the total bile salt components. The major salts of bile acids are glycine and taurine. Bile acids induce bile flow, inhibit (by feedback) cholesterol synthesis, and promote dispersion and absorption of lipids and fat-soluble vitamins.

A number of natural bile salts and several partially synthetic derivatives are used therapeutically as choleretics, including dehydrocholic acid, which is the most potent hydrocholeretic agent. Naturally occurring bile acid conjugates such as glycocholate and taurocholate enhance bile flow to a lesser extent. Bile salts used therapeutically have a dual action in directly promoting fat absorption and stimulating biliary secretion after they have been absorbed. Overdosage with these compounds tends to cause diarrhea. UDCA is a natural bile acid constituting a very small portion of the bile acid pool. It is a degradation production of chenodeoxycholic acid. Among the bile acids, UDCA has the lowest hydrophobichydrophilic balance, the lowest capacity to make micelles, and the least potential for cholestatic or cellular membrane toxicity. Because cholestatic liver disease may be associated with accumulation of toxic bile acids, treatment with UDCA is appealing. Its efficacy in a variety of chronic liver diseases has been established. Its mechanism of action is not well understood but is probably related to bile acid metabolism.¹⁷¹ The use of UDCA in dogs suffering from selected cholestatic liver diseases has been documented.¹⁷² The disposition of UDCA has been studied in healthy cats.¹⁷³ Sporadic vomiting and diarrhea were reported, but otherwise the drug appears to be safe. Scientific studies establishing its safety and efficacy in diseased animals are indicated. Bile acids are effluxed from the canicular membrane into bial by a transport protein described as a "sister" to P-glycoprotein. However, selected bile acids, including UDCA, inhibit P-glycoprotein. ¹⁷⁴ The therapeutic implications in patients with cholestasis or being treated with UDCA are not clear.

Liver Protectants and Hepatotropic Agents

A comprehensive review of the treatment and management of hepatic disease is beyond the purview of this chapter. However, a selection of the drugs for treatment of liver failure are listed and the rationale for their use noted. The major pharmacologic properties of many of these substances are discussed elsewhere in this volume. Hepatotropic agents are those having a special affinity for the liver or exerting a specific effect. Lipotropic agents hasten removal of fat or decrease its deposition in the liver. Use of lipotropic agents (choline, methionine, cysteine, betaine, lecithin, hydroxocobalamin) to increase mobilization of hepatic lipid is of proven value only in cases in which deficiencies of these substances exist. Deficiencies may be present in hepatic disease as a result of anorexia or insufficient dietary protein. Patients receiving and consuming a nutritious diet with adequate amounts of protein do not require supplementation with lipotropic agents, but their use has not been shown to be detrimental.

S-adenosyl-L-methionine

S-adenosyl-L-methionine (SAMe) is an endogenous coenzyme composed of ATP and the sulfur-containing amino acid methionine. The methyl group attached to the sulfur of methionine is chemically reactive such that it can be donated (i.e., transmethylation) to a number of acceptor substrates. Up to 80% of methionine in the body is used to form SAMe in the liver, which is the major, but not sole, site of methylation reactions. Regeneration of SAMe depends on vitamins B₆ and B₁₂ and folic acid.¹⁷⁵ Transmethylation represents the primary function of SAMe, although sulfhydryl (transulfation) and aminopropyl (aminopropylation) groups also are donated. As such, SAMe is involved in more than 40 metabolic reactions in the body. Substrates are variable and include nucleic acids, proteins, and lipids. SAMe donates methyl groups to diverse compounds such as choline, creatine, carnitine, norepinephrine, DNA, and transfer RNA.

KEY POINT 19-38 Many hepatoprotectants either facilitate bile acid secretion or promote the activity of glutathione oxygen radical scavenging.

Aminopropylation yields compounds that affect cell and tissue repair. Transmethylation is important in detoxification, energy utilization, gene transcription and membrane functions that influence growth, and cellular signaling and adaptation. Transmethylation is necessary for formation of the phsopholipid bilayer of outer cell membranes and membrane fluidity. After donating its methyl group, SAMe is converted to S-adenosylhomocysteine, the precursor to transsulfuration reactions. Transsulfuration also is important, resulting in the formation of sulfur and thiolated compounds, glutathione (GSH; one of the principle antioxidants of the liver), cysteine (the rate-limiting substrate for GSH formation), and sulfates. Each is particularly important in detoxification and conjugation reactions, including bile conjugation and bile flow. Glutathione has many additional effects on cellular biology, including gene transcription, triggering proinflammatory cell signaling and apoptosis, and also is important as an intracellular scavenger of oxygen radical.

The importance of SAMe in GSH synthesis suggested a possible role in liver disease. Studies in humans have demonstrated that SAMe is associated with an increase in hepatic GSH in chronic liver disease. Bile flow increases, presumably in response to increased sulfate bioavailability; sulfated bile acids are more soluble than others. Lieber¹⁷⁵ reviewed the role of SAMe in the body and its role in the treatment of liver disease in humans.¹⁷⁶ In an original research report, Center and coworkers¹⁷⁷ also reviewed the role of SAMe, with an emphasis in the liver. Multiple hepatic functions are dependent on GSH. Howver, SAMe formation from methionine decreases with severe liver disease as a result of downregulation of SAME synthetase. Sequelae include impairment of multiple hepatic functions as well as retention of methionine, which may contribute to hepatic insufficiency.

Because SAMe is unstable and is destroyed in the GI tract, it must be administered as an enteric-coated product. After absorption, oral bioavailability of SAMe is low on account of first-pass metabolism. Gender differences in oral bioavailability exist for SAMe in humans, with peak concentrations threefold to sixfold higher in women compared with men. SAMe is minimally bound to serum proteins (in humans) and is able to penetrate into and accumulate in cerebrospinal fluid.¹⁷⁴

A case report¹⁷⁸ described the successful treatment of acetaminophen overdose (1 g/kg) in a dog with SAMe and supportive care; treatment was not begun until 48 hours after ingestion. Center and coworkers¹⁷⁷ examined the safety and effects of SAMe on the redox potential in red blood cells and the liver in normal, healthy cats (n=15) receiving 48 mg/kg of SAMe (Denosyl) orally once daily for 113 days. Plasma SAMe concentrations increased in concert with each dose. Peak concentrations approximating 1 to 1.5 µg/mL occurred between 2 to 4 hours after each dose; the disappearance half-life after oral dosing approximated 3 hours. Concentrations did not accumulate during the 113-day dosing period. Unmetabolized SAMe appears to be eliminated almost equally in urine and feces. In humans and normal cats, SAMe was not associated with adverse events. In clinically normal cats, the redox status of both red blood cells and hepatocytes was increased after 113 days of SAMe administration. Further, red blood cells became more resistant to osmotic lysis. Hepatic cysteine, GSH, and protein increased, the latter attributed to an anabolic effect of SAME. Bile flow also increased, and histologic improvement was noted in the seemingly normal cats that had asymptomatic nonsuppurative portal inflammation.

SAMe is among the supplements for which comparison of labeled and actual contents may not match. The hygroscopic nature of SAMe contributes to quality assurance issues in that improper formulation and storage can result in the loss of active ingredient. The lack of premarket approval suggests that consumers should take a proactive approach to ensuring the quality of purchased products. Manufacturers appear to have improved the predictability of high-quality product in that eight of eight manufactured products tested by Consumer Laboratories and reported on its website in 2007 passed evaluation (as of January 2010). This compares to 2003, in which one product was found with only 30% of its listed amount, and in 2000, when close to 50% of tested products contained less than the labeled content (www.consumerlab.com). Entericcoated products are available to protect SAMe from GI acidity; among the tests implemented by Consumer Laboratories is assurance of proper dissolution of enteric-coated products.

KEY POINT 19-39 The hygroscopic nature of SAMe may result in poor-quality product, and efforts should be taken to prescribe a product of known quality.

SAMe is available in several salt forms, each of which weighs a different amount and thus contributes variably to the total weight in mg. Care should be taken to dose on the active ingredient (i.e., SAMe). Salts include tosylate, disulfate tosylate, disulfate ditosylate, and 1,4-butanedisulfonate (Denosyl). For example, 200 mg of S-adenosyl-methionine disulfate tosylate contains only 100 mg of SAMe. The salt name should be included on the label as part of the chemical name, and the label should indicate the amount of active ingredient. SAMe also can be reviewed in the Herb and Plant Supplement at consumerlab.com¹⁷⁹

SAMe may be involved in a number of drug-diet interactions. Because it inhibits uptake of serotonin, any other compound that does likewise should be avoided or used cautiously. This includes antidepressant behavior-modifying drugs such as monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, tricyclics, tramadol, and selected herbs (such as St. John's wort).

Animal studies and clinical human studies indicate that SAMe improves biochemical parameters of liver function.¹⁸⁰

Endogenous concentrations are reduced in patients with cirrhotic liver disease. Production of sulfated compounds and phosphatidylcholine subsequently is reduced. In animal studies SAMe improved bile secretion impaired by a variety of toxins and by pregnancy. Drug-induced hepatotoxicity and chronic liver disease were also reduced, without occurrence of serious side effects.¹⁷⁶ SAMe may act synergistically with UDCA for treatment of chronic progressive liver disease.¹⁸¹ Although absorbed well after oral administration, SAMe undergoes extensive first-pass metabolism.¹⁸⁰ The compound is so hygroscopic that it is unstable unless protected; it might be most.

prudent to use products in bubble packets. Tablets cannot be broken without risking loss of efficacy. Caution is recommended when purchasing SAMe; an independent investigation that compared the content of SAMe with the labeled amounts found 6 of 13 products to be mislabeled. SAMe is marketed with silymarin (discussed in the next section) by Nutramax Laboratories for use in animals.

Milk Thistle

Silymarin has been reviewed by the Herb and Plant Supplement Encyclopedia at consumerlab.com. A member of the daisy family (Asteraceae), silymarin is one of the most important medical constituents of ripe seeds of the blessed milk thistle plant (*Silybum marianum*). The name reflects the legend that attributes the white leaf veins to a drop of the Virgin Mary's milk and the location of the hidden infant Jesus during the family's flight from Egypt. Other synonyms for milk thistle include Marian thistle, Mary thistle, St. Mary's thistle, Lady's thistle, Holy thistle, sow thistle, thistle of the blessed virgin, Christ's crown, Venus thistle, heal thistle, variegated thistle, and wild artichoke.

Silymarin is a combination of seven flavonolignans (a flavanoid). The most prevalent is silybinin (silybin), which itself is two different compounds, with others including silychristin (or silicristin), and silydianin (also silidianin). Although all parts of the plant have been used medicinally,¹⁸² the concentration of silymarin is highest in the seeds and leaves. Generally, the flavonoids are extracted. Silybin is often complexed with phosphatidylcholine, which improves its bioavailability. Dosing should be based on silybinin equivalents. As with flavonoids, the active ingredient of silymarin are potentially potent antioxidants, scavenging hydroxyl radicals, superoxide anions, and lipid oxygen radicals owing to lipid peroxidation.

Animal models (including tetrachloromethane hepatotoxicity in dogs and a variety of other hepatotoxicants) support a hepatoprotective effect. Its mechanism of hepatoprotection is not known. Suggested mechanisms include increased hepatic regeneration (by stimulating RNA polymerase, ribosomal RNA, and potentially DNA synthesis), scavenging of oxygen radicals, "stabilization of " hepatocyte cell membranes, and competitive inhibition of toxins that might otherwise bind to hepatic and damage cell membrane receptors (e.g., Amanita phalloides). In rat and mice models of acetaminophen toxicosis, silymarin was associated with higher concentrations of hepatic glutathione and superoxide dismutase in experimental compared with control animals. Silymarin can also bind to steroid receptors, although the clinical relevance of this is not clear. Antifibrotic effects have been demonstrated in animal models. Finally, antinflammatory effects may reflect inhibition of lipoxygenase and subsequent leukotriene synthesis.¹⁸²

KEY POINT 19-40 SAMe and milk thistle are among the few dietary supplements for which evidence of efficacy for treatment or prevention of liver disease exists.

Silymarin is poorly water soluble, and concentrated products are considered necessary for effective absorption. According to Consumer Laboratories, most studies involving silymarin are based on extract products that contain 70% to 80% silymarin on a weight basis. However, some products composed of seed powder contain only 1.5% silymarin. Quality assurance is likely to be an issue with silymarin: of eight products tested by Consumer Laboratories, only two contained the labeled amount. The remaining seven products ranged from 19% to 85% (median 64%). When properly labeled, the source of milk thistle (generally the seed) should be noted on the product. Care must be taken when dosing on the basis of label information; doses range from 15 to 1200 mg, reflecting in part the source and type of preparation. For example, pills made from seed powder contain about 9 to 15 mg of silymarin compared with 112 to 240 mg for pills made from dry extracts. Differences in doses may also reflect different salt preparations. In humans the phosphatidylcholine preparation may be more orally bioavailable, leading to a dose that is lower (1.5 to 3 mg/kg twice daily) compared with a 70% extract (3 mg/kg twice to thrice daily).

As a flavonoid, silymarin is an inhibitor of P-glycoprotein and should be used cautiously with drugs known to serve as substrates for the transport protein. Silymarin may also inhibit selected CYP450 (specifically P450 2C9) enzymes.

Milk thistle is used to prevent or treat a number of medical conditions, including hepatitis (acute or chronic), and to protect the liver from toxicants, including medications. Milk thistle is the most common alternative medicine used in humans for treatment of liver diseases, with more than 50% of users claiming efficacy. Other proposed health benefits of silymarin include improved diabetic control. An intravenous preparation of silybinin is available in Europe for treatment of mushroom poisoning caused by *A. phalloides*. Note that as of January 2010, of the 10 milk thistle products tested by Consumer Laboratories, nine did not pass, the primary reason being that the actual amount was less than the label claimed amount.

Miscellaneous Vitamins, Minerals, and Nutrients Choline

Choline is an indispensable metabolite of the body. It forms part of a number of endogenous compounds, particularly phospholipids. Phosphatidylcholine, lysophospholipids, plasmalogens, and sphingomyelins are phospholipids that contain choline. The mode of action of choline as a lipotropic agent is unknown. It may promote conversion of liver fat into cholinecontaining phospholipids, which are more rapidly transferred from the liver into blood. Choline is also essential for synthesis of phospholipids that are used in intracellular membranes concerned with lipoprotein synthesis. It is thought that the lipotropic agents methionine, betaine, and lecithin are beneficial because they contain choline or promote choline synthesis. The requirement for choline is well recognized in all conditions predisposing to fatty infiltration of the liver, including diabetes mellitus, malnutrition, and cirrhosis. Greater than normal quantities of choline seem to be necessary for prevention of a fatty liver when the liver is already damaged. Choline deficiency is not the only cause of fatty liver in these conditions, nor will choline supplementation alone restore the liver to full functional competence. Choline is, however, extremely valuable in the multitherapeutic approach to prevention and cure of fatty liver.

Selenium and Vitamin E

Selenium is now known to be essential for tissue respiration and is protective against dietary hepatic necrosis. It is extremely active and is only required in minute amounts. Vitamin E enhances the action of selenium, but both are required.

Selenium is an essential component of glutathione peroxidase, which catalyzes oxidation of reduced glutathione:

(2)Glutathione-SH + H_2O_2 (reduced form) \rightarrow Glutathione - S - S glutathione + 2 H_2O (oxidized form)

This glutathione peroxidase catalyzes removal of hydrogen peroxide and fatty acid hydroperoxides and thus exerts a protective effect on all cells but especially on muscle, liver, and erythrocytes. The essential substances required for removal of peroxides are reduced glutathione and glutathione peroxidase. Vitamin E maintains glutathione in the reduced form by preventing formation of hydroperoxides; it is an antioxidant and thus reduces the amount of glutathione peroxidase required. Cysteine (*N*-acetylcysteine) is required for the reduced sulfhydryl radical of glutathione and is generally present in adequate quantities. Selenium and vitamin E enhance each other's action and together protect cells, especially hepatocytes, against harmful buildup of peroxides.

Vitamins

In the presence of liver disease, the fat-soluble vitamin K should be supplemented because hepatic stores may be quite rapidly depleted. The water-soluble vitamins of the B-complex group are frequently employed in therapeutic regimens for hepatic insufficiency. Few controlled studies have been carried out in this regard, but the rationale behind their clinical use is based on ensuring an adequate supply of metabolic cofactors.

Hydroxocobalamin (previously called vitamin B_{12}) is stored in the liver, mainly in mitochondria, but there is also a microsomal fraction. This microsomal vitamin may be of importance in hepatic protein metabolism. Microsomal cell fractions from the livers of hydroxocobalamin-deficient animals are defective in the incorporation of methionine and alanine into protein. General liver protein synthesis is depressed in hydroxocobalamin deficiency.

Hydroxocobalamin has a lipotropic effect. It is involved in metabolism of labile methyl groups and in formation of choline. Hydroxocobalamin is also necessary for overall utilization of fat. When intake is low, however, the demand for this vitamin in hematopoiesis exceeds that for any other clinically recognizable physiologic function.

Glucose and Fructose

The liver resists many forms of injury when its stores of carbohydrate and protein are adequate; its efficiency is impaired when hepatocytes are laden with fat. Administration of a hypertonic solution of glucose and fructose produces favorable responses in a variety of hepatic abnormalities. A high glycogen content appears to protect liver cells from damage, and inhibition of gluconeogenesis (which occurs with administration of both insulin and glucose) may play an important role. Under the influence of insulin, hepatocytes undergo glycogen storage, hypertrophy, and hyperplasia. Insulin has a major anabolic effect on the liver.

TREATMENT OF SPECIFIC (NON-INFECTIVE) DISORDERS OF THE GASTROINTESTINAL TRACT

Treatment of gastrointestinal disorders frequently involves drugs that target the disease rather than the gastrointestinal tract. Enhanced discussion of such conditions or the drugs used to treat them might be found in their respective chapters (i.e., Treatment of Bacterial Infections [Chapter 8], Glucocorticoids [Chapter 30] or Immunomodulators [Chapter 31]). Treatment of specific infectious diseases also will be found in chapters that address treatment of the causative organisms.

Diseases of the Oral Cavity

The primary treatment for the feline eosinophilic granuloma complex is glucocorticoids,183 given orally (prednisone, 1 to 2 mg/kg twice daily), subcutaneously (methylprednisolone acetate, 20 mg every 2 weeks), or intralesionally (triamcinolone, 3 mg weekly). Progestational compounds such as methylprogesterone may prove beneficial, but side effects associated with long-term use (including hyperadrenocorticism and diabetes mellitus) should limit their use to cases that have not responded to any other (properly administered) drug therapy. Up to 50% of treated cats may relapse. Because of the potential impact of leukotrienes on eosinophil trafficking (see the section on inflammatory bowel disease), leukotriene receptor antagonists might be considered. Stomatitis may be a reflection of an autoimmune skin diseases, renal disease, microbiologic infection (viral, bacterial, or fungal) or may be idiopathic. Antimicrobial therapy should be considered in cases of idiopathic stomatitis; therapy may be necessary on a chronic, intermittent basis. Drugs should target anaerobic organisms (e.g., metronidazole, a penicillin derivative, or clindamycin). Glucocorticoid therapy should be used cautiously in stomatitis unless an autoimmune disorder has been diagnosed or other causes (including infectious ones) have been ruled out.

Diseases of the Esophagus

Megaesophagus

Myasthenia gravis is the most common cause of secondary megaesophagus in dogs. It is diagnosed on the basis of response

to edrophonium chloride, a short-acting anticholinesterase.¹⁸⁴ Effects of the drug on skeletal muscle occur within 1 minute of intravenous administration and last up to 10 minutes or longer in some myasthenic patients. Drug therapy of megaesophagus associated with myasthenia gravis targets improvement in muscular activity with anticholinesterase therapy (pyridostigmine bromide, 1 to 3 mg/kg orally every 12 hours) and suppression of the immune response with glucocorticoid or other immunosuppressive therapy (e.g., azathioprine). Pyridostigmine improves appendicular muscle strength but may not improve pharyngeal or esophageal function. Prednisone tends to be the preferred glucocorticoid but may contribute to muscle weakness. Azathioprine does not have many of the side effects of glucocorticoids, but remission takes longer to achieve (up to several weeks), and neutropenia may limit treatment. Mycophenolate mofetil is a lymphocyte-inhibiting immunomodulator used orally to prevent graft-versus-host rejection in human renal transplant patients. The drug inhibits purine synthesis but only in lymphocytes (both B and T lymphocytes), and side effects are limited to GI upset. The drug can be given orally, causing response within 4 hours of administration. The drug has proved efficacious for treatment of myasthenia gravis in dogs (5 to 10 mg/kg every 12 hours orally).¹⁸⁵ Thyroid hormone replacement (thyroxine) may also prove helpful. Treatment for megaesophagus for which an underlying cause cannot be found is difficult. A number of drugs that stimulate GI smooth muscle have been recommended, including metoclopramide and cisapride, with varying reports of success. Neither of these two prokinetic drugs are likely to be effective in the striated muscle of the esophagus; further, enhanced lower esophageal sphincter tone might impede esophageal emptying. Bethanechol may stimulate propagating contractions in selected dogs. Drugs that relax the lower esophageal sphincter (anticholinergics and calcium channel blockers) have not proved effective. A major focus for treatment of myasthenia gravis is prevention of aspiration pneumonia and treatment or prevention of esophagitis.

Esophagitis

Esophagitis should be treated by correction of the underlying etiology. It is commonly associated with ingestion of a corrosive or hot (thermally) material. The feline esophagus appears to be particularly susceptible to drug-induced esophagitis (discussed in the following section). Antibiotic therapy in such cases should be reserved for esophageal perforation. The mucosa can be protected by administration of sucralfate administered as a slurry (1 g in 10 mL warm water), 5 to 10 mL every 6 to 8 hours. Lidocaine solution (Xylocaine viscous solution) may be administered orally (2 mg/kg every 4 to 6 hours) to minimize pain. Esophagitis caused by gastroesophageal reflux should respond well to medical management. In addition to protecting the damaged mucosa with sucralfate, drug therapy targets increasing gastric pH and tightening the lower esophageal sphincter. Antisecretory drugs (e.g., famotidine, omeprazole) help minimize damage induced by gastric acid and pepsin. Among the antihistaminergic drugs, ranitidine and nizatidine have prokinetic activity in humans comparable to that of cisapride, an effect evident within 1 hour after administration.¹²⁸ Interestingly, a peppermint-caraway oil preparation induced relief from dyspepsia equal to that produced by cisapride in human patients.¹⁸⁶ Antacids may also prove beneficial; products containing alginic acid may provide additional protection of the esophagus by providing a barrier of foam. Prokinetic drugs should be administered to tighten the lower esophageal sphincter. Indeed, metaclopramide or cisapride is probably as effective as antisecretory drugs in preventing further esophageal damage associated with gastric reflux. Glucocorticoids can be used to minimize esophageal stricture formation resulting from damage to the esophagus that extends into the muscular layers. Therapy should include tapered doses of glucocorticoids followed by reevaluation at 2-week intervals. Pentoxifylline may be an alternative or adjuvant therapy, particularly for drug-induced esophagitis.187

Gastroesophageal Reflux

Up to 60% of humans are considered to be at risk for developing perioperative gastroesophageal reflux (GER), whereas GER was demonstrated in 17% to 55% of healthy dogs. The difference in incidence of GER between these studies might be attributable to differences in the anesthetic agents used.

Metaclopramide prevents GER in unanesthetized dogs, as was demonstrated experimentally.¹⁸⁸ Wilson and coworkers¹⁸⁹ also prospectively studied the effect of metoclopramide on GER (defined when esophageal pH to <4 or an increase to >7.5 that lasted more than 30 seconds) in anesthetized dogs. Animals were undergoing orthopedic surgical procedures; anesthetic protocols (morphine and acepromazine as premeds and thiopental for induction) and surgical positioning were the same in treatment and placebo (saline) groups. Blinded and randomization methods were not clear. The authors determined, after reviewing the medical records of dogs undergoing the same surgical procedures and anesthetic protocols, that 55% of dogs experienced GER. A high dose (1 mg/kg followed by constant-rate infusion [CRI] 1 mg/kg/hr) but not a low dose (0.4 mg/kg followed by 0.3 mg/kg/hr CRI) of metoclopramide reduced the relative risk of GER by 54%. The timing of metoclopramide administration in relation to anesthesia was not provided. Vomiting occurred preoperatively in 55% of animals but was not a predictive factor for the risk of GER. No adverse effects attributed to treatment were identified. Preoperative vomiting in response to preanesthetic agents was not a risk factor for GER in dogs, whereas the duration of surgery (but not anesthesia) tended to be a risk factor.¹⁹⁰ Wilson and coworkers¹⁹⁰ compared the effects of pre-anesthetic morphine to mepiridine with or without acepromazine in healthy dogs (n = 30) using a randomized design. When compared with morphine, treatment with meperidine alone or with acepromazine before anesthesia was associated with a 55% and 27% risk reduction in risk of developing GER. In this same study, GER was detected in 51 of 90 dogs within 36 minutes of induction isoflurane (n = 14), halothane (n = 19) or sevoflurane (n = 18).

Esophogeal Motility and Oral Medications

The association of doxycycline administration with esophageal lesions in cats^{191, 191a} has led to several studies focusing on passage of medications through the feline esophagus. In one study, approximately 50% of capsules were retained in the midcervical esophagus of cats for longer than 240 seconds. Trapped capsules passed into the stomach if a small amount of food was administered.¹⁹² A prospective study used fluoroscopy to document the esophageal transit of barium tablets (20 mg) or capsules (size 4) in cats.¹⁹³ The percentage of swallows needed for successful passage (movement of the medication into the stomach) of each medication was determined when administered with or without a follow-up bolus of water (6 mL). Success was only 36.7% 5 minutes after administration, compared with 90% at 30 seconds and 100% at 90 seconds if the medication was followed with a water bolus. The study was performed in a nonrandomized fashion, with the "wet" study always following 5 minutes after a "dry" study. Retention of dry medicaments was generally in the cervical esophageal region.¹⁹³ Treatment should consist of an antisecretory drug, sucralfate, and metoclopramide. An anti-inflammatory may be helpful; glucocorticoids have been used, but pentoxyfylline might also be considered.

Diseases of the Stomach

Acute Gastritis

Acute gastritis is best treated by resolution of the underlying cause, whether it is diet, infectious agents or chemicals (including drugs or toxins), or metabolic diseases (e.g., renal or liver disease). Chemicals, including hydrochloric acid and bile acids, can induce vomiting as a result of direct damage or hypertonicity. Inflammation, if allowed to progress, can result in erosion and ulceration. Although most patients with acute gastritis improve in 1 to 5 days, some patients require supportive therapy.¹⁹⁴ Depending on the patient, supportive therapy (in addition to nothing given orally) may include fluid therapy, antiemetics, and protectants or adsorbents. Fluid therapy with balanced crystalloids may require the addition of potassium. Bicarbonate is rarely indicated; glucose supplementation may be indicated in some patients. Any of the antiemetics previously discussed can be used, although phenothiazine derivatives should be withheld until volume replacement has begun. Metaclopramide is useful when given either peripherally or centrally; maropitant is likely to be very effective. Among the protectants, bismuth subsalicylate has proved most useful in decreasing vomiting associated with acute gastritis. However, gastric distention from the drug may cause the animal to vomit; therefore prudence is indicated in its use.

Gastric Ulceration and Erosion

There is no sensitive indicator of damage to the GI mucosa; damage may be quite extensive before hematemesis or melena is noted. Damage to the GI mucosa (erosion or ulceration) probably occurs more frequently than anticipated. For example, up to 25% of human patients admitted to intensive care units have gastric erosions; by the third day of hospitalization, this number increases to 90%. The risk of translocation of enteric pathogens is increased in these patients, suggesting an important role for prophylactic anti-ulcer therapy. Sucralfate has been recommended as the preferred method of prophylaxis in patients in whom enteral nutrition is not possible.¹⁹⁵ Diseases in which mucosal damage should be anticipated and treatment implemented include but are not limited to mast cell disease, renal disease, liver disease, and IBD. The underlying cause of ulceration must be resolved; additionally, antisecretory drugs and antacids are indicated for treatment of mucosal damage.

Nonsteroidal antiinflammatory drugs. The most commonly recognized cause of GI ulceration in dogs is probably use of NSAIDs. The primary mechanism of ulceration by NSAIDs is inhibition of both the constitutive and inducible forms of cyclooxygenase, the enzyme responsible for formation of the cytoprotective prostaglandin E (see Chapter 29). The latter (inducible) enzyme is particularly important for healing in the damaged gastrointestinal mucosa. Alteration of ion (probably hydrogen) transport across the mucosa also has a variable role in ulcer formation, depending on the NSAID used (e.g., aspirin).¹⁹⁶ Ulcerogenic drugs (e.g., glucocorticoids, which also inhibit the inducible cycclooxygenase) but potentiate ulceration caused by NSAIDs. Treatment of NSAID-induced GI ulceration includes discontinuation of the drug; replacement of missing prostaglandins by administration of cytoprotectants such as misoprostol; providing cytoprotection through sucralfate; and inhibiting acid secretion by administration of an antisecretory drug (e.g., ranitidine or omeprazole). Sucralfate, misoprostol, H₂-receptor antagonists and proton-pump blockers have been studied either as sole agents or in various combinations for their ability to prevent GI ulceration in patients requiring high doses or long-term NSAID therapy. Among them, misoprostol probably provides the most consistent protection, followed by sucralfate and then antisecretory drugs. Although famotidine was found to be equal in efficacy to misoprostol for treatment of NSAID-induced ulceration in humans,¹⁹⁷ the H₂-receptor blockers are described as having only limited efficacy, particularly for ulcers in the stomach, unless it is used at higher than (generally twice) recommended doses¹⁹⁸ Proton pump inhibitors have proved superior to H₂receptor antagonists for treatment of NSAID-induced ulceration.198

KEY POINT 19-41 Sucralfate has been associated with effective prevention of ulcers associated with nonsteroidal antiinflammatory drugs and stress.

The effect of misoprostol (3 mg/kg orally every 8, 12, or 24 hours) on gastric injury induced by aspirin (25 mg/kg orally every 8 hours) was studied prospectively in normal dogs (n = 24; 6 dogs per group) using a parallel, placebo-controlled design. Animals were dosed with aspirin and either placebo or misoprostol, the latter at 8- or 12-hour intervals, for 28 days with gastroscopy performed on -9, 5, 14, and 28 days. Visible lesions were scored on a scale of 1 (mucosal hemorrhage) to 11 (perforating ulcer). Median total scores between the placebo or misoprostol at 24 hours were significantly greater than scores in the group receiving misoprostol at 8-or 12-hour intervals.

In contrast, no differences were measured between placebo and misoprostol at 24-hour intervals. Differences were not detected among groups for vomiting, diarrhea, or anorexia.¹⁹⁹

In cases of NSAID overdosing (including accidental ingestion), prophylactic administration of both sucralfate and misoprostol is recommended along with an antisecretory drug. The duration of antiulcer therapy depends in part on the elimination half-life of the drug and the amount of NSAID ingested. The elimination half-life of some of the drugs is several days, suggesting that toxic concentrations may remain in the bloodstream for some time (1 to 2 weeks). Omeprazole may prolong the half-life of the NSAID, suggesting that treatment duration should err on the side of too long rather than too short. Prevention of NSAID-induced ulceration in humans is best accomplished with proton pump inhibitors; omeprazole was superior to either ranitidine or misoprostol after 6 months of NSAID therapy for reducing the risk of either gastric or duodenal ulcer.²⁰⁰ Omeprazole also may be the preferred choice in dogs; at least twice daily dosing also is recommended for famotidine.⁸⁷ Because of its potential to impair drug metabolism, omeprazole might be less desirable than the antihistaminergic antisecretory drugs when preventing ulcers in order to avoid prolonging NSAID half-life. Administration of cytoprotective agents for treatment of ulcers depends on the drug and the amount ingested. In general, treatment should extend at least 1-2 weeks after the inciting NSAID has been eliminated (i.e., at least 5 half-lives of the inciting NSAID or longer in the case of accidental ingestion that saturates drug metabolizing enzymes). Administration of cytoprotective antacids such as magnesium-aluminum hydroxide combinations with a meal may provide further protection.

Stress ulcers. A European meta-analysis (Mantel–Haenszel test) found that sucralfate was superior to H_2 antisecretory drugs and equal to antacids in the prevention of macroscopic stress bleeding in long-term ventilated patients in an intensive care unit. Further, the incidence of pneumonia (caused by nosocomial organisms) was less in those ventilated patients receiving sucralfate compared with antacids or antisecretory drugs.²⁰¹

The efficacy of omeprazole (20 mg orally once daily) in prevention of exercise-induced gastric ulceration in Racing Alaskan Sled Dogs (three teams of 16) was tested using a randomized placebo design.²⁰² Response was based on endoscopic scoring of the gastric mucosa after completion of the race (0=least, 3=numerous bleeding ulcers). Mean score was significantly less (0.65) for treatment compared with placebo (1.09), although diarrhea was worse in the treatment group (54%) compared with placebo (21%). The percentage of animals that developed ulcers between the two groups was not reported. Williamson and coworkers²⁰³ subsequently reported on the efficacy of famotidine in this study.

Helicobacter species. H. pylori infects over 50% of the global human population. Infection will persist for life, unless specifically treated. All infected persons develop gastritis, with 15% of infected persons developing peptic ulceration. Infection also is associated with an increased risk of gastric adenocarcionoma and mucosa-associated lymphoid tissue

lymphoma; indeed, it is classified as a class 1 carcinogen by the World Health Organization.^{209a} The role of *Helicobacter* species as causal agents in GI diseases in dogs and cats is being elucidated. It is likely that a causal relationship exists between the organism and the disease.

A causal relationship also has been suggested in ferrets, cheetahs, and cats. Clinical signs attributed to Helicobacter organisms in dogs and cats include chronic vomiting and diarrhea, inappetence, pica, and fever.²¹⁰ More than 70% of human patients with GI ulceration associated with Helicobacter organisms are cured of their ulcerative disease if Helicobacter is successfully eradicated. The pathophysiology of Helicobacter in part reflects urease-mediated conversion of urea to ammonia and bicarbonate. Ammonia causes local tissue damage, whereas bicarbonate appears to facilitate deeper colonization of the organism into the mucosa.²¹⁰ Cytokine production by the organism appears to be associated with inflammation and ulcerogenesis; biochemical changes in the mucosa also contribute to disease. Treatment includes a colloidal bismuth (i.e., bismuth subsalicylate), an antibacterial that targets Helicobacter (metronidazole, amoxicillin, or clarithromycin), and an antacid (an H₂-receptor antagonist or omeprazole). Bismuth accumulation causes cell wall damage and subsequent cell lysis. Among the antibacterials selected, amoxicillin is associated with the greatest and clarithromycin with the least amount of microbial resistance in humans. Resistance to metronidazole is also increasing. The duration of therapy in humans is several weeks. Reports of similar therapy in dogs and cats support but do not conclusively prove this approach may be beneficial in dogs and cats suffering from selected GI diseases. One study reported marked improvement in 90% of dogs and cats treated with a combination of metronidazole, amoxicillin, and famotidine for 3 weeks. Sucralfate may also be of benefit.

Gastric Dilatation–Volvulus

Therapy for gastric-dilatation volvulus (GDV) focuses on management of this acute and potentially life-threatening disease and long-term prevention. Medical management of the patient with acute disease focuses on resolution of the dilatation or volvulus and treatment of the sequelae of the syndrome. The sequelae of GDV that are most life-threatening are decreased cardiac preload (compression of the posterior vena cava and hepatic portal systems by the enlarged stomach), ischemia of the gastric wall (with loss of the mucosal barrier and increased risk of perforation), and congestion of abdominal viscera with subsequent endotoxemia and disseminated intravascular coagulation. Although they are potentially later in onset, cardiac arrhythmias also may become life-threatening. Shock should be treated with a balanced crystalloid electrolyte solution or hypertonic saline. Shock doses of glucocorticoids (methylprednisolone) may ameliorate some of the signs or clinical sequelae of endotoxemia although evidence for such use is lacking. Free radical scavengers (deferoxamine or allopurinol) may help reduce damage caused by reperfusion. Methylprednisolone may also be helpful in minimizing the effects of oxygen radicals The impact of prophylactic lidocaine on reperfusion injury was retrospectively studied in dogs (n = 51; 47 nontreated dogs served as control). Animals receiving lidocaine for cardiac arrhythmias were excluded from study. Dogs received either a loading dose (2 mg/kg intravenously) followed by CRI or a CRI alone (0.05 mg/kg/min) for at least 3 hours. No difference was detected in survival or complications between the two groups, although hospitalization was longer in the treatment group.²⁰⁴

Decompression of the dilated stomach can be facilitated by chemical restraint or sedation. Oxymorphone may be the drug of choice. Cardiac arrhythmias are most commonly ventricular in origin but may include atrial arrhythmias such as fibrillation. Intravenous lidocaine is the preferred drug for ventricular arrhythmias, administered initially as an intravenous bolus followed by a CRI (75 µg/kg/min). Procainamide can be used (intravenously, including CRI if lidocaine is ineffective; mexiletine) may be preferred. Amiodarone may also be used to acutely treat atrial fibrillation. Use of anti-secretory drugs is recommended to minimize the effects of hydrochloric acid on the already damaged mucosa. Although antimicrobials may be indicated, their use ideally is limited to situations in which contamination is known (i.e., surgical) or translocation is likely. Corrective surgery, including gastropexy, may be indicated. Medical management of chronic GDV has not been well established. Motility modifiers (metaclopramide, cisapride) and H2-receptor antagonists may be indicated, particularly after an acute episode, to minimize the accumulation of gastric secretions. However, their efficacy has not been established.

Gastric Motility Disorders

Dietary management of delayed gastric emptying should precede pharmacologic management. Underlying causes, including electrolyte abnormalities, should be corrected, and use of concurrent drugs (e.g., anticholinergics, alpha-adrenergics, opioid antagonists) that might alter motility or response to prokinetic agents should be discontinued. Prokinetic agents can be added when dietary management fails; cisapride is preferred.

Vomiting

For many causes of vomiting, studies regarding the etiology, prevention or treatment in animals are lacking. Accordingly, much of the information is drawn from the human literature. The discussions are offered as points of consideration, recognizing that relevance to dogs or cats remains to be demonstrated.

Chemotherapy-induced Emesis

Ellebaek and Herrstedt²⁰⁵ reviewed the prevention and treatment of nausea associated with chemotherapy in humans. The relative emetogenic potential of antineoplastic agents was described. In humans level 1 agents (lowest potential; <10% of patients) include chlorambucil, hydroxyurea, interferon α , tamoxifen, and vincristine; level 2 (10% to 30%): asparaginase, fluorouracil, gemcitabine, melphalan, paclitaxel, and thiopeta; level 3 (30% to 60%): cyclophosphamide (at <600 mg/m₂), doxorubicin, methotrexate (<1000 mg/m₂), and mitomycin; level 4 (60% to 90%): busulfan, carboplatin, cyclophosphamide ($\geq 600 \text{ mg/m}_2$), doxorubicin ($>60 \text{ mg/m}_2$), methotrexate ($\geq 1000 \text{ mg/m}_2$), and mitoxantrone; and level 5, the highest (>90% incidence): cisplatin ($\geq 60 \text{ mg/m}_2$), cyclophosphamide (1000 mg/m_2), pentostatin, and others.^{205a}

Chemotherapy-induced vomiting appears to reflect the release of serotonin from enterochromaffin cells of the GI mucosa with subsequent stimulation of type 3 vagal afferent 5-HT₃ serotonin receptors in the mucosa, the nucleus tractus solitarius of the medulla oblongata, and the CRZ. At the CRZ, D₂, opioid, and 5-HT₃ receptors stimulate vomiting. Neurokinin receptors in humans are responsible for the delayed phase of vomiting associated with cisplatin anticancer chemotherapy. Maropitant appears to be effective for control of chemotherapy-induced emesis in dogs.^{205a,b} Rau and coworkers demonstrated the efficacy of maropitant (2 mg/kg PO once daily) for control of vomiting associated with doxorubicin administration in dogs (n = 25) with cancer. Dogs were studied using a randomized, placebo-controlled study (n = 24) for 5 days posttreatment. Both vomiting and diarrhea were significantly less in the treatment group.^{205a} D₂ antagonists, such as phenothiazines and butyrophenones, have limited efficacy in humans in preventing acute vomiting associated with chemotherapy, with their use limited primarily to combination therapy for breakthrough nausea and vomiting. In a comparative study of humans undergoing cisplatin chemotherapy, antiemetic efficacy of metoclopramide was evident at 0.54 mg/L with efficacy as an antiemetic being dose dependent.²⁰⁶ Glucocorticoids, and specifically dexamethasone, improve the antiemetic efficacy of metoclopramide in humans; trials in dogs or cats are lacking. However, acute nausea induced by chemotherapeutic agents appears to be best prevented by the combination of dexamethasone (0.22 mg/kg intravenously) with serotonin antagonists. Among the antiserotinergic drugs, no differences in clinical efficacy appear to exist between ondansetron and dolasetron; however, granisetron, although not necessarily more effective, may last twice as long, perhaps because of its tighter affinity for serotonin receptors.

Postoperative Nausea and Vomiting

The use of antiemetics to prevent or treat postoperative nausea was reviewed by Ku and Ong.²⁰⁷ The incidence of postoperative vomiting in humans receiving volatile anesthesia ranges from 20% to 30%. Risk or predictive factors include age, gender (greater in females), history of vomiting or motion sickness, and duration and type of surgery and anesthesia. Opioid preanesthetics increase and alpha-2 agonists decrease the risk. Intraoperative drugs that increase the risk in humans include nitrous oxide (especially in patients already vomiting), whereas the more potent volatile anesthetics are associated with less vomiting compared with the less potent anesthetics. Propofol as an inducing agent causes less vomiting than do thiopental, etomidate, and ketamine; propofol also may reduce vomiting associated with general anesthesia.²⁰ The impact of anticholinergics (atropine) or neuromuscular blockade antagonists (neostigmine) on postoperative emesis is less clear, although the incidence is reduced with the combination of the two agents. As with preoperative opioids, postoperative opioids increase the risk of nausea and emesis (due to direct stimulation of the CTZ and decreased GI motility) even if pain is effectively controlled. The incidence of vomiting associated with opioid-induced analgesia can be reduced by using those opioids associated with less emesis, and balanced analgesia.

Treatment of postoperative emesis is approached by either preventing or rescuing the patient. Drugs used as preventives include antagonists of H₁ receptors (dimenhydrinate), muscarinic receptors (scopolamine patch), and 5-HT₃ receptors (ondansetron or other carbazalone derivatives). Glucocorticoids (dexamethasone [0.11 to 0.14 mg/kg] and methylprednisolone), whose antiemetic mechanisms are unknown, also are recommended (administered intravenously) in patients with a high risk. Their use is more effective when combined with other antiemetics, particularly 5-HT₃ antagonists. The NK₁ receptor antagonists have recently undergone investigation, with early information in humans suggesting that NK₁ antagonists may be more effective than 5HT₃ receptor antagonists; accordingly, maropitant is reasonable choice in dogs or cats. Combinations are recommended over single drugs when treating breakthrough vomiting or nausea. Examples include 5-HT₃ receptor antagonists with antihistaminergic drugs (e.g., ondansetron with cyclizine or promethazine) or combinations of droperidol, metoclopramide, or dimenhydrinate.²⁰ Combinations with an NK₁ receptor antagonist should be considered. Ideally, the combination would not include a drug that has already failed to control vomiting.

Postoperative lleus

In humans, the time for gastric motility to recovery postoperatively ranges from 24 to 48 hours, the colon 48 to 72 hour. Thus, even with uncomplicated ileus, the time to recovery after surgery is 72 hours or less. The efficacy of metoclopramide in treating or preventing postoperative ileus has been studied in humans with conflicting results.²⁰⁸ In an observational, prospective study design, Seta and Kale-Pradhan²⁰⁸ found no difference in time to first bowel movement in intensive care unit patients that received metaclopramide postoperatively compared with those that did not. The drawbacks of this study include its design (nonrandomized, nonblinded, and non-placebo controlled) and very small sample size (n = 32; 16 per group). The authors reviewed the impact of metoclopramide on the effects of postoperative ileus in the report. Differences in dose, poor end points, and variability in study subjects (including surgical procedures) preclude consensus among the studies. Further, differences in opioid use among treatment groups generally has not been addressed. Time to reduction in oral feeding was a more frequent positive indicator of response to metoclopramide than was time to first bowel movement. However, the authors caution that the time to first bowel movement more likely reflects initiation of an oral diet, and studies using both outcome measures must address cause and effect. The review of the studies regarding the effect of metaclopramide on postoperative ileus are inconclusive.

The effect of lidocaine as a prokinetic for treatment of postoperative ileus after abdominal surgery has been the subject of a Cochrane Review of randomized clinical trials in humans.²⁰⁹ A review of 39 trials found that the data were insufficient (generally owing to inconsistent outcomes, small sample size, or poor data-collection methods) to recommend the use of CCK-like drugs, cisapride, dopamine antagonists, propranolol, or vasopressin. The authors noted that cisapride has been withdrawn from the marked, and further consideration was not given. Fifteen trials had reviewed alvimopan, a peripheral mu receptor antagonist that currently is an investigational drug. The authors noted that alvimopan may prove effective but further information was needed to define the criteria for use. Erythromycin was found to be consistently ineffective. Of the drugs studied, only intravenous lidocaine or neostigmine were considered potentially effective, but further assessment based on clinically relevant outcomes was indicated. No major adverse events to any of the drugs was noted in the review.

For postoperative ileus induced by opioids, treatment options include stimulant laxatives, oral naloxone, prokinetic agents (metoclopramide should follow an opioid antagonist), and potentially alvimopan. Misoprostol (high dose; approximately $6 \mu g/kg$ in humans) also might be considered; because this dose might be associated with nausea (in humans), a lower dose, given more frequently, may be necessary. Therapy should begin early.

Small Intestinal Diseases

Diarrhea

Acute diarrhea. Like vomiting, diarrhea should be managed by providing supportive therapy, treating symptoms, and resolving the underlying cause with specific therapy.²¹⁰ Generally, intestinal causes of acute diarrhea include diet, toxins or drugs, and infections (including viral, microbial, and parasitic). A number of extraintestinal diseases include diarrhea as a manifestation. For many diarrheas rehydration and maintenance of hydration and electrolyte balance are the cornerstones of therapy Antiemetics should be used to control vomiting accompanied by acute diarrhea. Those antiemetics that cause hypotension (e.g., phenothiazine derivatives) should be withheld until fluid replacement has begun. Protectants and adsorbents are indicated for diarrheas associated with toxins (including "garbage enteritis") and may be used for nonspecific (undiagnosed) causes of acute diarrhea. Kaolin may be useful for its adsorbent properties. Bismuth subsalicylate provides both adsorbent and antiinflammatory effects and is the preferred antidiarrheal agent for toxinassociated diarrheas.

Motility modifiers must also be used with discretion for treatment of diarrhea. Hypomotility rather than hypermotility is the more likely abnormality, and most motility modifiers cause hypomotility. Further, such drugs are often associated with side effects. However, among the motility modifiers, opioid drugs such as loperamide increase resistance to outflow as well as provide antisecretory effects. As such, of the motility modifiers, the opioid derivatives are preferred for short-term use as long as toxins, drugs, or obstructive disease have been ruled out as causes. Anticholinergic motility modifiers are reserved for psychogenic causes of acute diarrhea.

Viral Enteritis

There is no specific treatment for diarrheas of viral origin. Fluid therapy, electrolyte replacement, and antiemetics are indicated, depending on the severity of clinical signs. Among the viral causes of diarrhea, canine parvovirus stands out for its severity and life-threatening nature. Intensive, aggressive care such as that offered at tertiary hospitals can increase survival rates to 96% compared with 67% at local practitioners. The rate of survival with no therapy may range from 64% to 79%.²¹¹ Supportive therapy centers around the intravenous administration of balanced electrolytes (e.g., lactated Ringer's solution) with potassium replacement. Damage to the mucosal barrier and risk of bacterial translocation should be addressed with parenteral antibiotics. The use of the viral neuromidase inhibitor olstamavir may be helpful in this regard. Antibiotics should target both aerobes and anaerobes. E. coli was identified as an organism associated with septicemia in canine parvovirus^{212,213}; however, C. perfringens may also play a role.²¹⁴ Because of the life-threatening nature of sepsis, combination therapy with a beta-lactam antibiotic (amoxicillin may be preferred to cephalexin because of a better anaerobic spectrum) and an aminoglycoside (gentamicin, amikacin) is recommended. Vomiting and the life-threatening nature of the illness preclude oral administration of antibiotics. Ceftiofur has been used by some clinicians because of its efficacy toward E.coli; however, its limited spectrum (toward anaerobes) might limit efficacy for treatment of parvovirus-associated bacteremia; adverse events also may be an issue. Fluorinated quinolones should be avoided if possible because of the risk of cartilage defects in young, growing animals. Because fluid therapy is likely to be intensive in these patients, and because most patients are pediatric, an increased volume of distribution should be anticipated and higher higher doses of antimicrobials, particularly water soluble, may be indicated. Treatment of septic shock may include drugs that target eicosanoids and other mediators of endotoxic shock. Prevention of endotoxemia or its effects, is reasonable, although reaching consensus regarding effect through randomized clinical trials is limited by study designs.²¹¹ Glucose may be added when indicated by clinical signs consistent with septicemia. Glucocorticoids and flunixin meglumine have historically been advocated to ameliorate some of the negative sequelae resulting from endotoxemia, with benefits more likely if treatment occurs within 4 hours of the onset of endotoxemia. Shock doses of glucocorticoids should be used. Controversy regarding the use of flunixin meglumine centers primarily on the risk of GI damage. However, damage is generally so severe at the time of clinical presentation that it is reasonable to assume that the use of a single dose of flunixin meglumine is not likely to contribute to further damage. An additional benefit of flunixin meglumine is its potent visceral analgesic effect, which may be important is alleviating the marked pain and its negative pathophysiologic sequelae. Because cyclooxygenase 2 is the predominant eicosanoid mediating the sequelae of shock, any of the newer injectable NSAIDs that target cyclooxygenas 2 (e.g., carprofen, meloxicam, firocoxib) presumably should be equally effective in treatment or prevention of endotoxic shock. Opioids should

be avoided because of their inhibitory effect on expelling luminal contents.

KEY POINT 19-43 Although gram-negative coliforms clearly should be targeted in patients with viral enteritis for which translocation is a concern, anaerobes also should be targeted.

Although currently experimental, compounds targeting endotoxin may prove to be an important adjuvant to patients suffering from sepsis. Examples include endotoxin serum or a bacterial toxoid (Salmonella typhimurium; 10 mL/kg). The latter is commercially available. Transfusions with fresh whole blood or plasma can be beneficial in some dogs, particularly those that are hypoproteinemic or anemic. The impact of a recombinant amino terminal fragment of bactericidal permeability-increasing protein (rBPI21; an antimicrobial and endotoxin-neutralizing agent) was studied in dogs (n = 40) with viral enteris. Treatment (3 mg/kg intravenously over 30 minutes, followed by 3 mg/kg intravenously over 5.5 hours) was implemented using a randomized placebo (n = 9 dogs treated with canine plasma protein) controlled design. Outcome measures included plasma endotoxin concentration, severity of clinical signs, and survival of parvovirus. No treatment effect could be identified ; however, contributing factors were insufficient sample size and biased patient selection toward animals that are less ill than the average infected animal.²¹¹

Treatment of diarrhea associated with parvovirus is generally not indicated. Until the mucosa has had time to heal, drugs intended to prevent or resolve diarrhea are not likely to be effective.

Bacterial Enteritis

The role of antimicrobial therapy in the treatment of diarrhea should be closely examined. Bacterial infection is not a major cause of diarrhea, nor does infection appear to perpetuate small intestinal diseases. More important, use of antimicrobial agents does not appear to improve the course of most acute diarrheas. Antimicrobials (neomycin, ampicillin) may, in fact, worsen diarrhea, perhaps because of suppression of normal microflora. Use of antimicrobials for treatment of diarrhea should be based on a diagnosis of intestinal bacterial infection (overgrowth detection, based in part, on fecal gram staining) or in cases of mucosal damage sufficiently severe to allow bacterial translocation. In the latter case, clinical signs generally include hemorrhagic diarrhea, fever, and abnormal white blood cell counts. Systemic antimicrobial therapy is indicated for bacterial translocation.

Despite the low incidence (less than 4% of cases of acute diarrhea), bacterial infections have been associated with both acute and chronic enterotoxigenic diarrhea of both small and large intestines. Diagnosis and antibacterial treatment are best based on culture and susceptibility data when possible. The most likely therapy for each of the infecting organisms is enrofloxacin, trimethoprim–sulfonamide combinations, and chloramphenicol for *Salmonella*; erythromycin, enrofloxacin, furazolidone, doxycycline, neomycin, clindamycin,

or chloramphenicol for C. jejuni; a prolonged course of trimethoprim-sulfonamide combinations, tetracycline, or chloramphenicol for Yersinia enterocolitica (prognosis is guarded); metronidazole for C. difficile; and amoxicillin, ampicillin, metronidazole, tylosin, or clindamycin for C. perfringens. For E. coli the role will be difficult to establish. Clostridium piliformis (formerly Bacillus piliformis: Tyzzer's disease) is a less common, although rapidly fatal, cause of acute hemorrhagic enterocolitis. The organism appears to be nonresponsive to antimicrobials, wih therapy being supportive in nature. Salmon poisoning (Neorickettsia helminthoeca) is an endemic, fatal cause of diarrhea in dogs in the Pacific Northwest. As with other rickettsial organisms, tetracycline (oxytetracycline, doxycycline) is the treatment of choice. Oral therapy (in the absence of vomiting) includes tetracycline, chloramphenicol, sulfonamides, and penicillins. Therapy should continue for 2 to 3 weeks; the trematode vector can be treated with fenbendazole for 10 to 14 days (50 mg/kg, once daily). Because bacterial infections as a cause of diarrhea are often associated with some type of toxin production, motility modifiers should be avoided. Bismuth subsalicylate may be beneficial for both its adsorbent and antiinflamamtory effects.

Hemorrhagic Gastroenteritis

This syndrome of uncertain etiology is characterized by a packed cell volume (PCV) that may be as high as 80%. Hemoconcentration rather than dehydration is the cause. Treatment requires prompt and rapid but appropriate volume replacement with a balanced electrolyte solution until the PCV falls below 50%. Fluid therapy should continue for an additional 24 hours to maintain the PCV at 50% or lower. Disseminated intravascular coagulopathy may develop if fluid therapy is not instituted rapidly.

Chronic Diarrhea

Treatment of chronic diarrhea should be based on removing the underlying causes. This is perhaps more important than in acute diarrhea because drugs used to symptomatically treat acute diarrhea should not be continued on a long-term basis. Chronic IBD is discussed later as a separate entity.

Bacterial overgrowth is increasingly being recognized as a cause of chronic intermittent small bowel diarrhea in dogs. Because no sensitive, specific, and widely available diagnostic test is available, diagnosis is difficult unless an underlying cause (e.g., partial intussusceptions, tumors, foreign body) can be identified. Oral treatment should include broad-spectrum antibiotics, such as tylosin (10 to 20 mg/kg every 12 hours) or metronidazole, a drug effective against anaerobes (10 to 20 mg/kg every 12 hours). The use of probiotics should be considered as previously discussed.

Intestinal **fungal disease** may also manifest as chronic diarrhea. Prognosis is generally poor to fair. Intestinal histoplasmosis should be treated with an orally administered azole drug. Itraconazole is the drug of choice (5 to 10 mg/kg every 12 hours) followed by ketoconazole (10 to 15 mg/kg every 12 hours); both drugs should be given 3 to 4 months after clinical signs of remission. Voriconazole also might be considered.

conazole or ketoconazole) is indicated in animals in which the

disease is diagnosed before tissue damage and infiltration. Protozoal diseases of the small intestine include coccidioidomycosis, cryptosporidiosis, and giardiasis. Pentatrichomonas hominis also has been associated with diarrhea, particularly in puppies and kittens. Diagnosis of each infection is based on identification of the organism or of cysts in feces. Treatment of coccidioidomycosis includes sulfadimethoxine (50 to 65 mg/kg once daily orally for 10 days); trimethoprimsulfonamide combinations (30 mg/kg orally once daily for 10 days), quinacrine (10 mg/kg orally once daily for 5 days), or amprolium (100 mg [small dogs] to 200 mg [large dogs] of 20% powder once daily in gelatin capsules, or 1 to 2 teaspoons of 9.6% amprolium per gallon of free-choice water for 1 to 2 weeks). There is no effective treatment of cryptosporidiosis in dogs. This infection is generally self-limiting in immunocompetent animals. A number of therapies can be used to treat giardiasis. Metronidazole (25 to 30 mg/kg orally twice daily for 5 to 10 days) is the treatment of choice, although up to a third of animals may not respond. Metronidazole benzoate has demonstrated efficacy in treatment of feline giardiasis based on a study in 26 chronically infected cats, 10 of which also were infected with Cryptosporidium parvum.215 Cats were treated with 25 mg/kg orally twice daily for 7 days; the drug was prepared as a solution. It is not clear if the dose was based on active ingredient (i.e., metronidazole base) or total drug. All cats were negative for three consecutive fecal examinations (based on indirect immunofluorescence assay) for the 15 day after treatment study period. Albendazole (25 mg/kg orally every 12 hours for 2 days) can be used in dogs, but safety and efficacy have not been reported in cats. Fenbendazole (50 mg/ kg orally once a day for 3 days) may also be effective. Furazolidone (4 mg/kg orally every 12 hours for 5 to 10 days) can be used in cats, although toxicity may limit its use. For nonresponsive cases in dogs, quinacrine (6.6 mg/kg orally every 12 hours for 5 days) can be used, although side effects (anorexia, lethargy, vomiting, and fever) are common. Ipronidazole (126 mg/L drinking water) is a poultry drug that can be used for treating groups of animals. Tinidazole (currently not available in the United States; 44 mg/kg once orally) may also be useful. Pentatrichomoniasis should respond to a 5-day course of metronidazole therapy; tinidazole for 3 days may also be useful. Both drugs can be used according to previously described dosing regimens.

Short Bowel Syndrome

Short bowel syndrome occurs after surgical removal of a large portion of the small intestine. Resultant malabsorption results in malnutrition and diarrhea. The impact of the resection on bowel function and the ability of the remaining bowel to adapt to the loss depend on the extent and site of resection. Dogs have functioned with an absence of clinical signs following resection of up to 85% of the small intestine. Preservation of the ileum is important because of its role in slowing transit and absorption of vitamin B_{12} and bile acids. Medical management focuses primarily on correction of secondary ill effects. Exocrine pancreatic insufficiency should be treated with enzyme supplementation. Gastric hypersecretion should be treated with H₂-receptor antagonists. Bacterial overgrowth should be treated with appropriate antimicrobial therapy (e.g., metronidazole, tylosin). Cholestyramine can be used to bind excessive bile acids that result in diarrhea. Occasionally, motility modifiers may be indicated to slow transit time. The opioids are preferred because of their effects on segmentation and thus retention of luminal contents.

Bacterial translocation. Bacterial translocation refers to the movement of gastrointestinal origin microbes or their products across the intact gastrointestinal tract into normally sterile tissues and subsequent direct infection or inflammation causing tissue injury, organ failure, and death. The treatment of subsequent sepsis is addressed in Chapter 8. Bacterial translocation ideally is prevented.^{151a-c} Among the choices to prevent bacterial translocation are antimicrobials (selective gastrointestinal or digestive decontamination; SDD) and probiotics. The concept of SDD has been promoted and studied in the human critical care patient. Steinberg has reviewed the impact of bacterial translocation (in the surgical patient)^{215a} and Schultz and co workers have reviewed the conclusions of several metaanalysis that focus on SDD in the critical care patient as part of their report of a clinical trial involving SDD with a favorable outcome. ^{215b} In general, scientific clinical evidence supporting SDD is lacking, and as such, SDD has not become a standard of care for the critical care patient. Nonetheless, Schultz has demonstrated a benefit of SDD in a population of critical care patients receiving ventilator support. In their review, the authors indicate that the risk of emergent resistance as a sequelae of SDD-a major antagonist argument against its routine implementation-did not occur in one clinical trial: indeed, SDD was associated with decreased resistance in this trial. This might be a reasonable expectation particularly if principles of judicious use are applied (see Chapter 6). Care must be taken when extrapolating the results of meta-analysis regarding SDD use in humans to the veterinary patient in that the applicability of the sample human populations may not represent the diseases with which veterinary criticalists are faced. Drug choices for SDD include oral drugs that target gram-negative coliforms but are not orally bioavailable, coupled with systemic antimicrobials targeting the same. However, Schulz and coworkers have also demonstrated that oral absorption of drugs normally characterized by no oral bioavailability may indeed occur in the critical care patient.^{215c} As such, further caution is recommended when using SDD. There is a need for well-designed clinical trials that address SDD with antimicrobial therapy are lacking in the veterinary critical care patient.

The use of probiotics to prevent colonic bacterial translocation in human patients undergoing abdominal surgery was reviewed by Lenoir-Wijnkoop and coworkers.¹⁵¹ The rationale targets the increased risk of bacterial translocation associated with surgical trauma, portal hypertension, decreased hepatic function and immunosuppression. Several controlled clinical trials have been implemented using synbiotics. One study in human liver transplant recipients found that the incidence of infection was much lower (3%) in patients receiving antibiotics plus a highly concentrated combination product of four fibers (2.5 g each of beta-glucan, resistant starch, inulin, and pectin) and four probiotics (10¹⁰ Lactobacillus plantarum, Lactobacillus paracasei, Lactobacillus mesenteroides, and Pediococcus pentosaceu) compared with those patients that received antimicrobials only (48%). A recent controlled clinical trial in humans undergoing pancreatic surgery found that the combination of probiotics and selective bacterial decontamination had no effect on bacterial translocation and other selective outcome measures.^{215d}

Diseases of the Large Intestine

Diarrhea

Diarrhea associated with the large intestine should be approached in the same manner as diarrhea of the small intestine. Chronic IBD is discussed as a separate entity.

Irritable bowel syndrome. IBS, spastic colon, or nervous colitis is a poorly described functional disorder afflicting dogs and is diagnosed by ruling out other causes of large bowel diarrhea. Effective treatment is complicated by the intermittent nature of the syndrome.²¹⁶ Dietary management should be stressed for long-term management. Some large bowel diarrheas may respond to dietary fiber (psyllium). Intermittent bouts of diarrhea attributed to IBS can be managed with administration of short-term opioid antidiarrheals (1 week or less). Anticholinergics can be used to reduce intestinal spasms, particularly those associated with pain and tenesmus. Combination anticholinergics and sedatives (e.g., chlordiazepoxide and clidinium) also may prove useful.

Treatment of IBS in humans was reviewed by Spanier and coworkers.²¹⁷ Whereas the prevalence in humans is as high as 24%, the role of IBS as a cause of diarrhea in dogs or cats is not clear. In humans no specific therapy emerges as clearly effective, causing afflicted patients to seek out alternative therapies. A review of clinical trials reveals therapies of variable efficacy to include probiotics (*L. acidophilus, Candida* and others); herbal products such as aloe or peppermint oil; and non-medicinal therapies such as colonic irrigation, acupuncture, psychotherapy, and meditation. None was well supported, but positive scientific evidence was greatest for Chinese herbal therapy and psychological therapy.²¹⁷

Clostridium spp. C. difficile has reached epidemic proportions in human medicine, with antimicrobial-induced suppression of normal flora as a major risk factor. Those drugs most commonly associated with its emergence included clindamycin, penicillins, and cephalosporins; fluoroquinolones have also been identified in humans (see Chapter 8). Environmental contamination and fecal-to-oral transmission are important, with hand carriage by health care personnel occurring in human patients in much the same way as with methicillin-resistant *Staphylococcus aureus*. In humans a new strain has emerged with increased virulence. Outbreaks have increased in the hospital setting, with community-acquired infections increasing in North America and Europe.²¹⁸ Clinical signs range from mild diarrhea to pseudomembranous colitis to toxic (and potentially fatal) megacolon. Clostridial toxins increase with deletion of the gene that downregulates production. Pathophysiology reflects binding of toxin by intestinal cells, disruption of epithelial tight junctions, and inflammation. Watery diarrhea is the clinical hallmark of infection. A seasonal pattern has been described for selected human hospitals.²²⁰ Enterotoxicosis associated with C. perfringens is also emerging as a cause of large bowel diarrhea primarily in dogs (see Chapter 8). Diagnosis is based on a reverse latex agglutination test available in many human laboratories. Acute treatment includes metronidazole, ampicillin, or amoxicillin. Tylosin may be effective for cases requiring long-term treatment. High-fiber diets (or psyllium) may also be helpful. Other bacterial diseases of the large intestine were discussed as causes of diarrhea in the small intestine.

Clostridial resistance may have already emerged toward newer 8-methoxy fluoroquinolones used to treat the organism (e.g., gatifloxacin and moxifloxacin).²²¹

Antibiotic-responsive diarrheas. Several chronic enteropathies afflicting dogs are reported to respond to a number of antibiotics, leading to the term *antibiotic-responsive diarrhea* (*ARD*). The distinction of antibiotic-responsive diarrhea from small bowel diarrheas associated with (idiopathic) small intestinal bacterial overgrowth is not clear.²²² Small bowel diarrhea of German Shepherd Dogs typifies the syndrome. Antibiotics to which animals have responded include tetracycline, metronidazole, ampicillin, tylosin, and enrofloxacin.

Tylosin-responsive chronic diarrhea was described in dogs (n = 14).²²² Middle-aged, large-breed dogs are more commonly affected with clinical signs referable to both the small and large bowels. However, the study is complicated by study design (e.g., all dogs were treated with tylosin 1 month before starting the study, and animals that responded to sequential therapies were dropped from the study). Nonetheless, the authors reported that all animals responded to tylosin (6 to 16 mg/kg orally once daily) within 3 days (most commonly within 24 hours), with clinical signs recurring within 30 days of discontinuing therapy in 86% of dogs. Other failed therapies attempted with recurrence included prednisone treatment (for 3 days; partial response) or Lactobacillus rhamnosus probiotics (no responders). On the basis of response to tylosin, potential pathogens have been proposed, including C. perfringens, campylobacters, and Lawsonia intracellularis. A proposed rationale for the syndrome is the existence of an as of yet to be identified specific enteropathogenic common to the canine GI tract that is susceptible to tylosin.

Several antimicrobials have beneficial immunomulatory effects in the GI mucosa (as reviewed by Westermarck and coworkers²²²). These include metronidazole and fluoroquinolones (ciprofloxacin and enrofloxacin). The use of enrofloxacin to treat inflammatory bowel disease is discussed later. Probiotics have been shown to be effective for pediatric antimicrobial diarrhea, but not that associated with *C. difficile. Trichomoniasis* is caused by *Entamoeba histolytica* and *Balantidium coli*, protozoal organisms associated with diarrhea of the large

intestine in dogs and cats. Treatment of trichomoniasis was delineated in the section on diseases of the small intestine.

Treatment of *B. coli* infection has not been delineated in animals but, based on the response in humans, might include the use of tetracyclines or metronidazole.

Megacolon. Initial medical management of megacolon associated with mild constipation should include bulk laxatives and more active laxatives such as bisacodyl or docusate sodium suppositories. As constipation progresses to obstipation, enemas and evacuation under general anesthesia are implemented. In severe cases broad-spectrum antimicrobials may be indicated to decrease the potential for bacterial translocation across the damaged mucosa. Long-term medical management should be accompanied by dietary management. Laxatives and periodic enemas are indicated. Prokinetics such as cisapride have had variable success but should be tried. Earlier use is more likely to be prevent progression from constipation to obstipation in cats. Erythromycin demonstrated a prokinetic effect on colonic motility but did not provide a clinically evident benefit in human patients with postoperative colonic ileus.¹⁸³ Antisecretory drugs with anticholinesterase activity (e.g., ranitidine, nitazidine) might also be considered.

Inflammatory Bowel Disease

Pathophysiology

IBD is characterized by infiltration of inflammatory cells in the gastric or intestinal mucosa (or both).^{194,223} Its emergence in predisposed animals is facilitated by the large immune system and its multivariate responses presented by the GI tract, coupled with the vast number of antigens from ingested microbes, parasites, food, toxins, endogenous microbes or their products, and other materials. Increased intestinal permeability to antigens probably plays a role, but it is not clear if this is an initiating event or a sequela. Disruption of the intricate balance between microbe and host leads to breakdown of mucosal tolerance. This key event leads to initiation, progression, and reemergence of disease.²²³ Loss of mucosal tolerance generally requires a loss of the normal barrier, as might occur with loss of cadherins. Immunologic dysfunction largely reflects altered T-cell [CD-4] activity. High concentrations of IL-10 and 18, and TGF-ß promote T cell differentiation to the Th-1 phenotypes, resulting in high concentrations of IL-2, INF- γ , and TNF-alpha.²²⁴ A third factor in the loss of mucosal tolerance is the presence of endogenous microflora.

KEY POINT 19-44 Effective treatnment of of IBD is complicated by the complex interaction between microbes, the gastrointestinal tract, and the local immune response.

German and coworkers²²³ reviewed IBD in dogs, and Allenspach and coworkers²²⁵ described risk factors for therapeutic failure. Canine IBD is a group of diseases that are highly variable in cause and presentation. Manifestations and treatment depend on cell type (with lymphocytic-plasmacytic most common, followed by eosinophilic), region affected (any location but most commonly small intestine) and breed (e.g., histiocytic [large macrophages] ulcerative colitis of Boxers,

protein-losing enteropathies of Soft Coated Wheaten Terriers, gluten sensitivity of Irish Setters, and immunoproliferative enteropathy of Basenjis).²²³ The type of predominating cell (lymphocytic, plasmocytic, eosinophilic, or histocytic) that causes inflammation can serve as a basis of the classification and, to some degree, treatment of IBD.²²⁶ Overgrowth of small intestinal bacteria in response to either a primary (e.g., idiopathic) or secondary (e.g., acquired) disorder has been studied as a potential cause, particularly in German Shepherd Dogs; IgA deficiency has been suggested.²²³ Although commonalities exist between human and canine IBD, the most common forms in human include ulcerative colitis and Crohn's disease. Ulcerative colitis is diffuse and superficial, involving predominantly neutrophils, with some lymphocytes and plasma cells, particularly in the ileum. Crohn's disease is focal and segmental, characterized by chronic pyogranulomatous inflammation. When extrapolating therapeutic options between human and canine or feline IBD, considerations must also include differences in the pathophysiology of the diseases among species. Even within species, preferred therapies and extent of response is too variable among canine and feline populations to be predicted without supportive diagnostic (histopathologic) data. Accordingly, treatment should be approached individually (Table 19-5). A scoring system has been proposed for dogs to facilitate treatment.226

The "4-R's" approach to treatment of Crohn's disease in humans includes removal (underlying causes such as inappropriate diet), replacement (missing nutrients, such as vitamin B_{12}), re-inoculation with "friendly" bacteria (L. acidophilus and L. bulgaricus along with fructose oligosaccharides), and repair. Dietary considerations in the role of (human) IBD have been reviewed by Shah.²²⁷ The role of gut flora, GI immunity, and IBD based on models and spontaneous disease has been reviewed in humans.^{228,229} A series of studies using interleukin 10-deficient mouse colitis models demonstrated the influence of different bacterial substrates at different sites of inflammation. Inflammation best responded to a combination of vancomycin-imipenem or neomycin-metronidazole compared with ciprofloxacin and metronidazole. Response to the latter was effective for acute but not chronic colonic inflammation. Narrow-spectrum antimicrobials such as ciprofloxacin were more effective in preventing but not treating experimentally induced colitis²³⁰ (see also the discussion of antibiotic-responsive diarrhea). Studies have demonstrated that inflammatory disease will not evolve experimentally in microbe-free environments but can be experimentally induced by transfer of T-cells reactive to bacterial antigens. In human patients with IBD, lesions are worse in those areas with highest microbial counts. Although the role of potential pathogens has been intensively studied, emerging data suggest that it is the commensal, rather than pathogenic, microbes that are contributing to the disease. As such, perpetuation of the disease may reflect abnormal signaling between host immune system and microbes and a loss of host tolerance for microbes. Accordingly, treatment for IBD targets not only suppression of the inflammatory response but also manipulation of the contributing microbiota with either antimicrobials or probiotics.

Table 19-5 Products for Treatment of Inflammatory Bowel Disease Catagory Superside Disease		
Category	Product	Example Drug or Active Compound
	Undigested carbohydrates	
	Undigested proteins	
Supplement	Iron	
	Protein	
	Water- and fat-soluble vitamins	
	Cyanocobalamine	
	Trace elements	
	Electrolytes	
Antiinflammatories	Aminosalicylates	
	Mesalazine (5 aminosalicylic acid, 5 ASA)	Asacol (Mesalamine) Increased stability in acid medium; absorption slowed)
		Salofalk (coated with ethylcellulose)
	Sulfasalazine	Sulfapyridine diazotized to 5 ASA
	Pentoxyfylline	
	Leukotriene receptor antagonists	
mmunomodulators	Cyclosporine	
	Glucocorticoids	
	Systemic	
		Prednisolone (preferred to prednisone in cats and possibly some dogs)
		Prednisone
	Topical (oral)	Budesonide
	-	Fluticasone
		Tixocortol pivolate
	Topical (foams; rectal)*	Hydrocortisone acetate
	-	Prednisolone metasulphobenzoate
		Hydrocortisone sodium phosphate
		Prednisolone sodium phosphate
	Enema	Methylprednisolone
		Betamethasone valerate
		Beclometasone diproprionate
		Budesonide
Directed polypeptides	Role not yet elucidated	
Probiotics	Lactobacilus acidophilus, bulgaricus	With fructose oligosaccharide
	Bifidobacterium?	
	Others	
Antibiotics	Metronidazole	
	Fluoroquinolone	Enrofloxacin [†]
	Others (e.g., Tylosin)	
Protection	Sucralfate	
	Antisecretory drugs	Famotidines, proton pump inhibitors
	Polysulfated glycosaminoglycans	Glucosamine, chondroitin sulfates

Table 10-5 Products for Treatment of Inflammatory Bowel Diseas

^{*}Foams adhere to mucosa and are for colonic disease. Administered at night. [†]Histocytic ulcerative colitis.

Unfortunately, IBD is a diagnosis of exclusion and is made after other causes of inflammatory disease of the GI tract have been ruled out. Food allergies or intolerance; infections by fungal, bacterial, or parasitic organisms; and neoplasms must be ruled out or their role in the pathophysiology identified and treated accordingly. Confirmation of the diagnosis is based on biopsy, which also is necessary to identify the predominant inflammatory cell associated with the disease and the most appropriate therapy. For example, eosinophilic infiltrates may respond to dietary management alone. Monitoring response to therapy should include, in addition to clinical signs, serum folate and cyanocobalamin concentrations; serum albumin levels can be used as a monitoring tool in animals with proteinlosing enteropathy. Allenspach and coworkers²²⁵ retrospectively determined that hypocobalaminemia (<200 ng/mL), along with hypoalbuminemia, is a risk factor for therapeutic failure.

Initial medical management may vary with the severity and length of disease. In dogs, particularly, elimination of an irritating diet and antibiotic-responsive causes might be considered before biopsy. This is best accomplished by a welldesigned clinical trial in the patient. The role of diet in human IBD has been well reviewed.²²⁷ Feeding the animal an elimination diet containing novel or highly digestible protein foods or (particularly for colonic disease) a high-fiber diet (e.g., yams, sweet potatoes, pumpkin) might be considered first. The role of diets with altered n:3 to n:6 omega-fatty acid ratios or hydrolyzed diets (protein molecules are small and presumably nonantigenic) is not yet clear but may be promising.²²³

Antiinflammatories remain the cornerstone of therapy for IBD in dogs and cats. Use of glucocorticoids should be reserved for animals in which biopsy has confirmed a diagnosis of IBD. Indiscriminate use of glucocorticoids can be dangerous, particularly in areas in which fungal causes of GI disease are not uncommon. In addition, use of glucocorticoids in patients with GI lymphoma may render the neoplasia resistant to further glucocorticoid therapy used as part of a combination antineoplastic regimen. Glucocorticoids are indicated in dogs and cats with lymphocytic-plasmacytic IBD. Prednisolone (2.2 mg/kg/day orally) should result in clinical response within 1 to 2 weeks. Therapy should continue at the same rate for another 2 weeks (beyond clinical response) and then slowly be tapered. More severe cases of IBD or cases that do not initially respond to prednisolone may respond to dexamethasone (0.22 mg/kg/day orally).Because glucocorticoids impair healing in the gastrointestinal mucosa (by virtue of cyclooxygenase 2 inhibition), antisecretory and cytoprotectant drugs are indicated. Indeed, their use is indicated in general to facilitate healing development of multidrug resistance has been implicated as a cause of therapeutic failure with glucocorticoids in some human patients with IBD; expression of mucosal multidrug resistance may ultimately be used to determine response of IBD patients to therapy.²³¹ Several mechanisms of glucocorticoid resistance have been described in humans and may be relevant to dogs or cats.²³² These include heterogenicity of the disease process itself, overexpression of the MDR1 gene causing increased P-glycoprotein-mediated

efflux of glucocorticoid from target cells; impaired glucocorticoid-receptor signaling; and activiation of epithelial proinflammatory mediators such as nuclear factor kappa B.

KEY POINT 19-45 Although glucocorticoids are the cornerstone of inflammatory bowel disease therapy, glucocorticoids also impair gastrointestinal healing, and gastroprotective therapies should simultaneously be implemented.

Humans generally do not tolerate systemic glucocorticoids as well as dogs or cats, leading to effective alternative therapies for IBD.²³³ For example, 80% of human ulcerative colitis cases are successfully controlled with a variety of 5-aminosalicylic acid preparations. Rectal glucocorticoid foams have also proven useful for diseases involving the colon. "Topical" budesonide is as effective as systemic glucocorticoids and is better tolerated than systemic glucocorticoids. Glucocorticoids are the cornerstone of therapy for Crohn's disease; more severe disease responds to higher doses of steroids. The extrapolation of these treatments to dogs and cats is limited in part because colonic disease is not as common (limiting applicability of therapies targeting the colon). Further, the extent of first-pass metabolism of budesonide is not known. A number of therapies should be considered in dogs or cats that do not respond to initial therapy or for which glucocorticoids are not tolerated or contraindicated. Various immunomodulators should be considered. In humans, these have included cyclosporine and mycophenolate mofetil.. Allenspach and coworkers²³⁴ reported on the use of cyclosporine for treatment of IBD in dogs (Chapter 19). Overall, cyclosporine was considered effective in 78% of the animals. In humans, long-term cyclosporine may facilitate long-term control when used in combination (but not alone) with other immunomodulating drugs. Leukotrienes appear to be involved in chronic allergic diseases such as IBD, atopy, and asthma. A role has been described in signaling and trafficking between eosinophils and lymphocytes in affected tissues, and in the IL-5 eotaxin induced differentiation, proliferation, and release of eosinophils at the level of the bone marrow. Accordingly, leukotriene receptor antagonists (e.g., zafirlukast or montelukast; see Chapter 29) might be considered as the sole agent in mild disease in those animals in which glucocorticoids are contradicted, in combination for nonresponders, or as dose-sparing agents. The role of TNF-alpha in Crohn's disease of humans has led to some scientific support for pentoxifylline (also referred to as oxpen*tifylline*).²³⁵ It has proved useful in mouse models of colitis²³⁶ and in humans as a dose-sparing agent when combined with glucocorticoids or directed polypeptide therapy.237

Sulfasalazine (20 mg/kg every 12 to 24 hours orally in cats; 50 mg/kg/day divided every 8 to 12 hours in dogs) may also be beneficial in cats and dogs with IBD. Response may take 1 to 2 weeks. As a sulfonamide, sulfasalazine may cause immune-mediated diseases ascribed to other sulfonamide antibiotics; use of the drug should be based on a histologic diagnosis whenever possible. Newer 5-aminosalicylate (sulfasalazine-like drugs) such as mesalazine and olsalazine (10 to 20 mg/kg every 12 hours) might be considered; both may decrease tear production in dogs. Omega fatty acid (fish oil) products also may be helpful for their antiinflammatory effects; response may take several weeks.

Animals that continue to be unresponsive to medical management of IBD may respond to azathioprine (0.3 mg/kg every other day, orally in cats; 2.2 mg/kg/day in dogs). Response may take up to 5 weeks. Side effects of azathioprine are sufficiently severe that a diagnosis of severe IBD should be confirmed (based on biopsy) before its use. White blood cell counts should be monitored weekly and the drug temporarily discontinued if neutrophil counts drop below 2000/uL.

The role of directed polypeptides in the management of refractory human IBD is emerging.^{238,239} Emerging therapies are targeting co-stimulatory molecules which are responsible for initial interactions between T cell receptors and macrophage MHC antigen complexes.²²⁴ Endotoxin and cytokines interact directly or indirectly with a variety of co-stimulatory molecules, including CD40-ligands (with T-cells) and B-7, an immunoglobulin that serves as a ligand for C28 (also a T cell co-stimulatory molecule). Because many of these therapies represent proteins foreign to dogs and cats and because animals are already affected by a dysfunctional immune system, caution is recommended with their use. Side effects can be profound in humans and may preclude adaptation to dogs or cats. Use in dogs and cats should be implemented only after collecting intensive scientific support.

Antibiotic therapy is intended to resolve bacterial overgrowth that might be contributing to the inflammatory process and either mimicking or contributing to IBD. However, response may just as likely reflect immunomodulation rather than antimicrobial therapy. Therapy for overgrowth in the large intestine should target clostridial organisms (metronidazole or ampicillin), whereas broader-spectrum drugs (tylosin, ampicillin) should be used for small intestinal disease. *C. perfringens* overgrowth in the small intestine may be difficult to detect; drug therapy that targets this organism includes tylosin and ampicillin. Metronidazole therapy in conjunction with glucocorticoids is indicated not only for its antibacterial effects but also because it appears to have immunomodulatory capabilities; indeed, this may explain why it may be effective as the sole therapy in some cases of IBD.

Nonhypoproteinemic dogs with lymphocytic-plasmacytic enteritis responded to a combination of oral antiinflammatory agents (prednisone, 1 mg/kg twice daily slowly decreased to 0.5 mg/kg every 48 hours) and antimicrobial agents (metronidazole 10 mg/kg twice daily for 21 days); most dogs also received oral cimetidine (0.5 mg/kg bid) and metaclopramide (0.5 mg/kg bid) for 90 days.²⁴⁰ Treatment dogs (n = 16) received a prescription diet. A group of normal animals (n = 9) were studied as untreated controls. Dogs were studied for 120 days, with outcome measures including clinical signs, endoscopic lesions and histopathy of endoscopic biopies. After treatment, the mean activity index diminished from 7.3 at baseline to 1.7, 0.8, 0.5, and 0.19 at baseline, on days 30, 60, 90, and 120, respectively. Further, gastric and duodenal endoscopic lesions decreased in 75% of animals, although no significant reduction was detected histologically.

Hostutler and coworkers²⁴¹ have retrospectively described a series of cases (n = 9) of canine histoycytic ulcerative colitis responsive to antibiotics. The common drug among all nine dogs was enrofloxacin, with or without combinations of amoxicillin or metronidazole. Four of the dogs had failed to respond to antiinflammatory therapy that included combinations of prednisolone, azathioprine, or sulfasalazine, with or without other antibiotics, for a duration of 1 to 20 weeks. The remaining five dogs responded to antibiotics alone. Diarrhea resolved within 3 to 12 days of treatment with enrofloxacin at standard recommended doses. Although three dogs remained asymptomatic for 7 to 14 months, some dogs have required therapy for 2 to 21 months or longer.

Among the more promising approaches of therapy that do not directly suppress inflammation is the use of probiotics (see the earlier discussion of biotherapeutics). Probiotics are intended to replace the pathogens with healthy flora that have developed host tolerance. Their use in patients with IBD should be strongly considered; however, notably lacking is scientific evidence regarding their use. Necssary information ranges from characterization of the normal state of microbiota in the canine and feline gastrointestinal tract to its state in patients with IBD; the optimal replacement microbiota; and clinical trial evidence of response when used as either sole or combined therapy. Further, deficiencies in product quality may limit effective response. None the less, attention must be given to this approach to therapy. The role of probiotics in the treatment of IBD in humans has been reviewed.^{228,229} Randomized controlled clinical trials in humans have demonstrated resolution or improvement of IBD compared with controls (placebo or 5-aminosalicylic acid) after treatment with probiotics containing bifidobacteria, lactobacilli, and streptococci as core microbes.^{228,229} However, because the pathophysiology of IBD and endogenous microbiota (and presumed response to biotherapeutic) varies with site, age, diet, species, and other factors, scientific evidence of efficacy of biotherapeutics in IBD may be slow to emerge. Human and mice model data are not necessarily relevant to either dogs or cats; studies in target species are needed to support efficacy. Further, the microbiota of individuals with IBD is different from that in normal animals and (has been described as unstable). Accordingly, although biotherapeutics are largely safe in normal animals, the unknown impact of colonization of microbes in the diseased intestine mandates that discretion (and knowledge) accompany biotherapeutic use. Marteau and coworkers²²⁸ reviewed the role of biotherapeutics in the treatment of IBD. Several studies suggest that E. coli and Bacteroides vulgatus, both normal flora, in particular, may be reasonable targets of therapy. Members of bifidobacteria and lactobacilli generally tend to be the most likely organisms to provide protection against IBD, but species differences in normal flora are likely to mandate clinical trials in target species as a basis of proof.

KEY POINT 19-46 The mechanism of efficacy of selected antimicrobials for treatment of inflammatory bowel disease may reflect immunomodulation more that antibacterial effects. Associated clinical signs of IBD that may require medical management include vomiting, small or large bowel diarrhea, flatulence, and occasionally GER. Hematochezia may be present with colitis. Diarrhea is the primary presentation of IBD in dogs. Vomiting occurs less commonly with gastric and enteric IBD; hematochezia occurs consistently in colitis. Anorexia and weight loss occur to variable degrees in IBD. Use of antisecretory drugs is indicated, in part to provide GI protection; sucralfate likewise is indicated, particularly in the presence of erosive or ulcerative disease and glucocorticoid therapy.

Supplementation of cobalamin should be considered at least in cats with chronic inflammatory disase of the small intestine associated with hypocabalaminemia. Ruaux and coworkers²⁴² studied 19 cats severly deficient in cobalamine (based on serum concentrations) during and after treatment (250 units subcutaneously once weekly) for 4 weeks.

Treatment for Helicobacter spp. might also be considered. Leib and coworkers²¹⁶ demonstrated marked improvement in dogs with IBD when they were treated for Helicobacter spp. Chronically vomiting dogs with spirochetes and either normal or inflamed stomach or duodenum (based on biopsy samples) were studied. Dogs were assigned to receive twice daily for two weeks "triple" therapy (amoxicillin 15 mg/kg, metronidazole 10 mg/kg and bismuth subsalicylate at 13 to 26 mg/kg [0.25 to 2 262-mg tablets, depending on body size), either with or without famotidine (0.5 mg/kg). Potential therapeutic benefits of bismuth subsalicylate include antibacterial effects, altered microbial adhesion, protection agains ulcerative effects, and decreased resistance to metronidazole (as reviewed by Leib and coworkers²¹⁶). Placebos apparently were not given and blinding was not ascribed; assignment to either group was by coin toss, and although other therapies were discouraged, some dogs did receive other antibiotics as well as antiinflammatory therapies. Dogs were reevaluated at 4 weeks and 6 months. No significant treatment effect emerged in the famotidine group, with the frequency of vomiting reduced by 86% and organisms eradicated in approximately 75% of dogs in both groups. On the basis of this study, the authors concluded that famotidine did not enhance response to therapy; however, caution is recommended in basing therapy on this conclusion, in part because the ability of the study to detect a famotidine effect was not identified. In humans eradication of Helicobacter might be expected in more than 90% of human patients receiving "quadruple" (i.e., with antisecretory drugs) therapy. As with other investigators, recrudescence or re-infection of dogs with Helicobacter after presumably successful eradiction (based on the presence of the organism rather than molecular techniques) is not unusual. In Leib's study²¹⁶ close to 50% of dogs negative for Helicobacter at 4 weeks were positive by 6 months, suggesting improved therapy is still needed.

Liver Diseases

With few exceptions, treatment of liver disease is nonspecific, being primarily supportive and symptomatic.²⁴³ Feline hepatic lipidosis is largely a nutritionally managed disease and as such is not discussed in this chapter; however, future considerations

should be made in the role of adipose hormones in the initiation or perpetuation of the syndrome. Recommended supplements include L-carnitine (250 to 500 mg/cat), taurine (250 mg), B vitamins at twice the standard recommended dose, vitamin C (30 mg/kg), vitamin E (100 to 400 mg/cat), and elemental zinc (7 to 8 mg/cat). Supplemenation with vitamin K (e.g., 0.5 to 1.5 mg/kg) also may be indicated.

Acute Hepatic Failure

Supportive therapy includes intensive fluid therapy with a balanced electrolyte solution to which potassium chloride, B vitamins, and (particularly in the presence of hypoglycemia or septicemia) glucose has been added. Coagulopathies are likely to reflect disseminated intravascular coagulopathy (stimulated by massive endothelial damage in the liver), impaired coagulation protein synthesis, or both. Clinical coagulopathies should be treated with heparin and replacement therapy (fresh whole blood or plasma or fresh frozen plasma). Rapid destruction of hepatic storage sites of vitamin K may also contribute to bleeding disorders, and replacement therapy may be indicated. Gastric ulceration should be anticipated and GI bleeding minimized by the use of antisecretory drugs. However, cimetidine is not recommended because of its negative effects on hepatic enzyme activity; omeprazole likewise might be used only cautiously. Antibiotics are indicated because of increased risk of bacteremia. Bacteria are likely to be gram-negative coliforms or anaerobes from the GI tract or Staphylococcus spp. Combination antimicrobial therapy is indicated for full antibacterial coverage. No documented studies have established the usefulness of drugs intended to support the liver as it heals or overcomes acute hepatic necrosis. Intrahepatic glutathione is an important scavenger of oxygen radicals, and its depletion probably contributes to inflammatory damage. Replacement in the form of acetylcysteine (e.g., Mucomyst) is certainly indicated for acetaminophen overdose but also might be considered in any case of acute hepatic necrosis. Cimetidine, a potent inhibitor of hepatic microsomal enzymes, might be considered in cases of acute hepatic failure associated with the formation of toxic drug metabolites, such as acetaminophen. However, its routine use in other cases of acute disease is discouraged because of its inhibitory effects.

KEY POINT 19-47 Acute drug hepatopathies might be treated with intravenous *N*-acetylcysteine.

Treatment for hepatic encephalopathy focuses on decreased absorption of encephalotoxins generated by microbes from protein and fat degradation. Medical management should be implemented in conjunction with dietary management. Lactulose is a semisynthetic disaccharide that is metabolized by colonic bacteria to lactic acid. In addition to the osmotic laxative effect, which causes evacuation of the luminal contents, acidification of the contents results in ionization of ammonia, precluding its absorption across the rectal mucosa. It can be administered either orally or, in severe cases of encephalopathy, as a retention enema (three parts lactulose to seven parts saline, administered at 20 mL/kg every 4 to 6 hours). The enema should be retained for 15 to 20 minutes. Lactitol is an alternative to lactulose that is less sweet and perhaps better tolerated. It is administered as a powder (500 mg/kg daily orally). Oral doses for longterm management with either lactulose or lactitol should generate two to three soft stools a day. Povidone-iodine (10%) given as an enema also acidifies luminal contents and provides some antibacterial activity. Selective microbial decontamination may reduce formation of encepahlotoxins. Neomycin (22 mg/kg orally twice daily or as an enema in water) also decreases bacteria responsible for formation of encephalotoxins. Other antimicrobials used for long-term management of hepatic encephalopathy include metronidazole (7.5 mg/kg orally every 8 to 12 hours) and ampicillin (22 mg/kg orally every 8 hours). With severe encephalopathy glucose-containing fluids may help prevent accumulation of ammonia in neurons.

Benzodiazepine receptors increase in patients with hepatic encephalopathy; use of benzodiazepine receptor antagonists such as flumazenil can be effective in human patients, but its efficacy is less well established in animals. If the drug is used, animals should be monitored for seizures. Intracranial pressures may increase in some patients; treatment should include mannitol (1 mg/kg of a 20% solution intravenously over 30 minutes, at 4-hour intervals) and furosemide. Glucocorticoids appear to offer no advantage to patients suffering from hepatic encephalopathy and may be contraindicated for treatment of increased intracranial pressure associated with hepatic encephalopathy.

Vomiting in patients with acute or chronic liver disease should be treated with antiemetics active at the CTZ or emetic center. Metoclopramide has been the first drug of choice, followed by a phenothiazine derivative; maropitant might reasonably replace either. Impaired hepatic function may increase the duration of action of the drug, whereas dehydration may increase plasma drug concentrations. Dosing regimens should take these changes into account. Volume replacement should take place before treatment with phenothiazine antiemetics in the dehydrated patient.

Chronic Hepatic Diseases

Halting hepatic inflammation. As with acute hepatic disease, treatment of chronic disease focuses on removal or correction of the inciting cause and supportive and symptomatic therapy. Long-term management should be accompanied by discontinuation of any drugs that are contributing to the chronic damage to the liver and dietary regimen. Drugs intended to remove the inciting cause are used in diseases for which the diagnosis is clear. For example, cecoppering agents are indicated in dogs predisposed to copper storage disease. However, Poldervaart and coworkers²⁴⁴ retrospectively reviewed hepatitis in dogs and concluded that the role of copper as a cause or contributor to acute or chronic hepatitis may be underestimated. Drugs used to treat copper-related hepatic disease include D-penicillamine (10 to 15 mg/kg orally 30 minutes before a meal, every 12 hours; start with a lower dose and increase after the first week) and, for animals that cannot tolerate D-penicillamine,

trientine (2,2,2-tetramine, 10 to 15 mg/kg orally twice daily). In Bedlington Terriers with copper hepatotoxicosis, 2,3,2-tetramine (7.5 mg/kg orally every 12 hours) may be used instead of trientine (and may result in greater copper elimination), but the drug must be reformulated. A more controversial treatment for copper storage disease focuses on decreased absorption of copper in the diet by treatment with zinc acetate (5 to 10 mg/kg or 100 mg for the first 3 months and 50 mg thereafter orally every 12 hours, 1 hour before each meal). This treatment should be started at a young age, before hepatic accumulation of copper has occurred. Monitoring plasma zinc concentrations every 2 to 3 months has been recommended to ensure therapeutic concentrations and to prevent toxic concentrations of zinc that might lead to hemolytic anemia (therapeutic range of zinc is 200 to 500 µg/dL; higher than 1000 µg/dL is considered toxic).

Suppression of hepatic inflammation in chronic liver disease is problematic but critical if the progression of chronic to cirrhotic disease is to be halted. Underlying causes should be identified and removed. Consideration should be given to the role that insulin resistance, adioponectin, and adiponectin have in perpetuating the inflammatory response.⁴ Hepatic damage by drugs often is reversible if the drug is discontinued before fibrosis has occurred. Drug-induced hepatic disease is often dose and duration dependent, meaning that the risk of toxicity increases with higher doses (plasma drug concentrations) and long-term therapy. Consequently, single doses or short-term therapy with a hepatotoxic drug is not likely to lead to chronic hepatic disease. Examples of drugs associated with chronic liver disease in dogs are discussed in Chapter 4. Anticonvulsants (primidone, phenobarbital, and phenytoin) and heartworm preventive (oxibendazole-diethylcarbamazine) are among the most commonly used drugs associated with hepatic disease. However, any drug metabolized by the liver and to exposure is considerable (ie, large initial doses, or long duration of exposure) might be considered as a possible cause of liver disease.

Identifying the role of infection as a continued cause of liver disease may be difficult. However, with the exception of ascending chronic cholangiohepatitis, bacterial infection as a cause of chronic liver disease is uncommon. Because the liver is well perfused, any antimicrobial with a good gramnegative spectrum should be effective. However, as disease progresses and fibrosis deposition occurs, drugs that are more lipid-soluble should be considered Because of the loose but increasingly characterized association of *Helicobacter* spp. and cholangiohepatitis in cats,²⁴⁵ treatment for helicobacter might be considered.

Idiopathic chronic hepatitis (chronic active hepatitis or chronic active liver disease) is generally detected by increases in serum alanine transferase activity (greater than 10 times normal) and alkaline phosphatase activity (greater than 5 times normal). Biopsy should provide a confirmation as well as a histologic description on which therapy and response to therapy can be based. Inflammation usually is controlled with immunosuppressant drugs; evidence of piecemeal necrosis, bridging necrosis, and fibrosis indicates their need. Prednisolone (1 to 2 mg/kg orally a day) should be administered until clinical remission occurs (generally 7 to 10 days) and the dose then gradually tapered (decreased every 10 days) until a minimum effective dose has been established. Clinical signs, clinical pathologic changes (at 1- to 2-week intervals), and ultimately a repeat hepatic biopsy (at 2 to 3 months) should be monitored for response to therapy. Note that glucocorticoids can increase serum bile acids, and the failure of these to decrease is not necessarily indicative of continued damage. More aggressive immunosuppressive therapy is implemented if glucocorticoids cannot be tolerated or if the progression of hepatic disease cannot be halted with glucocorticoids. Azathioprine therapy is initiated (2 mg/kg/day or 50 mg/m² orally given every day for 7 days, then every other day), with prednisolone therapy continued for the first 7 days and then alternated with azathioprine thereafter. Weekly white blood cell counts should be performed to detect bone-marrow suppression by azathioprine; therapy should be suspended for 5 to 7 days if the neutrophil count drops below 2000 cells/µL or the platelet count below 50,000/µL. Lymphocytic or sclerosing cholangitis/cholangiohepatitis in cats may also respond to glucocorticoid therapy (2.2 mg/kg orally a day). In order to avoid the adverse events associated with azaothioprine or other anti-inflammatory drugs, alternative therapies might be considered. Pentoxifylline is among these alternative drugs for additional control of inflammatory disease.²⁴⁶ The role of mycophenolate or cyclosporine in treating immune-mediated liver disease has not been addressed.

Ursodeoxycholic acid has proved beneficial in both dogs and cats with chronic liver disease, particularly if it is associated with a significant cholestatic component. The dose in patients with chronic hepatitis (8 to 10 mg/kg) is less than that in patients with primary biliary cirrhosis or sclerosing cholangitis (10 to 5 mg/kg/day). Note that more studies are needed to describe the clinical efficacy of ursodeoxycholic acid in dogs and cats. The drug appears to be safe; cats showed no evidence of adversity when dosed with 10 mg/kg orally for 8 weeks. Dehydrocholic acid (10 to 15 mg/kg orally every 12 hours) has also been recommended in cats with cholangiohepatitis and "ludged bile." Note, however, that less evidence is available to support the efficacy of this bile acid and that it is among the lipid-soluble and thus potentially hepatotoxic bile acids. A deletion in an efflux transport protein has been identified as the underlying cause of biliarly mucoceole in dogs; its role in feline diseases has yet to be identified. Ascorbic acid (25 mg/kg/day orally) has been suggested as supportive therapy in dogs with chronic hepatic disease because the liver is less able to produce this vitamin. Zinc therapy has also been suggested to reduce copper deposition in the damaged liver.

When the progression of disease cannot be halted and, specifically, fibrotic tissue deposition continues, antifibrotic drugs can be considered. Prednisolone provides some prevention of collagen deposition. Colchicine appears to improve (histologically) the progression of cirrhosis in human patients, but evidence is lacking in dogs because of lack of controlled trials. Adverse reactions have not been reported in dogs receiving colchicine (0.03 mg/kg/day orally) for 6 to 30 months.

Sequelae of Chronic Liver Disease

Management of GI ulceration was previously discussed. As disease progresses, the likelihood of ulceration increases not only because of impairment of the mucosal barrier but also because of increased risk of bleeding resulting from coagulopathies. Bleeding into the GI tract increases the risk of hepatic encephalopathy. Treatment of hepatic encephalopathy was discussed under acute hepatic failure.

Control of ascites can be difficult with chronic disease. Fluid accumulation is more likely to reflect increased sodium and water retention (stimulated by portal hypertension) rather than decreased albumin, although hypoalbuminemia may contribute to ascitic fluid formation. Dietary restriction of sodium should be the targeted method by which ascitic fluid formation is controlled. If this is insufficient, diuretic therapies should be instituted. Because ascites may be associated with high aldosterone concentrations, spironolactone (1 to 2 mg/kg orally every 12 hours) might be the first diuretic used. The dose may be doubled in 1 week if there has been little response. Note that its cardioprotective effects (see Chapter 15) may also potential contribute to control of inflammation in the liver. Because spironolactone is a potassium-sparing diuretic, potassium supplementation may not be necessary and may be dangerous. If the patient continues not to respond to spironolactone, furosemide therapy can be instituted (1 to2 mg/kg orally every 8 to 12 hours initially and then titrated to a minimum effective dose daily, every other day, or every third day). Care must be taken not to dehydrate the patient. Total eradication of ascitic fluid need not be the goal of diuretic therapy.

Animals with chronic (including cirrhotic) liver disease are increasingly susceptible to bacterial infections and specifically to septicemia. However, routine use of antimicrobials is not recommended in order to avoid advent of resistance; fluoroquinolones in particular should be avoided routinely. Previous exposure to antibials should be considered as drugs are empirically selected to treat septicemia. Both gram-negative coliforms and anaerobes should be targeted with antimicrobial therapy.

As hepatic disease progresses to end-stage disease, note that patients are more susceptible to disseminated intravascular coagulation. This syndrome should be anticipated in patients and managed accordingly.

A review of of 41 relevant articles regarding the use of SAMe in human patients with liver disease, including a focus on cholestasis.¹⁷⁹ Most studies enrolled only a small number of patients, and the quality of the studies were markedly variable. The review concluded that SAMe was more effective than placebo in reducing hyperbilirubinemia and pruritis associated with cholestasis, in studies comparing SAMe with traditional therapy (ursodeoxcycholic acid) for liver disease, although two clinical trials indicated that ursodeoxycholic acid was preferred to SAMe for cholestatic pruritis associated with pregnancy. The remaining studies were too diverse with regard to diagnosis to allow conclusions to be drawn.

Sixteen placebo-controlled clinical trials were reviewed in human patients with a variety of chronic liver diseases who were receiving milk thistle. As with the SAMe studies, poor study methods or reporting limited effective evaluation, causing reviewers to have difficulty with interpretation of results. In general, meta-analyses indicated small treatment effects, with some statistical significance favoring milk thistle for treatment of selected liver disorders based on improvements in aminotransferases and liver function tests. Milk thistle was associated with few adverse events, and these generally were considered minor.²⁴⁷ Cholangitis and cholangiohepatitis in the cat are frequently associated with IBD or pancreatitis. In the cat, the common association may reflect the proximity of the bile duct to the pancreatic duct. Treatment is similar to that for chronic liver disease, including SAMe and silymarin, choleretics, and antimicrobials (to decrease bacterial and toxin load), which target gastrointestinal microflora. Immune suppression is indicated in nonsupprative disease, particularly if associated with IBD. In the dog, the presence of fibrosis may indicate the need for antifibrotics (e.g., colchicine or elemental zinc).

PORTOSYSTEMIC SHUNTING

In his original report of cerebrospinal fluid concentrations of potential mediators of hepatic encephalopathy, Holt and coworkers²⁴⁸ reviewed the pathophysiology of neurologic abnormalities associated with portosystemic shunting.

Among the proposed altered mediators, which might serve as targets of drug therapy, are monoamine and amino acid neurotransmitter systems, endogenous benzodiazepines and their receptors, and ammonia. Upregulation of genes encoding peripheral GABA-like receptors has been proposed as a cause of altered neurotransmission. Accumulation of potential neurotoxins, including GABA, has also been proposed. Others include include short-chain fatty acids, mercaptans, false neurotransmitters such as tyramine, octopamine, betaphenylethanolamines; manganese, and ammonia. Ammonia is associated with increased cerebrospinal fluid tryptophan, possibly because of direct stimulation by way of the neutral amino acid transport proteins at the blood-brain barrier. In the absence of a urea cycle, CNS ammonia is removed by transamination of glutamate into glutamine, which occurs in astrocytes by way of a specific astroglial enzyme in rats. Glutamine, in turn, however, may competively inhibit blood-brain barrier transport proteins responsible for efflux of the large, neutral amino acids. Supporting this mechanism, clinical signs of hepatic encephalopathy resolved in rats with portosystemic shunting treated with methionine sulfoximine, an inhibitor of glutamine synthetase.

A Cochrane review of clinical trials studying the use of probiotics for treatment of nonalcoholic fatty liver disease and nonalcoholic steatohepatitis found insufficient evidence to support or refute treatment. However, the use of probiotics and synbiotics to support liver function or treat liver also disease has been reviewed by Lenoir-Wijnkoop and coworkers.¹⁵¹ The rationale reflects the impact that these agents might have on the microbiota of the gut–liver axis, a term used in human medicine to refer to the impact that gut-derived endotoxins and active metabolites have on the liver. Upregulation of

proinflammatory cytokines may contribute to inflammation progressing to fibrosis and lipid peroxidation. Theoretically, modulation of the gut microflora might reduce these detrimental microbiota effects. Again, in a mouse model, a probiotic containing three species of Bifidobacterium, four species of Lactobacillus, and Streptococcus thermophilus decreased the extent of (alcohol-induced) liver disease. In a human clinical trial, treatment of a synbiotic containing fructooligosaccharides, Bifidobacterium, and seven species of Lactobacillus (L. acidophilus, L. rhamnosus, L. plantarum, L. salivarius, L. bulgaricus, L. lactis, L. breve plus) decreased liver enzymes and (in the alcoholic group) increased hepatic function in patients with nonalcoholic fatty liver disease and alcoholic cirrhosis. More intriguing, a prospective, randomized study in human patients with liver cirrhosis associated with minimal hepatic encephalopathy positively responded to a symbiotic containing four probiotic non-urease-producing strains (L. plantarum, L. paracasei, Leuconostoc mesenteroides, Pediococcus pentosaceus) and four fibers (beta-glucan, resistant starch, inulin, pectin). The fecal microbiota was recolonized with non-urease-producing Lactobacillus spp., urinary pH decreased along with serum ammonia and endocoxin. Hepatic encephalopathy was reversed in 50% of patients, and hepatic function improved in 50% of patients receiving the symbiotic.

Diseases of the Pancreas and Acute Pancreatitis

The combination of feline trypsinogen-like imunoreactivity and abdominal ultrasound findings appear to be able to diagnose feline pancreatitis with high sensitivity and specificity.²⁴⁹ Steiner et al provides evidence that exocrine pancreatic insufficiency does occur in cats and can be diagnosed on the basis of feline trypsin-like immunoactivity.²⁵⁰ Cobalamin but not folic acid absorption is impaired in exocrine pancreatic insufficiency. Decreased folic acid indicates concurrent intestinal disease.

Medical management of acute pancreatitis is supportive and symptomatic, allowing the pancreas to "rest" and heal. Drugs that may contribute to pancreatitis^{251,252} should be discontinued. Suspected drugs include thiazide diuretics, furosemide, azathioprine, L-asparaginase, sulfonamides, and tetracyclines. Glucocorticoids, bromide, phenobarbital, and H₂-receptor antagonists have also been implicated. Glucocorticoids may impair macrophage clearance of alpha-macroglobulin complexes (protease inhibitors complexed with proteolytic enzymes), thus predisposing the pancreas to stimulation by CCK.

Animals should be fasted to prevent pancreatic stimulation. Fluid therapy consisting of balanced electrolytes should be administered for at least 3 to 4 days, depending on the severity of the case. Electrolytes and acid–base therapy should be monitored; hypokalemia should be anticipated and treated accordingly. Because of the risk of subclinical hypocalcemia, sodium bicarbonate should be used cautiously because alkalosis can precipitate a hypocalcemic episode in these patients. Antiemetics should be used in animals that continue to vomit. Ideally, a drug that acts both centrally and peripherally, such as metoclopramide, should be chosen. Analgesic therapy is indicated in patients with moderate to severe pain. Opioid analgesics such as butorphanol or buprenorphine should be considered. Meperidine has been recommended as well, although its short duration of action may preclude effective use. Fresh whole blood or plasma may replace alpha macroglobulins responsible for clearing the pancreas of proteolytic enzymes and may increase plasma albumin. This may be important, particularly in the case of severe pancreatitis or that associated with disseminated intravascular coagulation. The advent of disseminated intravascular coagulationshould be treated accordingly.

Protease inhibitors such as aprotinin (250 mg or 1,500,000 kallikrein inhibitory units intraperitoneally every 6 to 8 hours) may be more effective in dogs than in humans because of differences in potency.²⁵³ However, the drug may be prohibitively expensive. Alternatively, 5000 kallikrein inhibitory units/kg intravenously every 6 hours has been recommended but is not as preferred as intraperitoneal injection. Selenium (0.1 mg/kg every 24 hours by intravenous infusion administered as selenious acid [40 µg/mL]) may be helpful.

Because oxidative stress plays a major role in the early stage of acute pancreatitis, antioxidant therapy might be considered. Among the antioxidants studied is N-acetylcysteine, which intracellularly is converted to a reduced GSH provider, which directly scavenges reactive oxygen species. N-acetylcysteine (1000 mg/kg every 3 hours intraperitoneal [IP]) was effective in reducing outcome measures (cytokines, conjugated dienes, lung injury, survival) associated with acute pancreatic in a mice ceruline or diet model when administered prophylactically (1 hour before induction or with the diet).²⁵³ Glucocorticoid therapy is controversial because of the potential for these drugs to contribute to pancreatitis. Even in patients suffering from shock, the role of glucocorticoids is not clear. However, it is unlikely that a very shortterm administration of glucocorticoid therapy (i.e., one to two doses) will be harmful in patients with fulminating pancreatitis. Methylprednisolone succinate is probably preferred because of the oxygen-scavenging ability of this glucocorticoid compared to others. Inhibition of gastric secretions with H₂-receptor antagonists, proton pump inhibitors, antacids, or drugs targeting the pancreas and its secretion (e.g., atropine, calcitonin, and somatostatin) has not yet proved effective for the treatment of acute pancreatitis. With time, natural or synthetic enzyme inhibitors directed toward pancreatic secretions may become useful (and available). In very acute cases or repetitive cases, insulin therapy may be indicated in the presence of persistent hyperglycemia indicative of diabetes mellitus.

Manipulation of microflora may be a target of treatment for pancreatitis. The role of parenteral antibiotics is not clear in the treatment of acute pancreatitis, and caution is recommended because of the risk of emergent multidrug-resistant microorganisms. If the decision is made to use parenteral antimicrobials, a number of drugs will penetrate the pancreas effectively. As with any infection involving the abdomen, gram-negative coliforms should be the primary target, but anaerobes should not be overlooked. Trimethoprim–sulfonamide combinations have been suggested, although sulfonamides are one of the groups of drugs implicated in the cause of pancreatitis. Bacterial depopulation of the GI tract by antimicrobials decreases the risk of bacterial translocation, thus potentially reducing the incidence of systemic organ failure. However, the advent of multidrug-resistant bacteria is negatively affecting widespread implementation of antibacterial prophylaxis. The use of probiotics for treatment of pancreatitis was reviewed in humans.¹⁵¹ Use targets that small proportion of patients for which acute pancreatitis shifts from mild to severe and life threatening. As reviewed by Lenoir-Wijnkoop and coworkers,151 a clinical trial in humans found the incidence of pancreatic necrosis to be less (1 of 22, or 5%) in a group receiving a probiotic compared with a group that received a heat-inactivated probiotic (7 of 23, or 30%). A multicenter clinicial trial in Europe is further investigating the use of B. bifidum W23, B. infantis W52, L. acidophilus W70, L. casei W56, Lactobacillus salivarius W24, and Lactococcus lactis W58; these specific organisms were selected on the basis of their ability to survive in the GI environment associated with pancreatitis. In a rat model, probiotic use increased survival in acute pancreatitis. Although the use of probiotics in prevention of acute pancreatitis appears promising, the potential risk for (pathogenic) colonization of the necrotic pancreas with the probiotic microorganisms has not been effectively addressed. In human medicine the advent of pancreatitis actually has been associated with IBD. Chronic pancreatitis may reflect generation of autoantibodies toward pancreatic acinar cells, which may reflect hapten formation and drug allergies.²⁵⁵

A number of drugs used (in humans) to treat IBD have been associated with the advent of acute pancreatitis in those patients. These include mercaptopurine, azathioprine, coricosteroids, sulfasalazine, and 5-aminosalicylic acid products.²⁵⁵ For the former, treatment of chronic pancreatitis should focus primarily on treatment of IBD, whereas the latter includes discontinuation of the inciting drug.

Exocrine Pancreatic Insufficiency

Clinical signs associated with exocrine pancreatic insufficiency (e.g., diarrhea, weight loss, polyphagia) reflect decreased intraduodenal concentrations of pancreatic enzymes and, to a lesser degree, bicarbonate or other materials. These deficiencies result in malassimilation of fats, carbohydrates, proteins, fat-soluble vitamins, and cobalamin. Additionally, the number and composition of the small intestinal bacterial flora may change, contributing to the clinical signs. Accordingly, supplementation of B vitamins and cobalamin and treatment with probiotics should be considered.

Medical management of exocrine pancreatic deficiency should be supported by dietary management. Enzyme replacement using commercially available products should be sufficient in most animals. Use of the powder in two daily feedings (two teaspoons of the nonenteric product per 20 kg) with each meal should resolve diarrhea within 3 to 4 days and promote weight gain. Because commercial dried pancreatic extracts are relatively expensive, chopped pig or cow pancreas (certified as healthy) can be used (3 to 4 ounces per 20 kg) in lieu of the commercial preparation. Fresh pancreatic tissue can be frozen for 3 to 4 months without apparent loss of pancreatic enzyme activity.

Commercial powders are not particularly efficient; much of the enzyme activity is rapidly lost due to inactivation by gastric acidity. For animals that do not respond to therapy initially, attempts can be made to improve the action of the enzymes. Of the methods suggested to improve efficiency or reduce gastric loss (including preincubation with food and addition of bile acids), inhibition of gastric acid secretions appears most useful. An H₂-receptor antagonist can be given with food or, to further improve efficacy, 30 to 60 minutes before feeding. Enteric coating not only does not appear to improve efficiency but may further decrease availability of the enzymes.

Supplementation of vitamin B_{12} (250 µg intramuscularly or subcutaneously once weekly for 1 month) and vitamin A (tocopherol; 400 to 500 IU once daily with food for 30 days) may be necessary for some patients and might be considered in animals in whom diarrhea persists despite enzyme replacement. Bacterial overgrowth may become a problem in some patients because of the presence of undigested nutrients that serve as a nutrient source for bacteria. Long-term antibiotic therapy is discouraged because of the risk of altered microflora and damage to the GI mucosa. Short-term therapy with oral metronidazole, tylosin, or oxytetracycline should prove beneficial in cases where bacterial overgrowth is causing malabsorption and diarrhea. Occasionally, animals may also have IBD, which contributes to clinical signs. Treatment with glucocorticoids may be indicated for 7 to 14 days.
