NORMAL RESPIRATORY PHYSIOLOGY

Airway Caliber Changes

Nervous innervation to the smooth muscle of the respiratory tract is complex. The parasympathetic system provides the primary efferent innervation, with acetylcholine as the primary neurotransmitter.^{1,2} Its fibers are responsible for the baseline tone of mild bronchoconstriction that characterizes the normal respiratory tract through M₃ muscarinic receptors. The effects are balanced by bronchodilation resulting from β_2 -receptor stimulation.^{3-5,} In contrast, α -adrenergic stimulation can contribute to bronchoconstriction.^{2,4,6} A third, largely understood nervous system, referred to as the *nonadrenergic*, *noncholinergic system* or the *purinergic system*, also innervates bronchial smooth muscle.^{1,7} This system mediates bronchodilation by way of vagal stimulation. The afferent fibers of this system are probably irritant receptors, and although the neurotransmitter has not yet been conclusively identified, vasoactive intestinal peptide has been implicated in the cat.^{8,9} Malfunction of this system has been associated with bronchial hyperreactivity, which often characterizes asthma.⁷

The intracellular mechanisms that transmit signals from the nervous system to smooth muscle depend in part on changes in the intracellular concentration of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) (Figure 20-1). The effects of these two secondary messengers are reciprocal such that the increased intracellular concentration of one is associated with a decreased concentration of the other. Cyclic AMP-induced bronchodilation is decreased by α -adrenergic stimulation and increased by β_2 -receptor stimulation.³ In contrast, cGMP-induced bronchoconstriction is increased by stimulation of muscarinic (cholinergic) and, indirectly, histaminergic receptors (see Figure 20-1). The relative sensitivity of bronchial smooth muscle to histamine-induced

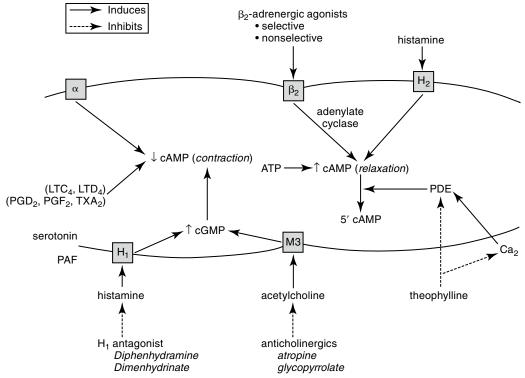

Figure 20-1 Factors determining bronchial smooth muscle tone. Reciprocal changes in cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) determine muscle tone. Contraction occurs when cAMP levels are decreased by events such as α -adrenergic stimulation or when cGMP levels increase in response to muscarinic receptor (M₃) stimulation by acetylcholine or H₁-receptor stimulation by histamine. Calcium (Ca²⁺) and several mediators can also induce bronchoconstriction. Increased cAMP levels induced by β -adrenergic or histamine (H₂) receptor stimulation counteract muscle contraction. Inhibition of phosphodiesterase (PDE) also causes increase cAMP. Although the effects of most inflammatory mediators are best counteracted by preventing their release, several drugs may be used to antagonize smooth muscle contraction regardless of the etiology. *LTC*, Leukotriene C; *LTD*, leukotriene D; *PAF*, platelet-activating factor; *PGD*₂, prostaglandin D₂, *PGF*₂, prostaglandin F₂; *TXA*₂, thromboxane.

and acetylcholine-induced bronchoconstriction varies with the location and species.^{5,10,11} Peripheral airways in dogs are more susceptible than in cats to acetylcholine; feline airways, in general, are more sensitive to acetylcholine and serotonin than histamine.¹² Smooth muscle receptors are also susceptible to stimulation by a variety of chemical mediators (see Figure 20-1), which may also modulate cAMP and cGMP.¹³⁻¹⁵

KEY POINT 20-1 The normal state of the airway is one of bronchoconstriction, mediated by the parasympathetic system (via cGMP). However, this is offset by sympathetic (via cAMP) bronchodilation.

Control of bronchial smooth muscle tone is very complex and depends on input from sensory receptors. At least five types of sensory receptors have been identified in cat lungs, all of which can be classified as irritant (or mechanoreceptor), stretch, or J-receptors.⁷ All appear to be innervated by the parasympathetic system. Irritant receptors, located beneath the respiratory epithelium, occur in the upper airways² and, in cats, as far peripherally as the alveoli.¹ Physical, mechanical, or chemical stimulation of these receptors results in tachypnea, bronchoconstriction, and cough. As reviewed by Canning,^{7a}

rapidly adapting receptors (RARs) terminate in or below the epithelium primarily of intra-pulmonary, but to some degree, extra-pulmonary airways. They can adapt within 1 to 2 seconds to changes in airway mechanics and are subject to activation by multiple stimuli, including chemical mediators. In contrast, slowly adapting receptors (SARs) may be responsible for physiologic responses (i.e., termination of inspiration and initiation of expiration). SARS centrally inhibit respiration and decrease airway smooth muscle tone. However, they may facilitate cough. Cats have few SARS but many RARs.^{7a} C-fibers represent the majority of fibers innervating the airways and lungs. They are physiologically similar to nociceptors of other tissues. They appear to synthesize neuropeptides (e.g., substance P) that influence the central and peripheral nerve terminals. Mediators stimulating C-fibers vary: in dogs, pulmonary subtypes do not (but bronchial subtypes do) respond to histamine, and in other animal models, they do not respond to serotonin or adenosine. C-fibers regulate airway defense reflexes, interacting with RAR, although the scientific description of these fibers is not clear. C-fibers and RARS interact with the spinal cord through central sensitization. Subsequent heightened reflex responsiveness may occur; tachykinins (including substance P) appear to play a role in hyperreflexia,

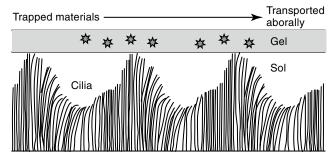

Figure 20-2 The mucociliary apparatus represents the first line of defense for pathogens entering the respiratory tract. Cilia are bathed in a water or sol layer. When the cilia beat in synchrony, the movements send forward (orally) the mucoid or gel layer that lies on top of the cilia. Materials trapped in this layer also move forward to be either swallowed or expectorated.

an effect prevented by neurokinin receptor antagonists. Convergence of vagal afferents in the nucleus of the solitary tract may explain in part the close relationship between vomiting and coughing. Receptors also converge in the ventral respiratory column of the medulla. Airflow velocity appears to be the most critical factor determining stimulation of irritant receptors in the upper airways.¹ Airway constriction sufficient to cause airflow velocity to exceed a specific threshold results in a vagally mediated cough reflex and bronchoconstriction. Airways can also be occluded by mucus and edema or by chemical mediators released during upper airway infections.⁷

In addition to the cough receptors, afferent nerves, efferent nerves and effector muscles, the cough reflex also consists of a poorly defined cough center.

Respiratory Defense Mechanisms

In addition to the cough and sneeze reflexes, two other systems provide the major defense of the respiratory tract against invading organisms or foreign materials: the mucociliary apparatus and the respiratory mononuclear phagocyte system.² The mucociliary apparatus (Figure 20-2) is the first major defense and consists of the ciliary lining of the tracheobronchial tree and the fluid blanket surrounding the cilia. Nervous innervation to the cilia has not yet been identified. Although ciliary activity increases with β -adrenergic stimulation, this may simply reflect the sequelae of β -adrenergic stimulation on respiratory secretions.¹⁶ Two types of secretions form the fluid blanket of the respiratory tract.¹⁷ The cilia must be surrounded by a low-viscosity, watery medium to maintain their rhythmic beat. A more mucoid layer lies on top of the cilia and serves to trap foreign materials inspired with air. The synchronous motion of the cilia causes the cephalad movement of the mucous layer and any trapped materials.

Changes in the viscoelastic properties of mucus such that it becomes either too watery or too rigid will result in mucus transport that is less than optimal.² Mucus released by goblet cells results from direct irritation² and is not amenable to pharmacologic manipulation. Surface goblet cells, which are uniquely prominent in feline bronchioles,¹⁸ increase in number with chronic disease. Submucosal glands of the bronchi secrete both a serous and a mucoid fluid. The secretions tend to be more fluid than that of the goblet cells, but the degree varies with the stimulus. The normal consistency of the combined secretions of the tracheobronchial tree is 95% water, 2% glycoprotein, 1% carbohydrate, and less than 1% lipid.² Glycoproteins increase the viscosity of the secretions, providing protection and lubrication. Infection and chronic inflammatory diseases can have a profound effect on respiratory secretions. The glycoprotein component tends to be replaced by degradative products of inflammation such as DNA and actin.¹⁷ Goblet cell numbers increase with a subsequent increase in the viscosity of respiration secretion. Parasympathetic, cholinergic stimulation increases mucus secretion, whereas *β*-adrenergic stimulation causes secretion of mucus, electrolytes, and water.^{2,16}

KEYPOINT 20-2 The importance of the mucocilary escalator to treatment of respiratory disorders should not be underestimated. Its viscosity must be balanced if secretions and their entrapped materials are to be properly cleared from the airways.

The second major component of the pulmonary defense system is the respiratory mononuclear phagocyte system. In cats, calves, pigs, sheep, and goats, this includes both alveolar macrophages and the pulmonary intravascular macrophages (PIMs).¹⁹ The PIMs are resident cells that are characterized by phagocytic properties and thus cause the release of inflammatory mediators. The clearance of blood-borne bacteria and particulate matter in these species is accomplished by PIMs rather than hepatic Kupffer cells and splenic macrophages as in most other species.¹⁹ The pharmacologic significance of the mononuclear phagocyte system reflects their role in inflammation (Figure 20-3; see also Figure 20-1). A number of preformed (e.g., histamine and serotonin) and in situ (e.g., prostaglandins, leukotrienes, and platelet-activating factor [PAF]) mediators are released by inflammation cells.¹³⁻¹⁵ Each is capable of inducing a variety of adverse effects that tend to decrease airway caliber size: edema, chemotaxis, increased mucus production, and bronchoconstriction (Table 20-1). The involvement of PIMs in both experimental and natural respiratory diseases of animals suggests that release of chemical mediators from these cells may be important in the pathogenesis of bronchial diseases.

KEYPOINT 20-3 The pulmonary intravascular macrophage system of cats may contribute to their predisposition to inflammatory respiratory diseases (compared with dogs).

SURFACTANT

The primary function of surfactant is to decrease surface tension in alveoli, affecting lung mechanics and gas exchange. However, pulmonary surfactant also affects pulmonary defense mechanisms.²⁰ Surfactant is a complex mixture of lipids and

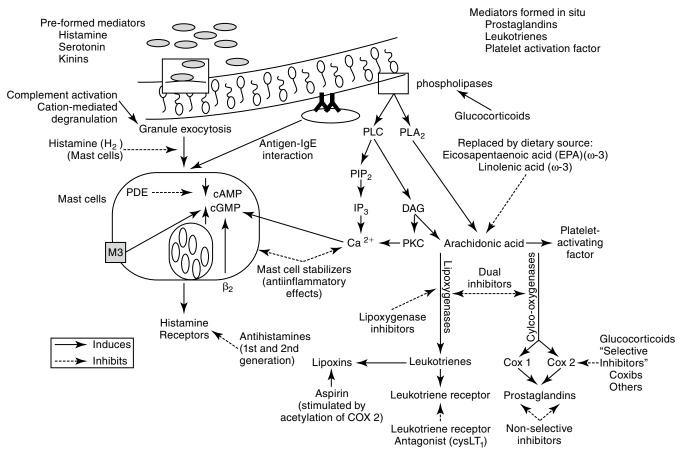

Figure 20-3 The formation of mediators important in the pathogenesis of respiratory disease. Leukocytes and other cells release arachidonic acid metabolites and platelet-activating factor (PAF) after activation of phospholipases by a variety of stimuli. Mast cell degranulation induced by both immune and nonimmune stimuli is also accompanied by arachidonic acid metabolism as well as by the release of preformed mediators that are stored in the granules. Intracellular mechanisms that induce mast cell degranulation include increased calcium (Ca²⁺), increased cyclic guanosine nucleotide (cGMP) mediated by muscarinic (M₃) receptors, or decreased cyclic adenosine nucleotide (cAMP) mediated by α -adrenergic receptor stimulation. Drugs used to prevent mediator release include glucocorticoids, which are one of the few classes of drugs that can prevent activation of phospholipases (mediated by lipocortin) and thus release of arachidonic acid metabolites and PAF. Inhibition of prostaglandin synthesis by nonsteroidal antiinflammatory drugs may prove beneficial but also may lead to increased formation of leukotrienes by providing more arachidonic acid. Leukotriene actions can be blocked either by leukotriene receptor antagonists or by blockade of leukotriene receptors. Mast cell degranulation can be prevented by stimulation. Drugs that block β -adrenergic receptors are contraindicated in most respiratory diseases. *DAG*, diacylglycerol; *IP*₃, inositol triphosphate; *PIP*₂, phosphatidylinositol; *PKC*, protein kinase *C*; *PLC*, phospholipase C; *PLA*₂, phospholipase A₂.

proteins synthesized and secreted by alveolar type II cells with relative consistency among mammalian species.²⁰ In humans the proportion of components is predominantly phospholipids (80%) but includes proteins (12%) and other lipids (8%). The phospolipids principally comprise phosphatidylcholine (85%), the most important to reduction of surface tension being dipal-mitoylated phosphatidylcholine (DPPC). Four surfactant-associated proteins (SP) are named A through D. Both SP-A and SP-D enhance phagycytosis of bacteria and viruses and regulate type II pneumocytes. The primary role of SP-B and SP-C is reduction of surface tension, particularly in terminal airways. A number of nonspecific host defense mechanisms have been attributed to surfactant.²⁰ Enhanced stability of the alveolar lining film allows it to serve as a nonspecific barrier

to microorganism adhesion and subsequent pulmonary invasion. Muciliary transport is improved by its viscoelastic and rheologic properties. Particle clearance is enhanced, in part through an apparently stimulatory effect on chloride ion transport. Antiinflammatory effects reflect superoxide dismutaseand catalase-mediated oxygen radical scavenging and reduced neutrophil production of superoxide.^{20,21} Direct antibacterial and antiviral properties have also been attributed to surfactant. Both SP-A and SP-D appear to provide a first line of defense by acting as collectins that target carbohydrate structures on a variety of pathogens. Alveolar macrophage response is increased by SP-A; SP-D enhances macrophage release of oxygen radicals. Cytokines (e.g., tumor necrosis factor [TNF]- α interleukin [IL]-1 β , and IL-6) release is stimulated by SP-A.

Table 20-1 Inflammatory Mediators and Their Proposed or Known Role in Asthma						
Class	Source	Targeted Therapy	Function			
Lymphokines			Cytokines of lymphocyte origin			
IL-2	CD4 (T _h 2)	GLC	T cell growth and differentiation			
IL-3*	CD4 (T _h 2)	GLC	Hematopoietic growth factor			
IL-4	CD4 (T _h 2)	IL-4 antibodies; IL-4 receptor antagonists; GLC	T _h 2 and eosinophil promotion; IgE synthesis; increased low affinity IgE receptor synthesis; increased VCAM-1			
IL-5*	CD4 (T _h 2)	IL-5 antibodies; IL-5 receptor antagonists; GLC	Eosinophil activation, maturation, and mobilization			
IL-13	CD4 (T _h 2)	GLC	Eosinophil activation, IgE synthesis			
Chemokines			Chemotactic cytokines			
IL-8	Epithelial cells	GLC	Inflammation amplification through neutrophil activation; histamine and LT release from basophils			
RANTES [†]	Epithelial cells	CCR antibody	Inflammation amplification through eosinophil activation			
MCP-1 [†] , MCP-2, MCP-3 [†] , MCP-4 [†]		CCR antibody	Eosinophil chemoattraction			
MIP-α			VCAM-1 upregulation			
Eotaxin			Neutrophil activation; histamine and LT release from basophils; eosinophil mobilization (with IL-5)			
Proinflammatory Cytokines						
IL-1	Macrophages	GLC	T-cell activation; $T_h 2$ expansion; adhesion molecule (ICAM) upregulation			
IL-6 T	Macrophages		T cell and B cell growth factor, IgE synthesis			
TNF-alpha	Macrophages	Antibodies; inhibitors of TNF-converting enzyme inhibitors	Activation of antigen-presenting cells activated, epithelial cells and macrophages; increased airway hypersensitiv- ity; adhesion molecule (ICAM-1) increase			
GM-CSF*	Epithelial cells (and CD4 (T _h 2)		Amplification of inflammation through antigen presenta- tion; eosinophil activation;maturation and proliferation of hemopoietic cells; leukotriene induction			
Antiinflammatory Cytokines						
IL-10	CD4 (T _h 2)	Recombinant; GLC	Inhibition of proinflammatory cytokines (e.g., IL-2); promotion of T _h 2 from T _h 0 (in contrast to other antiin- flammatory cytokines)			
IL-12		Pending?	T _h 1 promoted, T _h 2 inhibited; IgE synthesis inhibited			
IL-1ra	Monocytes, macrophages, epithelial cells	Pending (retinoic acid: decreased expression)?	$\rm T_h2$ proliferation inhibited, IgE synthesis blocked			
IFN-γ	Th1	Recombinant; GLC	Antigen presentation; T _h 2 cells inhibited; eosinophil influx inhibited, macrophage and epithelial cells inhibited; Il-1-induced IgE synthesis inhibited			
Adhesion Molecules			Cell-to-cell communication through integrin binding molecules			
VCAM-1			Vascular (endothelial) adhesion to support eosinophil and lymphocyte movement			
ICAM-1			Intracellular adhesion			
MAdCAM-1			Mucosal adhesion molecule			

Continued

Table 20-1	Inflammatory Mediators and Their Proposed or Known Role in Asthma—cont'd				
Class	Source	Targeted Therapy	Function		
Integrins			Cell-to-cell communication through binding of adhesion molecules		
α4β1 (VLA-4)	Eosinophils	Receptor antibodies (natalizumab); recep- tor antagonists	Binds to VCAM-1; promotion of migration, activation, and increased survival of inflammatory cells.		
α4β7	Eosinophils		Binds to VCAM-1 and MAdCAM; promotion of migra- tion, activation, and increased survival of inflammatory cells.		

IL, Interleukin; *CD*, cluster of differentiation *4*; *GLC*, glucocorticoid; *IG*, immunoglobulin; *LT*, leukotriene; *MCP*, monocyte chemotactic protein; *MIP*, macrophage inflammatory protein; *CCR*, chemokine receptor; *VCAM*, vascular adhesion molecule; *ICAM*, intercellular adhesion molecule; *TNF*, tumor necrosis factor; *GM-CSF*, Granulocyte-macrophage colony-stimulating factor; *MAdCAM*, mucosal vascular cell adhesion molecule; *VLA*: very late antigen; *RANTES*, Regulated upon Activation Normal T-cell Expressed, and Secreted. *Eosinophils also a possible source.

†CCR.

Changes in surfactant have been associated with a number of respiratory diseases. In humans acute respiratory distress syndrome (ARDS) is associated with changes in the biochemical and biophysical characteristics of surfactant. As a result, surface tension increases, and the phospholipid, fatty acid, and protein profiles change. Serum proteins and inflammatory mediators directly inhibit or degrade surfactant. Abnormalities in the amount and both the phospholipid and the protein composition of surfactant have been associated with infectious diseases of the lungs. The ability of surfactant to suppress immune-mediated lung injury has been interpreted as a possible role of surfactant dysfunction in asthma. Elastase-induced dysfunction and impaired SP-A and -D also may contribute to the surface destruction associated with chronic obstructive pulmonary disease (COPD) and emphysema.20

PATHOGENESIS OF INFLAMMATORY RESPIRATORY DISEASES

Although it is not the only chronic disease of the respiratory tract, feline bronchial asthma has offered a model for understanding pathophysiology and identifying targets of drug therapy. The interaction of sensory receptors and mediators of bronchial tone is intricately balanced in the normal lung. A series of pathologic disturbances, however, severely disrupts the balance in bronchial asthma.

Asthma is a pathologic state of the lungs characterized by marked bronchoconstriction and inflammation.²²⁻²⁶ Although recent evidence is emerging that airway smooth muscle plays a role in asthma independent of inflammation,²⁷ the latter is an important contributor to disease and warrants a continued focus for drug therapy. Airways become hypersensitive to selected mediators (e.g., histamine and cholinergic stimulants).^{5,10} The terms *allergy* and *atopy* are often used interchangeably; however, for this discussion *allergy* refers to an uncommitted biological response to an antigen. The pathophysiology of chronic allergic diseases is discussed in Chapter 31. *Atopy* refers to an allergic response characterized by immunoglobulin E (IgE)–mediated antibodies. Atopy generally

reflects a genetic predisposition to IgE antibody production against environmental allergens. Most commonly, the allergic response is low grade and thus beneficial (removal of inciting allergen). However, in atopic patients the response, including IgE antibody production, is exaggerated. Asthma is one of several chronic atopic diseases characterized by an increasing incidence in human medicine; others include allergic rhinitis, atopic eczema, and inflammatory bowel disease.²⁸ Inflammatory mediators are the major contributors of the pathophysiology in asthma (see Table 20-1).^{22,23,25,26,29,30} Studies in several species have shown that initial exposure to an allergen activate mast cells, macrophages, and other cells lining the airways, increasing mucosal epithelial permeability. Subsequent mediator release not only directly and intensely affects airway inflammation, contraction of smooth muscle, and capillary permeability but also initiates release of chemotactic factors, local infiltration of activated eosinophils, and activation of T cells.31

The critical role of T cells in the initiation and perpetuation of asthma has been well documented³² and is supported by response in asthmatics to both glucocorticoids and cyclosporine.^{32,33} The exaggerated response that characterizes the atopic patient appears to reflect an imbalance in T_h1 versus T_h2 helper cells. Researchers in human medicine have postulated that atopic individuals fail (possibly as infants) to transition from a Th2-primary response (mediated by ILs 4, 5, and 13) to an "allergy protective" T_h1-mediated primary response. The T_h1 response is dominated by cell-mediated immunity, and delayed hypersensitivity (cytotoxic T cells) is initiated through macrophage production of IL-12 followed by production of interferon (IFN)-γ by T_h1 and natural killer cells. In normal infants the shift from T_h2 to Th1 might be stimulated by exposure to a variety of antigens, including microbes with cytosine and guanosine nucleotides (CpG repeats). The hygiene hypothesis suggests that atopy develops because subjects are not sufficiently exposed to allergens at a young age, perhaps as a result of early use of antimicrobials or lack of exposure to allergens (e.g., children exposed to one another at day care, or environmental factors [e.g., farms]).²⁸ The T_h2 response that characterizes inflammatory disease is associated with increased production of IL-4, IL-5, and IL-13. The IL-4 from T_h2 supports B-cell IgE synthesis. The T_h2 cells have a particular influence on eosinophils through IL-5, which regulates both differentiation and bone marrow release (mature and immature cells), and the chemokine eotaxin.²⁸ Subsequent accumulation of eosinophils in atopic tissue is influenced by continued recruitment by eotaxins, the presence of selective adhesion molecules, and delayed apotosis.²⁸

KEYPOINT 20-4 The inflammation associated with chronic allergic respiratory disease may reflect an imbalance between Th_1 and Th_2 cells.

The role of the bone marrow in the pathophysiology of atopy increasingly is emerging as potential target, leading to a systemic rather than local approach to therapy.³⁴ Signaling appears to occur between the lung and bone marrow, with IL-5 and/or eotaxin being the commonality.³⁵ Increased IL-3 may also play a role in eosinophil stimulation, whereas IL-18, IL-12, and INF- γ are inhibitory toward eosinophils.^{28,36} In animal models of asthma, including the canine *Ascaris* model, allergen exposure is associated with an increase in bone marrow to the lungs.³⁷ Interestingly, cysteinyl leukotrienes may influence eosinophil differentiation (in the presence of IL-3 or IL-5); leukotriene-receptor antagonists are able (in vitro) to suppress eosinophil differentiation.^{37,38}

Eosinophils contribute to mucosal damage through release of basic amines, cysteinyl leukotrienes, and PAF.²⁸ Inhibitory muscarinic (M₂) receptors are damaged, which facilitates persistent bronchoconstriction. Mediators are released following binding of allergens with the α chain of high-affinity IgE receptor (Fc \in RI α) on the cell. Regulation of IgE, which is found both on and in eosinophils, offers another potential target of therapy. IL-4 and IL-13 are the most important inducers of IgE production.²⁸

As permeability increases in response to inflammation, histamine and other inflammatory mediators are better able to reach and stimulate inflammatory cells located in the submucosa. The continued release of mediators is associated with stimulation of afferent nerve endings in the mucosa and reflex cholinergic bronchoconstriction. Mediators also increase microvascular permeability, induce chemotaxis, and stimulate mucous secretion. The release of cytotoxic proteins and toxic oxygen radicals further damages the respiratory epithelium, and the bronchial tree becomes hypersensitive. Mediators can also inhibit mucociliary function.²⁵ Mucus production increases as submucosal glands and goblet cells increase. The consistency of the mucus changes to become more viscous. Bronchial smooth muscle often hypertrophies and undergoes spasms.³⁹ Airway obstruction in chronic disease reflects bronchoconstriction, bronchial wall edema, and accumulation of mucus and cells. As the disease progresses, airways eventually become plugged and ultimately collapse. Chronic inflammation leads to fibrosis, which contributes to the collapse, and air

trapped within the alveoli can result in emphysema. Asthma is a disease of central and large as well as small (<2 mm) airways.⁴⁰ Regarding the type of asthma previously considered "silent," studies in humans have revealed the importance of a therapeutic focus on airways beyond the eighth or ninth generation of the bronchial tree. In humans asthma and allergic rhinitis commonly, but not always, co-exist,⁴⁰ and allergens associated with rhinitis may be too large to penetrate the lower airways.⁴¹

The complex physiology of asthma is exemplified by the reparative role that eosinophils also have. Damage repair contributes to airway remodeling through release of growth factors and matrix metalloproteinases.

INFLAMMATORY MEDIATORS IN THE RESPIRATORY TRACT

Histamine

Histamine is a vasoactive amine stored in basophils and mast cells. Airway mast cells are located primarily beneath the epithelial basement membrane in dogs.²⁴ Histamine produces a variety of effects (see Table 20-1) by interacting with specific receptors on target cells.^{12,42} At least four histamine receptors have been identified, 5,29,43,44 two of which have been found in the trachea of the cat.^{5,6} Interaction with the H₁ receptor causes an increase in intracellular calcium, and ultimately in cGMP (see Figure 20-3).²⁹ Histamine also stimulates cholinergic receptors in the airway.^{24,29} Histamine causes constriction in both central and peripheral airways in dogs and cats.^{12,24} The effects of histamine so closely mimic the pathophysiology of early asthma that, for many years, histamine was considered the major cause of the syndrome.²⁹ Lack of clinical response to H₁-receptor antagonists, however, led to the realization that other factors are more important. In contrast to H₁ receptors, stimulation of H₂ receptors causes an increase in cAMP and bronchodilation.²⁹ Thus antihistamine drugs that block H₂ receptors may be contraindicated in asthma. Some studies have suggested that a defect in H₂ receptors may contribute to airway hyperreactivity.²⁹ Finally, recent evidence suggests that histamine regulates both T_h1 and T_h2 cells. Further, cells perpetuating the allergic response may be influenced by histamine through H₄ receptors located on eosinophils, basophils, mast cells, and dendritic cells.43

Histamine contributes to bronchial occlusion by mechanisms other than bronchoconstriction. Mucous secretion is mediated via H₂ receptors and by secretion of ions and water via H₁ receptors.²⁹ Microvascular leakage resulting from contraction of endothelial cells also follows H₁-receptor stimulation.²⁹ Histamine is chemotactic to inflammatory cells, particularly eosinophils and neutrophils. Interestingly, histamine stimulates T-lymphocyte suppressor cells by way of H₂ receptors,⁵ a function that also may be depressed in human patients with asthma.²⁹ Histamine also has a negative feedback effect on further histamine release mediated by IgE.²⁹ Both of these latter effects are mediated by H₂ receptors and would be inhibited by H₂-receptor antagonists.⁵

Serotonin

Serotonin (5-hydroxytryptamine [5-HT]) is released during mast cell degranulation.²⁹ Although serotonin does not appear to be an important mediator of human or canine bronchial asthma, both the central and peripheral airways in cats are very sensitive to its bronchoconstrictive effects after aerosolization or intravenous administration.¹² Constriction may reflect interaction with serotonin receptors or enhanced release of acetylcholine. Serotonin may also cause profound vasoconstriction of the pulmonary vasculature and microvascular leakage.²⁹

Prostaglandins and Leukotrienes

Prostaglandins (PGs) and leukotrienes (LTs) are eicosanoids that are formed when phospholipase A₂ is activated in the cell membrane in response to a variety of stimuli (see Figure 20-3). Arachidonic acid (AA) is subsequently released from phospholipids and enters the cell. In the cell it is converted by cyclooxygenases to inflammatory, but unstable, cyclic endoperoxides. The actions of various synthetases and isomerases on the endoperoxides result in the final PG products, including PGE₂, PGF_{2a}, PGD₂, prostacyclin (or PGI₂), and thromboxane (TXA_2) . The amount of each PG produced in the lung varies with the cell type and species. The effects of the various PGs tend to balance one another. PGD_2 , $PGF_{2\alpha}$, and TXA_2 cause bronchoconstriction, whereas PGE1 and, to a lesser extent PGI₁, cause bronchodilation.^{1,29} Bronchoconstriction induced by PGD₂ is about 30 times as potent as that induced by histamine.

Imbalances between PGs may be important in the pathogenesis of bronchial disease. Both PGD₂ and TXA₂ have been implicated in immediate bronchial airway hyperreactivity.²⁹ Thromboxane A₂ appears to be the predominant AA metabolite produced by feline lungs,⁴⁵ although other PG mediators are also important.⁴⁵

The role of LTs in atopy has been increasingly scrutinized in recent years. Lipoxygenases catalyze the conversion of AA to hydroperoxyeicosatetraenoic acid (HPETEs), which are further metabolized to several hydroxy acids (HETEs) and LTs (Chapter 29). Eosinophils have been known to be preferentially activated 5-lipoxygenase²⁹; selective activation of lipoxygenase by antigenic challenge yields subsequent formation of the cysteinyl LTs (cystLTs: LTB₄ C₄, and D₄), recognized as the components of slow reactive substance of anaphylaxis.²⁹ However, both intermediate and end products of lipoxygenase are active in the respiratory tract (see Table 20-1).²⁹ Among these mediators are some of the most potent inflammagens known. For example, bronchial smooth muscle contraction and microvascular permeability mediated by LTC₄ and LTD₄ is 100- to 1000-fold more potent than that induced by histamine. Both LTs are potent stimulators of mucous release in the dog but appear to be less potent in the cat.²⁹ In humans airway allergen challenge increases LTs in urine and bronchoalveolar lavage (BAL) fluid with asthma and nasal secretions with allergic rhinitis.³⁵ Increases in LTs in plasma, BAL fluid, or urine of challenged cats is controversial, although cats experimentally infected with

dirofilariasis likewise exhibited increased plasma as well as BAL fluid cysLT concentrations (unpublished data). The cysteinyl LTs exert biologic effects through cysLT1 and cysLT2 receptors.³⁵ Binding by LTs to eosinophilic cysL1 receptors (particularly LTD4) results in chemotaxis and prolonged survival, effects that are blocked by LT-receptor antagonists.³⁵ Further evidence suggests that cysteinyl LTs are also involved in the initial systemic atopic response that is mediated from the bone marrow.^{35,46}

Platelet-Activating Factor

PAF is also formed after activation of phospholipase A₂ in cell membranes. It is a potent, dose-independent constrictor of human airways, and it is the most potent agent thus far discovered in causing airway microvascular leakage.^{22,23} PAF is also a potent chemotactant for platelets and eosinophils, both of which are a rich source of PAF. The effects of PAF may be mediated through LTs. PAF has been implicated as the cause of the sustained bronchial hyperresponsiveness that characterizes asthmatics.²³ The role of PAF in feline and canine respiratory diseases has not been addressed. Eosinophils are, however, a major cell type associated with feline bronchial disease and some canine diseases, and it is likely that PAF is an important inflammatory mediator.

REACTIVE OXYGEN SPECIES

Reactive oxygen species (ROS) are constantly formed in the lung as part of pulmonary defense toward microorganisms and neoplasm.²¹ Free oxygen radicals, hydrogen peroxide and hypochlorous acid are among the species formed. Their formation is mediated, in part, by other inflammatory mediators such as TNF, IL-1, IL-6, and IL-8, and AA derivatives (PGs, LTs, and PAF). Hyperoxia will enhance generation of ROS.²¹ Normal cells are generally protected from ROS by a tightly controlled redox balance and formation of endogenous antioxidants; formation is enhanced by exposure to antioxidants. Those located primarily intraceullularly include catalase, superoxide dismutase, and glutathione redox compounds (glutathione, glutathione peroxidase, and glutathione reductase). Primarily extracellular antioxidants include fat-soluble compounds (vitamin E), water-soluble compounds (vitamin C, cysteine, reduced glutathione, taurine), and high-molecular-weight antioxidants (mucus and albumin).21

Neuropeptides

Several chemicals stimulate release of inflammatory neuropeptides from sensory neurons enervating smooth muscles. Cells stimulating neuropeptide release include macrophages, T-cells, eosinophils, and mast cells; example neuropeptides include substance P and, to a lesser degree, calcitonin generelated peptide and neurokinin A.⁴⁷ As with other inflammatory mediators, neuropeptides are associated with vasodilation, increased permeability and mucus production, as well as histamine release. The role of cytokines in the coordination and persistence of chronic airway inflammation is integral and, not surprisingly, very complex. The integrated nature of their actions renders them simultaneously ideal as targets of drug therapy but potentially a source of adverse events should therapy be successful. Four cytokine classes have been proposed: lymphokines, chemokines, and proinflammatory and antiinflammatory cytokines (see Table 20-1). The role of lymphokines was largely addressed with the discussion of T_h cell role in atopy. Initiation of T_h2 cells is not clear, but appears to involve presentation of restricted antigens in the presence of IL-4 and IL-10. Perhaps the most notable lymphokine of asmtha is IL-5.48 Recruitment of eosinophils into the lungs-the hallmark of asthma-is IL-5 dependent. However, IL-5 also is integral to the differentiation, proliferation, and maturation of eosinophil progenitor cells in the bone marrow before recruitment into the lung.

Chemokines are cytokines that attract inflammatory cells, including eosinophils, monocytes, and T-lymphocytes. Two groups have been described based on proximity of cysteine residues to one another: CXC or α chemokines (separated by an amino-acid) and CC or β -chemokines (no separation; see Table 20-1). Chemokines exert their effects through rhodopsin-like G protein-coupled receptors (referred to as CXC-R or CC-R). Because certain cells express selected receptors, pharmacologic therapy increasingly will be designed to be selectively antiinflammatory.³¹ Among the cells influenced by chemokines are eosinophils, which in turn release more chemokines. Among the most notable drugs targeting proinflammatory chemokines, and particularly their transcription, are glucocorticoids (see Chapter 30). Newer therapies take advantage of the presence of antiinflammatory cytokines; indeed, glucocorticoids facilitate restoration of antiinflammatory cytokines such as IL-10.

Communication Molecules: Adhesion Molecules and Integrins

Communication between cells is facilitated by adhesion molecules that interact, by way of ligand binding, with receptors on the surface of inflammatory cells known as *integrins*. Integrins are present on many cells, with receptor specificity occurring for selective cells. Integrins are absent on T_h1 cells but are particularly prevalent on T_h2 cells, mast cells, and eosinophils. Interaction between adhesion molecules and integrins promotes migration, activation, and increased survival of inflammatory cells. Drugs that target eosinophilic integrins (α 4 β 1 and 7) offer a possible mechanism whereby selective control of inflammation may limit side effects.⁴⁹

DRUGS USED TO MODULATE THE RESPIRATORY TRACT

The syndrome of chronic bronchial disease is best treated by breaking the inflammatory cycle while immediately relieving bronchoconstriction. Thus antiinflammatory drugs and bronchodilators represent the cornerstone of therapy for many bronchial diseases. Other categories of drugs that are effective for the management of respiratory diseases, particularly in small animals, include antitussives, respiratory stimulants, and decongestants.

Bronchodilators and Anti-Inflammatory Drugs

Because of a shared intracellular mechanism of action, most drugs that induce bronchodilation also reduce inflammation. Bronchodilators reverse airway smooth muscle contraction by increasing cAMP, decreasing cGMP, or decreasing calcium ion concentration (see Figure 20-1). In addition, these drugs also decrease mucosal edema and are antiinflammatory because they tend to prevent mediator release from inflammatory cells (see Figure 20-3). Rapidly acting bronchodilators include β -receptor agonists, methylxanthines, and cholinergic antagonists.

β-Receptor Agonists

 β -receptor agonists (Figure 20-4) are the most effective bronchodilators because they act as functional antagonists of airway constriction, regardless of the stimulus.^{22,50,51} Few β -agonists generally have been sufficiently studied in animals to describe pharmacokinetics or pharmacodynamics.

Large numbers of β_2 -receptors are located on several cell types in the lung, including smooth muscle and inflammatory cells.³ The receptor is linked to a stimulatory guanine nucleotide-binding protein (G protein). The interaction between a β -agonist and receptor causes a conformational change in the receptor and subsequent activation of adenylyl cyclase on the inner cell membrane (see Figure 20-1).⁵² Adenylate cyclase converts adenosine triphosphate to cAMP, a second messenger for activation of specific protein kinases that ultimately activate enzymes responsible for airway smooth muscle relaxation. β-receptor agonists are most effective in states of bronchoconstriction. Additional effects of β-adrenergic receptors include increased mucociliary clearance, which reflects a decrease in fluid viscosity (presumed to reflect movement of chloride and water into the lumen) and an increase in ciliary beat frequency. Additionally, they inhibit cholinergic neurotransmission, enhance vascular integrity, and inhibit mediator release from mast cells, basophils, and other cells (see Figure 20-3).^{22,23,51,52} Eosinophil, but not lymphocyte, numbers appear to decrease, but long-term inflammation does not appear to be affected,⁵² probably because inflammatory cell β receptors are rapidly desensitized (discussed later). As such, long-term β -adrenergic use should be accompanied by antiinflammatory therapy.41

As with many membrane-associated receptors, high doses or repeated exposure to β -adrenergic agonists results in desensitization.⁵¹ The mechanism depends on the duration of therapy. Initial drug–receptor interaction causes phosphorylation, which interferes with G proteins. Longer exposure causes receptors to internalize such that they are not accessible by the drug; continued exposure causes downregulation of receptor mRNA such that the number of receptors is actually reduced.⁵² Reduction develops over several weeks before stabilizing. Desensitization may contribute to acute exacerbations of bronchoconstriction associated

with long-acting β -adrenergics. Bronchodilation will be less in the desensitized airway necessitating increased treatment frequency. However, frequent use may mask clinical signs associated with uncontrolled inflammation and care must be taken that long-acting β -adrenergics are not used instead of antiinflammatory therapy. Despite these shortcomings, β -adrenergics are the most the most effective bronchodilators.

The β -adrenergic agonists (see Figure 20-4) can be given by a variety of routes. In humans inhalation is preferred because it is equally effective to parenteral administration and is safer. However, drug delivery to the peripheral airways must be addressed as much as possible.

Nonselective β-Agonists

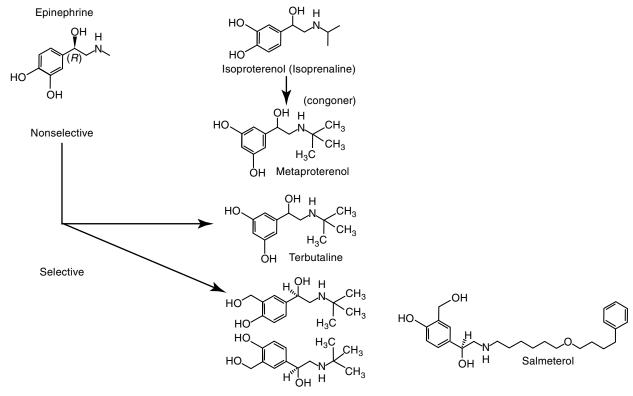

The nonselective β -agonists (i.e., capable of both β_1 and β_2 stimulation) such as epinephrine, ephedrine, and isoproterenol are used for acute and chronic therapy of respiratory diseases. Epinephrine and isoproterenol can be administered parenterally to achieve rapid effects, and drugs that can be given orally for chronic therapy include isoproterenol and ephedrine.⁶ Both epinephrine and ephedrine cause α -adrenergic activity, which may cause vasoconstriction and systemic hypertension and *may* contribute to airway constriction.⁴ Nonselective β -agonists may cause adverse cardiac effects as a result of β_1 -receptor stimulation. Aerosolization reduces the adverse effects of nonselective β -adrenergic agonists by increasing β_2 specificity, because only these β -receptors appear to line the airways.

β₂-Selective Agonists

At appropriate doses, β -selective agonists are not generally associated with the undesirable effects of β_1 -adrenergic stimulation. The more commonly used β -agonists are categorized as to their duration of action: intermediate (3 to 6 hours) and long-acting (>12 hours). The two long-acting bronchodilators, salmeterol and formoterol, both have extended side chains, are highly lipophilic, and are characterized by high affinity for the β -2 receptors. However, the long duration of salmeterol reflects binding to a specific site within the receptor, whereas that for formoterol reflects gradual release from the cell membrane lipid.⁵² The long-acting nature of bitolterol reflects its pulmonary metabolism to an active metabolite. However, it has a rapid onset of action and generally is used for acute therapy.

KEY POINT 20-5 Beta-adrenergic agonists are such effective bronchodilators that they may mask signs of inflammation that indicate ongoing disease.

Short-acting drugs that have been used in animals include albuterol, metaprotereno (a derivative of isoproterenol), and its analog terbutaline.⁴¹ Metaproterenol is less β -2 selective

Albuterol

Figure 20-4 Structures of selected beta-adrenergic drugs used to induce bronchodilation. Epinephrine is the least and albuterol or terbutaline the most selective for β -2 receptors. Most β -adrenergic drugs are present as enantiomers, as is demonstrated here for albuterol.

than other agents and more apt to cause cardiac stimulation.⁵² Therefore repetitive use should be pursued only cautiously. Albuterol, metaproterenol and terbutaline are available as oral preparations; each has been used apparently safely in dogs. Rapid first-pass metabolism reduces systemic bioavailability after oral administration; as such, oral doses are greater than parenteral doses. These drugs, but particularly metaproterenol, can cause β_1 side effects at high doses. Clenbuterol, also a β -2 selective agonist, is approved for use in horses. Although manufactured as the racemic mixture, pharmacologic effects are largely limited to the L-isomer.53 Tachycardia occurs in dogs at 0.4 mg/kg, which is only half of the therapeutic dose recommended in horses. Further, cardiac necrosis occurs at 2.5 mg/kg, which represents only a threefold increase over the equine therapeutic dose. Consequently, use of clenbuterol in dogs may not be prudent. Albuterol and isoetharine are examples of β_2 -selective agonists that have been administered by aerosolization to small animals.³⁰ Salbutamol is frequently used as a rescue bronchodilator in humans.⁵⁴

Inhalant Devices

With the advent of metered doses inhalers in the 1960s, beta-adrenergics became a common therapy for treatment of human asthma. Short-acting β_2 agonists administered by

Figure 20-5 An example of a device commercially available, intended as an adapter for inhalant metered dose devices marketed for human use.

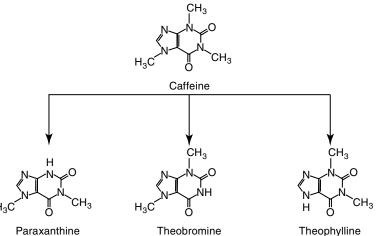

aerosol (Figure 20-5) include albuterol and its R enantiomer levalbuterol, metaproteronol, pirbuterol, bitolterol, and terbutaline (see Figure 20-4). Longer-acting (in humans) beta-2 adrenergic drugs tend to be more lipophilic and thus remain in the presence of a receptor for a longer time. Examples include salmeterol and formoterol (see Figure 20-4).40,41,55 The drugs differ in their effect and use. Short-acting products are associated with rapid symptomatic relief in human asthmatics when used at appropriate doses. However, use at high doses has been associated with an increase in mortality in humans, leading to their recommended use on an "only as needed" basis.40,55 On the other hand, improvement in pulmonary function in humans was sustained with prolonged used of long-acting beta-adrenergics,55 and thus such use was not associated with a decrease in symptomatic relief afforded by short-acting drugs. The duration of onset of long-acting betaadrenergics may be 1 or more hours. Although minimally effective by themselves for control of inflammation, long-acting beta-adrenergics appear to enhance responsiveness to glucocorticoids. Rebound hyperresponsiveness does not appear to occur with rapid discontinuation of the long-acting drugs. The development of tolerance (desensitization) has been discussed and is probably more likely with long-acting drugs.⁴¹ Because beta-adrenergics do not provide as much antiinflammatory control, their efficacy may be reduced in the presence of inflammation and combination therapy with an antiinflammatory drug (e.g., inhaled or systemic glucocorticoids), or use of theophylline may be indicated.40,55

Drugs that block β_2 -receptors such as propranolol are contraindicated in animals with bronchial disease. Inhalant devices are discussed more in depth in the following section.

Methylxanthine Derivatives

Pharmacologic Effects

Methylxanthines include caffeine, a potent respiratory stimulant, and theobromine, a recognized canine toxicant from chocolate and theophylline (Figure 20-6). Theophylline has been the cornerstone of long-term bronchodilatory therapy in animals,

Paraxanthine

Theophylline

Figure 20-6 Caffeine, which is used as a respiratory stimulant in humans, is metabolized to other methylxanthines, theobromine, theophylline, and paraxanthine.

particularly dogs. Its mode of action has been attributed to nonspecific inhibition of phosphodiesterases (PDEs) and increased concentrations of cAMP and cGMP (see Figure 20-1).41,56 This mechanism has been controversial, however, because theophylline does not inhibit PDE at therapeutic concentrations. However, this may reflect the existence of PDE as various isoenzymes (at least 11 members to this superfamily, each located in different sites within the cell, some of which are inaccessible to drugs).^{22,23,41} Inhibition of PDE4 and PDE5 results in bronchodilation whereas inhibition of PDE4 contributes to its antiinflammatory effects.⁴¹ The nonselective action of theophylline results in bronchodilation and inhibition of inflammation. Theophylline also is a competitive antagonist at adenosine receptors. The inhibitory neurotransmitter adenosine, which induces bronchoconstriction and during hypoxia and inflammation. Another mechanism by which theophylline induces bronchodilation, however, may be through interference of calcium mobilization.22,23

Compared to beta-2 agonists, theophylline is considered a weaker relaxant of airway smooth muscle.⁴⁰ As with β -agonists, theophylline is equally effective in large and small airways. Theophylline has other effects in the respiratory system that are important to its clinical efficacy.^{22,23,56} In addition to its bronchodilatory effects, it inhibits mast cell degranulation and thus mediator release (see Figure 20-3)⁵⁷; increases mucociliary clearance; and prevents microvascular leakage.58 Its antinflammatory effects appear to include modulation of cytokines, particularly of macrophage origin.⁵⁹ Finally, antiinflammatory effects of theophylline may also reflect nuclear activation of histone deacetylase.⁴¹ Decreased TNF- α and IFN- γ and increased IL-10 (antiinflammatory) have been reported. Pentoxifylline has similar antiinflammatory effects; its IV administration is addressed in Chapter 29. Increased mucociliary clearance has been reported in dogs.⁶⁰ In propofol-anesthetized cats (n = 6), no treatment effect could be detected in the mucociliary transport rate after oral administration of 25 mg/kg of a slow release (Slo-bid) product. The ability to detect a significant difference was not addressed. Further, the mucociliary the rate in untreated animals (22.2 \pm 2.8 mm/min) was perceived to be maximal, leaving no room for theophylline-induced increase. The impact of propofol is not clear, and theophyllline concentrations were not measured to confirm adequate concentrations. Thus the lack of efficacy may not reflect theophylline as much as failed delivery or altered response.

In addition to its antiinflammatory effects, a major advantage of theophylline, compared with other bronchodilators, may be its increased strength of respiratory muscles and thus a decrease in the work associated with breathing.^{56,62,63} This may be important to animals with chronic bronchopulmonary disease.

Disposition

Theophylline is one of the few drugs active in the respiratory tract whose disposition has been studied in animals. Because theophylline is not water soluble, it can be given only orally. Salt preparations of theophylline are available for either oral or parenteral administration. Dosing of the various salt preparations must be based on the amount of active theophylline (Table 20-2). Aminophylline, an ethylenediamine salt, is 80% theophylline, whereas oxtriphylline is 65% theophylline, and glycinate and salicylate salts are only 50% theophylline. Regular aminophylline is well absorbed (bioavailability of at least 90%) after oral administration in both dogs and cats.^{64,65} In dogs peak plasma drug concentrations for the theophylline base (approximately 8 µg/mL after a dose of 9.4 mg/kg) occur 1.5 hours after oral administration.⁶⁴ The volume of distribution (L/kg) and clearance (mL/min/kg) in dogs are, respectively, 0.59 ± 0.045 and 0.78 ± 0.13 . The extrapolated peak concentration after intravenous administration of 11 mg/kg aminophylline (8.6 mg/kg theophylline equivalent) was $22.94 \pm 5.8 \,\mu\text{g/mL}$.⁶⁶ In cats extrapolated concentrations after 10 mg/kg intravenous aminophylline approximated 10 µg/mL; volume of distribution (L/kg) and clearance (mL/min/kg) were 0.87 ± 0.07 and 0.87 ± 0.16 , respectively.⁶⁷ Interestingly, peak concentrations after intravenous or oral (sustained-release) products are higher in cats when dosed in the evening compared with the morning.68

More than 30 slow-release preparations exist for use in humans. Although several products have been studied in dogs and cats,68,69 their disposition is markedly variable and cannot be predicted on the basis of product name or description. Interchangability of products cannot be assumed, and monitoring is strongly encouraged to establish potential efficacy. For dogs, the rate of oral absorption of slow-release products is apparently faster than in humans. The extent of absorption varies with the preparation. Bioavailability of slow-release preparations varies from 30% (anhydrous theophylline 24-hour capsules; Theo-24, Searle Laboratories) to 76% (anhydrous theophylline tablets; TheoDur).69 The least variation among animals occurs for oxtriphylline enteric-coated capsules (Choledyl-SA Tablets; Parke-Davis) and a 12-hour capsular anhydrous theophylline (Slo-Bid Gyrocaps), which are approximately 60% bioavailable. The minimum effective concenteration recommended for humans (10 µg/mL) may not be reached by all slow-release products. Plasma drug concentrations during a 12-hour dosing interval varies, by almost 120% for the oxtriphylline product but only 48% for the anhydrous tablet (Theo-Dur), suggesting it may be the best product for use in dogs.⁶⁹ However, neither Theo-Dur nor Slo-Bid Gyrocaps are currently available for use in the United States. Although the mean residence time of the slow-release preparation was significantly longer by 1 to 2 hours than that of the regular preparation in dogs, the clinical significance of this difference is questionable.⁶⁹ More recently, Bach and coworkers⁶⁶ described the disposition of a generic (Inwood Laboratories) extended-release theophylline tablet (Theochron) or capsule (TheoCap) in dogs (15.5 mg/kg orally; n = 6). The oral bioavailability (%) of the tablet and capsules was 98 \pm 15.4 and 83.6 \pm 18.5%, respectively. The C_{max} (μ g/mL) was 17.4 ± 4.9 and 12.2 ± 2.8 for the tablet and capsule, respectively, whereas the elimination half-life was 10.9 ± 3.6 and 12.7 \pm 2.7. Drug concentrations remained within the recommended therapeutic range for 12 hours. The authors concluded that 10 mg/kg every 12 hours would result in theophylline concentrations in the therapeutic range.

Drug	Indicators	Dose	Route	Interval (hr)*
Acetylcysteine	Respiratory inflammation	3-6 mL/hr for 30-60 min (D) 125-500 mg	Nebulization IV, PO	12 12

Table 20-2 Doses of Drugs Used To Treat Disorders of the Respiratory Tract—cont'd

D, Dog; IV, intravenous; PO, by mouth; IM, intramuscular; C, cat; SC, subcutaneous; IBD, inflammatory bowel disease.

KEY POINT 20-6 Oral bioavailability of slow-release theophyllines may markedly vary among products and patients, contributing to toxicity or therapeutic failure.

Cats also have been studied. Although it is not distributed to all body tissues, theophylline is characterized by a relatively large volume of distribution in dogs (0.7 to 0.8 L/kg) and a smaller volume in cats (0.41 L/kg).^{64,69,70} Unlike human beings, distribution of theophylline is not limited by binding to serum proteins in dogs; serum protein binding is less than 12%.71,72 Elimination of theophylline is not dose dependent in dose ranges of 3 to 15 mg/kg. Dye and coworkers^{68,70} studied two sustained-release theophylline products (TheoDur and Slo-Bid Gyrocaps, William H. Rorer, Inc) in the cat. Although both products were reasonably (>75%) bioavailable in the cat, neither product is currently available in the United States. A more recent study addressed the disposition of a generic (Inwood Laboratories) extended-release theophylline tablet (Theochron; 15 mg/kg) and capsule (TheoCap; 19 mg/kg) in cats (n = 6).⁶⁷ The C_{max} (µg/mL) of the tablet and capsule was 17.8 ± 3.4 and 15.8 ± 3.1 , respectively. Although bioavailability of both products was 100% or greater, the elimination half-life for the tablet and capsule was 13.6 ± 3.9 hour and 18.3 \pm 8.0, respectively, compared with 11.7 \pm 1.8 hour for the intravenous preparation (aminophylline), suggesting that the drugs did not always act in an extended-release manner in cats. Nonetheless, drug concentrations remained within the recommended therapeutic range for 24 hours. These data suggested that once-daily administration in cats should be sufficient to maintain concentrations within the therapeutic range. (see Table 20-2). A longer dosing interval might be acceptable if evidence supports an antiinflammatory effect at even lower concentrations. Based on a chronopharmacokinetic study of these sustained-release products, dosing in the evening rather than in the morning appears to be associated with better bioavailability and less peak plasma theophylline concentration fluctuation.⁶⁸ A disadvantage of the use of the slow-release products for small animals is the limited dose sizes available. The product cannot be divided for more accurate dosing without altering the kinetics of slow release.

Theophylline is metabolized by demethylation in the liver. Theobromine may be an active metabolite in some species. Different rates of metabolism result in variable clearance rates and drug elimination half-lives among animals, and doses consequently vary.⁷² For example, the elimination rate constant of theophylline is less in cats (0.089/hr)⁷³ than dogs (0.12/hr), resulting in a longer half-life in the cat (7.8 hours) compared with the dog (5.7 hours),^{64,65} thus necessitating a smaller dose in cats.⁶⁹ Theophylline concentrations can be affected—most commonly increased—by a number of drugs, including fluorinated quinolones,⁷⁴ erythromycin and its congeners,⁷⁵ and cimetidine.⁷⁶

Adverse Reactions and Drug Interactions

Theophylline is associated with a wide range of adverse effects, including central nervous system excitation (manifested as restlessness, tremors, and seizures),⁷² gastrointestinal upset

(nausea and vomiting), diuresis, and cardiac stimulation (e.g., tachycardia). In a retrospective study of theophylline toxicity in human patients, clinical signs included severe vomiting (89%), seizures (21%), and cardiac arrythmias (16%).⁷⁷ Vomiting precluded treatment with oral charcoal but responded to metoclopramide. Therapy included mechanical ventilation, anticonvulsants or sedatives, and muscle relaxants. Because of the risk of toxicity, intravenous use should be limited to patients who have not responded to β -agonist therapy and are facing life-threatening disease. Compared with the salt preparations, theophylline is more irritating to the gastrointestinal tract than aminophylline.^{30,56} Rapid infusions or infusions of undiluted aminophylline can cause cardiac arrhythmias, hypotension, nausea, tremors, and acute respiratory failure.³⁰

Theophylline may be involved in a number of drug interactions; hepatic metabolism and potentially serious adverse effects should lead to cautious use with other drugs. Inhibition of drug-metabolizing enzymes by fluorinated quinolones has been described in human medicine and for both enrofloxacin and marbofloxacin in animals.78 For enrofloxacin 5 mg/ kg decreased theophyllline clearance by 43%79; a different study found a 26% decrease by marbofloxacin (5 mg/kg).⁷⁸ This translates to an increase in C_{max} by 31% for the ophylline, sufficient to contribute to toxicity. Indeed, the author has measured peak theophylline concentrations above 70 µg/mL and an elimination half-life of 19 hours in a dog concomitantly given enrofloxacin at 5 mg/kg. Clinical signs of theophylline toxicity emerged within 24 hours of beginning enrofloxacin therapy. Theophylline-terbutaline interactions do not appear to be clinically relevant, as has been shown in humans,⁸⁰ supporting their combined use for patients not responding to a single bronchodilator.

The application of therapeutic drug monitoring to guide therapy would assist in identifying the most appropriate dosing regimen, particularly when using slow-release preparations whose bioavailability might vary among patients, in patients receiving drug combinations that increase the risk of drug interactions, and in patients with hepatic dysfunction. Although a therapeutic range has not been established for small animals, the range recommended for humans (10 to 20 µg/mL) can be extrapolated until a more definitive range has been established. Dogs are apparently more tolerant of theophylline toxicity than are humans. In one study toxicity manifested as tachycardia, central nervous system stimulation (restlessness and excitement), and vomiting did not occur until plasma theophylline concentrations reached 37 to 60 µg/ mL. Doses of 80 to 160 mg/kg of a sustained-release preparation were required to induce toxicity.81 In cats concentrations as high as 40 µg/mL do not induce adverse reactions, although salivation and vomiting are common after administration of more than 50 mg/kg, and seizures may occur at doses greater than 60 mg/kg.82

The side effects of theophylline are dose dependent and might be prevented to a large degree by appropriate dosing. Therapeutic drug monitoring should facilitate the design of proper dosing regimens to prevent toxicity.

Anticholinergic Drugs

Pharmacologic Effects

Anticholinergic drugs compete with acetylcholine at muscarinic receptor sites.⁸³ In the respiratory tract, they reduce the sensitivity of irritant receptors and antagonize vagally mediated bronchoconstriction. The site of action of these drugs in the respiratory tract is controversial. In some studies bronchodilation is reported throughout the airways in asthmatic human patients and cats, whereas other investigators believe that the effects are confined to large airways.⁸³ The route by which anticholinergic drugs are administered influences their bronchodilatory effects. Despite their effect on bronchial airways, the anticholinergic drugs have not proved clinically effective in the treatment of bronchial diseases in animals, and their use is limited to treatment of bronchoconstriction associated with organophosphate toxicity or in animals in status asthmaticus unresponsive to bronchodilator therapy. The lack of clinical efficacy of anticholinergics may reflect nonselective drug-receptor interaction.^{22,23} Thus far, three types of muscarinic receptors have been identified in airways. M₃ receptors release acetylcholine, whereas M₂ receptors block its release. Nonselective blockade of muscarinic receptors by atropine and ipratropium may actually potentiate acetylcholine release by antagonizing the effects of M₂-receptor stimulation. Drugs specific for M₃ receptors may ultimately lead to successful treatment of bronchial disease with anticholinergics drugs.^{22,23} As with beta-adrenergic drugs, use of inhaled anticholinergic drugs reduces systemic adverse effects.

Atropine

Aerosolized atropine, a prototype anticholinergic drug, affects predominantly the central airways, whereas both central and peripheral airways are affected if the drug is administered intravenously.^{22,23} Because atropine is highly specific for all muscarinic receptors, it causes a number of systemic side effects, including tachycardia, meiosis, and altered gastrointestinal and urinary tract function.⁶⁴ In the respiratory tract, atropine reduces ciliary beat frequency, mucous secretion, and electrolyte and water flux into the trachea. The net effect is decreased mucociliary clearance, which is undesirable in patients with chronic lung disease.⁶⁴ Aerosolization of atropine does not reduce the incidence of respiratory adverse reactions. Atropine is well absorbed (in humans) after oral administration. In humans atropine has proved most useful for treatment of chronic bronchitis and emphysema, diseases that are characterized by increased intrinsic vagal tone.⁸³ Its adverse effects on respiratory secretions and ciliary activity, however, apparently negate its benefits to bronchial tone during longterm administration in animals. The primary indication for atropine in small animals is facilitation of bronchodilation in acutely dyspneic animals. It is the treatment of choice for life-threatening respiratory distress induced by anticholinesterases. A combination of atropine with either β -adrenergic agonists or glucocorticoids will cause better bronchodilation than either drug alone.⁸³

Ipratropium Bromide

Ipratropium bromide is a synthetic anticholinergic that is pharmacodynamically superior to atropine. Although the two drugs are equipotent, ipratropium does not cross the blood– brain barrier. It is not well absorbed after aerosolization, which limits the likelihood of adverse effects. Ipratropium has been studied in the dog but not in the cat.⁸³ Of the anticholinergic drugs studied in dogs, ipratropium appears to cause the greatest bronchodilation (twice as much as atropine) with the least change in salivation.⁸³ When inhaled, it is more effective in preventing bronchoscopy-induced bronchoconstriction compared with intramuscular atropine.⁵⁴ Unlike atropine, it does not alter mucociliary transport rates.

Ipratropium bromide is generally not promoted as a bronchodilator in dogs or cats. However, with the advent of inhalant devices, this may change. The combination of salbutamol (120 mg, 1 puff) and ipratropium bromide (20 mg, 2 puffs) was found to be superior to either drug alone in the prevention of BAL-induced bronchoconstriction in experimentally induced allergen sensitive, conscious cats (n = 18).⁵⁴ Drugs were administered using a pressurized inhalant metered devices (pMDI). with a spacing chamber connected through an inspiratory valve to a face mask.

Glycopyrrolate

Glycopyrrolate can also be used as a bronchodilator in small animals. Although its onset of action is slower than that of atropine,³⁰ its half-life is 4 to 6 hours compared with 1 to 2 hours for atropine. The potency after systemic therapy has apparently not been compared between the two drugs, although glycopyrrolate is twice as potent when aerosolized. The systemic side effects of glycopyrrolate are minimal.

Mast Cell Stabilizers

Drugs that stabilize mast cells are most effective in syndromes associated with marked mast cell activity. Included in this category may be newer antihistamines, discussed later. The stabilizing effects of β -adrenergic agonists, methylxanthines, and glucocorticoids (see Chapter 30) on inflammatory cells have been discussed.

Cromolyn

Although the mechanism of action of cromolyn is not certain, it appears to inhibit calcium influx into mast cells, thus preventing mast cell degranulation and the release of histamine and other inflammatory mediators (see Figure 20-3).^{22,23,84} At high concentrations, cromogylate inhibits IgE-triggered mediator release from mast cells.85 Some studies suggest that the activation of inflammatory cells other than the mast cells (e.g., macrophages, neutrophils, eosinophils) is also inhibited by cromogylate.²⁸ Cromolyn is most useful as a preventive before activation of inflammatory cells. It is not significantly absorbed after oral administration and is characterized by a short half-life (=). Thus effective therapy depends on frequent aerosolization, which limits its utility in the treatment of small animal diseases. Currently, cromolyn is the safest drug used to manage asthma in humans.⁸⁴ It is associated with only minor side effects, and its discovery has revolutionized the management of bronchial asthma in people. Because of its wide therapeutic window and its apparent efficacy in the control of many inflammatory cells, its use in the control of small animal bronchial disease warrants further investigation.

Calcium Antagonists

The efficacy of calcium antagonists in the management of asthma has yet to be identified.⁸⁶ Their potential benefits include prevention of mediator release, smooth muscle contraction, vagus nerve conduction, and infiltration of inflammatory cells.^{86,87} Most studies indicate that calcium antagonists have only a modest effect on airway smooth muscle contraction. Their antiinflammatory effects may ultimately prove of greater benefit.

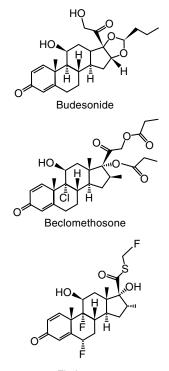

Drugs that Target Inflammatory Mediators

Glucocorticoids

Glucocorticoid use in dogs and cats is addressed in Chapter 30. In 1997 the National Heart, Lung, and Blood Institute Expert Panel Guidelines recommended control of mild persistent asthma with a single, long-term control medication with antiinflammatory properties.55 Accordingly, gluccocorticoids are the cornerstone of asthma therapy.88 The antiinflammatory effects of glucocorticoids reflect an inhibitory effect on essentially all phases of inflammation. Airway infiltration with eosinophils, mast cells, and basophils is decreased, although the effect on T cell population in the lungs is less clear. Glucocorticoids differentially downregulate T_b2 cytokines, including IL-4, IL-5, and IL-13, but appear to upregulate T_h1 cytokines, including IFN-y and IL-12. Most recently, glucocorticoids have been demonstrated to reduce eotaxin and other eosinophil-associated chemokines but have little effect on IL-8.89 Glucocorticoids have little effect on cys-LTs.⁹⁰ Glucocorticoids have a "permissive" effect on β -adrenergic receptors and help prevent desensitization, which may accompany therapy with long-acting drugs.

KEY POINT 20-7 The role of glucocorticoids as the cornerstone of inflammatory lung disease reflects both their antiinflammatory effects as well as their permissive effects of beta receptors mediating bronchodilation.

Glucocorticoid efficacy for treatment of respiratory inflammatory disease depends on therapeutic concentrations in and below the epithelium of all diseased airways. However, whereas systemic therapy might provide the most consistent exposure to diseased airways, it also provides the greatest exposure to tissues other than the lungs, leading to adverse effects. A number of approaches have been taken to minimize adverse effects of systemic glucocorticoids when used to treat asthma. Although dogs and cats appear to tolerate glucocorticoids better than humans, making these approaches less important, they nonetheless may be beneficial to animals. These include selective gene targeting, increased potency for the glucocorticoid receptors (allowing administration in specialized [inhalant] drug delivery systems), and development

Fluticasone

Figure 20-7 Structures of selected "soft" glucocorticoids used in inhalant devices for the topical treatment of respiratory inflammatory diseases. These drugs are very potent and often are characterized by first-pass metabolism such that swallowed drug will be minimally absorbed.

of drugs that undergo first-pass metabolism. Aerosol administration minimizes many side effects. The preferred route in humans with mild disease is low-dose inhaled glucocorticoids.⁵⁵ Beclomethasone was among the first aerosol glucocorticoids developed for inhalant therapy.⁴⁰ Corticoisteroids marketed as inhalant metered devices (MDIs; see later discussion) in the United States include beclomethasone dipropionate (Beclovent), triamcinolone acetonide (Azmacort), flunisolide (Aerobid), budesonide (Pulmicort), fluticasone propionate (Flovent), and mometasone (Asmanex) (Figure 20-7).

Aerosolized glucocorticoids, such as occurs with MDIs, result in local delivery of higher concentrations. Although side effects are minimized, up to 90% of an inhaled dose is still deposited on the oral mucosa or pharynx and swallowed in humans; a similar or greater proportion might be anticipated in animals. Thus multiple methods have emerged to reduce adversities without decreasing efficacy. The delivery device may influence adverse effects. Systemic side effects associated with deposition of glucocorticoids on the pharynx and central airways and local side effects in the upper airway (e.g., dysphonia in up to 50% of the patients) led to the inclusion of "spacers" that removed larger particles before they penetrated the pharynx.⁴⁰

Corticosteroid delivery of MDIs also has been improved by the advent of hydrocarbon fluoroalkyl (HFA)–propelled MDI. Beclomethasone dipropionate delivery to peripheral airways increases from 5% to 15% for the chlorofluorocarbon -propelled preparation to 50% to 60% with the HFA propellant.⁹¹ Not only is total lung delivery increased, but the depth of penetration also is enhanced, a potentially critical improvement for controlling progression of the disease.

The glucocorticoid itself has been manipulated to decrease adversity. Corticosteroids marketed in MDI vary up to fivefold or more in potency. The relative potency of drugs marketed as MDI roughly follows the following order: monmetasone, which exceeds both fluticasone and budesonide, which, in turn, are 2 to 3 times more potent than beclomethasone; triamcinolone is the least potent of these drugs. While potency does allow administration of a small dose, it does not predict clinical efficacy of inhaled glucocorticoids.⁹¹ Despite sixfold differences in potencies among inhaled glucocorticoids, comparative clinical trials in humans have failed to demonstrate differences in efficacy when drugs are administered at equipotent dosages.⁹¹ Further, dose response curves for inhaled glucocorticoids tend to be flat, indicating that increasing doses is not likely to enhance efficacy.

Ultimately, differences in pharmaceutical (delivery) and pharmacokinetic properties largely determine variable responses to inhaled glucocorticoids. Inhaled corticosteroids generally are delivered as microcrystals, which must dissolve in the epithelial mucosal fluid. Crystals must be water soluble to ensure local delivery before the mucociliary tract removes the drug. However, alteration of dissolution times may also affect local delivery and thus local effects. For example, the dissolution time for budesonide is 6 minutes compared with beclomethasone dipropionate (5 hours) and fluticasone (8 hours). Lipophilicity of the drug enhances uptake and the duration of local effects. The addition of a halogen increases tissue retention compared with nonhalogenated drugs. Lipophilicity is greatest for beclomethasone and fluticasone followed by budesonide, with triamcinolone followed by dexamethasone and, finally, prednisolone as the least liphophilic. Not surprisingly, the most lipophilic of the drugs also is associated with the greatest number of side effects, including suppression of the hypothalamic pituitary adrenal axis. In humans, fluticasone is both the most potent and most lipophilic glucocorticoid. As such, it is characterized by the greatest evidence of systemic side effects. As such, recommendations for humans are that high-dose fluticasone propionate (>500 mg twice daily) be used only on the order of a physician and that the dose be titrated down to the lowest effective dose. Budesonide offers an example of a different type of manipulation that may allow longer dosing intervals while minimizing side effects. Because of its structure (a free C21 hydroxyl group) (see Chapter 30), excess intracellular budesonide complexes with long chain fatty acids. The complex is inactive but probably allows persistence of the drug at the site, much as a depot form would, with reversible esterification occuring as receptors are depleted of active drugs. Other drugs with a free C21 hydroxyl include triamcinolone, flunisolide, and ciclesonide, although long-chain fatty acid esterification has not been determined for them. Neither fluticasone, nor beclomethasone dipropionate, and probably mometasone, form fatty acid esters.⁹¹

Finally, although most devices require or allow twice- to four-times-daily dosing, those designed for once-daily administration also should enhance efficacy through improved compliance. Poor compliance with use of inhaled glucocorticoids in human patients also led to the development of combinations of steroids with long-acting β_2 agonists (e.g., salmeterol/ fluticasone or formoterol/budesonide). Although compliance has improved, concern has arisen that the β_2 agonists will mask clinical signs that might otherwise indicate worsening of the disease.⁴⁰ Indeed, recent studies of the efficacy of inhaled beclomethasone diproprionate found improvements in clinical signs to be short-lived, probably because the inhaled drug does not control inflammation well.40 Reduced airway caliber will further decrease efficacy by reducing drug delivery to the peripheral airways. Antiinflammatory therapy should target both large and small airways if inflammation is to be suppressed.⁴⁰ Thus systemic therapy should be considered (either as sole therapy or in addition to systemic therapy) in animals with moderate to severe disease. The peak effect of inhaled glucocorticoids may not occur for 1 to 2 weeks after therapy has begun.

Inhaled glucocorticoids have been recommended for use in cats with asthma,39 although few studies have provided guidance. One abstract has reported a beneficial effect of flunisolide (250 µg/puff) but not zafirlukast (10 mg orally every 12 hours) in cats with experimental feline asthma.⁹² Reinero and coworkers93 compared the impact of inhaled flunisolide (250 µg puff twice daily) to that of oral prednisone (10 mg/day orally) and placebo on indices of inflammation and adrenal gland suppression in healthy cats (n = 6). No treatment effect was apparent with regard to serum immunoglobulin or cytokine activity. The inhaled glucocorticoid was associated with lower baseline cortisol compared with placebo and and lower cortisol after adrenocorticotropic hormone stimulation compared with oral and placebo therapy. A limitation of the study may have been the use of prednisone rather than prednisolone as is suggested by impact on cortisol concentrations, although oral therapy did impact both T and B cells. This study supports the potentially inappropriate use of prednisone in cats and suggests that topical flunisolide therapy may suppress the hypothalamic pituitary adrenal axis in cats with flunisolide.

Drugs that Target Leukotrienes

LTs are very potent causes of marked edema, inflammation, and bronchoconstriction.⁹⁴ Their role in the pathophysiology of inflammation and their inhibition are discussed in Chapter 30. Their inhibition by glucocorticoids may be limited, leaving a void in therapy.⁹⁰ The approval of drugs that specifically inhibit the formation of LTs or their actions have offered a new avenue of control of respiratory inflammatory disease (e.g., asthma) in human medicine. Two classes of drugs have focused on their impact on LTs: LT synthesis (5-lipoxygenase) inhibitors (zileuton) and LT-receptor antagonists (LRAs). The latter class has proved to be more effective (Figure 20-8). Currently, two LRAs are approved in the United States: zafirlukast, administered twice daily, and montelukast, administered once daily. The disposition of neither drug has been studied in dogs

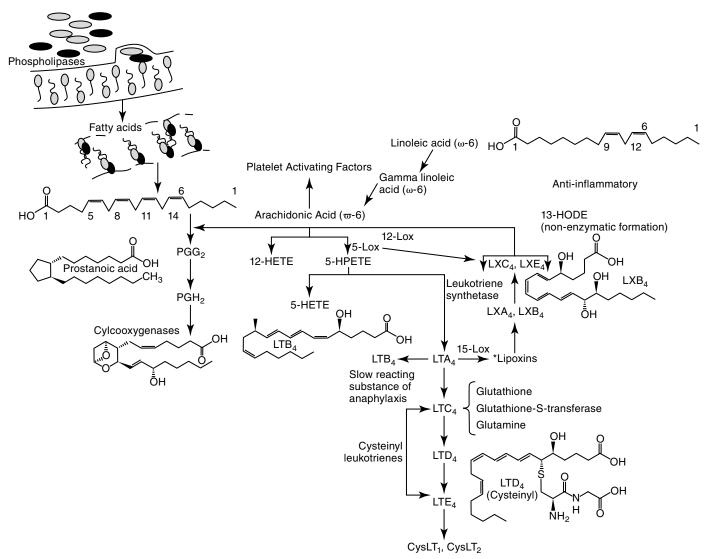

Figure 20-8 The arachidonic cascade and the formation of proinflammatory or antiinflalmmatory mediators catalyzed by lipoxygenases.

or cats; in humans the dosing intervals reflect a half-life of 5 and 10 hours, respectively.

KEY POINT 20-8 Leukotriene receptor antagonists should be considered for both local and peripheral control of respiratory inflammation in mild cases, as adjunct therapy in poor responders, and in patients intolerant to glucocorticoids.

In human clinical trials, LRAs inhibit early- and late-phase bronchoconstriction and increased bronchial hyperresponsiveness in response to allergens; accumulation of inflammatory cells and mediators in bronchial lavage fluid; and acute bronchospasms stimulated by exercise, cold air, and aspirin.⁹⁵ Their bronchodilatory effects are less than that of long-acting β -adrenergics, whereas the antiinflammatory effects are less than those of glucocorticoids.⁹⁰ However, response does occur to single doses. In contrast to β -adrenergics, tolerance does not develop toward LRA effects. Their use has been associated with improvement of asthma either as sole therapy (instead of low-dose inhaled glucocorticoids) in mild to moderate asthma or as add-on therapy regardless of disease severity in glucocorticoid nonresponders.⁹⁵ The LRAs are well tolerated, particularly compared with glucocorticoids. A subset of asthmatics treated with LRAs have developed Churg– Strauss syndrome, a state of systemic hypereosinophilia. However, its emergence may reflect decreased doses of glucocorticoids permitted once LRAs are begun rather than a toxic effect of LRAs.⁹⁰

Recommendations regarding the role of LRAs in treatment of human asthma are dynamic. Currently, because they are less effective than glucocorticoids, their role as monotherapy is not recommended, even with mild disease. In contrast, LRAs have proved effective as monotherapy for treatment of allergic rhinitis in humans.⁹⁰ For asthma, because of their unique mechanism of action, LRAs have been combined with a number of other drugs used to treat asthma. For example, glucocorticoids minimally affect cys-LT; as such, combination with LRAs would be expected to have an additive effect, as has been demonstrated when combined with inhaled glucocortiocids. The combination of LRAs and glucocorticoids generally is as effective as glucocorticoids combined with β -adrenergic agonists. The use of an LRA as part of triple therapy (i.e., with corticosteroids, β -adrenergics) is a reasonable, albeit understudied, therapeutic approach in patients not responding to dual therapy. Finally, LRAs also have been recommended in the treatment of aspirin-sensitive asthma (discussed later).

The role of LTs in the treatment of feline asthma was previously discussed. Therapy with LRAs has had little scientific support, although this should not preclude their use, particularly in animals that have not sufficiently responded to or cannot tolerate (e.g., diabetics) corticosteroids. Receptors for LTs have yet to be identified in the smooth muscle of airways in cats; further, LTs have not been identified in the urine or plasma of cats with experimentally induced asthma.⁹² However, LTs were associated with experimentally induced heartworm disease in cats.⁹⁶ The recent approach to asthma as a systemic response mediated at the level of the bone marrow warrants consideration of the use of LRAs for treatment of feline asthma, particularly in nonresponders or patients that cannot tolerate glucocorticoids. Other potential indications would include control of inflammation in dogs in which glucocorticoids are contraindicated or pulmonary diseases characterized by eosinophilic infiltrate. Anecdotally, LRAs appear to be safe in both dogs and cats, although no study has confirmed their safety.

Nonsteroidal Antiinflammatory Drugs

The role of nonsteroidal antiinflammatory drugs (NSAIDs) in the treatment of respiratory inflammatory diseases requires definition.97,98 Both LTs and PGs are important in the pathophysiology of inflammatory diseases. Although NSAIDs effectively block PGs through inhibition of cyclooxygenase, they do not negatively affect lipoxygenase. Rather, in the aspirin-sensitive asthmatic (human) patient, aspirin and NSAIDs that selectively inhibit cyclooxygenase I shunt AA toward 5-lipoxygenas and the overproduction of cys-LTs.90 They have no effect on other chemical mediators of inflammation. Additionally, NSAIDs nonselectively block all PGs, including those that provide some protection during periods of bronchoconstriction.99 Some studies have shown that LT production increases in response to NSAID therapy, perhaps by providing more AA for lipoxygenase metabolism. Currently, labels include a contraindication for use in human patients with aspirin-induced asthma. However, although more studies are needed, thus far the newer NSAIDS generally are not associated with emergence of asthma.¹⁰⁰

Currently, the use of NSAIDs for the treatment of respiratory diseases in small animals is limited to aspirin therapy as treatment for thromboembolism associated with heartworm disease.^{101,102} Aspirin is the preferred NSAID because at low doses it irreversibly inhibits TXA₂, an important contributor to pulmonary arterial vasoconstriction that accompanies thromboembolism. Current efforts in NSAID research are oriented toward identifying drugs that successfully inhibit both arms of the AA metabolic cascade or specific PG or LT inhibitors. The use of selective TXA₂ inhibitors for selected feline respiratory diseases is an example.⁴⁵ Among the NSAIDs that might be considered, are the dual inhibitors, such as tepoxalin, which target both PGs and LTs.

Antihistamines

A number of nonantihistaminergic drugs act to ameliorate the effect of histamine (Figure 20-9). However, in general, histamine is not recognized to be a major contributor to clinical signs of asmtha based on the limited control of clinical signs afforded by antihistaminergic drugs. Those drugs that prevent histamine release may be of most benefit because they will also prevent release of other inflammatory mediators associated with asthma.

Drugs that interact with beta receptors and stimulate cAMP depress histamine release. Thus epinephrine can be used prior to or *early* during anaphylaxis to reduce histamine release. However, most of the histamine has already been released by the time treatment occurs, and in fact, most of the beneficial effects of epinephrine during anaphylaxis result from physiologic antagonism of histamine-induced bronchoconstriction. Glucocorticoids impair histamine release through their permissive effects on beta-adrenergic receptors. Additionally, glucocorticoids are lytic to neoplastic mast cells. The newer (but not older) antihistamines such as cetirizine or loratadine may inhibit histamine release from mast cells.¹⁰³ These newer products have not been widely used in animals, although the disposition of several is discussed in Chapter 29.

The use of H₁ blockers may be detrimental in animals with chronic disease because of their effects on airway secretions.²⁹ The role of H₂ receptors in bronchodilation, mucous secretion, and inflammation suggests that H₂-receptor blockers should also be used with caution.^{5,29} Among the drugs for which anecdotal discussion suggests efficacy for treatment of tracheal collapse is doxepin, a tricyclic antidepressant that is also characterized by marked H₁ antagonism. Efficacy may be related to antiinflammatory effects or some level of central nervous system depression.¹⁰⁴ Alternatively, local anesthetic actions may be contributing to efficacy.¹⁰⁵ Although not yet clinically available, drugs that specifically target H₄ receptors may prove useful through control of signals mediating chronic allergic responses. Cyproheptadine is an antiserotinergic, antihistaminergic drug. Because feline airways are exquisitely sensitive to the constrictor effects of serotonin, this drug may prove particularly useful in cats either alone or as an adjunct to bronchodilators or glucocorticoids.¹⁰⁶ The disposition of cyproheptadine has been described in cats (n = 6).¹⁰⁷ It is characterized by 100% oral bioavailability, a volume of distribution of 1 ± 0.5 l/kg and an elimination half-life of 12.8 ± 9.9 hours, supporting a once- to twice-daily dosing interval. A single intravenous dose of 2 mg was well tolerated. An oral dose of 8 mg yielded a C_{max} of 419 ± 99 ng/mL. Both the intravenous and oral dose were well tolerated. Studies following transdermal administration are pending.

ANTITUSSIVES

The goal of antitussive therapy is to decrease the frequency and severity of cough without impairing mucociliary defenses (Figure 20-10). Whenever possible, the underlying cause should be identified and treated. Cough suppressants should be used cautiously and are contraindicated if the cough is productive.² Irritants and perhaps chemoreceptors and stretch

Leukotriene Receptor Antagonists

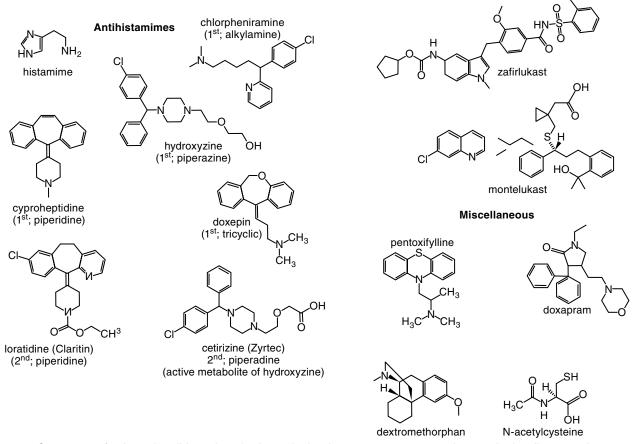

Figure 20-9 Structures of selected antihistaminergic drugs, leukotriene receptor antagonsists, and miscellaneous drugs used to treat disorders of the respiratory tract.

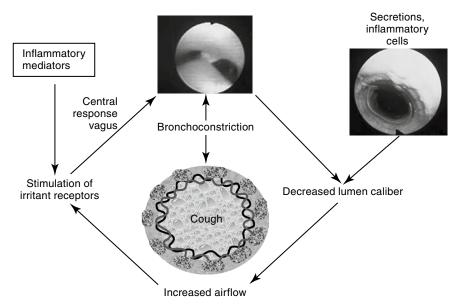

Figure 20-10 The most potent stimulus for the cough reflex is decreased airway caliber size. The subsequent increase in airflow velocity irritates stretch receptors. The vagus nerve serves as the afferent and efferent limbs of the cough reflex, which is mediated centrally by the respiratory center in the medulla. Accumulation of debris and inflammatory mediators can either irritate receptors or decrease airway luminal caliber. Cough is accompanied by bronchoconstriction, which can further exacerbate coughing.

receptors initiate the cough reflex.^{2,73} Bronchoconstriction is probably the most frequent and important cough stimulus. The cough reflex can be blocked peripherally, either by facilitating removal of the irritant with mucolytics or expectorants or by blocking peripheral receptors to induce bronchodilation, or it can be blocked centrally at the cough center in the medulla (see Figure 20-4).^{2,108} Mediators targeted for treatment of cough might be opioid, serotonin (5-HT1A), nociceptin, or gamma amino butyric acid-B agonists and neurokinin (NK-1 or NK-2) or N-methyl-D-aspartate (NMDA) antagonists.^{7a-c}

KEY POINT 20-9 Cough might be reduced peripherally through therapies that increase airway caliber size. This includes bronchodilation or facilitating removal of intraluminal debris.

Centrally active antitussives are classified as narcotic and non-narcotic drugs. 108,109

Opioid Antitussives

Opioid (narcotic) antitussives depress the cough center sensitivity to afferent stimuli. They can, however, be associated with strong sedative properties, as well as constipation, when administered chronically. Morphine, codeine, and hydrocodone are the narcotics most commonly used to control coughing. As class II drugs, each is subject to the Controlled Substances Act of 1970 and can be used for cough suppression in both dogs and cats. Other opioids may have antitussive actions but are generally not used for that indication. Examples include diphenoxylate, a drug to which powerful antitussive actions have been ascribed.

Codeine

Codeine is the prototype narcotic antitussive and one of the most effective drugs available to suppress the cough reflex. Codeine phosphate and codeine sulfate can be used either alone or in combination with peripheral cough suppressants or decongestants. Over-the-counter preparations are available for human use. Compared with morphine, codeine is equally effective as a cough suppressant but is less suppressing to other central centers and causes less constipation. Side effects of codeine include nausea and constipation. Codeine is also addressed in Chapter 28.

Hydrocodone

Hydrocodone is a more potent antitussive than codeine but causes less respiratory depression. It is probably the most commonly used antitussive for dogs. Hydrocodone bitartrate is a hydrolysis product of dihydrothebaine.

Butorphanol

Butorphanol tartrate is probably more commonly used as an analgesic. Reclassified as a Schedule IV drug, it is now subject to the Narcotics Act. It is approved for use as an antitussive for dogs. As an antitussive, it is 100 times more potent than codeine and 4 times more potent than morphine.¹¹⁰ In dogs, after subcutaneous administration, butorphanol concentrations peak at 1 hour. Mean half-life is 1.7 hours, with a duration of activity of 4 hours or more. Butorphanol is characterized

by a wide safety margin. The LD_{50} in dogs after intramuscular administration is 20 mg/kg.¹¹¹ Therapeutic concentrations cause minimal cardiac or respiratory depression. Side effects include sedation, which can be significant and desirable; nausea; some diarrhea; and appetite suppression. The narcotic agonist/antagonist butorphanol tartrate is a potent antitussive when given orally or parenterally in dogs and cats.

Non-Narcotic Antitussives

Non-narcotic antitussives commonly used in veterinary medicine include the narcotic agonist/antagonist butorphanol and dextromethorphan.

Dextromethorphan

Dextromethorphan hydrobromide (see Figure 20-9) is a semisynthetic derivative of opium. It is the d-isomer of the codeine analog of methorphan. Unlike its L-enantiomer, levomethorphan, it lacks narcotic, direct analgesic, or addictive properties. It is an acid receptor antagonist and as such is also discussed in Chapter 28. Antagonists of NMDA receptors are powerful antitussives in some species (including humans). Dextromethorphan's metabolite dextrorphan also is active. Because sedation is unusual after its use, it is classified as nonnarcotic. Its antitussive mechanism is not certain; only the D-isomer has antitussive activity, which is similar to codeine in potency. Dextromethorphan interacts with sigma receptors (previously thought to be opioid receptors). Its onset of action is rapid, being fully effective within 30 minutes after oral administration. It is metabolized by CYP2D6, a drug-metabolizing enzyme found to be deficient in a significant proportion of the human population. Dextromethorphan is commonly found in over-the-counter cough preparations. It can be used safely in cats. In humans it can release histamine and therefore is not often recommended for atopic children. Its use with selective serotonin uptake inhibitors and monoamine oxidase inhibitors is discouraged. Studies in humans have shown that the combination of dextromethorphan with a bronchodilator is superior to dextromethorphan alone for the control of cough.¹¹²

Noscapine

Noscapine is a nonaddictive opium alkaloid (benzylisoquinoline) that has antitussive effects similar to those of codeine.¹¹³ Its use for small animals appears to be limited.

Neurokinin Receptor Antagonists

The role of NK-antagonists in control of cough is being elucidated. Their appeal reflects, in part, the increasingly recognized role of tachykinins in mediating cough and hyper-reflexivity. A potential role of NK antagonists in control of asthma in humans was recognized in the 1990s, although their clinical role has not been recognized.^{113a} Their role for control of cough is supported by a number of reviews.^{113a,b} Although the antiemetic maropitant (see Chapter 19) has not been studied for treatment of cough in dogs, its anecdotal use is supported by response to other NK-1 antagonists.^{113b} Cough (mechanical intrathoracic tracheal stimulation) was reduced by 52% in dogs receiving an experimental NK1 antagonist.

Peripheral Bronchodilators

Bronchodilators (previously discussed) are powerful peripheral antitussives because they relieve irritant receptor stimulation induced by mechanical deformation of the bronchial wall during bronchoconstriction. Ephedrine peripherally induces bronchodilation, and as both a bronchodilator and decongestant it is a common constituent of over-the-counter cough preparations. Theophylline and isoproterenol are also common ingredients found in some preparations. Other peripheral antitussives include mucokinetic agents and hydrating agents.¹⁰⁸

Bronchodilators counteract irritant receptor stimulation induced by mechanical deformation of the bronchial wall during bronchoconstriction. Increased fluidity of secretions and ciliary action may facilitate removal of accumulated materials, thus decreasing airway caliber size, airflow velocity, and turbulence-induced receptor stimulation. As such, previously discussed bronchodilators can be effective peripheral antitussives. Several drugs classified as bronchodilators are found in overthe-counter cough preparations for their antitussive-effective effects. Ephedrine is both an α and a β agonist; additionally, it causes the release of norepinephrine from sympathetic neurons. It peripherally induces bronchodilation, and as both a bronchodilator and a decongestant, it is a common constituent of over-the-counter cough preparations. It is present in herbal agents as ma huang or ephedra. Ephedrine is a potent central nervous system and cardiac stimulant and can contribute to hypertension and dysuria as a result of its α -adrenergic effects. Theophylline and isoproterenol are also common ingredients found in some preparations. Other peripheral antitussives include mucokinetic agents and hydrating agents.¹⁰⁸

MUCOKINETICS

Mucokinetic drugs facilitate the removal of secretions from the respiratory tree. They are indicated for conditions associated with viscous to inspissated pulmonary secretions such as are commonly associated with chronic bronchial diseases. Mucokinesis can be induced by drugs that improve ciliary activity (e.g., β -receptor agonists and methylxanthines) or by drugs that improve the mobility of bronchial secretions by changing viscosity. Viscosity of bronchial secretions can be decreased by hydration (e.g., sterile or bacteriostatic water or saline), increasing pH (e.g., sodium bicarbonate), increasing ionic strength (sodium bicarbonate and saline), or by rupturing sulfur (S-S) linkages in the mucus (e.g., acetylcysteine or iodine). Hydrating agents can be administered parenterally (i.e., isotonic crystalloids) or by aerosolization. Home aerosolization can be easily achieved with a humidifier or steamed bathroom or with a commercially available aerosolizer. The efficacy of aerosolization in liquefying airway secretions is controversial,²⁶ with the greatest benefit occurring in the upper airways. Bland aerosols such as water and saline can actually be detrimental to mucociliary function.²⁶ The efficacy of ionic solutions or alkaline solutions compared with that of water on enhanced mucous mobility is controversial.²⁶

Bromhexine

Bromhexine is a mucolytic that acts at the level of the mucussecreting gland, decreasing the formation of mucoid secretions. On the basis of product information, in humans it is rapidly absorbed after oral absorption but undergoes extensive first-pass metabolism, resulting in an oral bioavailability approximating 20%. It is highly bound to plasma proteins. Its distribution includes penetration of the blood-brain barrier. Metabolites are excreted in the urine mainly as metabolites, resulting in an elimination half-life of up to about 12 hours. Although characterized by low toxicity, the mucolytic effects will occur in other areas of the body. Accordingly, caution is recommended for use in patients with a history of gastrointestinal ulceration. The impact in the patient with a urinary tract infection is not known. A Cochrane review¹¹⁴ that focused on the efficacy of mucolytics in human patients with bronchiectasis found that bromhexine facilitated removal of mucus associated with infection, but the number of clinical trials was too few to allow meta-analysis.

Acetylcysteine

Acetylcysteine (*N*-acetyl-L-cystein) (NAC) (see Figure 20-9) is the N-acetyl derivative of the naturally occurring amino acid L- cysteine. It is the mucolytic drug most widely used by humans.^{26,115} Although it appears to be efficacious after aerosolization, oral administration has become the preferred route.¹¹⁵ In Europe the drug is available in solid and powder dosing forms. Unfortunately, only the solution, which is unpalatable and malodorous, is approved for use in the United States. The powder is available as a chemical reagent from several chemical companies and application to food or as a capsule might be considered.

KEY POINT 20-10 The beneficial effects of *N*-acetylcysteine, which include control of inflammation as well as mucokinesis, can be realized with oral as well as inhalant therapy.

Regardless of the route of administration, the mechanism of NAC reflects destruction of mucoprotein of the disulfide bonds by a free sulfhydryl group. The subsequent smaller molecules are less viscid and less able to efficiently bind to inflammatory debris. As a thiol compound, NAC is a radical scavenger, able to directly interact with oxidants such as hydrogen peroxide, hydroxyl radicals, and hypochlorous acid.²¹ In addition to these direct effects, as a cysteine, NAC appears to promotes cellular glutathione production, a critical intracellular scavenger of radicals.¹¹⁶ Increased intracellular glutathione appears to contribute to the control of inflammation.¹¹⁷ A number of animal studies indicate efficacy of NAC in the prevention and therapy of lung injury associated with oxygen radicals.^{116,118} These effects may be additive with dexamethasone.¹¹⁹ However, although NAC has an antiinflammatory effect, it has an apparent dose-dependent, paradoxical effect on polymorphonuclear cells. Respiratory burst is suppressed but phagocytosis is increased in humans receiving increasing doses of 6 to 18 g (60 to 180 mg/kg) of NAC by constant slow intravenous infusion.¹¹⁶ In contrast, at a low mucolytic dose (300 mg or approximately 4.5 mg/kg three times daily in humans), respiratory burst is increased. The impact of high doses can be beneficial in the presence of inflammatory disease or syndromes associated with ischemia/reperfusion or endothelial cell activation but detrimental in the presence of infectious diseases; lower doses might be recommended in the presence of infectious disease dependent on leukocyte activity. Acetylcysteine appears to induce respiratory tract secretions, probably by way of a gastropulmonary reflex. Effects on bronchial secretions appear to be clinically relevant. Acetylcysteine improved gas exchange in a study of dogs with experimentally induced methacholine bronchoconstriction.¹²⁰ The effects of NAC in human patients with COPD is not conclusive, with study results ranging from no effect to clinical effect.

In humans acetylcysteine is rapidly absorbed from the gastrointestinal tract and extensively distributed to the liver, kidneys, and lungs, where it may accumulate. It is rapidly metabolized by the liver to the natural amino acids cysteine and cystine.^{115,121}

The indications for oral acetylcysteine therapy for humans include toxic inhalants (including tobacco smoke), bronchitis, COPD, cystic fibrosis, asthma, tuberculosis, pneumonia and emphysema, and ARDS.¹¹⁷ Installation of a 10% to 20% solution has also been used to clean and treat chronic sinusitis.¹¹⁵ Physiotherapy will enhance the efficacy of acetylcysteine. For example, one study in humans with COPD (n = 523) could not establish a beneficial effect of NAC (4.5 mg/kg every 8 hours orally) for 3 years in prevention of deterioration of disease.¹²² However, a potential beneficial effect was found in those patients not receiving inhaled steroids. In contrast, Sutherland¹²³ performed a meta-analysis from eight trials (randomized n = 2,214) and concluded that that NAC significantly reduced the odds of experiencing exacerbations, including in active smokers. This report also found a greater effect when persons using inhaled glucocorticoids were removed, suggesting that inhaled steroids attenuate the effect of NAC. Accordingly, the authors concluded that treatment with NAC may be beneficial in a subset of patients with COPD.

Acetylcysteine therapy is associated with few adverse affects. In humans doses as high as 500 mg/kg are well tolerated,¹²¹ although vomiting and anorexia can occur. Kao and coworkers¹²⁴ retrospectively performed a meta-analysis to review the adverse events in humans receiving NAC intravenously for treatment of acetaminophen toxicity. Of the 187 patients receiving the drug, seven adverse events were reported, six of which were cutaneous and rapidly responded to antihistamines. The authors concluded that the rate of adversities was low. The median LD₅₀ in dogs after oral use is 1 g/kg and parenterally 700 mg/kg. Because it is metabolized to sulfur-containing products, it should be used cautiously in animals suffering from liver disease characterized by hepatic encephalopathy. Aerosolization of NAC can cause reflex bronchoconstriction as a result of irritant receptor stimulation and should be preceded with bronchodilators.

No scientific support appears to exist for the use of NAC in animals with lung disease. Historical successful use focuses in treatment of acetaminophen toxicosis. The author has used these high doses (144 mg/kg intravenously followed by 70 mg/kg 12 hours later) in life-threatening pulmonic conditions, including pneumonia. Other conditions to consider include but are not necessarily limited to chronic bronchial diseases, chronic sinusitis, electrical-cord bites, and other respiratory syndromes associated with inflammation. Although NAC in the form of Mucomyst might be administered orally, an alternative method is procurement of a scientific-grade granule product (e.g., Spectrum Chemicals). Further, many health-food stores offer NAC in capsular form for reasonable prices, although the quality of the products may not be known.

EXPECTORANTS

Expectorants such as potassium iodide are common ingredients in over-the-counter cough preparations. Expectorants increase the fluidity of respiratory secretions through several mechanisms and are often used as adjuvants for the management of cough by facilitating removal of the inciting cause. Bronchial secretions are increased by vagal reflex after gastric mucosa irritation (iodide salts) and directly through sympathetic stimulation or by volatile oils that are partially eliminated by way of the respiratory tract. Although the combination of expectorants with antitussives in over-the-counter cough preparations may seem irrational, the antitussive drugs in these combination products do not appear to prevent stimulation of the cough reflex induced by liquefied secretions commonly included in over-the-counter cough preparations. Their mechanism of action is unknown, although they may be ineffective at the doses used in cough preparations.

Iodide Preparations

Potassium iodide is a saline expectorant capable of increasing secretions by 150%. Ethylenediamine dihydriodide, used as a nutritional source of iodine in cattle, may be useful for the treatment of mild respiratory diseases. Iodide preparations should not be used in pregnant or hyperthyroid animals or in milk-producing animals. Demulcent expectorants such as syrup are often used as the vehicle for cough medicaments but have no apparent expectorant value. They may, however, be useful for treatment of cough caused by pharyngeal irritation.

Stimulant Expectorants

Stimulant expectorants are used more commonly for coughing associated with chronic bronchial diseases. Guaiacol and its glyceryl ether guaifenesin (glyceryl guaiacolate) are wood tar derivatives. Neither the volume of viscosity nor respiratory secretions appear to change after treatment with guaifenesin, although airway particle clearance increases in bronchitic human patients.

Miscellaneous Expectorants

Among the chemicals that potentially contribute to COPD are DNA and actin.¹⁷ The ability of bovine pancreatic deoxyribonuclease (DNase) to decrease the viscosity of lung secretions led to its approval in the early 1960s. However, adverse reactions (probably to contaminating enzymes) limited its use. Recombinant technology allowed the development of human DNase (rhDNase; dornase alfa) which is used in the treatment of cystic fibrosis. Expiratory volume increases and the incident of clinical exacerbations is reduced when used (2.5 mg by aerosolization) on an alternate-day basis.¹⁷ rhDNase has been used for management of both acute and chronic disease, although time to response is longer in patients with the most severe disease. The effects of DNase may decrease with longterm therapy, and concerns have been raised that its effects may be merely cosmetic, masking clinical signs indicative of serious disease.¹⁷ The cost of rhDNase may preclude use in animals, particularly if clinical effects with long-term use are not definitive.

Aerosolized hypertonic (5.85%) saline (10 mL twice daily) also have demonstrated efficacy in human patients with cystic fibrosis. Postulated mechanisms focus on osmotic draw of fluid into the airway lumen or cleavage of mucin bonds, either of which decreases mucus viscosity. Bronchodilators should be administered before aerosolization to prevent bronchoconstriction.

DECONGESTANTS

The indications for decongestants include sinusitis of allergic or viral etiologies and reverse sneezing or other complications of postnasal drip. Information regarding the use of decongestants in animals is largely based on extrapolation from human patients for which allergic rhinitis and the common cold are the more common indications. Often decongestants are administered as a single drug combined with expectorants.

The two major categories of drugs used as decongestants are the histamine (H₁) receptor antagonists (e.g., dimenhydrinate, diphenhydramine, chlorpheniramine, and hydroxyzine, as well as newer second-generation drugs such as loratadine and cetirizine) and the sympathomimetic drugs (i.e., α -adrenergic agonists) (such as ephedrine [EDE], pseudoephedrine [PSE], and phenylephrine [PNE]).¹²⁵⁻¹²⁷ These drugs can be given topically to avoid the systemic effects associated with oral therapy.

Stimulation of α_2 -receptors concentrated on precapillary arterioles results in vascular smooth muscle vasoconstriction. Blood flow to the nasal mucosal capillary bed is reduced; excess extracellular fluid associated with congestion and a "runny" nose is thus decreased. α -receptors are concentrated on the postcapillary venules; when stimulated, the venules act as capacitance vessels that reduce blood volume in the mucosa. Mucosal volume decreases, reducing congestion. Sympathomimetic drugs mimic norepinephrine. Direct-acting agents stimulate one (PNE: α_1) or both types of α -receptors, depending on drug chemistry. Indirect-acting agents (PSE) displace norepinephrine from nerve terminals and sometimes block its reuptake, effectively increasing its action on postjunctional α -receptors. Some drugs (e.g., PSE, EDE) are both direct and indirect in their actions. Prolonged use of agents that act indirectly (e.g., EDE) may deplete storage granules, and the animal may become refractory to its effects. Alternatively, downregulation of receptors (tachyphylaxis) may result in refractoriness.^{126,127}

Topical agents containing sympathomimetic drugs (i.e., nasal sprays) act within minutes, with minimal side effects. In contrast, rebound hyperemia is common, particularly with extended use of the drugs. The mechanism of rebound hyperemia is not clear but may result from secondary β -adrenergic effects, as β -receptors upregulate or desensitize α -receptors. Regardless of the cause, repeated contraction of the vasculature can result in ischemia and mucosal damage, perhaps as a result of loss of nutrition. Oral treatment of sympathomimetic drugs can be associated with a number of adverse reactions. Systemic vasoconstriction may cause hypertension; cardiac stimulation may result in tachycardia or reflex bradycardia. Stimulation of the central nervous system may also prove problematic, particularly with lipid-soluble agonists such as ephedrine. Stimulation of urinary sphincter α -receptors may result in urinary retention. Mydriasis may decrease aqueous humor exit and can prove detrimental in patients with glaucoma. Because of their effects on endocrine and other organs associated with metabolic function, these drugs should not be used in patients with metabolic disorders, including thyroid disease and diabetes mellitus. The relationship between plasma drug concentration and nasal decongestant efficacy with the α -agonists appears to be minimal, suggesting that topical therapy is as efficacious. In addition, oral administration of some drugs (e.g., PNE) is limited by first-pass metabolism, which prevents therapeutic concentrations of the drug from being reached. Thus topical therapy may be the preferred route for sympathomimetic drugs. Note, however, that in the United States PSE is an "old drug" and as such is exempt from Food and Drug Administration regulation, which includes various topical formulations. However, issues regarding substance abuse have led to a Schedule III status for PSE (along with EDE and phenylpropanolamine) with the Drug Enforcement Agency.

Antihistamines are effective for the treatment of allergic rhinitis in human patients. In this scenario, they relieve and prevent itching and rhinorrhea but not nasal congestion. Thus antihistamines are frequently combined with sympathomimetic drugs. The efficacy of these drugs for the treatment of symptoms related to the common cold (and, presumably, unknown microbial causes in animals) has not been proved. Sedation is the most common side effect of the first-generation antihistamines (diphenhydramine). Newer antihistamines (e.g., chlorpheniramine) are associated with minimal sedation. In contrast to other causes of rhinitis, topical decongestants may be more of a risk for patients with allergic rhinitis because of the risk of drug reaction (rhinitis medicamentosa). This side effect does not occur with topical therapy. Because the antihistamines are safer than the sympathomimetic drugs after oral administration, this may be the preferred route for antihistamines.125

Formulations of topical preparations can influence drug efficacy. Controlled-release polymers can decrease the rate of drug dissolution (and thus its ability to reach cellular targets). Although these differences may not be clinically relevant, it is important to realize that bioequivalency of the topical decongestant products containing older drugs may vary. The major disadvantage of topical agents is their short duration of action.

Respiratory Stimulants

Caffeine, as previously noted, is a respiratory stimulant often used to treat premature infants. It appears not to affect dogs and cats in that capacity. Doxapram (see Figure 20-9) is a respiratory stimulant that acts indirectly by stimulating chemoreceptors of the carotid arteries, which in turn stimulates the respiratory center. It may be helpful in counteracting the depressant effects of opioids or other drugs. In humans high doses may be associated with hypertension and tachycardia. The effect of doxapram (2.2 mg/kg intravenously) on laryngeal function was studied in healthy dogs (n = 30) preanesthetized with butorphanol and acepromazine followed by propofol (4 mg/kg intravenously) induction. Improved respiratory effort and laryngeal motion led the authors to suggest routine use of doxapram during laryngoscopy.¹²⁸

AEROSOLIZATION AS A ROUTE OF DRUG ADMINISTRATION

Aerosolization of drugs (inhalation therapy) is characterized by several advantages. Higher drug concentrations in target tissues leads to lower doses, thus enhancing efficacy while minimizing toxicity (e.g., anticholinergics, glucocorticoids, and beta-adrenergics). Additionally, response to therapy may be more rapid than that to systemic therapy. Hepatic first-pass metabolism after oral administration is circumvented, which serves to prolong the pharmacologic effect of selected drugs (e.g., β -adrenergic agonists and beclomethasone). In human medicine, with the development of more effective inhalant devices, asthma is predominantly treated with inhalant medications. The primary indications for aerosolization in small animals also has been direct delivery of drugs to the respiratory tract and to facilitate liquefaction and mobilization of respiratory secretions. However, the use of human inhalant devices designed to treat asthma is generally accepted for cats, although use in dogs is less common.

The success of patient response to aerosolized drugs is more likely to reflect adequate drug delivery rather than drug efficacy. Three factors determine the amount of drug reaching the airways: anatomy, ventilation, and aerosol characteristics.¹²⁹ The anatomy of the respiratory tract is designed to filter inhaled particles. Indeed, up to 90% of particles produced by pMDI are removed before they reach the airways in humans.¹²⁹ The more tortuous the airways traversed by an aerosol, the smaller the percentage delivered. Canine and feline anatomy is likely to contribute substantially to deposition in the oral pharynx and upper airways.

Variations in tidal volume; airflow rates; and respiratory rate, depth, and pattern also will affect the amount of drug delivery. In humans breath holding is particularly important to drug delivery.¹²⁹ With progression of chronic disease, or with moderate to severe acute disease, aerosol therapy may become less effective as the respiratory pattern becomes shallow and rapid. For stressed animals, tachypnea will further decrease depth of aerosol penetration decreases, with more drugs deposited in upper airways. The utility of aerosolization may be further limited because of stimulation of irritant receptors and reflex bronchoconstriction.^{26,130} Resistance by the animal to aerosolization may further exacerbate respiratory distress and thus affect the site of particle deposition.

Among the characteristics of the aerosol that will influence airway deposition are diameter, shape, electrical charge (for particles less than 1 µm in size), density, mass, hygroscopicity, and preparation type (i.e., solution versus suspension).^{2,113,129,131,132} The optimum particle size for particle (and drug) deposition in the trachea is 2 to 10 µm and in peripheral airways, 0.5 to 5.0 µm. Differences in methods, devices, diseases, and drugs have generated a number of contradictory reports regarding the best particle size for aerosolized drug delivery in diseased humans. Most studies suggest penetration of small airways is best accomplished with particles 1.5 µm or less in size, although others have found maximum improvement in lung function with an aerosol of 3 µm particles.^{129,131} Jet and ultrasonic nebulizers (described later) tend to generate heterogenous particles of that range from 1.2 to 6.9 and 3.7 to 10.5 µm in size, respectively. Spinning disk nebulizers produce particles that range from 1.3 to 30 µm. For inhalant devices, particle size generated for MDIs varies from 1 to 35 µm, but particle size is dependent on (inspiratory) flow for dried-powder inhaler (DPI) devices.129

Aerosol deposition also will be affected by the technique of delivery (i.e., mask versus endotracheal tube and nose versus mouth). Larger particles generated by aerosol devices will be impacted on masks, pharynx, and in upper airways (or endo-tracheal tubes). Indeed, oral absorption of particles is sufficient that side effects to inhaled glucocorticoids in humans tend to reflect systemic response to the drugs. In animals grooming may increase the risk of systemic side effects to drugs deposited on the face during mask administration. One method whereby drug delivery is enhanced, thus increasing efficacy and safety, is the device used for drug delivery. Modern aerosol therapy is administered through one of three devices: nebulizers, MDIs, and DPIs.^{131,133,134}

Two basic types of nebulizers have been developed: jet and ultrasonic.131,133 The ultrasonic nebulizer is based on a high frequency (1-3 MHz) vibrating piezoelectric crystal that generates a fountain of liquid in the chamber. Droplet size decreases as vibration frequency increases. Jet nebulizers are based on the Bernoulli principle. Compressed gas (air or oxygen) is forced through a narrow orifice, creating a low-pressure area at the outlet of the adjacent liquid feed tube. Drug in solution is drawn from a fluid reservoir and shattered into droplets by the gas stream. Breath-enhanced jet nebulizers have an added valve system that directs inspired air to the well during inspiration. This second source of air optimizes the number and size of particles. Still, the amount of drug delivered by nebulizers to airways (in humans) can be as little as 10%. In humans adapters have been added that time drug release with the initial inspiratory effort, increasing the amount of drug delivery to airways to up to 69%; such adapters are not likely to be helpful in animals. Other factors particularly affecting nebulized drug delivery include solution viscosity, ionic strength, osmolarity, pH, and surface tension. Acidic and nonisotonic solutions increase the risk of bronchoconstriction, coughing, and irritation of the lung mucosa. High drug concentrations may also decrease the drug output; foaming is a particular problem with ultrasonic units.

A number of companies offer reasonably priced (\$70 to \$250 or above) portable compressor-based nebulizing units. Compressors that accompany the nebulizers can generate air at pressures (20 to 40 psi) and airflow velocities (7 to 10 mL) comparable to oxygen-based flow meters (e.g., Omron Healthcare Inc, www.omronhealthcare.com). Aerosol units are small enough to be placed in an aquarium of appropriate size or, for large dogs, can be adapted to a mask. For tracheostomized patients, infant or adult tracheostomy masks that deliver aerosol directly into the tracheostomy are available. Although aerosol units are generally reusable, attention must be made to keep units sterile; great care must be taken to ensure that nebulizers remain free of microorganisms between uses. Adherence to cleansing procedures after each use of nebulizing equipment should be strict. Cold sterilization agents should be effective against *Pseudomonas* spp. Manufacturers of reusable equipment recommend washing it in warm soapy water, rinsing it well, and soaking it (including the tubing) for 30 minutes in a solution of 1 part vinegar and 3 parts water. Disposable equipment should be replaced frequently; replacement after use in patients with infection is particularly encouraged.

The MDI has been described as a revolutionary change for aerosol therapy in humans; it is the most commonly used device. ^{88,133,134} The aerosol of an MDI is driven by a propellant. The more common older chlorofluorocarbons (CFCs) are being replaced by hydrofluoroalkanes (HFAs), which contain no chlorine and thus do not affect the ozone layer. The HFA-propelled MDIs also lack the "cold Freon" effect that causes human patients to fail to inspire completely. The drug in an MDI is emitted at a high velocity (>30 m/s) through a nozzle. However, as with nebulizers, only a small percentage of drug (10% to 20%) reaches peripheral airways, with most (in humans) being deposited in the oropharnyx. Surfactants enhance particle stability in the presence of CFC propellants; ethanol is similarly used for HFA propellants. For HFAs drugs are delivered as a solution rather than as a micronized suspension. As such, particles released by the device valve are much smaller; referred to as extra fine, the average size is 1.1 μm, compared with 3.5 to 4.0 μm in size for the CFC. The smaller size enhances deeper airway penetration.⁴⁰ Indeed, the pattern of particle deposition with HFA propellants (60% deposited in small airways rather than the oropharynx) is reversed compared with that for CFC propellants.¹³⁴ Spacer tubes, valved holding chambers, and mouthpiece extensions have been added to minimize the need for hand-breathinhalation coordination, thus improving delivery. Spacers and holding chambers yield an aerosol that is more uniform in lung distribution and characterized by deeper penetration in peripheral airways. Breath-activated MDIs also have been developed, which, as with nebulizers, minimize the need for hand-breath-inhalation coordination. Despite these innovations, studies using radiolabeled aerosols in normal humans have documented that less than 20% (usually only 10%) of drug reaches the airways, even if the respiratory pattern is optimal.^{40,134} The DPI was designed to eliminate the need for hand-inhalant coordination necessary for the MDI. Drug aerosol of DPI is generated by air forced through powder. Particles are aggregated and too large for effective delivery. However, dispersal into smaller particles is accomplished by turbulent airflow. In contrast to MDIs, DPIs do not require spacers. A number of types of DPIs are available, ranging from single-dose devices loaded by the (human) patient to multiunit dose devices in a blister pack, blister strip, or reservoir. However, a major disadvantage of DPIs in veterinary medicine is the dependency of particle size on inspiratory effort. Each DPI is characterized by a different airflow resistance; finer particles require more resistance to air flow, which, in turn, requires greater inspiratory effort. Consequently, DPI application may be limited in animals. The use of nebulizers or inhalant devices in small animal patients is largely based on anecdotal reports. One study demonstrated that a radiopharmaceutical will be distributed to peripheral airways in cats using a simple face mask.¹³⁵ To maximize the site of particle deposition, animals to be aerosolized should be pretreated with a β -adrenergic or methylxanthine bronchodilator 10 minutes before aerosolization, or (potentially less preferable) a bronchodilator should be included in the aerosolized medicament (e.g., 100 mg aminophylline). Care should be taken not to overhydrate and flood the respiratory tract. Treatments of approximately 30 to 45 minutes should be repeated every 4 to 12 hours. In humans aerosolization is a well-established route of administration for bronchodilators and antiinflammatories^{26,136} (Box 20-1) and is recommended for dogs for selected infectious tracheobronchitis.¹³⁷ In veterinary patients aerosolization is more commonly used for administration of antimicrobials and mucolytics. Indications include asthma, chronic bronchial disease, and infections of both lower and upper airways. The dose of drug to be nebulized is generally not scientifically derived. A general approach would be dilution of the calculated systemic dose in a sufficient volume of saline necessary for a 30-minute aerosol. Drugs prepared by the manufacturer in irritating solutions (e.g., NAC) should be diluted. The choice of antibiotic to be aerosolized should be based on efficacy against the targeted organism. Because the amount of drug that reaches the site can not easily be quantitated and minimum inhibitory concentrations based on aerosolized drug have yet to be defined, the use of culture data based on the minimum inhibitory concentration (a plasmabased target) is a reasonable approach.

Adaptations to inhalant devices for animals range from modifications in inhalant masks³⁹ with a one-way valve that limits drug movement to inhalation to simple administration through an empty toilet paper roll "spacer" that facilitates adequate exposure during inspiration. Cats breathe six to seven times after the medication is dispensed from the inhaler. Despite innovations designed to enhance small airway penetration with inhalant devices, the smallest airways

are likely to remain untreated. Additionally, aerosol therapy is limited to the epithelial surface of the airways. Finally, compliance in humans with inhaled therapy is poorer than with systemic therapy.⁴⁰ As such, the use of inhalant devices should be accompanied by frequent thorough monitoring. Inhalant antimicrobial therapy should not replace systemic therapy. The factors decreasing small airway drug delivery in animals are likely to be greater than in humans. As such, scientific support is paramount to guide the appropriateness of and indications for inhalant bronchodilator and antiinflammatory therapy as a replacement for systemic therapy.

DRUG THERAPY OF SPECIFIC DISEASES OF THE RESPIRATORY TRACT

Treatements of infectious diseases of the respiratory tract are discussed in Chapter 9; diseases associated with chronic inflammation are also addressed in Chapter 19.

Therapy of Fungal Infections of the Nose

Nasal aspergillosis in dogs is difficult to treat and generally most successful if medical management is accompanied by surgical débridement. Topical therapy includes flushing the nasal mucosa with povidone-iodine solutions (10%) every 8 hours for 6 to 8 weeks after surgery; a 10% solution of clotrimazole in polyethylene glycol, instilled in nasal tubes and administered twice daily or in direct contact for 1 hour during surgical exploration; or enilconazole (10%) at 5 mg/ kg instilled into nasal tubes twice daily for 7 to 14 days. Topical therapy should be accompanied by systemic therapy with itraconazole. Treatment of fungal infections is discussed in greater depth in Chapter 11.

Therapy of Disorders of the Trachea

Tracheitis

Resolution of underlying causes is important to successful control of the inflamed trachea. Noninfectious causes (e.g., exposure to smoke, cough) are more common than infectious causes. In addition to resolution of the underlying cause, drug therapy should be implemented to control symptoms. Cough can be controlled with peripheral or central antitussives or a combination thereof. Over-the-counter preparations that contain expectorants can prove helpful. Humidifying secretions (liquefaction of mucoid material) becomes increasingly important with chronic tracheitis and may include nebulization four to six times a day or exposure in a steam-filled bathroom for 15 to 20 minutes three times daily. Physical therapy (coupage) should be implemented after liquefaction of secretions. Short-term therapy with short-acting glucocorticoids may help break the cough cycle, although care must be taken that glucocorticoids do not exacerbate the underlying condition.

Antibiotics are indicated for infectious tracheitis/tracheobronchitis. Infectious tracheobronchitis in dogs (kennel cough) is a complex syndrome caused by multiple organisms, including viruses, bacteria, and mycoplasma. This syndrome is discussed with bronchial diseases.

Structural Disorders of the Trachea

Pharmacologic management of structural disorders of the trachea focuses on supportive therapy.

Hypoplastic trachea. Slight or moderate tracheal hypoplasia may respond to bronchodilator therapy. Recurrent infections (bacterial) should be anticipated because of a poorly functioning mucociliary tract. Although prophylactic antibiotic therapy is discouraged to avoid emergence of resistance, antibiotic therapy during active infection should be anticipated. Culture and susceptibility data may be particularly important for these patients because recurrent infections are more likely to occur in them than in animals with a normal trachea. Drugs that facilitate mucociliary clearance should be considered on a daily basis; these might include mucokinetic drugs. More serious episodes of respiratory compromise might benefit from NAC therapy administered by any route. The use of bronchodilators should be considered; although

the tracheal diameter may not be affected, the effects of these drugs on peripheral airways can be beneficial. Supportive actions should also include weight control, avoidance of smoke and other environmental contaminants, and avoidance of actions or drugs that can compromise the immune response.

Tracheal collapse. Tracheal collapse as a cause of respiratory distress can progress to a life-threatening situation. Early therapy may help decrease or slow the progression of the syndrome in some animals, simply by decreasing damage to the trachea as a result of paroxysmal coughing. Tracheal rings in afflicted animals lose their ability to remain firm, leading to collapse. The characteristic "goose honk" cough is dry and chronic. Most commonly afflicting smaller breeds, tracheal collapse is often associated with chronic valvular (cardiac) disease, and it is important to differentiate between the two. Diagnosis requires proper radiographic examination and motion studies with either a fluoroscope or a bronchoscope.

Drug therapy targets control of the cough with bronchodilators and centrally acting antitussives. Severe coughs may require narcotic antitussives associated with sedation (a desirable characteristic in some patients) until the cough is controlled. Mucokinetic drugs may also be helpful. Short-term glucocorticoid therapy may be important to minimize the inflammatory response to damage induced by paroxysmal coughing. Nebulization may be helpful, but pretreatment with bronchodilators is probably important. The use of bronchodilators should be considered for their effects on peripheral airways. Digitalization reportedly has been beneficial in some patients that do not respond to other therapies.¹³⁸

Proteoglycan content and size of tracheal cartilage matrix changes that accompany age have been demonstrated in a number of species, including humans.^{139,140} Hamaide and coworkers¹⁴⁰ suggested that age-related changes may lead to compliance changes that accompany tracheal ring collapse. Trachea collapse appears to reflect loss of rigidity associated with decreased glucosamine glycan chondroitin sulfate. A number of old studies have demonstrated uptake of labeled glucosamine by cartilage rings under in vitro conditions, suggesting cartilage turnover may be sufficiently rapid that supplementation may be beneficial. Accordingly, supplementation in the form of injectable and oral products as is recommended for osteoarthritis is a reasonable approach for preventing or supporting other therapies for tracheal collapse. The role of glutamine and chondroitin sulfates in supporting damaged or healing cartilage in osteoarthritis is addressed in Chapter 29. Response, if it is to occur, will be prolonged in onset, depending on the rate of tracheal proteoglycan turnover.

Bronchial Diseases

Diagnosis of bronchial diseases should be based on physical examination, thoracic radiography, tracheal or bronchial wash, and bronchoscopy. Examination for structural defects, cytologic studies, and microbial cultures are among the diagnostic tools of use for bronchial diseases.

Canine Infectious Tracheobronchitis

Bordetella bronchiseptica is the bacterial organism most commonly associated with kennel cough. Viral organisms include canine parainfluenza, canine herpes, and canine distemper viruses. The clinical syndrome is characterized by a dry, hacking, paroxysmal cough in an otherwise healthy animal. Clinical signs of this highly contagious syndrome generally appear 3 to 5 days after exposure. Tracheal cytology should reveal neutrophils and bacteria. Therapy of uncomplicated cases is supportive. Antitussives, in relative order of efficacy (least to most), include dextromethorphan (antitussives), butorphanol, and hydrocodone. Hydrocodone may be associated with sedation, which may be beneficial in cases of paroxysmal coughing. Antimicrobial therapy in uncomplicated cases (lasting 7 to 10 days) is discouraged; indeed, most antimicrobials used empirically (e.g., amoxicillin) generally do not penetrate bronchial secretions in sufficient quantities to be effective.

In contrast, antibiotic therapy (in addition to other supportive therapy) is indicated for complicated infections or for dogs whose coughing persists after 2 weeks and for which evidence exists of secondary bacterial infection. Other indicators of complications include any evidence of infection occurring lower than the upper bronchi or systemic signs of illness. Because of the complicated nature, and particularly if the patient has received previous antimicrobials, selection of the appropriate antibiotic should be based on a properly collected culture at the site of infection (not a pharyngeal or laryngeal swab). Selection of an antimicrobial empirically is complicated by the possibility of mycoplasma as a causative agent. Selection of antimicrobials for treatment of respiratory tract infections is discussed in Chapter 8.

Therapies intended to support mucociliary function should be continued. Because coughing associated with kennel cough can be paroxysmal, a single treatment with a short-acting glucocorticoid might be considered to ameliorate some of the effects of inflammation. In the immunocompromised animal, however, this may lead to spread of infection.

Feline Bronchial Diseases

Feline bronchial diseases include feline bronchial asthma as well as acute and chronic bronchitis and emphysema. It is characterized by damage or hypertrophy (or both) of the airway epithelium; increased production of airway secretions; and spasms of bronchial smooth muscle, which itself may become hypertrophied.³⁹ Causes of feline bronchial diseases have not been found, but a type I hypersensitivity reaction has been suspected as a cause of asthma. Initial contact between the allergen and bronchial mucosa may lead to the release of histamine and other mediators that allow penetration of the allergen into the submucosa. The resultant inflammatory response to the allergen leads to the characteristic disease. The source of inflammatory mediators includes essentially any cell of the respiratory tract, white blood cells, and platelets. Smooth muscle hypertrophy and increased mucus and inflammatory cell infiltrate (particularly eosinophils) characterize asthma and its clinical signs. Acute bronchitis is generally reversible and short in duration but can be life-threatening.

Should airway inflammation persist, bronchitis may become chronic. Inflammation lasting 2 to 3 months can lead to deposition of fibrous tissue; these lesions tend to be irreversible. Emphysema can occur as a result of chronic bronchitis and is characterized by enlarged airspaces with destruction of bronchiolar and alveolar walls and airway collapse. Cough is the most consistent clinical sign of bronchial disease in cats. Respiratory distress may be absent or episodic, particularly in the presence of bronchial asthma.

Diagnosis should be based on thoracic radiographs, a complete blood count (which may reveal eosinophilia), tracheal or bronchial wash (particularly if bacterial or parasitic causes are suspected), and fecal examination (for parasitic causes). Cultures of Mycoplasma species should be performed whenever possible, particularly in nonresponders. Treatment should include environmental management. In particular, exposure to smoke (e.g., cigarette, fireplace) should be avoided; other potential environmental allergens include litter dust, perfumes, household cleaning products, deodorants, and insulation products. Asthma in cats has been classified according to the severity (mild, moderate, and severe) of clinical signs in order to facilitate the need for treatment.³⁹ However, clinicians are urged not to become too complacent in their approach to the disease and to ensure that seemingly mild disease does not progress to a more severe state in the absence of therapy. The primary focus of therapy is control of inflammation. Control of inflammation in peripheral airways may be paramount to successful therapy.

Management of Acute Asthma

Acute respiratory distress resulting from bronchial disease should be handled as a medical emergency. Administration of drugs should be accompanied by oxygen therapy and rest. The hydration status of the patient should be assessed at presentation and corrected if indicated. Overzealous fluid therapy can prove detrimental, however, and should be avoided. Therapy should include bronchodilators, glucocorticoids (for their permissive effect on β_{-2} adrenergic receptors) and as necessary, anticholinergics.

Glucocorticoid therapy should be initiated in conjunction with bronchodilators in cats with status asthmaticus. The permissive effects of glucocorticoids are likely to improve response to bronchodilator therapy. Rapidly acting drugs such as prednisone sodium succinate should be administered at presentation and again at 4 to 6 hours.^{6,30} Prednisolone is preferred to prednisone; the latter should not be given orally (see Chapter 30). Alternatively, dexamethasone or dexamethasone phosphate may be administered because of its antiinflammatory potency. Oral bronchodilator and glucocorticoid therapy can begin when the patient is stabilized.

Among the bronchodilators, β_2 -adrenergic agonists are preferred (although doses have not been well established for animals), but nonselective agonists can be equally effective in critical cases. Parenteral rather than oral administration will ensure the most rapid onset of action, although use of a shortacting inhalant beta-adrenergic also might be considered (see the discussion of inhalant devices). Note that epinephrine has

marked β_1 (and α) effects and in the presence of hypoxemia can cause fatal cardiac arrhythmias. Aerosolization should not replace, but can be used in concert with, parenteral administration if the stress of aerosolization is not dangerous to severely dyspneic animals. Subcutaneous epinephrine can be administered at presentation and, if the patient responds, repeated every 30 minutes for several doses.³⁰ Terbutaline can also be administered subcutaneously either instead of epinephrine or for animals that fail to respond to epinephrine. Aminophylline can be infused intravenously (2 to 5 mg/kg in 5% dextrose or saline) in animals that fail to respond to β-agonists.³⁰ The addition of atropine or glycopyrrolate may facilitate bronchodilation. Exacerbation of hypoxia is a complication of bronchodilator therapy, particularly with theophylline, due to drug-induced pulmonary vasodilation, and the potential for ventilation-perfusion mismatching necessitates administration of humidified oxygen. The use of an anticholinergic (atropine preferred) also should be considered after therapy with beta-adrenergics and glucocorticoids.

Reinero and coworkers¹⁴¹ addressed the impact of flunisolide (inhaled glucocorticoid), prednisone, zafirlukast, and cyproheptadine along with placebo on inflammatory mediators in an experimental model of feline asthma (n = 6) using a randomized crossover design. The only significant changes detected were a decrease in the percentage of eosinophils in bronchoalveolar lavage fluid for both prednisone and flunisolide compared with control and the content of allergen-(Bermuda grass) specific IGE in serum in cats receiving oral glucocorticoids. The power of the study to detect significant differences and the use of prednisone were limitations of the study.

Long-term management of feline asthma. Response to glucocorticoids in the acute management of respiratory distress in cats may indicate a favorable response to long-term management. Glucocorticoids are the preferred drug, particularly in cats with moderate to severe disease, for control of inflammation. Prednisolone is the most commonly preferred maintenance drug, although triamcinolone is acceptable, prednisone is discouraged. Initially, doses should be as high as 2 to 3 mg/kg divided two to three times a day. A 2- to 3-week trial may be indicated to establish efficacy and need. Maintenance doses are likely to markedly vary among animals and should be slowly tapered to a minimum effective dose 1 to 2 weeks after therapy is started. Doses as little as 1.25 mg/ cat every 72 hours may be sufficient in some animals. Glucocorticoid therapy should be maintained for a minimum of 2 months; complete cessation of therapy may not be possible in selected cases. Therapy should be continued for several weeks after cessation of signs to resolve residual and clinically inapparent small airway disease. Tracheal cytology may be helpful in identifying the continued need for antiinflammatory therapy both before and after therapy is discontinued. Repositol forms of glucocorticoids might be avoided because of the risk of exacerbation of disease.³⁰A study in humans found the repositol form of methylprednisolone just as effective as a tapering regimen of oral glucocorticoids upon hospital discharge that followed acute management of asthma; however, the intent of the therapy was to slowly withdraw the drug with no continued therapy. Because remission of clinical signs appears to be more difficult in animals that have received these drugs, if therapy is anticipated to continue beyond the duration anticipated for reposital therapy, daily dosing should continue or care should be taken to avoid relapse. For animals for which daily glucocorticoids cannot be given consistently doses of 2 to 4 mg/kg can be given every 10 to 30 days to control clinical signs. In cases of exacerbation in patients receiving glucocorticoids, intermittent high doses of intravenously administered or aerosolized glucocorticoids, and particularly beclomethasone dipropionate, in conjunction with oral maintenance glucocorticoids can be used to treat animals whose disease worsens.³⁰ Alternatively, megestrol acetate has been recommended instead of intermittent high doses of glucocorticoids in cats with refractory bronchial asthma.³⁰

Addition of bronchodilator therapy should be considered for animals that do not respond sufficiently to glucocorticoid therapy. Intermittent use may help during periods of exacerbation of disease, although long-term therapy may be necessary for some animals. Bronchodilators may decrease the amount of glucocorticoids necessary to control clinical signs. Oral theophylline is the bronchodilator most commonly used for long-term bronchodilator therapy in dogs and cats,^{6,30} although terbutaline can be used as an alternative, particularly in animals refractory to theophylline. Alternating between theophylline and β -agonists may prevent the incidence of refractoriness owing to downregulation of β-receptors. Alternatively, the combination of the two should be considered, particularly in nonresponders; an additive response might be expected.¹⁴² Monitoring serum theophylline concentrations is encouraged, particularly in animals that do not respond sufficiently or in animals receiving long-acting theophylline products. Theophylline, particularly long-acting products, might be given to cats in the evening to maximize therapeutic efficacy.

The use of cyclosporine, cyproheptadine, and LRAs as antiinflammatories should be considered in cats that have not sufficiently responded to or cannot tolerate glucocorticoid or bronchodilator therapy. The treatment of asthma as a chronic inflammatory disease is also addressed in Chapter 31. Cats suffering from A. suum-induced airway reactivity had decreased reactivity and remodeling after receiving CsA; differences were noted with 24 hours of therapy.^{141b} Schooley and coworkers¹⁴³ examined the effect of cyproheptadine (8 mg orally twice daily) or cetirizine (5 mg orally twice daily) in cats (n = 9) with experimentally induced asthma (Bermuda grass allergen) using a randomized crossover design. Although no significant differences were detected, the percentage of eosinophils in bronchoalveolar lavage fluid was less in the cats treated with cyproheptadine (27 \pm 16%) and cetirizine (31 \pm 20%) compared with those in the placebo group $(40 \pm 22\%)$.

The role of inhalant devices in treatment of feline asthma. Despite the paucity of well-designed, controlled clinical trials, the use of MDIs for the control of feline asthma is now a generally accepted method of administering glucocorticoids or bronchodilators to asthmatic cats.³⁹ Studies are emerging. For

example, response to orally administered prednisone, inhaled flunisolide, zafirlukast, or cyproheptadine was studied using a controlled crossover design in cats (n = 6) with experimentally induced (Bermuda grass allergen) asthma.¹⁴¹ Significant findings were limited to decreased eosinophils in bronchoalveolar lavage fluid for both glucocorticoid groups. On the basis of this study, response to inhaled glucocorticoids might be anticipated in the cat with spontaneous asthma, but the authors' conclusions that inhaled glucocorticoids might serve as an alternative to oral glucocorticoids should be applied to longterm management only with caution.

Drug delivery in cats using inhalant devices is anecdotally described.³⁹ Care must be taken to coordinate breath intake with drug administration, which is facilitated by the presence of spacer. In animals with mild disease, use of inhaled glucocorticoids (e.g., fluticasone propionate preferred, others include flunisolide, budesonide, and beclomethasone dipropionate) has been recommended twice daily.³⁹ Inhaled short-acting beta-adrenergics (e.g., albuterol preferred, others include pirbuterol, bitolterol) are used as needed to control exacerbations or in animals for which clinical signs do not occur every day. However, client compliance should be ensured when using inhalant devices as primary therapy. Additionally, control of small airway inflammation may remain a concern. For animals with moderate disease (clinical signs have affected daily life, but cough and wheeze are not persistent), oral glucocorticoids should be added short term (e.g., 5 days twice daily followed by 5 days once daily). Systemic effects of inhaled glucocorticoids should preclude the need for tapering oral glucocorticoid doses further as they are discontinued. For severe disease both systemic and inhaled glucocorticoid therapy should be considered. Systemic therapy may include intravenous dexamethasone during an acute crisis. Inhaled bronchodilators should be continued as needed up to 4 times a day. For cases that continue to be refractory, the addition of cyproheptadine has generally found more support than LRAs.

The small number of feline studies precludes drawing conclusions regarding the use of other drugs (e.g., cyproheptadine, antihistamines, LRAs) or combination therapies for treatment as asthma. Their sole use should not be considered in animals with moderate or severe disease, and caution is recommended even for mild disease that might be insidiously progressive. Oral bronchodilator therapy also should be considered in animals with moderate to severe disease or in animals for which inhalant therapy is not reasonable or effective because of poor drug delivery or other reasons.

Canine Chronic Bronchitis

Acute bronchitis is not as likely to present as a life-threatening situation in dogs and refers primarily to duration of clinical signs. Inflammation that persists more than 2 months may cause permanent damage to airways and is referred to as *chronic bronchitis*.¹⁴⁴ *Bronchiectasis* refers to irreversible dilation of the bronchi and can be a sequela of chronic bronchitis (inflammation) that does not resolve. The underlying cause is rarely identified but may include allergies; inhaled irritants (including cigarette smoke); viral, microbial, or parasitic

infections; and heartworm disease. Bacterial infections are more difficult to diagnose, should be based on quantitative rather than qualitative assessment, and generally are not initiators of chronic disease.¹⁴⁴ Foreign bodies are a less common cause. As with cats, eradication of the underlying cause is paramount to halting the progression and therapeutic success. Diagnostic aids are the same as discussed for cats. Medical management of chronic airway disease in dogs is frustrating and should be approached as a perpetuating, slowly progressive, noncurable disease. As such, resolution of identifiable inciting causes (including triggers such as cigarette smoke) and conditions that confound success should accompany drug therapy. Owners may have to adjust their tolerance levels. Additionally, therapy should be accompanied by weight loss and physical therapy (mild exercise or coupage to facilitate movement of respiratory secretions).

Allergic bronchitis is not a common or easy diagnosis in dogs. The canine respiratory tract is probably more resistant to antigenic stimulation as a cause of cough compared with that of cats (and humans). Parasitic infections including heartworm disease must be ruled out. If airway cytology supports an allergic response and the underlying cause has not been identified or yet eradicated, glucocorticoids are indicated. A minimum effective dose should be rapidly established. Longterm glucocorticoid therapy may not be indicated for dogs unless the disease is associated with eosinophilic or mononuclear infiltrates; this is particularly true for patients with bronchiectasis.

Medical management of chronic bronchitis in dogs must be modified for the individual patient. Exposure to irritants such as secondary cigarette smoke must be avoided. Bronchodilator therapy provides the mainstay of medical management of chronic bronchitis in many dogs. Ideally, bronchodilators will also facilitate movement of secretions and control inflammation. Drugs used for cats can be used for dogs; the major difference is in frequency of administration, which will be more common in dogs. Response generally is based on improvement in clinical signs; therapeutic monitoring is encouraged for theophylline products, particularly for dogs that do not sufficiently respond and in dogs receiving delayed-release products intended for human use. Both terbutaline and albuterol can be used for dogs and might be considered in combination with theophylline for nonresponders for which therapeutic concentrations of theophylline have been maximized or on an alternating basis with theophylline.

Control of inflammation may be facilitated by the use of NAC; additionally, its expectorant and mucolytic effects also should prove beneficial. LRAs should be considered as well. Glucocorticoids should be used only if cytologic examination indicates a large mononuclear or predominantly eosinophilic component to the inflammation. Use should be implemented only after appropriate quantitative culture techniques have failed to yield microbes in the presence inflammatory cytology. However, the role of *Mycoplasma* also must be ruled out. Ideally, inhaled glucocorticoids are preferable to systemic. However, their role is less well established for dogs than for cats.

The routine use of antimicrobials for the treatment of chronic diseases is and potentially contraindicated. Distinction between infection and colonization should be made whenever possible. The risk of causing a resistant infection in the presence of a chronic progressive disease suggests that antimicrobial selection be based on quantitative culture (> 2.7×10^3 colony-forming units/mL) based on a properly collected sample¹⁴⁴ and be designed such that microorganisms (and particularly first-step mutants) are killed (rather than inhibited). High doses for a shorter duration of time are preferred to doses that target the minimum inhibitory concentration of the infecting organism. Drugs that penetrate bronchial secretions well are preferred in the presence of adequate susceptibility. Selection of the antimicrobial should be based on culture and susceptibility data. Cytologic findings should be used to guide the need for antimicrobial therapy; culture data are likely to enhance therapeutic success. Antimicrobial therapy should target Bordetella. The potential of infection with Mycoplasma should not be overlooked. A trial course of antimicrobials is indicated if cytologic findings are supportive of microbial infection; care should be taken to use an antimicrobial effective against Mycoplasma before microbial infection is ruled out. In general, when possible, drugs that accumulate in phagocytic cells should be considered when treating pulmonary conditions. A more comprehensive discussion of antimicrobial therapy for respiratory tract infections can be found in Chapter 8.

The role of antitussives in the treatment of diseases depends on the character of the cough. Inflammation and infection can result in mediator release and cough without an increase in bronchial secretions. Narcotic antitussives are generally indicated if the cough is nonproductive and is paroxysmal and irritating in of itself. Use of glucocorticoids is indicated if airway inflammation is the major contributing factor (as opposed to accumulation of airway secretions). In the case of productive cough, the use of expectorants or mucolytic antitussives may exacerbate cough as is intended if accumulated debris is to be removed. Hydration of respiratory secretions is critical to effective mucociliary transport function. As such, diuretics are contraindicated, and daily water intake must be maintained. Exposure to humidified air (i.e., humidifiers, vaporizers, or a visit to the bathroom during family member showers) is likely to facilitate liquefaction of respiratory secretions.

Pulmonary Diseases

As with other regions of the respiratory tract, causes of pulmonary diseases include viral, microbial, and parasitic infections; allergic (hypersensitivity) or immune-mediated diseases; and, although rare, nonspecific causes of interstitial lung disease. Malignancy of the lungs is discussed elsewhere. Supportive therapy should include bronchodilators and a means to maintain airway hydration (mucokinetics or mucolytics). NAC should be considered for both its antiinflammatory and mucolytic actions. Pentoxifylline also should be considered. Bronchodilators should not be used indiscriminately. Although they can contribute to both bronchial relaxation and controlled inflammation, they may also be associated with ventilation-perfusion mismatching. Diuretics are contraindicated unless vascular overload has led to pulmonary edema.

Oxygen is a consistent supportive therapy for the hypoxic animal; positive pressure ventilation is indicated for patients with poor pulmonary compliance. Physical therapy (coupage) is indicated in conditions associated with accumulation of respiratory secretions. Glucocorticoids are indicated for selected acute and chronic inflammatory conditions. Use in acute conditions generally is intended to minimize the acute inflammatory response; methylprednisolone is often recommended for immediate short-term therapy because of its ability to scavenge oxygen radicals.

Immune-Mediated Diseases

Diseases of the respiratory tract associated with eosinophilic infiltrates of the bronchi were discussed earlier with chronic causes of tracheobronchitis. Eosinophilic infiltrates that target lung parenchyma, referred to as *pulmonary infiltrates with eosinophils*, are associated with a spectrum of conditions ranging from mild diffuse infiltrates to granulomatous responses characterized by nodular masses that are visualized radiographically.

As with bronchial diseases, medical management of immune-mediated diseases should be accompanied by removal of any suspected allergen. Immunosuppressive doses of glucocorticoids are indicated for animals that do not respond to environmental changes. An exception is made for eosinophilic granulomatosis, for which cytotoxic drugs (cyclophosphamide) are indicated. For nongranulomatous disease, glucocorticoid therapy may need to be long term. Adherence to general principles of glucocorticoid use is indicated (i.e., tapering to a minimum effective dose, alternate-day therapy, and slow withdrawal). Granulomatosis, whether eosinophilic or lymphoid, is accompanied by a poor prognosis. Combination therapy should include cyclophosphamide (50 mg/m² orally every 48 hours) and immunosuppressive doses (1 mg/ kg every 12 hours) of prednisone. NAC and bronchodilators should be used as previously discussed.

Vascular Diseases

Pulmonary Hypertension

Because pulmonary hypertension is most commonly a secondary problem, treatment should focus on eradication of the underlying cause; its treatment is addressed in Chapter 14. Causes can be precapillary (alveolar hypoxia caused by lung disease or high altitude) or postcapillary (congenital heart disease with left to right shunting of blood or acquired heart disease). Dirofilariasis is probably the most common cause of pulmonary hypertension in dogs; bronchial asthma might be a cause in cats.

Pulmonary Edema

As in any tissue, excessive fluid accumulation in the lungs occurs as a result of increased hydrostatic pressure, decreased oncotic pressure, lymphatic blockage, or changes in vascular permeability. Increased hydrostatic pressure generally occurs as a result of volume (vascular) overload. In contrast to fluid dynamics in other tissues, hydrostatic pressure in the lungs is low, and lymphatic flow is high. Expansion of lymphatics, as well as fluid movement into the alveoli, can accommodate marked increases in capillary pressure. Thus capillary hydrostatic pressures must markedly increase for excessive fluid to accumulate in the lungs. Hypoalbuminemia is not a likely cause of pulmonary edema. Rather, vascular overload as a result of overcirculation is a common cause of pulmonary edema secondary to increased oncotic pressure. Left-sided heart failure is the most common cause of vascular overload. Regardless of the cause of pulmonary edema, oxygen therapy and actions that minimize stress and anxiety of the patient are indicated. Unless contraindicated, bronchodilators should be administered.

Diuretics are indicated for treatment of pulmonary edema associated with volume overload (increased hydrostatic pressure). Drugs that cause sodium and chloride excretion (i.e., furosemide) may be more effective, particularly in cases of sodium and water retention. Attention might be made to selection based on underlying cause (e.g., aldosterone antagonists in the presence of high aldosterone output). Diuretics are contraindicated for patients that are hypovolemic. Use in normovolemic animals should be cautious and the dose titrated to the minimum needed to control clinical signs associated with pulmonary edema. In life-threatening situations of pulmonary edema associated with volume overload, venous dilators can be used to increase the capacitance of the vascular system, thus "drawing" the increased volume into the veins, away from the heart and pulmonary system. Topically applied nitroglycerin or morphine sulfate (0.1 mg/kg intravenously as needed) can be used for this purpose. Morphine has the added advantage of sedating animals whose anxiety is contributing to hypoxia. Methylxanthines such as theophylline might be helpful in the short term because they also bronchodilate, and in the patient with heart failure they may improve contractility. They will also, however, increase oxygen demand by the heart, and their diuretic effects are short lived (2 to 3 days).

Pulmonary edema as a result of increased vascular permeability probably occurs more frequently than is anticipated. Any disorder that causes inflammation of the lungs will contribute to pulmonary edema of the lungs. The extreme manifestation of permeability-induced pulmonary edema is ARDS, which has been described in humans. The fluid contains protein that, as long as it is present, will continue to provide oncotic draw of fluid into the parenchyma. Pulmonary edema of this type is difficult to treat. Pulmonary wedge pressure is normal; vascular overload is not present. In this situation diuretics will serve to decrease fluid retention only at the cost of extracellular fluid volume and thus are not an effective treatment. Glucocorticoids might be indicated to decrease inflammation and support bronchodilation, although their use is controversial. Among the glucocorticoids, methylprednisolone should be considered because of its ability to scavenge oxygen radicals. Vasodilators might be used; the therapeutic intent of these drugs is not certain, but decreased delivery of blood to the lungs and a further decrease in wedge pressure may decrease movement of blood into the parenchyma. Vascular shunting and hypotension may, however, preclude their use. Newer therapies are likely to target mediators responsible for permeability, such as TNF or nitric oxide, or replace surfactant.

MISCELLANEOUS

Aspiration Pneumonia

Clinical signs resulting from aspiration pneumonia may result from mechanical obstruction in small or large airways, and the inflammatory response to foreign materials (including gastric acid or other chemicals), bacterial infection is. Decreased pulmonary compliance and bronchoconstriction are likely to be a source of some of the clinical signs. Oxygen therapy, bronchodilatory therapy, and positive pressure ventilation are indicated, the latter particularly for patients with poor pulmonary compliance. Bronchoscopy can be used to guide removal of visible foreign material. Glucocorticoids might be used to minimize the inflammatory response during the initial phase of therapy; methylprednisolone and NAC might be considered to minimize oxygen radical damage. Immunosuppression probably negates the advantages of controlled inflammation after 48 hours of therapy. Among the drugs to be considered is pentoxifylline. Its early use (immediately after aspiration) as a loading dose followed by infusion resulted in 17% mortality versus 67% mortality in placebo-controlled rats.¹⁴⁵ In another study involving rats and measurement of inflammatory mediators, pre-treatment was found to be superior to post-aspiration treatment, suggesting preventative therapy might be considered in patients at high risk for post-operative aspiration. ¹⁴⁵ Routine antibiotic coverage should be avoided to minimize the risk of resistance until evidence of a bacterial component in the inflammatory process exists.

Near Drowning

Standard supportive therapy for near drowning includes oxygen, positive pressure ventilation, and therapy for shock. Bronchodilators may be of benefit. Using a rat model of hydrochloride-induced lung injury, pretreatment with pentoxifylline significantly reduced damage, with some benefit shown in animals whose treatment was withheld until post injury. Further, pentoxifylline administered as a continuous infusion significantly reduced lung injury in dogs in which near-drowning was experimentally induced.^{145a} Therapies for treatment of inflammation associated with aspiration should be considered. Use of glucocorticoids is controversial; however, use of methylprednisolone is appealing because of its oxygen-scavenging abilities. NAC therapy may be useful for its oxygen radical-scavenging effects as well as other benefits. Short-term therapy may be of benefit. Use of antimicrobials should probably be reserved for evidence of infection. Supportive therapy should also target the advent of cerebral edema; an additional advantage of using methylprednisolone is minimizing oxygen radical damage in the event of cerebral hypoxia.

Smoke Inhalation

Oxygen therapy is critical for removal of carbon monoxide; the half-life of carboxyhemoglobin decreases from 4 to 0.5 hours in the presence of 100% oxygen. Other supportive therapy includes airway hydration (as needed), bronchodilators, and (if indicated) positive pressure ventilation, and drugs intended to control inflammation.¹⁴⁷ Short-term administration of glucocorticoids (methylprednisolone preferred) may be of benefit to minimize inflammation and oxygen radical damage and to facilitate bronchodilation. However, pentoxifylline should also be considered. Using an ovine model, pentoxifylline administered continuously after induction of smoke inhalation injury was associated with less hypoxia and ventilation perfusion mismatching, pulmonary hypertension and markers of inflammation.¹⁴⁷

Chylothorax

The pathophysiology of chylothorax, or the accumulation of lymphatic fluid in the pleural cavity, is not well understood. Beyond repetitive drainage, both surgical and medical management are limited in success. Rutin is a non-anticoagulant coumarin a flavone benzo-y-pyrone plant fruit extract (bioflavonoid) from the Brazilian fava d'anta (Dimorphandra). It acts to stimulate macrophage removal of proteins and thus removes the oncotic flux of fluid into tissues. It has been used to treat selected causes of peripheral limb edema associated with protein exudation in human patients. It is available in health food stores as a supplement. Response may take several weeks to months. There appear to be no toxicities associated with the drug. Several case reports cite partial resolution of chylous effusion in cats receiving 50 mg/kg orally every 8 hours.¹⁴⁸⁻¹⁵⁰ In humans, octrenotid is an octapeptide omatostatin-mimicking drug used to treat acromegaly. However, it also has been used (based on case reports) successfully with a medium chain triglyceride diet to control chylothorax associated with cardiac surgery.151

Diseases of the Pleura

A number of diseases are associated with pleural effusion, and successful management of the effusion largely depends on resolution of the underlying diseases. Thus pleural effusion resulting from cardiac failure, neoplastic disease, and other causes is treated by treatment of the cause; pleurodesis is used as needed to manage life-threatening effusion. Pleurodesis stimulated by lavage of irritating substances (with the intent of "closing" the pleural space by causing fibrosis) is strongly discouraged. An exception is made for empyema, which can be a primary disease.

Empyema

Empyema refers to the accumulation of infectious inflammatory material within the pleural space. Infection can be an extension of a primary pulmonary lesion, the result of direct penetrating trauma, or by way of a lymphatic or hematogenous route. Accumulation of inflammatory debris provides a continued colloidal draw of fluid into the cavity. Lymphatic obstruction by debris further worsens the ability of pleural fluid mechanics to resolve the accumulation. Thus chest drainage is critical to successful control. Microbiologic examination (including Gram stains initially pending culture and susceptibility data) should be the basis of initial antimicrobial selection. Subsequent daily cytologic studies with Gram staining should provide the basis for response to therapy. The fluid should be recultured if bacterial growth has not changed for 2 to 3 subsequent days or if the morphology of the organism changes. Note that absence of an organism on Gram stain does not necessarily indicate the absence of organisms at the site of infection. Because the incidence of anaerobic infections in empyema is high in dogs and cats, both aerobic and anaerobic cultures should be collected. Care must be taken to collect the anaerobic culture properly. Despite the presence of organisms on Gram stains, cultures often do not yield growth. Thus antimicrobial therapy often must be empirical.

Empirical therapy should include drugs effective against likely infecting organisms, including anerobic organisms (see Chapter 8).

Dietary Therapy Drug Therapy Oral Antidiabetic Agents Acute Metabolic Complications DISEASES OF THE ADRENAL GLANDS Hypoadrenocorticism Hyperadrenocorticism DISORDERS OF THE PITUITARY GLAND Disorders of Growth Hormone

Hormones fall into two broad categories. The majority are peptides and amino acid derivatives, including complex polypeptides (e.g., thyroid-stimulating hormone [TSH]), intermediate-size peptides (e.g., insulin), small peptides (e.g., thyrotropin-releasing hormone [TRH]), dipeptides (e.g., T₄ and T_3), and derivatives of single amino acids (e.g., catecholamines). The remainder consists of steroid derivatives of cholesterol, of which there are two types: those with an intact steroid nucleus (e.g., adrenal and gonadal steroids) and those in which the B ring of the steroid has been cleaved (e.g., vitamin D). In general, the cellular effects of hormones are achieved either through interactions with cell membrane receptors, thus stimulating a cascade of intracellular reactions often involving secondary messenger systems, or through passive diffusion to the cellular nucleus, stimulation of protein synthesis, and subsequent formation of the effector protein(s). Protein hormones typically interact with cell membrane receptors, an exception being thyroid hormones, whereas steroidal hormones passively diffuse through the cell membrane to the nucleus.

Drug therapy for the endocrine system is implemented to either replace a deficient hormone or prevent or reduce the formation or effects of an overabundant hormone. Hormones may also be administered to provocatively test for the presence of an endocrine disease. Understanding the proper uses of the drugs depends on an appreciation of the normal physiology of each endocrine system, including mechanisms of control and behavior of target tissues (Table 21-1).

DISEASES OF THE THYROID GLAND

Synthesis of Thyroid Hormones

The protein thyroglobulin is synthesized by the endoplasmic reticulum and Golgi apparatus of thyroidal follicular cells and is released in vesicles into the colloid within follicular lumens. Iodine is accumulated by an active transport process in thyroidal follicular cells (Figure 21-1). Once in the follicular lumen, iodine is rapidly oxidized and combined with a tyrosine residue within thyroglobulin to form monoiodotyrosine. Monoiodinated tyrosines are then joined to form diiodinated tyrosines; further combinations yield triiodinated tyrosine (i.e., triiodothyronine $[T_3]$ and thyroxine $[T_4]$), which contains four iodine molecules (Figure 21-2). The enzyme thyroid peroxidase mediates oxidation of iodine and formation of monoiodinated and diiodinated tyrosines as well T₃ and T₄. Four or more sites exist within the thyroglobulin molecule for the generation of thyroid hormones; generally, each molecule contains three or four molecules of T₄ and zero to one of T₃ (humans). The preformed hormones are released from the follicular colloid upon stimulation with TSH, with much greater quantities of T₄ being released than T₃. The hormones are transported bound to one of several transport proteins in the bloodstream and are delivered to target cells. At a target cell, both hormones are taken up. Intracellularly, T_4 is deiodinated on its outer ring to produce T_3 , which is actually the active hormone that causes physiologic effects. In contrast, deiodination of the inner ring produces physiologically inactive reverse T₃ (rT₃). Thyroid hormones stimulate many metabolic processes, including activity of many enzymes; metabolism of vitamins and minerals; regulation of other hormones; and stimulation of calorigenesis, protein and enzyme synthesis, and carbohydrate and lipid metabolism.

^{*}A table is included in the chapter that lists drug doses for treating endocrine diseases. Please note that monitoring and tailoring of therapy is typically required in the treatment of endocrine diseases. The table contains starting doses only. Please see the text for details on monitoring and recommended dosage adjustment.

Table 21-1	Endocrine Drugs and Recommended Dose	S*	
Drug	Dose	Route	Interval (hr)
Drugs Used To Dia	ngnose/Treat Hypothyroidism		
rhTSH	50-100 µg/dog (D)	IV	
Sodium levothyrox	ine 20 μg/kg (D)	РО	12
	5-10 μg/kg (D)	IV	12
	50-100 µg/cat (С)	РО	24
Sodium liothyronir		РО	8
	4.4 μg/kg (C)	РО	8-12
Orugs Used To Tre	at Hyperthyroidism		
Atenolol	2 mg/kg or 6.25 mg/cat	РО	24
Methimazole	2.5-7.5 mg/cat	PO, transdermal	12†
Potassium iodide	1-2 drops SSKI/cat	PO (in gelatin capsule)	24
	50-100 mg/cat	РО	24
Propranolol	2.5-7.5 mg/cat	РО	8-12
Orugs Used To Tre	at Hypocalcemia/Hypoparathyroidism		
Calcitriol	Loading: 20-40 ng/kg	РО	24
	Maintenance: 5-15 ng/kg	PO	24
Calcium (oral)	1.0-4.0 g/d (D) [‡]	РО	
. /	0.5-1.0 g/d (C)	РО	
Calcium gluconate	5-15 mg/kg (0.5-1.5 ml/kg)	IV over 20 min	1-12
(10% solution)	5-15 mg/kg (0.5-1.5 ml/kg)	SC diluted in 2-4 parts saline [§]	1-12
Ergocalciferol	Loading: 4000-6000 U/kg	РО	24
	Maintenance: 1000-2000 U/kg	РО	24-168
Magnesium sulfate	1-2 mEq/kg	IV	24
Orugs Used To Tre	at Hypercalcemia		
Alendronate	10 mg/cat (C)	PO with butter and water	Once weekly
Dexamethasone	0.1-0.22 mg/kg	IV, PO, SC	12
Etidronate	5-15 mg/kg (D)	PO	12-24
Furosemide	5 mg/kg (b)	IV	12 21
urosennae	2-4 mg/kg	IV, PO, SC	8-12
Pamidronate disod		IV, diluted in saline, over 2-4 hr	
Prednisone [®]	1-2.2 mg/kg (D or C)	IV, PO, SC	12
reumoone	5-10 mg/cat (for idiopathic hypercalcemia		12
almon calcitonin	4-6 IU/kg	SC	8-12
Sodium bicarbonat	<u> </u>	IV slowly	0 12
		17 510 117	
-	at Hypoglycemia/Insulin Overdose	117	A
Dextrose (50%)	0.5 g/kg diluted 1:4	IV	As needed
•	at Diabetes Mellitus		
Acarbose	25-200 mg/dog (D)	PO with meals	12
<u></u>	12.5-25 mg/cat (C)	PO with meals	12
Glipizide	2.5-5 mg/cat (C)	РО	12
Insulin			
Glargine	0.25 U/kg if BG	SC	12
	<360 mg/dL (C)	SC	12
	0.5 U kg if BG >360 mg/dL (C)	30	12
Lente	0.25 U/kg (D) 0.25 U/kg if BG	SC	12-24
Lente	<360 mg/dL (C)		
	0.5 U kg if BG	SC	12
	>360 mg/dL (C)		
NPH	0.25 U/kg	SC	12-24
Regular [†]	1-3 U/cat	IV, IM, SC	
	See text

Drug	Dose	Route	Interval (hr)
Drugs Used To Treat Diabete		Houto	
Magnesium	0.75-1 mEq/kg/d	IV infusion in 5% dextrose for DKA	
Metformin	25-50 mg/cat (C)	PO	12
Phosphate	0.01-0.03 mMl/kg/hr 0.03-0.12 mMl/kg/hr	IV infusion for DKA IV infusion for DKA	
Vanadium	0.2 mg/kg (C)	РО	24
Drugs Used To Diagnose and	d Treat Hypoadrenocorticism		
ACTH	5 μg/kg (D)	IM, IV	
	$125 \ \mu g/cat (C)$	IV	
Calcium gluconate	0.5-1.0 mg/kg	IV over 20 min.	
Desoxycorticosterone	2.2 mg/kg (D)	IM, SC	25-28 days
pivalate (DOCP)	10-12.5 mg/cat (C)	IM	28 days
Dexamethasone	0.5-2.0 mg/kg	IV	2-6
Fludrocortisone	0.01-0.02 mg/kg (D)	РО	24
	0.1 mg/cat (C)	РО	24
Hydrocortisone	2-4 mg/kg	IV over 2-4 min	8
Methylprednisolone acetate	10 mg/cat (C)	IM	28
Prednisone	0.1-0.22 mg/kg	РО	12-24
Prednisolone sodium succinate	1-2 mg/kg	IV over 2-4 min	2-6
Regular insulin	0.06 to 0.125 U/kg	IV, plus 20 mL of a 10% glucose solution	
Sodium chloride	0.1 mg/kg	РО	24 divided into 2-3 doses
Drugs Used To Diagnose or	Treat Hyperadrenocorticism		
ACTH	5 μg/kg (D)	IM, IVI	
	125 μg/cat (C)	V	
Dexamethasone	Low-dose test		
	0.01-0.15 mg/kg (D)	IM, IV	
	0.1 mg/kg (C)	IM, IV	
	High-dose test		
	0.1-0.15 mg/kg (D)	IM, IV	
	1.0 mg/kg (C)	IM, IV	
Ketoconazole	5-20 mg/kg (D) 5-10 mg/kg (C)	PO PO	12 12
l Domaonyl		PO	
l-Deprenyl	1-2 mg/kg (D)		24
Metyrapone	65 mg/kg (C) 30-70 mg/kg (C)	PO PO	8 12
Mitotane	Pituitary-dependent disease:	10	12
WIROtalle	Loading: 20-25 mg/kg (D)	РО	12
	Maintenance: 40-50 mg/kg/wk (D)	PO	Divided into 2-3 doses
	Adrenal tumor:		
	Loading: 25-37.5 mg/kg (D)		12
	Maintenance: 50-100 mg/kg (D)	РО	Divided into
		РО	2-3 doses
Trilostane	2.2-6.7 mg/kg (D)**	РО	12-24 with food
Drugs Used To Treat Hypera	ldosteronism		
Amlodipine	0.625-1.25 mg/cat	РО	12-24
Potassium gluconate	2-6 mEq	РО	24
Spironolactone	2-4 mg/kg	РО	12

Table 21-1 Endocrine Drugs and Recommended Doses*—cont'd						
Drug	Dose	Route	Interval (hr)			
Drugs Used To Treat Hormo	ne Deficiency					
Growth hormone (porcine)	U/kg (D)	SC	3 times/wk			
Medroxyprogesterone acetate	2.5-5 mg/kg (D)	SC	28 days			
Proligestone	10 mg/kg (D)	SC	3 wk			
Drugs Used To Treat Diabete	es Insipidus					
Chlorothiazide	20-40 mg/kg (D)	РО	12			
DDAVP	1-4 drops (intranasal preparation)	Ocular drop	8-12			
	0.1 mg/dog	PO	8			
Hydrochlorothiazide	2.5-5.0 mg/kg (D)	PO	12			
	12.5 mg/cat (C)	РО	12			

rhTSH, Recombinant human thyroid-stimulating hormone; D, dog; IV, intravenous; PO, by mouth; C, cat; SSKI, saturated solution of potassium iodide; SC, subcutaneous; BG, blood glucose concentration; IM, intramuscular; ACTH, adrenocorticotropic hormone; DDAVP, I-deamino-(8-D-arginine) vasopressin.

*This information is meant only to guide the reader toward choosing an initial drug dose for the various endocrine disorders discussed in this chapter. Endocrine diseases are by nature dynamic disorders, and the dose of any drug will certainly change over time. Concurrent diseases or medications, as well as individual variability toward response to and tolerance of a drug, must be a factor in drug selection and dose calculations. Please see the text for details on monitoring and recommended dosage adjustment.

[†]Alternative protocols possible; see text.

⁺⁺Multiple forms exist; see text.

[§]Use cautiously; possibility of calcinosis cutis has been reported.

[¶]Should not be used to treat hypercalcemia until the cause is known.

IMinumum 4-hour IV saline.

**Initiate as close to 2 mg/kg q24h or 1 mg/kg q12h as possible.

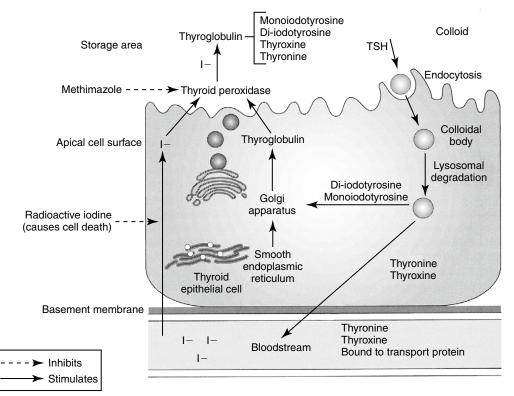

Figure 21-1 Synthesis of thyroid hormones. Iodine is concentrated in the apical cell colloid. At the same time, thyroglobulin is synthesized by the smooth endoplasmic reticulum and Golgi apparatus. At the apical cell surface, thyroglobulin and then tyrosine are iodinated, iodotyrosyl precursors are coupled to form thyronine and thyroxine, and all are stored in colloid. Thyroxine peroxidase mediates iodinization of the thyroglobulin–iodotyrosyl complexes. When signaled by thyroid-stimulating hormone (TSH), thyroglobin (as a colloid droplet) is engulfed by pinocytosis into the apical cell. Lysosomal degradation releases thyroxine and thyronine, which enter the blood stream, and the iodotyrosyl precursors, from which iodine is released and recirculated. The thyroid hormones reach target tissues bound to a circulating protein. Once inside the cell, thyroxine is converted to thyronine, the physiologically active thyroid hormone. Targets of thyroid hormone inhibition include administration of radioactive iodine, which is accumulated in active cells, ultimately leading to their destruction; methimazole, an inhibitor of thyroid peroxidase (controls but does not cure hyperthyroidism); and control of peripheral tissue response to excessive thyroid hormone release. *I*, lodine.

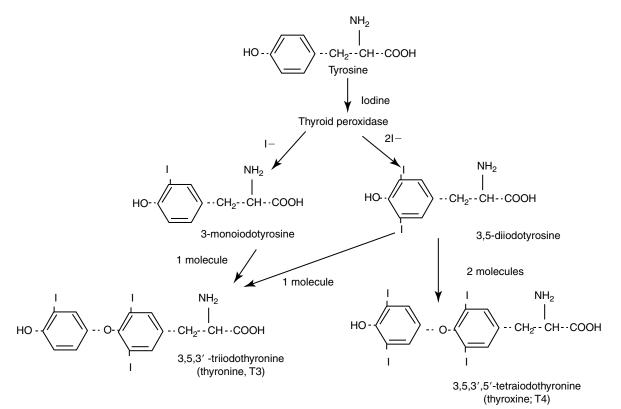

Figure 21-2 Iodination of tyrosine results in the formation of the monoiodinated and diiodinated precursors. Combinations of the two yield triiodothyronine and thyroxine. This reaction and the iodination of tyrosine are mediated by thyroid peroxidase.

They also have marked cardiac inotropic and chronotropic effects, stimulate erythropoiesis, and affect virtually every body tissue.

Hypothyroidism

Pathophysiology

Spontaneous hypothyroidism is a common endocrinopathy in dogs and exceedingly rare in cats. In primary hypothyroidism, which accounts for 99% of cases of spontaneous canine disease, the thyroid gland itself is affected. Cells are lost as a result of either lymphocytic thyroiditis or idiopathic atrophy; neoplastic destruction is rare. Secondary hypothyroidism results from a deficiency of pituitary TSH. Congenital secondary hypothyroidism can result from pituitary malformation or isolated thyrotroph (i.e., TSH-secreting cell) abnormalities. Acquired secondary hypothyroidism is rarely seen due to pituitary neoplasia. Tertiary hypothyroidism results from a lack of hypothalamic TRH and has not been reported in dogs. Congenital absence of the thyroid gland and iodine deficiency are rarer causes of hypothyroidism. Cats suffering from clinically evident hypothyroidism generally develop the disorder in response to iatrogenic removal or destruction of thyroidal tissue as treatment for hyperthyroidism. Congenital primary hypothyroidism occurs uncommonly in kittens, and iodine deficiency is even rarer.

The clinical signs of hypothyroidism refer to multiple body systems. Dermatologic signs include bilateral, nonpruritic, localized, or diffuse alopecia. The hair coat is dry, coarse, and slow to grow. Hyperkeratosis, scaling, or seborrhea may be present. Immunosuppression may lead to secondary pyoderma. Cardiac abnormalities may develop with severe hypothyroidism, including bradycardia and a weak apex beat. Various mild electrocardiographic and echocardiographic changes may be noted, such as increased left ventricular endsystolic diameter, decreased systolic left ventricular posterior wall thickness, and decreased fractional shortening. However, no substantiated reports of congestive heart failure secondary to canine hypothyroidism exist. Possible reproductive disorders include abnormal estrous cycles and lack of libido. Neuromuscular dysfunctions include weakness or stiffness, muscle wasting, neuropathies, and facial muscle weakness. Gastrointestinal signs are uncommon, but constipation is most likely to occur, if anything. Diarrhea may occur in hypothyroid dogs, but a cause-and-effect relationship has not been established. In cats lethargy and obesity are the most common clinical manifestations. Clinical laboratory abnormalities of hypothyroidism in dogs and cats include normocytic, normochromic, nonregenerative anemia and hypercholesterolemia with hypertriglyceridemia or hyperlipidemia.

Myxedema coma is a rare endocrine emergency resulting from decompensation of severe chronic hypothyroidism. *Myxedema* refers to dermal accumulation of glycosaminoglycans, which bind water and cause an increased skin thickness and nonpitting edema, mostly in the face, jowls, and distal extremities.¹ Myxedema coma is characterized by profound weakness, bradycardia, hypotension, hypoventilation, hypothermia without shivering, and altered mentation ranging from dullness and depression to stupor or coma. The actual mortality rate is not known but is thought to be high, primarily because myxedema coma is not widely recognized. The diagnosis should be made clinically, and therapy should be initiated without waiting for results of thyroid hormone concentrations.¹ In addition to the biochemical abnormalities typical of hypothyroidism, additional findings may include hypoxia, hypercarbia, hyponatremia, and hypoglycemia. Serum thyroid hormone concentrations are typically very low or undetectable.

In humans the presence of concurrent disease and altered mentation are essential features for supporting a diagnosis of myxedema coma. In one study of seven hypothyroid dogs for which intravenous levothyroxine therapy was deemed necessary, five dogs had altered mentation. Of those five, all had concurrent disease and four had myxedema. Because of the low incidence of myxedema coma, it is not known if there is a breed predilection, but in a study by Pullen and Hess,² three were Rottweilers, two were mixed breeds, one was a Cocker Spaniel, and one was a Shetland Sheepdog. Rottweilers were overrepresented. Treatment is with intravenous levothyroxine (discussed later).

Baseline and Provocative Testing of Thyroid Status

Diagnosis of hypothyroidism can be challenging. Hormones typically measured include T_4 , free T_4 , and TSH. If serum total T_4 concentration is normal, it is highly unlikely that the dog is hypothyroid.³⁻⁶ Because nonthyroidal factors such as drugs, illness, and age affect T_4 , if the T_4 concentration is below normal, the dog may or may not be hypothyroid,^{3-5,7} and further testing is required. Breed may also affect reference ranges.^{8,9,10}

Thyroid hormones are bound to plasma proteins. Approximately only 0.1%, of circulating hormone is unbound and thus available to cells and physiologically active. Most laboratories measure total (bound and unbound) T_3 and T_4 concentrations. A number of techniques purportedly quantify the fraction of unbound thyroxine (i.e., free T_4 [f T_4]), including equilibrium dialysis, the gold standard for comparison with other methods, and several immunoassays that indirectly detect fT_4 . Currently, methods that depend on equilibrium dialysis are the most accurate measurements of fT_4 ; measurement of fT_4 by analog radioimmunoassay techniques offer no diagnostic advantage over measurement of total T_4 . Regardless of the test, normal thyroid hormone concentrations will vary with the laboratory and the kit used; any test must be validated for the target species (i.e., dog or cat).

Because the pituitary–thyroid axis functions to maintain free, not total, T_4 within a certain range, fT_4 is less affected by nonthyroidal factors; therefore measurement of serum fT_4 concentration more accurately reflects thyroidal axis status. Accordingly, fT_4 is a more sensitive and more specific test for diagnosis of hypothyroidism, but it is also not as good a standalone test as once believed (discussed later). Measurement of serum fT_4 concentration can be the initial test for diagnosis of hypothyroidism or can be used in dogs found to have low total T_4 concentrations. Serum TSH concentration can also be measured to help establish a diagnosis of canine hypothyroidism. In primary hypothyroidism TSH concentration should be elevated owing to lack of negative feedback of serum T_4 on the pituitary (i.e., in normal dogs T_4 feeds back and suppresses TSH secretion). Although 99% of canine hypothyroidism cases are believed to be due to primary thyroidal failure, only approximately 63% to 82% of hypothyroid dogs have elevated serum TSH concentrations.¹¹⁻¹⁴ The reason for the discrepancy is unknown but is likely due to inadequacy of currently available assays. Of the hormones measured to diagnose hypothyroidism, however, TSH measurement is the most specific—that is, it has the smallest chance of a falsepositive result.

The effect of nonthyroidal illness on testing can be quite significant. Dogs that are ill because of a disease but that do not have hypothyroidism can have low T_4 and fT_4 concentrations; if the disease is severe (e.g., a dog is in intensive care), a 44% chance exists that the fT_4 concentration will be below normal even though the dog is not hypothyroid. Serum TSH concentration, however, is less affected by nonthyroidal factors. Therefore in sick dogs the first choice for diagnosis of hypothyroidism would be a combination of TSH, fT_4 , and T_4 ; second choice a combination of TSH and fT_4 ; and third choice a combination of TSH and T_4 . If the results are ambiguous (i.e., some parameters suggest hypothyroidism, and others do not), the ideal would be to resolve the nonthyroidal illness, if possible, and retest the dog at that time or possibly to perform a TSH stimulation test, if available.

Bovine TSH previously was used as the provocative agent for TSH stimulation testing but is no longer available. Thyrogen, recombinant human TSH (rhTSH), can be used instead. The optimal protocol for distinguishing normal and hypothyroid dogs, however, remains to be determined, although results of studies evaluating rhTSH in dogs are promising.¹⁵⁻¹⁷ Doses of 50 to 100 µg/dog given intravenously with samples taken before and at 4 or 6 hours after injection are likely appropriate. Euthyroid animals should respond to TSH stimulation with increased T₄ concentration, whereas hypothyroid animals should not. Reconstituted rhTSH can be stored at 4°C for 4 weeks and at -20°C for 8 weeks without loss of biological activity.¹⁸

Measurement of serum T_3 concentration is not helpful for diagnosing hypothyroidism. Most T_3 is derived from intracellular metabolism or conversion by peripheral tissues of T_4 to T_3 and reverse T_3 (r T_3). Thus most body T_3 is located within cells, and serum T_3 concentration does not reflect total body levels. A previous argument for measuring serum T_3 concentration was the belief that some dogs were "poor converters" and could produce T_4 but not T_3 . The theory was apparently substantiated by finding normal serum T_4 but nondetectable T_3 concentrations in a small percentage of dogs. Such discrepant results are now known, however, to be an artifact caused by the presence of T_3 autoantibodies. Insofar as poor conversion has never been proved and currently is not believed to exist, measurement of serum T_3 concentration is not recommended.

Autoantibodies made against T₄ or T₃ can be measured and can be a marker of immune-mediated destruction of the thyroid gland. Autoantibodies typically cause spurious elevations in serum T_3 or T_4 concentrations, so their presence should be suspected if either hormone is measured in a patient suspected to be hypothyroid and the concentration of either or both hormones is reported to be greater than the reference range. However, the clinical and prognostic significance of autoantibodies is unknown. The presence of autoantibodies does not mean a patient is hypothyroid. If autoantibodies are suspected, serum fT₄ concentration should be measured by equilibrium dialysis for the best assessment of function.¹⁹ If the serum fT_4 concentration is within the reference range, thyroidal function is normal at that time but the patient should be reevaluated periodically (e.g., every 3 months) for development of hypothyroidism. If serum fT₄ concentration is low, the dog is likely hypothyroid. One study followed 234 dogs with normal T₄ and TSH levels and elevated antithyroglobulin antibodies (TGAA) for 1 year. Only 19% developed clinical signs of hypothyroidism or consistent laboratory values (or both). Another 57% remained TGAA positive without signs or laboratory evidence of hypothyroidism, 8% went from positive to borderline results, and 15% became TGAA negative.²⁰

Calculation of the percentage of uptake of radioactive pertechnetate ($^{99m}TcO_4$) has proved to be a useful tool aiding in the diagnosis of thyroidal illness in humans and cats and may also be valuable for dogs with primary hypothyroidism. Normal lobes of canine thyroid glands are uniformly intense, symmetric ovals, slightly smaller than the parotid salivary glands, and have smooth and regular margins. The parotid glands also concentrate ^{99m}TcO₄⁻, and the normal uptake ratio between these the thyroid and parotid glands is 1:1. In 14 dogs with histologically confirmed primary hypothyroidism, the percentage of uptake of 99mTcO4- distinguished hypothyroid dogs from dogs with nonthyroidal illness.²¹ The dogs with nonthyroidal illness had ^{99m}TcO₄⁻ uptake ranging from 0.39% to 1.86%, similar to what has been described in healthy Beagles. The hypothyroid dogs had ^{99m}TcO₄⁻ uptake ranging from 0.03 to 0.26%. In fact, of the tests examined in the study (T_4 , fT₄, TSH, and TSH and TRH stimulation tests), scintigraphy was the only one that did not have overlap between the two groups of dogs. Limitations of the test include requirement for specialized equipment and the fact that reference ranges have not been defined in a large number of dogs from a variety of breeds. Additionally, increased ^{99m}TcO₄⁻ uptake can occur with a diet high in iodine and has been reported in a hypothyroid dog with thyroiditis,²² so false-negative results are possible. The final complicating factor is that in humans with thyroiditis, the ^{99m}TcO₄- uptake pattern depends on disease stage. The role scintigraphy holds in aiding in the diagnosis of canine hypothyroidism remains to be defined.

Another area that has received recent attention as an ancillary test in the diagnosis of canine hypothyroidism is ultrasonography. In healthy dogs and dogs with nonthyroidal illness, the thyroid gland lobes are fusiform in the longitudinal plane and triangular in the transverse plane, have a smooth thyroid capsule, and homogenous echotexture, usually hyperechoic

or isoechoic to the sternothyroid muscle.23,24 The ultrasonographic description of the thyroid gland lobes of hypothyroid dogs is more variable. However, they tend to be either round or ovoid on the transverse view. Echotexture may depend on whether the animal has thyroglobin autoantibodies. Thyroid lobes from antibody-positive hypothyroid dogs were homogenously hypoechoic to the sternothyroid muscle, whereas the lobes of those that were antibody negative were heterogeneous in echotexture.²³ However, another study did not find a difference based on thyroglobin autoantibody status; thyroid lobes were reported to be hypoechoic to the sternothyroid muscle.²⁴ Additionally the volume of the glands is smaller in hypothyroid dogs. A thyroid volume of less than 0.05 mL/kg was reported to be 81% sensitive, 96% specific, and 91% accurate for the diagnosis of primary hypothyroidism.²³ Care should be taken with the use of this modality for diagnosing canine hypothyroidism because ultrasonography is highly user dependent and substantial interobserver variability exists when taking measurements.

Therapy of Hypothyroidism

Disposition of thyroid hormones. Thyroidal hormone disposition varies between preparations and species. Although thyroid hormones are bioavailable after oral administration, T₄ absorption can be decreased by a number of factors such as the type of preparation and intraluminal contents of the ileum or colon, where most absorption occurs. In humans bioavailability ranges from 40% to 80%. Because of differences among formulations, some authors recommend initiating therapy with a brand-name product.²⁵ However, the pharmacokinetics of T₄ is idiosyncratic; some dogs achieve higher postpill concentrations when treated with a generic brand. No evidence exists that a single brand is consistently better than another. Therapy can probably be started with any brand, but if a dog does not respond, another brand should be administered to see whether better results and higher postpill levels can be achieved; if the first brand tried is generic, the second should not be. In contrast to T₄, T₃ is well absorbed (95% in humans) from the gastrointestinal tract.

In dogs the half-life of T_3 and T_4 is 5 to 6 hours and 12 to 15 hours, respectively. However, the half-life of T_4 may be dose dependent.²⁶ The short half-life makes avoidance of fluctuations in serum concentrations during a 12- to 24-hour dosing interval difficult. However, the status of intracellular T_3 concentration is not well known; the impact of fluctuating T_4 may be minimized by physiologic conversion. Steady-state concentrations will occur at five drug half-lives (i.e., 75 hours for T_4 and 30 hours for T_3 in dogs). On the other hand, clinical response varies depending on the complication of hypothyroidism present. The first evaluation after starting supplementation should occur after about 4 weeks of therapy in order to judge blood levels as well as therapeutic response. Certain abnormalities (e.g., dermatological) can take up to 3 months to resolve once therapeutic blood levels have been achieved.

Preparations. Thyroid hormones can be supplemented as crude extracts of animal origin or as synthetic preparations. The biological activities of animal-origin products, such as

desiccated thyroid and thyroglobulin, vary, however, and therapeutic failure with these products is not uncommon. Thus synthetic products are recommended.

Several synthetic thyroid hormone products are available as T_4 or T_3 individually or in combination. Sodium levothyroxine (T_4) is the drug of choice for most patients. If T_4 therapy has failed to achieve a response in a dog with confirmed hypothyroidism, T₃ can be administered, but failure of T₄ therapy is very rare. If no apparent response to T_4 is seen or inadequate blood levels are achieved with appropriate dosing, another brand of T_4 should be used first before prescribing T_3 . The diagnosis of hypothyroidism should also be reevaluated if resolution of clinical signs does not occur with documentation of adequate blood concentrations and a sufficient duration of therapy. Combination products generally contain T₄ and T₃ at a ratio of 4:1, the proportion of thyroid hormones secreted in normal humans. Use of combination products is not recommended. The administration frequency of T_4 and T_3 should differ, orally absorbed T₄ is converted as needed to T₃ by target cells so therapy with T₄ alone usually achieves adequate T₃ concentrations, and use of combinations may result in serum T₃ concentrations that produce thyrotoxicosis.¹

Plasma half-life of T_4 varies among dogs, and a marked variability in the dose necessary to achieve therapeutic concentrations exists. Beginning doses of T_4 should be 20 µg/kg every 12 hours for dogs and 50 to 100 µg once daily in cats. After resolution of clinical signs, approximately 25% of dogs maintain adequate blood levels and a good therapeutic response with once-daily dosing. Initial doses as low as 5 µg/kg may be indicated in dogs with concurrent illness, especially cardiac, to allow the body to slowly adapt to the increase in oxygen demand that may accompany thyroid hormone replacement. The dosage can then be increased over the following 3 to 4 weeks.

Pharmacokinetics of oral liquid levothyroxine suggest that once-daily dosing should be adequate,²⁷ and administration of liquid levothyroxine (Leventa Intervet/Schering-Plough) once daily in 35 hypothyroid dogs was recently evaluated.²⁸ Dogs were started at a dose of 20 µg/kg once daily and monitored every 4 weeks (adjustment phase). At the reevaluation visit, serum T_4 and TSH concentrations were obtained 4 to 6 hours after the pill was administered, and dose adjustments were made if the T_4 value did not fall within the target therapeutic range. Once clinical signs resolved and T_4 concentrations were within the target range, the adjustment phase ended and the maintenance phase began. To assess long-term efficacy, dogs were then reevaluated at 9 and 22 weeks, with the same parameters measured at each visit and dosages adjusted as needed.

The starting dose of 20 µg/kg was also the maintenance dose in 79% of the dogs. Maintenance doses for the remaining dogs were 10 µg/kg (3%), 15 µg/kg (3%), and 30 µg/kg (15%). In the maintenance phase, dose adjustments were required for 16% of dogs. The median dose was 24 µg/kg once daily. Clinical signs improved within 4 weeks in 90% of dogs and within 4 weeks in 100%. Body condition scores initially assessed as overweight or obese had normalized in 52% of dogs by week 22, and dermatologic abnormalities had resolved in 68%. Peak serum T₄ concentrations were within the target therapeutic range in 65% of dogs at the first follow-up visit after beginning the maintenance phase of the study and in 79% of dogs at the 22-week examination. The remaining dogs had clinical control of the disease, but transiently low T_4 concentrations. Reported adverse events included sudden death in one dog after 47 days of treatment, vomiting after administration of the solution in two dogs, and reddish discoloration of hair coat in one dog.

Intravenous levothyroxine is used in the treatment of dogs with myxedema coma. In 7 dogs given intravenous levothyroxine, the median dose was 7 μ g/kg. Three of the seven dogs were given intravenous levothyroxine once. To resolve the neurologic issues, the remaining dogs received a total of 5, 6, 10, or 13 doses each. The injections were given every 12 hours in three of four dogs and every 8 hours in the remaining dog. The dogs were started on oral levothyroxine within 24 hours of the last intravenous dose.²

Sodium liothyronine (T_3) should be reserved for patients not responding to T_4 therapy. Dosing should start at 4 to 6 µg/kg every 8 hours for dogs and 4.4 µg/kg every 8 to 12 hours for cats. Clinical improvement may take 4 to 6 weeks; twice-daily administration can begin at that time.

Response to Therapy

Therapeutic Drug Monitoring. Variability in blood concentrations after oral administration of T_4 can be very large because of differences in disposition, including bioavailability, so monitoring is an important tool with which to guide therapy. Blood concentrations should not be monitored until steadystate concentrations of the hormone have been reached and sufficient time for a physiologic response to the new concentration has passed. Thus concentrations should be monitored 1 month after therapy has begun.

For monitoring a sample should be drawn 4 to 6 hours after the pill is administered. At that time, serum T₄ concentration should be in or slightly above the upper half of the reference range. TSH concentration can also be measured in the same sample and can be helpful. Increased values are associated with inadequate therapy, but TSH concentrations within the reference range are not interpretable; dogs with both adequate and inadequate control can have TSH concentrations within the reference range.²⁹ Measurement of fT₄ probably is unnecessary and does not add any more information, except in patients who have T₄ autoantibodies; in such patients T₄ concentration as measured by radioimmunoassay is falsely elevated. Whether measurement of prepill hormone concentrations is helpful remains controversial. If T₃ is the sole supplement, peak concentrations can be collected 3 hours after administration of the pill if an 8-hour dosing interval is being used. With subsequent retesting, samples should be collected at the same time as previously, so comparisons between tests across time in the same patient are more valid.

Interpretation of thyroid hormone concentrations must be made in the context of clinical signs. Animals should be supplemented for 1 to 3 months before clinical efficacy can be judged. Although no clinical signs of thyrotoxicosis may be present, whether increased serum T_4 concentrations without clinical signs of hyperthyroidism are detrimental has never been studied. In humans elevated postpill T_4 concentrations are strictly avoided. Low serum T_4 concentrations should also be interpreted with response to therapy. The effects of concurrent drug therapy or other diseases that might influence the metabolism of thyroid hormones must be considered. Drug dose can be changed to achieve the therapeutic range. However, the pharmacokinetics of T_4 are not linear—that is, to achieve a 15% change in serum T_4 level, a 25% change in dose, not a 15% change, may be required.³⁰

Effects of other drugs on thyroid hormones. Numerous drugs can affect thyroid hormone concentrations. The reader is referred elsewhere for complete information.^{31,32}

Glucocorticoids, phenobarbital, sulfa antibiotics, tricyclic antidepressants, and nonsteroidal antiinflammatory agents, among others, have been shown to decrease T_4 , T_3 , fT_4 , and TSH.

Hyperthyroidism

Pathophysiology

Neoplasia of the thyroid gland, whether benign or malignant, is the most common cause of hyperthyroidism. In cats a benign tumor is the etiology in approximately 99% of cases, whereas in dogs a thyroid tumor leading to hyperthyroidism is almost always malignant. (Note, however, that most canine thyroid tumors do not cause hyperthyroidism; at least 90% of canine thyroid tumors are nonfunctional, and they can cause hypothyroidism as a result of the destruction of normal thyroidal tissue.) Occasionally, administration or accidental ingestion of thyroid hormones can cause thyrotoxicosis.

The clinical signs of hyperthyroidism reflect abnormalities in several body systems as a result of excessive concentrations of T_4 and T_3 . Increased energy expenditure results in weight loss and polyphagia. As skin protein synthesis and blood flow increase, the hair coat changes. Increased renal blood flow, glomerular filtration rate (GFR), and renal tubular activity account for polydipsia and polyuria; loss of medullary interstitial tonicity can also contribute. Vomiting may reflect a direct effect on the chemoreceptor trigger zone, overeating, or gastrointestinal hypermotility. Malabsorption and hypermotility can cause diarrhea. Thyroid hormones may directly stimulate the central nervous system, causing behavioral changes that typify hyperthyroid cats (i.e., nervousness, hyperkinesis, agitation). Occasionally, hypokalemia develops, which may explain the weakness that affects some cats.

Heat and stress intolerance, panting, and respiratory distress may be related to decreased pulmonary vital capacity, decreased pulmonary compliance, slightly elevated body temperature, and cardiac stimulation (associated with catecholamine release). Cardiac disturbances include tachycardia, premature cardiac contractions, and gallop rhythms. Secondary cardiac hypertrophy can occur, which is distinct at a microscopic level from that seen with primary idiopathic hypertrophic cardiomyopathy. Thus cats with hypertrophy secondary to hyperthyroidism have thyrotoxic cardiac disease, not hypertrophic cardiomyopathy. Long-standing untreated thyrotoxic cardiac disease can progress to congestive heart failure. Thyroid hormones directly affect the cardiac muscle, as well as increase the needs of peripheral tissues, causing a high cardiac output state and an increase in myocardial oxygen demand. Peripheral resistance, on the other hand, is generally decreased. Catecholamines may contribute to the positive inotropic and chronotropic effects of thyroid hormones on the heart. Thyrotoxicosis probably increases the myocardial responsiveness to catecholamines by increasing the number of catecholamine receptors.

Baseline and Provocative Testing

Baseline serum T_4 concentration can be measured to diagnose hyperthyroidism and is sufficient in the majority of cases as it is elevated in approximately 91% of hyperthyroid cats.³³ (It is important to remember, however, that rare normal cats may have an elevated T_4 .) The other 9% of cats represent those with early or mild hyperthyroidism where serum T_4 concentration can fluctuate in and out of the normal range³⁴ or cats with concomitant nonthyroidal illness. Nonthyroidal illness can suppress serum T_4 concentration,³⁵ so the serum T_4 concentration in hyperthyroid cats can be within the normal range.^{36,37} As a result, resting serum T_4 concentrations obtained from cats must be critically evaluated and the possibility of further testing considered.

If the serum T₄ concentration of a hyperthyroid cat is within the reference range, it will typically be in the upper half of the range. If a serum T₄ concentration is in the lower half of the reference range, it is highly unlikely (but not impossible) that the cat is hyperthyroid, and another diagnosis should be considered. In sick, older cats with normal thyroidal function, serum T₄ concentration is usually low,³⁵ so the finding of a T_4 even in the upper half of the reference range in such a cat may indicate hyperthyroidism. If the T₄ concentration is in the upper half of the reference range but there hyperthyroidism is still suspected, further diagnostics should be pursued. Options for additional tests include the following: (1) measurement of serum fT_4 concentration by equilibrium dialysis; (2) repeat measurement of total T₄ concentration (Because serum T₄ concentration may fluctuate in and out of the normal range, on a second test the sample may be drawn by chance while the T₄ concentration is above normal and diagnostic. Unfortunately, there is no way to predict when this will occur.); (3) performance of a T_3 suppression test or TRH stimulation test. These latter two tests are valid, good tests, although they are more labor intensive and often not necessary.

As in dogs, serum fT_4 concentration in cats is less affected by nonthyroidal factors than is total T_4 concentration and is a more accurate reflection of thyroid function. For example, fT_4 concentration is elevated in 94% of mildly hyperthyroid cats, whereas total T_4 concentration is elevated in only 61%.³³ However, fT_4 concentration may also be elevated in 6% to 12% of sick, euthyroid cats.^{33,38} To help discriminate between hyperthyroid and sick euthyroid cats, a total T_4 should be measured along with fT_4 concentration. Sick euthyroid cats with an elevated fT_4 typically have T_4 concentrations that are within the lower half of or below the reference range. Thus if the T_4 concentration is in the upper half of the normal range or above and the fT_4 concentration is elevated, this is consistent with a diagnosis of hyperthyroidism. If the T_4 concentration is in the lower half of the normal range or below and the fT_4 concentration is elevated, the cat is very unlikely to be hyperthyroid, and another diagnosis should be sought.

Measurement of serum T_3 is not very helpful for diagnosis and is not recommended. Overall, only 67% of hyperthyroid cats have an elevated T_3 concentration.³³ In cats with mild hyperthyroidism, only 21% actually have an elevated serum T_3 concentration.³³

Performance of pertechnetate scans to diagnose hyperthyroidism is quite useful overall. Uptake of radioactive pertechnetate can confirm hyperthyroidism as well as delineate functional thyroid tissue, establish the extent of thyroid involvement, and possibly detect metastasis (some metastases, but not all, will concentrate radioiodine). For cats in which biochemical evidence of hyperthyroidism is clear, scans will clearly identify functioning tissue. However, false-positive results may occur;³⁹ in other words, nonhyperthyroid cats can have a scan suggesting the presence of hyperthyroidism, and timing of a scan after methimazole therapy may affect results.⁴⁰

Relationship of Treatment for Feline Hyperthyroidism to Renal Disease

Treatment of hyperthyroidism can lead to decreases in GFR and unmask chronic renal disease,⁴¹⁻⁴⁵ and no therapy appears to be safer than another. However, how best to assess cats before definitive therapy (i.e., radioactive iodine [¹³¹I therapy] or surgery) is unknown. Although one study determined that a GFR value of 2.25 mL/kg/min might represent a cutoff for deciding whether renal failure is a possibility,⁴³ measurement of GFR is not easily obtained and GFR measurements vary depending on the technique used,46 with each laboratory needing to determine its own guidelines. Furthermore, in two studies, hyperthyroid cats with GFR greater than 2.25 mg/kg/min were azotemic 30 days after treatment;^{42,44} whether this simply reflects a difference in methodology is unclear. Unfortunately, no readily available clinical indicators, including urine specific gravity, exist.^{47,48} Cats with pretreatment urine specific gravity greater than 1.035 may develop azotemia with treatment.⁴⁸

Therefore the best option is probably to treat cats transiently with methimazole until serum T_4 concentration is adequately controlled and then maintain euthyroidism for 30 days. When the serum T_4 concentration is maintained within the normal range, renal function and the effect of definitive therapy can be assessed. Many cats exhibit an increase in serum blood urea nitrogen (BUN) or creatinine concentration (or both) with therapy, but the clinical result must be assessed as the most important parameter. Most cats improve clinically despite the increased renal parameters when their hyperthyroidism is treated. If they improve and the renal failure is not clinically apparent, the hyperthyroidism can be definitively treated.

Whether all cats that are to undergo ¹³¹I treatment or thyroidectomy need to have their kidney function evaluated with a methimazole trial remains to be determined. We prefer performing a trial on all cats before definitive therapy is undertaken. Certainly, if there is any question about the adequacy of renal function, trial therapy with methimazole is warranted. If renal failure becomes clinically apparent during the trial, methimazole administration should be stopped and therapy for renal failure instituted. Once the cat is stable again, the hyperthyroidism should be controlled as best as possible for life with methimazole and therapy for renal failure continued. Alternatively, if a trial is not performed and renal failure becomes overt because of definitive correction of hyperthyroidism, exogenous thyroid hormone can be supplemented in an attempt to support the kidneys, but the efficacy of such therapy is unknown and may be questionable.⁴⁹ A balance must then be struck between creating iatrogenic hyperthyroidism and maintaining renal function.

Drugs Used To Control Hyperthyroidism

Hyperthyroidism may be medically controlled with methimazole and ipodate. Both can be used as either the sole drug to manage hyperthyroidism or in preparation for surgery or radioiodine administration. Propylthiouracil administration is not recommended because of associated possible severe adverse effects. In general, methimazole blocks synthesis of thyroid hormones and, specifically, thyroid peroxidase activity necessary for coupling of tyrosine residues by acting as a preferential substrate for the enzyme. As a result, T_3 and T_4 are not secreted. Carbimazole is a methimazole prodrug currently used in Europe but not available in the United States. It appears to be equal in efficacy but safer than methimazole. Controlled-release carbimazole tablets are now available in Europe. Based on pharmacokinetics in normal cats the controlled-release formulation may be appropriate for once-daily dosing;⁵⁰ however, dosing has not been evaluated in hyperthyroid cats. Ipodate is a cholecystographic agent that acts primarily by inhibiting conversion of T₃ to T₄ but also has some direct inhibitory effects on thyroid hormone secretion.

Overall, methimazole is highly effective at reversing thyrotoxicosis and maintaining euthyroidism. In 262 spontaneously hyperthyroid cats, methimazole treatment lowered the serum T₄ in more than 99%.⁵¹ A very small percentage of cats may be truly methimazole resistant. In the 262 cats, clinical side effects occurred, unrelated to the dose of methimazole used, in 18%, including anorexia (11%), vomiting (11%), lethargy (9%), excoriation of the face and neck (2%), bleeding (2%), and icterus (2%). Anorexia, vomiting, and lethargy typically happened during the first month of therapy and resolved despite continued drug administration. However, in eight cats, gastrointestinal side effects persisted and required cessation of therapy. Treatment with methimazole was also permanently stopped in cats that developed liver failure (e.g., vomiting, anorexia, and icterus), excoriated faces or necks, or a bleeding tendency.⁵¹ Myasthenia gravis has been reported after treatment with methimazole in four cats. In two cats, prednisone was used to control the myasthenia.⁵² Lymphadenomegaly, which resolved with discontinuation of methimazole administration, was reported in a single cat.53

On hematologic screening, eosinophilia, lymphocytosis, leukopenia, thrombocytopenia, and agranulocytosis may be noted. The milder adverse effects—eosinophilia, lymphocytosis, and leukopenia—are usually noted within 1 to 2 months of initiation of treatment and are transient despite continued therapy. The more serious complications (e.g., thrombocytopenia, agranulocytosis) occur in a minority of cats ($\leq 3\%$) within the first 3 months of therapy and necessitate permanent discontinuation of methimazole administration.⁵¹ The mechanism of hematologic disorders induced by methimazole is not understood. Interestingly, bleeding occurred in one cat without a decrease in platelet number, so thrombocytopenia is not the only mechanism that can cause a bleeding tendency. In human patients receiving propylthiouracil, vitamin K therapy reduced bleeding caused by hypoprothrombinemia; however, the benefits of vitamin K therapy have not been studied in cats receiving thyroid peroxidase inhibitors.⁵⁴ Immunologic effects, including induction of positive antinuclear antibodies (ANAs), can occur. The risk of developing a positive ANA result appears to increase with length of therapy and dose. However, clinical signs of a lupuslike syndrome (e.g., dermatitis, polyarthritis, glomerulonephritis, thrombocytopenia, fever) or hemolysis do not occur.⁵¹

A starting dose of 10 to 15 mg/day divided into two or three daily doses depending on the severity of the hyperthyroidism has been recommended. The goal for cats on methimazole is to have a serum T₄ concentration in the lower half of the reference range. Postpill timing does not matter. Although some cats require methimazole only once daily for adequate control, methimazole generally is more effective twice daily.55 For the first 3 months, the period during which most adverse effects develop, cats receiving methimazole should be evaluated every 2 to 3 weeks with a complete physical examination, determination of serum T_4 concentration, complete blood count (CBC), and measurement of liver enzymes and bilirubin. Renal parameters should also be monitored to assess kidney function. Although cats with a subnormal serum T_4 concentration typically are not clinically hypothyroid, development of a positive ANA titer may be related to dose. Thus the minimal dose necessary to maintain serum T₄ concentration in the lower half of the reference range, and not below, should be used. If serum T₄ concentration remains high and poor compliance or difficulty in giving the medication has been ruled out as the cause of persistent hyperthyroidism, the methimazole dose should be increased in 2.5- to 5-mg increments to a maximum of 20 mg/day. If hepatopathy, facial excoriation, a bleeding tendency, or serious hematologic consequences occur, the medication should be halted permanently and alternative therapy used. After the first 3 months, serum T₄ concentration should be determined every 3 to 6 months to evaluate adequacy of therapy. Because blood dyscrasias are unlikely but not impossible after 3 months of therapy, a CBC need be performed only if clinical signs suggest agranulocytosis, hemolysis, or thrombocytopenia.⁵¹

To prevent development of adverse effects, other authors have recommended an initial dose of 2.5 mg twice daily for 2 weeks.⁵⁶ If after this period an owner observes no untoward side effects, the physical examination reveals no new problems, and a CBC (including platelets) is within normal limits, the dosage should be increased to 2.5 mg thrice daily for an additional 2 weeks. A similar recheck should then be completed, including measurement of a serum T_4 concentration. If serum T_4 concentration is within or near the normal reference range, the dose may be maintained for 2 to 6 weeks to determine the need for any further dosage adjustments. The dosage should be increased by 2.5 mg/day increments to a maximum of 20 mg/ day (assuming correct methimazole administration) or until the hyperthyroidism is controlled.⁵⁶ Monitoring for adverse effects should be done as previously described.

Because of the relationship between hyperthyroidism and renal disease (as previously discussed), a third protocol has been advocated if abnormal renal parameters are present. Methimazole should be administered at a dose of 2.5 mg twice daily for 2 weeks, then 2.5 mg thrice daily for 2 weeks, then 5 mg twice daily for 2 weeks, and finally 5 mg thrice daily as needed. The serum T₄ concentration, BUN, creatinine, phosphate, and a CBC should be evaluated at the end of each 2-week period. The dose escalation should stop once serum T₄ concentration has normalized. If the serum T_4 can be decreased to within the reference range and the renal parameters remain stable or improve, antithyroid medications may be continued or a permanent therapy may be considered. If clinical signs of renal disease worsen with therapy, treatment of the hyperthyroidism should be reevaluated. Some cats may be healthier without treatment.⁵⁶ Alternatively, the dose of methimazole can be titrated to achieve the best control possible of the hyperthyroidism while maintaining adequate renal function.

Methimazole can be given transdermally. Although methimazole in pleuronic lecithin organogel (PLO) is absorbed poorly in healthy cats after a single dose,⁵⁷ it is likely that chronic dosing leads to improved absorption and resolution of hyperthyroidism as transdermal methimazole can be used to treat hyperthyroidism.⁵⁸⁻⁶⁰ The transdermal route may take longer, however, to bring about remission. In a randomized, prospective study of hyperthyroid cats, owners dosed their cats with methimazole orally (tablets) or transdermally (in PLO; 50 mg/mL) at 2.5 mg every 12 hours.⁵⁹ Of cats treated transdermally 56% were euthyroid at 2 weeks, which was significantly fewer cats than the control rate in response to oral administration (88%); by 4 weeks the difference was no longer statistically significant (67% control with transdermal methimazole versus 82% for oral), but the lack of difference may have been due to a small number of cats remaining in the study at 4 weeks. Whether transdermal administration for a longer period of time would have controlled the hyperthyroidism in more cats was not evaluated. An advantage of transdermal methimazole is a significantly decreased rate of gastrointestinal adverse effects. However, the incidence of hepatopathy, facial excoriation, and blood dyscrasias is similar for both the transdermal and oral routes. Some cats develop erythema at the transdermal dosing site, but it is typically not severe enough to require drug discontinuation.⁵⁹

Methimazole administration does not affect tumor size. Clinical signs will recur with discontinuation of the drug. Methimazole can be used before surgery to decrease serum T_4 concentrations to within the reference range to stabilize the patient. Discontinuation of methimazole 2 weeks before radionuclide scanning or therapy has been recommended. Because radionuclide uptake is increased in normal tissue for 9 days after discontinuation of methimazole therapy,⁴⁰ treatment within that window may increase the risk of iatrogenic hypothyroidism with radioiodine administration.

In humans, use of cholecystographic agents for treatment of hyperthyroidism has been studied, and the radiopaque organic iodine agent ipodate has shown some success. Experience with ipodate in veterinary medicine has been limited. A single study of 12 spontaneously hyperthyroid cats was performed using calcium ipodate granules reformulated into 50-mg capsules.⁶¹ Initial dosage was 50 mg/cat, administered orally twice daily. The dosage was increased to 150 mg (100 mg in the morning, 50 mg at night) and then 200 mg (100 mg orally twice daily) at 2-week intervals if serum T₃ did not normalize or if other abnormalities attributable to hyperthyroidism failed to resolve satisfactorily. (Because the main mechanism of action of ipodate is to inhibit conversion of T₄ to T_3 , monitoring of serum T_3 concentrations is necessary to judge efficacy.) Only eight cats responded during the 14-week study period; seven of these were treated at a dosage of 100 mg/day, and one required 150 mg/day. Interestingly, serum T₃ concentration decreased in the responders and declined into the normal range in two nonresponders as well. No adverse clinical signs or hematologic abnormalities attributable to ipodate treatment were noted.⁶¹ The reason for poor response in four cats was not apparent. Lack of efficacy of ipodate has been noted in human patients, especially those with Graves' disease and severe hyperthyroidism. The effect of ipodate may be transient in some cats, given that two cats clearly had relapsed at the end of the 14 weeks.

Thus cholecystographic agents may be a feasible alternative to methimazole for medical treatment of feline hyperthyroidism and may be a good option for cats that require medical treatment but cannot tolerate methimazole. The need for special formulation of capsules may limit availability. Unfortunately, efficacy of treatment cannot be predicted, although cats with severe hyperthyroidism are less likely to respond. If treatment is efficacious, serum T_3 concentrations will normalize and clinical signs will abate. Owners should also be warned that a positive response might be transient. Unfortunately, ipodate is no longer available. Iopanoic acid has been recommended for use at the same dosage, but no studies exist proving its efficacy.

Drugs Used To Cure Hyperthyroidism

Compared with medical therapy that simply controls hyperthyroidism, ¹³¹I therapy provides a cure. The goal of ¹³¹I therapy is to restore euthyroidism with a single dose of radiation without producing hypothyroidism. Surgery can also cure the disease, but ¹³¹I is the definitive treatment of choice in cats with ectopic thyroid tumors that are not surgically accessible (e.g., intrathoracic). In addition, ¹³¹I may be the best way to treat metastatic carcinoma. Radioactive iodine, like stable iodine, is actively taken up by and stored in thyroidal tissue. The emitted β particles cannot travel far, thus limiting damage to adjacent normal tissues. Because normal tissue has atrophied and is quiescent, ¹³¹I will be concentrated within a thyroid tumor(s), and normal tissue is relatively spared from destruction by the radioactive particles.

The ¹³¹I dose can be administered orally, subcutaneously, or intravenously but is usually given subcutaneously to avoid the stress of intravenous catheterization or injection and the possibility of vomition of radioactive material. The major disadvantages of radioactive iodine therapy include accessibility (a limited number of facilities are licensed to use radiopharmaceuticals, but this is changing), cost, and the possible extent of hospital stay while radioactivity decreases in the patient (potentially up to 2 weeks, depending on local radiation safety regulations). After discharge, cats will continue to excrete a small amount of radiation for 2 to 4 weeks, and close contact with the cat should be minimized during this time.

TSH increases ¹³¹I uptake of the thyroid gland in humans, and rhTSH is routinely administered before ¹³¹I treatment to lessen the ¹³¹I dose and minimize irradiation of nonthyroidal tissues. Whether rhTSH would increase the uptake of ¹³¹I in thyroid glands of hyperthyroid cats was recently examined.⁶² Five hyperthyroid cats were given 25 µg rhTSH intravenously 1 hour before ¹²³I administration; ¹²³I can be used to visualize hyperfunctional tissue and will be handled by the body like ¹³¹I but will not cure hyperthyroidism. The same cats were given another ¹³¹I injection 8 days later without first receiving rhTSH. The rhTSH increased radioactive iodine uptake by the thyroid gland by 7.33%, which was statistically significant. Thus hyperthyroid cats undergoing ¹³¹I therapy may require a lower radioactive iodine dose if given rhTSH before treatment, but further studies are needed to optimize the rhTSH dose and the interval between its administration and the ¹³¹I injection.

Administration of ¹³¹I by any route appears to be relatively safe. Pain or discomfort in the area of the thyroid gland presumably reflects radioactive thyroiditis and should resolve within several days of therapy. A transient voice change has been noted in one cat⁶³ and transient dysphagia in eight.⁶⁴ Although many cats develop a subnormal serum T_4 concentration following ¹³¹I administration, a low serum T_4 concentration in itself does not mean hypothyroidism is present. Because nonthyroidal diseases can suppress serum T_4 concentration, nonthyroidal disease should always be excluded before a diagnosis of hypothyroidism is made. Supplementation is required only if clinical signs of hypothyroidism develop. Although 11% of cats have a low serum T_4 concentration after ¹³¹I therapy, approximately only 2% require L-thyroxine supplementation.⁶⁴

Clinical signs of euthyroidism generally occur within 1 to 3 weeks of 131 I administration; the first sign generally is normalization of appetite and weight gain. Therapeutic failure rate is approximately 2%. If T₄ is still elevated 3 to 6 months after 131 I administration, the hyperthyroid state is unlikely to resolve without further treatment. Most of these cats will respond to a second dose of 131 I. $^{63-67}$ In one study 2.5% of cats had a relapse of hyperthyroidism 1.1 to 6.5 years after initial radioiodine treatment.⁶⁴

Percutaneous ultrasound-guided intrathyroidal injection of ethanol or percutaneous radiofrequency ablation of thyroidal tissue has been tried as a means of targeting and destroying thyroid tumors. After treatment of unilateral disease with percutaneous ethanol injection (PEI), resolution was obtained lasting at least 12 months.⁶⁸ However, only a small number of cats were studied. Bilateral PEI for bilateral disease led to mortality in one cat, likely because of laryngeal paralysis. Treating bilateral disease with staged injections has not shown longterm success, with the longest remission obtained being 27 weeks.⁶⁹ Adverse effects include mild gagging, voice change, Horner's syndrome, and laryngeal paralysis; are usually transient; and resolve in 8 weeks or less.^{68,69}

Radiofrequency ablation was used to treat four cats with unilateral thyroid disease and five cats with bilateral disease.⁷⁰ The nine cats were administered 14 treatments. Of the cats with unilateral disease, three became clinically and biochemically euthyroid for 1, 6, and 18 months; the fourth cat became clinically euthyroid for 6 weeks, although the serum T_4 concentration remained slightly above the reference range. Interestingly, all cats with bilateral disease had treatments on one side and remission was obtained after 1 to 3 treatments for 1 to 6 months. Repeat therapy was used in some cats to induce a second or third remission when clinical signs returned. Transient Horner's disease was the sole clinical complication and was seen after 3 of the 14 treatments. Clinically inapparent laryngeal paralysis was noted in one cat during laryngeal examination.⁷⁰

Neither ethanol injection nor radiofrequency ablation is currently widely available for treatment of feline hyperthyroidism, and both require considerable experience. Radiofrequency ablation also requires specialized equipment.

Drugs Used To Control Clinical Signs of Hyperthyroidism

Thyroid hormones may increase the number or sensitivity of β-receptors in the myocardium.⁵⁶ Tachycardia, myocardial hypertrophy, heart failure, and cardiac arrhythmias have been associated with thyrotoxicosis in hyperthyroid cats. Beta-adrenergic blockers (e.g., propranolol) have no effect on thyroid hormone concentration but decrease the neuromuscular and cardiovascular effects of hyperthyroidism, such as hyperexcitability, hypertension, and cardiac hypertrophy. These agents can be used in combination with an antithyroid drug such as methimazole or alone if a patient cannot tolerate antithyroid medications, and they may be helpful in preparing a patient for thyroidectomy or radioactive iodine by making the cat a better candidate for surgery or hospitalization. Nonselective β blockade by propranolol can reduce the hyperdynamic effects of thyroid hormones on the myocardium. In addition, propranolol inhibits conversion of T_4 to T_3 by peripheral tissues in hyperthyroid humans. Because propranolol does not directly affect the thyroid gland, however, patients are not returned to a euthyroid state. Propanolol dosing in cats suffering from cardiac disorders associated with hyperthyroidism should begin at 2.5 mg orally every 12 hours and be increased to 7.5 mg every 8 hours as necessary to control heart rate. If propranolol is being used to prepare a patient for surgery, therapy should continue for 14 days preoperatively. Care should be taken in patients with congestive heart failure because the negative chronotropic effects of propranolol may decrease myocardial reserve. In addition, as a nonselective β blocker, propranolol can cause bronchospasms, which may be lethal in cats with respiratory distress or may exacerbate feline asthma. Atenolol, a selective β_1 blocker, might be used instead of propranolol (2 mg/kg or 6.25 mg/cat once daily).

Administration of large doses of iodide (e.g., sodium or potassium iodide) for a short time (1 to 2 weeks) will cause transient hypothyroidism in normal animals. Organification of thyroid hormones is prevented and hormone secretion is reduced. The clinical effects of high-dose iodine therapy will occur in 7 to 14 days in humans; however, refractoriness to these effects will develop in several weeks to months. In hyperthyroid cats, iodine (50-100 mg orally, once daily) has been used to prevent an acute thyroid crisis (i.e., a thyroid storm) in patients undergoing thyroidectomy. One to two drops of a saturated solution of potassium iodide can be administered in gelatin capsules beginning 10 days before surgery.⁷¹

DISEASES OF THE PARATHYROID GLANDS

Normal Calcium Homeostasis

Calcium balance is maintained by the integrated influences of parathyroid hormone (PTH) on calcium and phosphorus reabsorption in bone and distal renal tubular cells and by the intestinal absorption of calcium as mediated by vitamin D (Figure 21-3). Of the total calcium present in serum, approximately 40% is protein bound, 10% is bound to other factors such as citrate or phosphate, and 50% is ionized. Serum ionized calcium concentration, which is the biologically active portion, normally fluctuates less than 0.1 mg/dL. Secretion of PTH is exquisitely sensitive to changes in ionized calcium concentration. Decreases in serum calcium concentration stimulate PTH secretion, which in turn causes increased calcium resorption from urine (distal renal tubule), increased mobilization of calcium and phosphorus from bone, and increased vitamin D synthesis. Parathyroid hormone mediates the activation of vitamin D (see Figure 21-3).

The main function of vitamin D is to increase gastrointestinal calcium and phosphorus absorption. In humans vitamin D (cholecalciferol) can be ingested or made by irradiation of cutaneous 7-dehydrocholesterol; the serum half-life of vitamin D is 19 to 25 hours, although the vitamin is stored in fat depots. In dogs vitamin D must be ingested; what occurs in cats is unknown. Cholecalciferol is converted to 25-hydroxycholecalciferol (25-OHD, calcidiol) in the liver by hepatic microsomal enzymes (see Figure 21-3). Once in circulation, 25-OHD is bound to a binding globulin. In humans 25-OHD has an elimination half-life of about 19 days. Calcidiol is further hydroxylated to the most potent form, 1,25-dihydroxycholecalciferol (calcitriol), in the renal proximal tubules. The enzyme responsible for hydroxylation of 25-OHD is inhibited by calcitriol in a negative feedback manner and by hyperphosphatemia. On the other hand, conversion of 25-OHD to

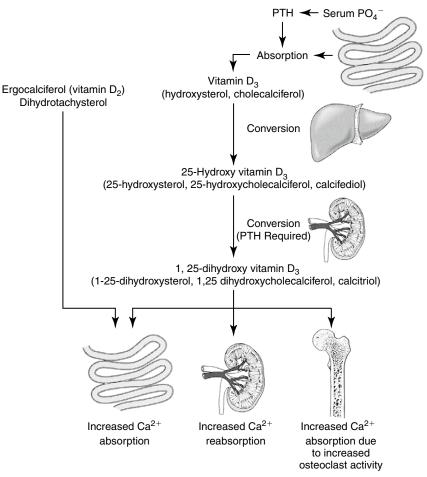

Figure 21-3 Calcium is very tightly regulated through the combined effects of parathyroid hormone (PTH), calcitonin, and vitamin D. The figure shows the activation of vitamin D and the way vitamin D and PTH act to increase serum calcium concentrations. Vitamin D must undergo several sequential activation steps before it is fully functional; calcitriol, the end product, acts to increase serum calcium concentrations and is essential for synthesis of PTH. Calcitonin, on the other hand, decreases serum calcium concentrations.

calcitriol requires PTH; thus without PTH, little to no calcitriol is made and there is practically no functioning vitamin D in the body. Renal and, to some degree, bone activities mediate the acute response to calcium homeostasis. Intestinal calcium reabsorption may take several days to occur, in part because of the time necessary for vitamin D synthesis or activation. Calcitriol is further hydroxylated to 1,24,25-(OH) 3-D₃ and subsequent metabolites that have variable activity.

Calcitonin, a polypeptide hormone secreted from thyroidal C (parafollicular) cells in response to hypercalcemia, is the least important regulator of calcium metabolism. It has a mild blood calcium–lowering effect by decreasing both the absorptive activity of osteoclasts and the formation of new osteoclasts. The main role of calcitonin may be to limit postprandial hypercalcemia. In normal animals the role of calcitonin is more important in juveniles. Calcitonin has minor effects on calcium handling by the gastrointestinal tract and at high doses promotes urinary calcium excretion.

Because ionized Ca is available to cells and is thus the biologically active form, it is critically important in the diagnosis of calcium disturbances. If ionized calcium is normal, even if total calcium is not, no further diagnostics are warranted. The correction formulas previously advocated and used to correct calcium concentration for serum albumin or protein concentration are no longer recommended.⁷² To know a patient's calcium status, the clinician must measure ionized calcium concentration.

Hypoparathyroidism

Pathophysiology and Diagnosis of Primary Hypoparathyroidism

Primary hypoparathyroidism in dogs can reflect destruction of the parathyroid glands by disease (e.g., lymphocytic parathyroiditis) or trauma, including surgical removal. The most common cause in cats is injury or removal of the parathyroid glands during thyroidectomy. Hypomagnesemia can be a cause or effect of hypoparathyroidism in dogs and cats. Cessation of PTH secretion results in the loss of calcium mobilization from bone, of calcium retention by the kidneys, and of calcium absorption from the intestines. The primary clinical manifestation of hypoparathyroidism reflects decreased serum calcium concentration. Hypoparathyroid patients may be hyperphosphatemic as a result of decreased renal phosphorus excretion. Measurement of serum PTH concentration is required to establish a diagnosis of hypoparathyroidism. Serum PTH concentrations below the reference range in hypocalcemic dogs and cats confirm the diagnosis, assuming the assay used is reliable and validated. Serum PTH concentrations in the low end of the reference range are not appropriate in hypocalcemic individuals, and a diagnosis of hypoparathyroidism can also be made.⁷³

Hypocalcemia

Hypocalcemia and, in particular, decreased serum ionized calcium concentration leads to neuromuscular hyperexcitability as the stabilizing influence of calcium on neuronal sodium permeability is lost. Although both central and peripheral nerves are affected, clinical signs are usually peripheral, ranging from latent tetany (e.g., muscle cramping, lameness, irritability) to muscle fasciculations and stiff gait to tetanic seizures. The concentration of ionized calcium below which tetany develops depends on the rate at which hypocalcemia develops. Furthermore, cerebrospinal fluid concentrations may be more critical and may remain stable in the face of fluctuations in serum concentrations. Despite the importance of calcium in cardiac contractility, clinical evidence of cardiac dysfunction generally does not develop. Differential diagnoses for hypocalcemia include primary hypoparathyroidism, acute and chronic renal failure, acute pancreatitis, puerperal tetany (eclampsia), intestinal malabsorption syndromes, nutritional secondary hyperparathyroidism, ethylene glycol toxicity, administration of phosphate-containing enemas, congenital vitamin D receptor defects, and hypomagnesemia.

Treatment of Hypocalcemia and Hypoparathyroidism

No treatment fully compensates for the absence of PTH.⁷⁴ The need for calcium therapy is based on serum calcium concentrations and clinical signs. Total serum calcium concentrations of 6.5 mg/dL might be considered critical; below 6 mg/dL generally results in clinical tetany, and below 4 mg/dL may be fatal.

Hypocalcemic tetany is a life-threatening condition, requiring immediate intravenous replacement. Because calcium can be lethal, it must be administered slowly to effect over 20 to 30 minutes. The amount of calcium in both oral and intravenous preparations varies with the salt. Because it is much less caustic if administered perivascularly, the calcium gluconate salt (10% solution: 9.3 mg calcium /mL) is preferred to the chloride (10% solution: 27.2 mg calcium/mL) and glucoheptonate (22% solution: 18 mg calcium/mL) salts. The dose of calcium for intravenous administration is 5 to 15 mg/kg (i.e., for the 10% gluconate salt solution [0.5 to 1.5 mL/kg] given slowly and intravenously. An electrocardiogram should be monitored during infusion; if bradycardia, premature ventricular contractions, or shortening of the Q-T interval is seen, the infusion should be slowed or briefly discontinued. Fluids containing bicarbonate, lactate, acetate, or phosphate cannot be used to administer calcium because the calcium will precipitate out of solution. Although seizures will stop once eucalcemia is established, other signs, such as nervousness, panting, and behavioral changes, may persist for 30 to 60 minutes after normalization of serum calcium concentration.⁷³ Correction of tetany should help resolve hyperthermia that developed as a result of excess muscle activity. Life-threatening hyperthermia should be treated as an emergency.

Duration of response to a single dose of calcium varies from 1 to 12 hours. The type of future therapy required depends on the cause of hypocalcemia. If primary hypoparathyroidism is diagnosed, long-term treatment with oral vitamin D is required insofar as no suitable commercial PTH preparations exist. Oral calcium supplementation will also be needed in the long-term, but parenteral calcium administration is required in the short-term. Oral maintenance therapy with calcium should begin as soon as possible, but oral calcium is not absorbed from the gastrointestinal tract until vitamin D therapy begins to take effect, which is usually in 1 to 5 days. In the meantime, continuous calcium infusion is recommended (60-90 mg/kg/day elemental calcium) until oral medications provide control. If initial hypocalcemia was severe, the dose administered should be in the upper end of the range. The dose can be decreased as the oral medications begin to work and based on serum calcium concentration.73 Intermittent intravenous infusions are not recommended because of the wide fluctuations in serum calcium concentrations that will occur.74

In theory, the gluconate salt can be given subcutaneously, diluted 1 part calcium to 2 to 4 parts saline, but this is not recommended. Although not fully conclusive that calcium gluconate was the cause, two case reports suggest that severe calcinosis cutis and subsequent sloughing resulted from subcutaneous administration of calcium gluconate.^{75,76} Calcium carbonate solutions can never be given subcutaneously.

The daily oral calcium dose is 25 to 50 mg/kg, divided in several doses. Parenteral calcium administration can be slowly discontinued beginning 1 to 2 days after initiation of oral treatment; the rate will depend on serum calcium concentrations. Calcium salts available for oral administration include lactate (13% elemental calcium available), gluconate (10% elemental calcium available), carbonate (40% elemental calcium available [tablet form]), chloride (27% elemental calcium available) and citrate (21% elemental calcium available). The carbonate form has the highest percentage of calcium; does not cause gastric irritation, as do other forms; and is a phosphate binder, lowering serum phosphate, which has positive effects on endogenous calcitriol synthesis. Thus it is the preferred oral form. Other salts containing smaller amounts of calcium may require many tablets to be administered as a single dose. Overthe-counter preparations (e.g., Tums, which contains calcium carbonate) can also be used for oral maintenance therapy. As vitamin D therapy becomes effective, calcium supplementation should no longer be necessary (discussed later).

Vitamin D therapy (Figure 21-4) is necessary for both absorption of orally administered calcium and normalization of calcium homeostasis. Patients should be hospitalized during induction of vitamin D therapy, until serum calcium

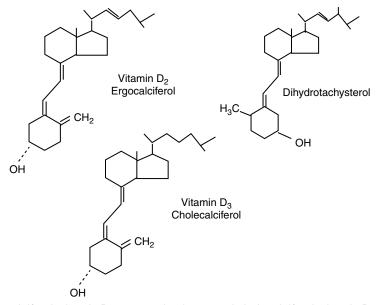

Figure 21-4 Structures of ergocalciferol, vitamin D_2 , present in plants, and cholecalciferol, vitamin D_3 , present in animals. Dihydrotachysterol is a congener of vitamin D_2 , currently not available commercially.

concentrations remain between 8 and 10 mg/dL without parenteral support. Vitamin D preparations vary in potency, time to onset (time to steady-state concentrations), and cost. Vitamin D can be administered as ergocalciferol (vitamin D_2) and calcitriol (active vitamin D_3). Vitamin D_3 is likely, however, to be better absorbed orally than is ergocalciferol. Bile is essential for adequate oral absorption; the majority of absorbed vitamin D occurs in chylomicrons in the lymph. Dihydrotachysterol (DHT), a synthetic form of vitamin D previously used to treat hypoparathyroidism, is no longer available.

Ergocalciferol, or vitamin D_2 (4000 to 6000 U/kg per day), is inexpensive and widely available. Large doses are necessary, however, to compensate for decreased potency in hypoparathyroid patients—it is an inactive form, and conversion to the active form will be impaired by low PTH concentrations in the patient. Large doses are also required to saturate fat depots (vitamin D is a fat-soluble vitamin). The effect of the medication is usually obvious 5 to 14 days after beginning therapy, and parenteral calcium can usually be discontinued 1 to 5 days after starting oral treatment.⁷³ Once the serum calcium concentration is in the target range of 8 to 10 mg/dL, ergocalciferol can be administered every other day. Serum calcium concentration should be monitored weekly, with the ergocalciferol dose adjusted to maintain calcium in the target range.73 The required maintenance dose is 1000 to 2000 U/kg once daily to once weekly.73

In patients in whom development of hypocalcemia can be anticipated (e.g., after parathyroid gland tumor removal), it may be necessary to start vitamin D supplementation preemptively. Guidelines exist, although they are unproven. If the serum calcium is below 14 mg/dL, vitamin D therapy is not recommended preoperatively. If calcium is above 15 mg/dL or a dog has more than one parathyroid mass, calcitriol therapy should be started the morning of surgery or immediately thereafter.⁷⁴ Even after a pet appears stable, rechecks are recommended monthly for the first 6 months and then every 2 to 3 months for life.⁷³ Hypercalcemia must be avoided because it can cause renal and other organ damage and numerous other problems. A disadvantage of ergocalciferol therapy is that because of high lipid solubility and body fat–store saturation, serum calcium concentrations can take up to 4 weeks to decline once ergocalciferol administration has been discontinued. Hypercalcemia should be treated aggressively if it occurs. Because of the risk of hypercalcemia and the difficulty of treatment, ergocalciferol is not recommended for treatment of hypoparathyroidism.

Calcitriol is the vitamin D of choice for treatment of hypoparathyroidism. Although calcitriol is significantly more expensive than ergocalciferol, it is much safer. As calcitriol is already active, small doses may be used and the dose may be adjusted frequently because of its rapid onset of action (1 to 4 days versus 5 to 21 days for ergocalciferol) and brief biological effect. If hypercalcemia occurs, the effects of this drug abate quickly after stopping therapy or with dose reduction.⁷³ A loading dose of 20 to 30 ng/kg daily can be administered for 3 to 4 days and then decreased to a maintenance dose of 5 to 15 ng/kg daily.⁷⁴ Doses should be divided and given twice daily. Reformulation may be required for veterinary patients; alternatively, a liquid form can be used to facilitate dose adjustments.

When calcitriol is used, dose adjustments should be made in 10% to 20% increments and only after enough time has elapsed for a previous alteration to take effect. Total calcium measurement is recommended daily in the initial phase, weekly during maintenance until a satisfactory serum calcium concentration is obtained, and then quarterly thereafter. The target for total serum calcium concentration, regardless of the form of calcium or vitamin D used, is just below the reference range. If hypomagnesemia is documented, magnesium sulfate (1 to 2 mEq/kg/day) should be administered. Correction of serum magnesium concentrations can decrease needed doses of vitamin D or calcium (or both).⁷⁴

If hypoparathyroidism is due to surgical intervention and expected to be temporary (e.g., at least one parathyroid gland was left after the thyroidectomy in cats or a parathyroid tumor was removed in dogs), calcitriol can be discontinued over time. In cats parathyroid function usually recovers in 2 weeks but can take up to 3 months; after removal of a parathyroid tumor in dogs, return of function of the remaining gland (or glands) can take up to 12 weeks.⁷⁴ Tapering of the calcitriol dose can begin after 4 weeks. If hypocalcemia returns, the calcitriol dose should be increased to the previous level and attempts at tapering made again later. If tapering after 3 months still results in hypoparathyroidism, permanent therapy with calcitriol will likely be necessary.⁷⁴

Oral calcium should be continued until serum calcium is maintained between 8 and 10 mg/dL, usually 1 to 2 days to several weeks after vitamin D therapy is started (depending on the vitamin D product used). Calcium can gradually be tapered over weeks as normal serum concentrations are maintained.

Because of potential nephrotoxic and other effects, hypercalcemia should be avoided. If hypercalcemia (>12 mg/dL) occurs at any time regardless of the product used, vitamin D administration should be discontinued until serum calcium concentration returns to normal. In addition, oral calcium supplements, if being given, also need to be ceased and the patient should be placed on a calcium-restricted diet.

Primary Hyperparathyroidism

Hypercalcemia

Multiple rule-outs for hypercalcemia exist. They can be remembered by the mnemonic *GOSHDARNIT*: Granulomatous disease, Osteolytic disease, Spurious (e.g., sample lipemia or hemolysis), Hyperparathyroidism, D toxicosis (i.e., vitamin D toxicosis), Addison's disease, Renal failure, Neoplasia, Idiopathic (only recognized in cats), and Temperature (hypothermia has been noted as a cause). The most common cause of hypercalcemia in dogs is malignancy.⁷⁷ Lymphosarcoma is most likely, but multiple myeloma and anal sac apocrine cell adenocarcinoma and others are possible. In cats idiopathic hypercalcemia is most likely, but neoplasia or renal failure are also possibilities. Squamous cell carcinoma and lymphosarcoma are the most common hypercalcemia-causing neoplasias in cats.⁷⁸

Assessing the phosphorus levels can aid in ranking differential diagnoses. The net effect of PTH is to increase serum calcium but decrease phosphorus. In primary hyperparathyroidism (PHPTH) the normal feedback mechanism of calcium on the parathyroid glands is lost. With elevated PTH hypercalcemia occurs with a low normal or low serum phosphorus concentration. The most common cause of PHPTH is neoplasia (functioning adenoma) of the chief cells of the parathyroid glands.⁷⁹ Hyperplasia of the parathyroid gland(s), multiple endocrine neoplasia, and hereditary hyperparathyroidism are less common causes. Secondary hyperparathyroidism generally occurs as calcium and phosphorus homeostasis becomes unbalanced (e.g., renal or nutritional secondary hyperparathyroidism).

Most neoplasias cause hypercalcemia by secreting the hormone parathyroid hormone related–peptide (PTHrP), which binds to PTH receptors affecting serum calcium and phosphorus just as PTH does, mimicking PHPTH. Hematologic malignancies growing in the bone marrow or metastases of solid tumors to bone can also cause hypercalcemia.

Vitamin D toxicosis leads to elevations in both calcium and phosphorus and can result from ingestion of cholecalciferolcontaining rodenticides or human antipsoriasis creams containing calcipotriene, a synthetic vitamin D_3 (e.g., Dovonex)⁸⁰ or from oversupplementation. Toxicity may not be evident until the drug has accumulated, which may take several weeks to months depending on the product. Granulomatous disease is an uncommon cause of hypercalcemia and may be due to the ability of macrophages to activate vitamin D independent of feedback mechanisms.

Unfortunately, the presence of renal failure can make interpretation of results difficult. Hypercalcemia can lead to renal failure and vice versa. If azotemia is present, phosphorus is likely to be elevated and cannot be used to help in ranking differential diagnoses. In addition, it can be hard to determine if the hypercalcemia or the renal failure came first. The clinician should be sure always to assess ionized calcium concentration. In the presence of azotemia, ionized calcium is often normal (and therefore not a cause for worry) when total serum calcium concentration is high. If ionized calcium is high, the diagnosis is likely PHPTH, whereas if the ionized calcium is normal to low, it is likely primary renal failure.

Clinical signs of hypercalcemia can be severe but are usually insidious and unnoticed. Polyuria and polydipsia are the most common in dogs. Hypercalcemia can cause secondary nephrogenic diabetes insipidus, initially increased and then decreased GFR, nephrocalcinosis, and soft tissue mineralization. Muscle weakness and atrophy, depression, anorexia, vomiting, shivering, bone pain, constipation, a stiff gait, and cardiac arrhythmias can also be seen. In cats presenting signs include vomiting, weight loss, dysuria, anorexia, inappropriate urination, lethargy, diarrhea, hematuria, pollakiuria, and stranguria. Signs of lower urinary tract disease may be seen in up to one third of hypercalcemic dogs and cats, which are prone to forming calcium-containing uroliths. Fibrous osteodystrophy of all bones, but particularly the skull, can occur with hyperparathyroidism.

Pathophysiology and Diagnosis of Primary Hyperparathyroidism

PHPTH results in hypercalcemia from autonomous PTH secretion from solitary or multiple parathyroid gland adenomas or hyperplasia or parathyroid gland carcinoma. Although no epidemiologic studies have been done, PHPTH is uncommon in dogs and rare in cats, primarily affecting older animals. It can occur in any breed, but it is an autosomal dominant, genetically transmitted disease in the Keeshond.⁸¹ Because

clinical signs tend to be absent to mild, hypercalcemia can be diagnosed on a serum biochemistry profile obtained for unrelated concerns. Given the numerous diseases that cause hypercalcemia, a minimum database of a hemogram, serum biochemistry profile, urinalysis, and urine culture should be obtained and a full, careful physical examination performed in all hypercalcemic animals.

If clinical signs are present, the most common ones involve the renal, gastrointestinal, or neuromuscular systems. Of the clinical signs reported in dogs with PHPTH, 81% had polyuria or polydipsia; 73% had either urinary tract calculi, a urinary tract infection, or both; 53% had decreased activity; and 37% had a decreased appetite; azotemia was documented in only 5%. The most commonly reported clinical signs in cats are anorexia, lethargy, and vomiting. In contrast to dogs, in which a parathyroid mass is rarely palpable, 11 of the 19 reported cats with PHPTH had a palpable mass.⁷⁹

In uncomplicated PHPTH, the biochemistry profile usually demonstrates persistently elevated total and ionized calcium, decreased to low-normal phosphorus, and normal BUN and creatinine levels. Assays for PTH and PTHrP are relatively sensitive, readily available diagnostic tools to help identify the cause of hypercalcemia. In general, in animals with PHPTH, serum PTH levels are within the normal reference range or elevated, and PTHrP is usually undetectable. In the face of hypercalcemia, a PTH concentration within the upper half of the reference range is wholly inappropriate and consistent with a diagnosis of PHPTH. In the face of hypercalcemia, a PTH concentration in the lower half of the normal range should raise suspicion for PHPTH, although it does not confirm it diagnostically.

Although previous reports state that 90% of dogs and cats with PHTPH have a solitary adenoma,⁷⁹ in one recent study, 42% of dogs had multiglandular disease.⁸² It is therefore important to identify all abnormal glands before or at the time of definitive treatment. Selective sampling and determination of serum PTH concentrations in both jugular veins have proved inconsistent in predicting the affected side, and this procedure is not recommended.^{79,82} Cervical ultrasonography can be a useful diagnostic aid in locating and identifying abnormal parathyroid glands, with reported sensitivity rates ranging from 42% to 100% when performed by highly experienced ultrasonographers.^{82,83} However, finding parathyroid glands with ultrasound requires a great deal of practice and skill.

Treatment of Primary Hyperparathyroidism

For PHPTH the only effective long-term therapy is ablation of the abnormal parathyroid tissue. Several methods of definitive treatment for PHPTH exist, but surgical excision is the most common, with cure rates up to 95% if all autonomously functioning tissue is removed.⁸³ In humans undergoing parathyroidectomy, PTH concentrations are measured preoperatively and intraoperatively 10 minutes after removal of the abnormal gland. A greater than 50% decrease in PTH concentration between the preexcision and postexcision samples is associated with successful removal of autonomously functioning tissue in humans. A minimum period of 6 months of normocalcemia postoperatively is considered curative in human medicine. With this in mind, a rapid intact PTH assay was recently validated in dogs. In 12 dogs the assay accurately detected increased serum PTH concentrations in all dogs with PHPTH preoperatively. A greater than 50% decrease in serum PTH levels between the preexcision and postexcision samples corresponded with a return to normocalcemia for at least 6 months in 92% of the dogs in the study.⁸²

Ethanol injection⁸⁴ or application of radiofrequency⁸⁵ has been reported for treatment of PHPTH. In a retrospective study, ethanol injection had only a 72% efficacy rate, whereas radiofrequency ablation and surgery had success rates of 90% and 94%, respectively, for medians of approximately 560 days.⁸³ Thus chemical ablation is not recommended. Unfortunately, radiofrequency ablation is not widely available and requires considerable expertise. With bilateral disease, staged treatments are needed.

Treatment of Hypercalcemia

Because hypercalcemia is best treated by addressing the underlying disorder, the cause should be delineated as quickly as possible and appropriate therapy instituted. Hypercalcemia can be damaging, especially to the kidneys, with severity appearing to depend on the phosphorus concentration. If the product of multiplying the serum calcium concentration by the serum phosphorus concentration is above 60 to 80, nephrotoxicity is likely.⁷⁹ If the etiology cannot be identified rapidly and continuing hypercalcemia is judged to be deleterious, clinical signs are present, or the hypercalcemia is idiopathic, the hypercalcemia should be addressed directly.

If treatment is deemed necessary, intravenous fluid therapy should be initiated. Dehydration may be present and should be corrected because it decreases GFR and can perpetuate hypercalcemia. Saline (0.9%) is the fluid of choice. Fluid deficits should be replaced and then fluid rates maintained at 120 to 180 mL/kg daily to promote calciuresis. Potassium supplementation is usually required to prevent hypokalemia.⁷⁹

Furosemide may be given to increase calcium excretion, but patients should be well hydrated first. Constant-rate infusion is typically recommended (5 mg/kg intravenously followed by a 5 mg/kg/hr infusion).⁷⁹ Lower doses (2-4 mg/kg 2 to 3 time daily, intravenously, subcutaneously, or orally) may produce a milder reduction in hypercalcemia. Thiazide diuretics are discouraged because they may increase renal calcium reabsorption.

Glucocorticoids have many beneficial effects; they decrease intestinal calcium absorption, reduce bone resorption, and increase renal calcium excretion. Prednisone (1-2.2 mg/kg twice daily, orally, subcutaneously, or intravenously) or dexamethasone (0.1-0.22 mg/kg twice daily, orally, subcutaneously, or intravenously) can be used. Steroid-sensitive hypercalcemias include lymphoma/leukemia, multiple myeloma, vitamin D toxicity, granulomatous disease, hypoadrenocorticism, and feline idiopathic hypercalcemia. Glucocorticoids should not be administered unless a definitive diagnosis is known. Even one dose can cause remission in a patient with lymphosarcoma. Although this could be beneficial in the short-term, it will make diagnosis impossible until remission ends. Furthermore, if standard combination chemotherapy is started after remission from prednisone alone is lost, it will be less effective, and, accordingly, overall prognosis will be worse.

Calcitonin (salmon calcitonin, 4-6 IU/kg subcutaneously, 2 to 3 times daily) can be used if other treatments fail. It can be an effective treatment for vitamin D toxicosis or other diseases in which bone resorption is a major cause of the hypercalcemia. In dogs the response may be short-lived, and anorexia, vomiting, or allergic reactions may occur. Information in cats is lacking.

Bisphosphonates, "osteoclast poisons," are believed to act by interfering with hydroxyapatite crystal dissolution or by direct action on osteoclasts. They may also be used if bone resorption is a major source of the hypercalcemia. Pamidronate disodium has been used to treat vitamin D toxicosis secondary to calcipotriene ingestion at a dose of 1.3 to 2 mg/ kg,^{86,87} as well as hypercalcemia associated with nocardiosis (one cat), idiopathic hypercalcemia and renal failure (one cat), lymphoma (two dogs), thyroid carcinoma (one dog), and multiple endocrine neoplasia (one dog).87 Given its potential nephroxicity, pamidronate should be diluted in saline and infused intravenously over a 4-hour period with a minimum of 4-hour diuresis both before and after the treatment.⁸⁷ Calcium and phosphorus normalize in 24 to 48 hours.^{86,87} The decrease in total and ionized calcium concentration after treatment is proportional to the degree of hypercalcemia.87 Treatment can be repeated if necessary, but may not be needed depending on the cause of the hypercalcemia. In one cat with idiopathic hypercalcemia, although a first treatment worked, a second and third did not. For the second and third treatments, previously frozen pamidronate was thawed and administered.⁸⁷ Whether lack of response was due to progression of the disease state or to instability of the pamidronate with freezing, storage, and thawing is unknown. Etidronate is an oral drug that has had limited use in dogs but may be helpful (5-15 mg/kg once to twice daily). Clodronate, which is not available in the United States, has been used successfully to treat experimentally induced vitamin D toxicity if given within 24 hours after vitamin D ingestion.⁸⁸ Clodronate toxicity and efficacy for treating accidental vitamin D overdose remain to be determined.

Sodium bicarbonate (1 to 4 mEq/kg intravenously by slow bolus) can be given during a hypercalcemic crisis. This does not always lower total serum calcium concentration but decreases the ionized portion, so adverse effects of the hyper-calcemia are less common.

It is unclear whether therapy for treatment of feline idiopathic hypercalcemia is required. One guideline is to make the decision using the previously described guidelines for emergency treatment: Treat if calcium continues to rise, the calcium-phosphorus product is greater than 60 mg/dL, the ionized calcium concentration is greater than 1 mg/dL above the reference range, or clinical signs or azotemia are present.⁸⁹ The aggressiveness of therapy depends on the clinical status and parameters present. If treatment is not pursued at first, calcium concentrations should be monitored every 1 to 3 months and the need for therapy reevaluated. With any treatment, ionized calcium may not normalize even though total calcium does,⁹⁰ so measurement of the ionized form is required for accurate assessment of therapeutic success.

Dietary therapy with a high-fiber diet was reported to be successful in five cats based on measurement of total serum calcium and/or resolution of clinical signs.⁹¹ Although dietary management was not effective in other cats,90 the recommended first line of treatment for idiopathic hypercalcemia is to place an affected cat on a diet that is not designed to acidify the urine; urine-acidifying diets have been theorized to contribute to development of hypercalcemia. High-fiber, oxalate-prevention, or renal diets can be implemented. If ionized calcium has not normalized after 3 months, prednisone therapy should be added⁸⁹ and may be successful.⁹⁰ The recommended starting dose is 5 to 10 mg per cat per day, but it can be increased to 10 mg twice daily if needed. Prednisolone may be preferred to prednisone.⁸⁹ Bisphosphonates may be useful, and intravenous pamidronate has been used in one cat.87 Although no peer-reviewed publications exist, use of alendronate (10 mg/cat/once weekly) has been successful for up to 1 year.⁸⁹ Because erosive esophagitis has been reported in women taking alendronate, the weekly pill should be followed with 6 mL of water given by a dosing syringe and then a small dab of butter on the cat's lips to increase licking and salivation.⁸⁹ Therapy for renal failure should be instituted as needed. Subtotal parathyroidectomy has not been successful.⁹⁰

DISEASES OF THE PANCREAS: DIABETES MELLITUS

Normal Physiology

Glucagon stimulates glucose production from both hepatic conversion of glycogen and metabolism of noncarbohydrates, such as amino acids and lipids, into glucose or glucose precursors (e.g., lipids to fatty acids and glycerol). Low blood glucose concentrations increase glucagon secretion from pancreatic α cells. Should glucose concentrations become too high, insulin secretion is stimulated from pancreatic β cells. Insulin lowers blood glucose by stimulating formation of glycogen from glucose in the liver, inhibiting peripheral formation of glucose from amino acids and lipids, and facilitating diffusion of glucose into cells in insulin-dependent tissues such as muscle and adipose tissue. As a result, amino acids are synthesized in muscle, and adipocytes produce and store fat. Insulin secretion is regulated by a negative feedback mechanism sensitive to blood glucose concentrations. As the blood glucose concentration decreases, pancreatic β cells secrete less insulin and blood glucose does not decline further. With lower serum insulin concentrations, insulin-dependent cells can no longer utilize blood glucose, whereas insulin-independent cells such as neurons, which obtain glucose by simple diffusion, continue to use any glucose that remains in the blood.

Diabetes mellitus (DM) is a progressive disease resulting from an absolute or relative insulin deficiency caused by insufficient insulin secretion from pancreatic β cells and is characterized by four stages in human patients. Prediabetic patients are normal but subsequently develop the disease; subclinical DM can be diagnosed only by sophisticated provocative tests. In latent DM, patients are clinically normal but respond abnormally to a glucose load, and in overt DM, patients have persistent fasting hyperglycemia. The duration of progression from stage I to stage IV can be weeks to years, depending on the type of DM.

How best to classify DM in veterinary medicine is controversial, with the current classification scheme adapted from human medicine. Type 1 DM is characterized by β -cell destruction with progressive, eventually complete, insulin insufficiency. Genetic susceptibility plays a role, and β -cell destruction is usually due to immunologic processes. Causes of type 1 DM in animals may include hereditary factors and pancreatic destruction by pancreatitis, viruses, or autoimmune disease. Insulin resistance, dysfunctional β cells, and increased hepatic gluconeogenesis characterize type 2 DM. A classification of "other specific types of diabetes" also exists, formerly referred to as "secondary" DM. On the basis of pancreatic islet histology, lack of β -cell antibodies, risk factors, and clinical behavior of the disease, type II DM appears to be the most common form in cats.92 Approximately 10% to 20% of diabetic cats have "other specific types of DM", which includes diseases that lead to β -cell loss, such as pancreatic neoplasia, and conditions such as hyperadrenocorticism or acromegaly that cause marked insulin resistance.93 The remaining cats are believed to be type I diabetics. DM in dogs is believed to be mainly type 1.94

DM can also be classified as insulin-dependent DM (IDDM) or non-insulin-dependent DM (NIDDM), depending on the need for insulin therapy to control glycemia, prevent ketoacidosis, and survive. Individuals with IDDM must receive insulin to prevent ketoacidosis, whereas control of glycemia and avoidance of ketoacidosis can be accomplished through diet, exercise, and oral hypoglycemic drugs in patients with NIDDM.⁹⁵ At the time of diagnosis, all dogs are likely to be insulin dependent, as would be expected with type 1 diabetics, and at least 75% of cats with type 2 DM are insulin dependent.⁹³

Management of persistent hyperglycemia is important to the progression of the syndrome, especially in cats. Cats may alternate between being insulin dependent and not, and the DM can go into remission for weeks to years with appropriate therapy. Persistent hyperglycemia can profoundly reduce insulin secretion and induce apoptosis in β cells, ultimately causing permanent DM in cats that at one point had a normal β cell mass,⁹⁶ a situation referred to as *glucose toxicity*. The effects begin within 2 days of onset of persistent hyperglycemia, and the impact on β cells increases with the magnitude of hyperglycemia.⁹⁷ Pancreatic βcell death by apoptosis occurs within 10 days of persistent hyperglycemia.97 The impact of glucose toxicity is more severe in the presence of reduced β cell mass, underscoring the importance of effective control and β cell preservation. Control of blood glucose, ideally with insulin but potentially with oral hypoglycemic therapy, may

allow β cells to regain insulin secretory capacity. As a result, the diabetic state is transient in 15% to 68% of cats^{96,98-100} and can require as much as 20 to 52 weeks of insulin therapy before remission is achieved.^{101,102}

Diagnosis

Presence of appropriate clinical signs (e.g., polyuria or polydipsia, polyphagia, and weight loss) and documentation of persistent fasting hyperglycemia (>200 mg/dL) and glycosuria are used to diagnose overt DM. Occasionally, a definitive diagnosis of DM may be difficult to make. Mild hyperglycemia, such as that induced by stress or certain diseases (e.g., hyperadrenocorticism), may uncommonly result in glycosuria. In nondiabetic cats, blood glucose concentrations may reach 400 mg/dL. Thus diagnosis of DM must be based on blood glucose and the presence of the classic signs. Unfortunately, the clinical signs are not unique to DM, and other differential diagnoses must be considered. On the other hand, some latent diabetic animals become overtly diabetic because of the presence of concurrent diseases; clinical signs of the precipitating disease may obscure the classic signs of DM. Hospitalization of a patient and reevaluation of blood glucose after the patient has adjusted to the new environment may help identify nondiabetic hyperglycemic states. Alternatively, urine can be monitored for the persistent presence of glucose at home. The presence of ketonuria strongly supports a diagnosis of DM. Identifying current drug therapy can also be important; progesterone or prolonged glucocorticoid therapy, which can precipitate DM, might support its diagnosis.

Measurement of glycosylated proteins can be used to corroborate a diagnosis of DM. Non-enzymatic, irreversible binding of glucose to hemoglobin results in the formation of glycosylated hemoglobin (GHb). Fructosamine refers to glycosylated serum proteins, mainly albumin, but glycated albumin (GA) also can specifically be measured in dogs and cats.^{103,104} Glycosylated proteins form at a rate proportional to the average blood glucose concentration, so the higher the mean blood glucose concentration over time, the greater the glycosylated protein concentrations should be. Glycosylated protein levels are also affected by the half-life of the native protein; the shorter the half-life, the quicker the concentration of glycosylated protein falls after correction of hyperglycemia. Albumin has a short half-life compared with that of red blood cells. Thus in dogs and cats, GHb reflects glycemic control over the previous 2 to 3 months. In comparison, in dogs fructosamine reflects the previous 2 to 3 weeks and GA the previous 1 to 3 weeks.¹⁰⁴ In cats plasma proteins may be more rapidly metabolized, and fructosamine concentrations reflect the glucose concentrations in the previous 7 days.105

One study suggested that fructosamine might be more sensitive than GHb for monitoring control,¹⁰⁶ but measurement of either can be helpful. Both parameters are typically not affected by stress.¹⁰⁷⁻¹¹² However, measurement of either is neither perfect nor absolute. Although in general, the higher the blood glucose concentration over time, the higher serum glycosylated protein concentrations should be, normal animals or well-controlled diabetics can have elevated concentrations of these substances, and, conversely, uncontrolled diabetic animals can have normal levels of either.^{110,111,113} Thus the gly-cosylated protein concentration must be interpreted in conjunction with all other data.

Dietary Therapy

Dietary therapy is very important for treatment of DM. Through unknown mechanisms, dietary fiber can delay gastrointestinal glucose absorption, reducing postprandial fluctuations in blood glucose and enhancing glycemic control. High-fiber diets have been traditionally recommended for diabetics, but this is now being questioned. Insoluble fiber is beneficial in diabetic dogs.^{114,115} However, the response of diabetic dogs to fiber varies between individuals. A recent study showed that high-fiber, moderate-starch diets were not advantageous for dogs with stabilized DM compared with a moderate-fiber, low-starch diet.¹¹⁶ Insoluble fiber, the type present in commercial feline high-fiber diets, can also improve glycemic control in diabetic cats.¹¹⁷ However, recent theories suggest that high-carbohydrate diets may lead to DM in cats, and high-protein diets may be more beneficial. The DM of cats on a high-protein, low-carbohydrate diet either resolved or was treatable with a reduced insulin dose.118,119

Although veterinary low-carbohydrate, high-protein prescription diets such as Purina DM or Hill's m/d are the first-choice dietary recommendation for most cats with DM, a carefully selected over-the-counter high-protein, lowcarbohydrate diet can provide the same degree of effective glycemic control as prescription diets¹²⁰ when financial constraints dictate the less-expensive option or when a cat will not readily eat a veterinary diet. Many canned over-the-counter diets are relatively low in carbohydrate content (<5.0g/100kcal), but information must be obtained from the manufacturer on specific brands and flavors to ensure that the target nutrient composition is being met. Most dry over-the-counter diets are higher in carbohydrate content. Thus, if a prescription dry veterinary low-carbohydrate, high-protein diet is not an option, it may, unfortunately, be more difficult to identify a good-quality dry food with low carbohydrate content. Caution should be used in feeding diabetic cats with concurrent renal disease a high-protein diet; a high-fiber diet may be a better choice.

Drug Therapy

Insulin is the mainstay of therapy in diabetic dogs and cats. Its administration must be integrated with meals, exercise, owner's needs, and other characteristics of the patient or pet owner's lifestyle; these factors have been described elsewhere.^{95,121-123} Although the ideal goal of insulin therapy is to maintain blood glucose concentrations as close to physiological as possible, this is difficult to do because exogenous insulin is administered as one or two large daily doses rather than in response to glucose concentrations. The realistic goal for insulin therapy, at least, should be elimination of the clinical signs of DM. Because secondary complications that dramatically alter the quality of health of human diabetics such as retinopathy or nephropathy appear to be rare in animals, near normalization of glucose concentrations may not be as important for diabetic dogs and cats as it is for human diabetic patients. Glucose concentrations should, however, be sufficiently controlled to prevent development of ketoacidosis and detrimental effects of hyperglycemia. Hyperglycemia is associated with an increased risk of bacterial infections; hepatic lipidosis; pancreatitis; and renal, hepatic, and pulmonary disease. Complicating problems that may alter response to insulin therapy must be identified in diabetics, as well as underlying diseases that led to the development of clinical signs in a covert diabetic.

Insulin Preparations

Insulin preparations are defined by modifications that alter time of onset and duration of action. They also vary in the source species and therefore in potential antigenicity. Chemical extracts of cattle and swine pancreases traditionally were the primary source. More recently, bacterially produced human recombinant products have been developed, but these are more expensive. More problematic, development of human products has led to discontinuation of several animal-source products that had been used successfully for controlling DM in dogs and cats.

The kinetics of individual insulin products vary markedly among species. Insulin products are generally classified as short-acting (e.g., regular insulin), intermediate-acting (e.g., neutral protamine Hagedorn [NPH], lente), or long-acting (e.g., PZI, Ultralente). The duration of action of regular insulin is the same in dogs and cats, but the duration of action of other insulins is typically shorter in cats than dogs. Intermediate- and long-acting insulins tend to be less bioavailable and thus less potent than short-acting insulins when given subcutaneously.

Regular insulin (zinc insulin crystals) is unmodified and acts the same whether crystalline or noncrystalline. Given intravenously, it begins working immediately, with maximal effects occurring at 0.5 to 2 hours and duration of effect being 1 to 4 hours. When insulin is given intramuscularly, time to effect is 10 to 30 minutes, time to peak effect is 1 to 4 hours, and duration of effect is 3 to 8 hours. When it is given subcutaneously, onset of effects occurs in 10 to 30 minutes, maximal effects occur at 1 to 5 hours, and duration is 4 to 10 hours. Inhaled insulin has recently been shown to be systemically bioavailable and physiologically active in dogs and cats, with an onset of action between 5 and 15 minutes¹²⁴ and a duration of action of 3 hours.¹²⁵ Neutral regular insulin will maintain its potency for as long as 18 months when stored at 5° to 25° C and will maintain 95% of its potency when stored at 37° C for 12 months.

Regular insulin is generally reserved for treatment of ketoacidosis. Use in daily maintenance therapy might include administration in combination with longer-acting products to provide a rapid onset with long duration of action; however, in general, such combinations are not needed or used. Insulin is available commercially in stable preparations of 70% NPH/30% regular or 50% NPH/50% regular (e.g., 70/30 or 50/50 insulin, respectively), but these are often quite potent, causing a rapid decrease in blood glucose concentration, and duration of effect is usually short.⁹⁵

Protamine zinc insulin (PZI) was developed to prolong the effects of regular insulin. The preparation is formed by mixing insulin, zinc, and protamine, a fish protein, in a buffered solution such that it precipitates as a poorly soluble form. Poor solubility prolongs the absorption time after subcutaneous administration and provides a slower onset of activity and a longer duration of action. For PZI insulin the onset of action occurs at 1 to 4 hours, and maximum effect occurs at 3 to 12 hours. Duration is 12 to 24 hours in cats, and it may be necessary to administer the drug twice daily (in approximately 25% of cats). Use of PZI Vet (Idexx Pharmaceuticals) is limited to the existing supply; in April 2008 the manufacturer announced that after the sale of its existing inventory, it would no longer manufacture or sell animal-based insulin. Although many pharmacists can compound bovine PZI insulin, the authors do not recommend its use because the potency of compounded insulins varies between bottles.

To replace PZI Vet, a similar formulation based on recombinant human insulin (Prozinc) has recently been developed by Idexx. Limited data exist evaluating its efficacy and safety in diabetic cats, and no published pharmacodynamic studies of Prozinc in cats are available. One study compared glycemic control achieved with Prozinc with that of PZI Vet in diabetic cats. Fifty cats with stable glycemic control on PZI Vet were switched to Prozinc on day 0. Serum fructosamine concentrations, body weight, and insulin dose were measured on days 0, 15, and 30. On day 30, the cats were switched back to PZI Vet. Owners' subjective assessments of their cats' glycemic control were obtained at all time points. There were 47 cats completing the study; three were removed because of diabetic remission (n = 1), hypoglycemia (n = 1), and fractious behavior (n = 1). In the cats that completed the study, no difference in glycemic control between the insulin types was detected. The only adverse event reported was hypoglycemia in one cat.¹²⁶ A second study evaluated Prozinc in 126 newly diagnosed and 13 poorly controlled diabetic cats.¹²⁷ Control was assessed on days 7, 14, 30, and 45 by evaluating clinical response, body weight, serum fructosamine, and serial blood glucose concentrations over a 9-hour blood glucose curve. Based on the measured parameters, 84% of cats were judged to have good glycemic control by day 45. Thus Prozinc appeared safe and efficacious in diabetic cats. Prozinc has gained FDA approval for use in diabetic cats.

Isophane (NPH) insulin, developed as a compromise between short-acting regular insulin and slow-acting PZI, is made by manipulating the ratio between insulin and protamine. Isophane insulin is more potent and faster-acting than PZI but shorter in duration. For NPH administered subcutaneously, onset of action occurs in 0.5 to 3 hours and maximum effects occur at 2 to 8 hours. Duration of action is as little as 6 to as long as 12 hours in cats and 18 hours in dogs. Twicedaily administration is usually necessary for adequate diabetic control.

Lente insulin does not incorporate protamine but contains insulin and high concentrations of zinc (10 times greater than that in regular insulin) in an acetate rather than a phosphate buffer. Adjustment of pH causes insoluble precipitates to form that are longer-acting (i.e., ultralente) compared with soluble, shorter-acting (i.e., semilente) preparations. Lente insulin is a mixture of approximately 70% ultralente and 30% semilente, and its effects begin immediately. In dogs, time to maximum effect is 2 to 10 hours and duration is 8 to 20 hours. In diabetic cats, time to maximum effect for lente is 2 to 5 hours and duration of effects is 8 to 12 hours.¹²⁸ Human recombinant forms of lente and ultralente insulins are no longer available. The only veterinary preparation of lente insulin is Vetsulin (Intervet), which is porcine in origin. Vetsulin is currently approved in the United States by the Food and Drug Administration for use in both dogs and cats; it has been available for many years in other countries under the name Caninsulin. It is the only insulin approved for use in dogs. Currently, ultralente is not formulated as a veterinary preparation.

Lastly, "designer" recombinant insulins are made in which the amino acid structure of the protein has been altered slightly in order to change the pharmacokinetic profile. One of these products, glargine (Lantus), is used in veterinary medicine. Glargine differs from human insulin in that glycine is substituted for asparagine at position 21 in the α chain of insulin and by addition of two arginine residues to the βchain. Glargine is a clear aqueous solution with a pH of 4. The interaction of the acidic insulin and the relatively neutral pH of subcutaneous tissues causes microprecipitates to form and thus gives a relatively constant systemic absorption profile. As formation of microprecipitates depend on the solution's acidity, glargine cannot be mixed or diluted.¹²⁹ Although marketed as a "peakless" insulin in humans, it does have peaks and nadirs in healthy cats. In nondiabetic cats given 0.5 U/kg glargine insulin once daily, the mean time to the glucose nadir was 14 hours.¹³⁰ It is long-acting, with blood glucose concentrations suppressed below baseline at 24 hours in approximately half the cats studied, whether given once daily (0.5 U/kg) or twice daily (0.25 U/kg).^{130,131} Another long-acting insulin analog, detemir, has lower within-subject variability compared with NPH and glargine in human type 1 or type 2 diabetics.^{132,133} In one study of detemir using healthy cats, the findings suggest that glargine may have a more rapid onset then detemir, but the peak effect of detemir may be more predictable. It also appears that detemir may have a longer duration of action than glargine.¹³⁴ There are no published studies evaluating detemir insulin in diabetic cats or dogs at this time.

The species of origin of insulin products potentially plays a role in therapeutic efficacy. Canine and porcine insulin have identical amino acid sequences, so porcine insulin is less immunogenic in dogs.¹³⁵ Reduced antigenicity may, however, be undesirable (discussed later). Porcine insulin has a shorter duration of action than does beef insulin in dogs; human insulin appears more potent than beef–pork insulin in cats, thus requiring lower (25%) dosing.

Commercial insulins are available in concentrations of 40 (U-40), 100 (U-100), and 500 (U-500) U/mL. One unit of insulin is equal to 36 µg. Syringes are available for the corresponding insulin concentration. Accurate dosing requires that the appropriate syringe be used. For U-100 insulin, low-dose syringes are highly recommended for patients requiring low doses.

Insulin should be mixed before administration by gently rolling the bottle between the palms of one's hands; aggressive shaking may denature the product. Although refrigeration is not necessary, extreme sunlight and heat can destroy insulin. Refrigeration can protect the insulin.

Insulin Therapy

Individual response to insulin varies greatly. In cats, differences in required doses probably reflect, at least in part, availability of endogenous insulin. Both dose and frequency of administration should be designed for an individual patient; it may be necessary to base frequency on a compromise between meeting client needs and minimizing fluctuations in blood glucose. Although long-acting preparations can initially be tried every 24 hours, a 12-hour interval usually proves necessary; the authors prefer starting with twice-daily dosing to achieve control sooner. In one study 94% of dogs required twice-daily dosing regardless of insulin type used for adequate control.¹³⁶

Regular insulin can be given by intravenous, intramuscular, or subcutaneous routes, but all other preparations should be given subcutaneously. Injection should occur in the lateral, not dorsal, thoracic or lumbar areas. The dorsum can be poorly vascularized, especially between the shoulder blades, and drug absorption can be erratic. Although some authors recommend a starting dose of 0.25 U/kg twice daily,⁹⁵ others recommend using 0.5 U/kg if the blood glucose is greater than 360 mg/dL and 0.25 U/kg if it is less than 360 mg/dL.¹³⁷ Dogs should be fed 50% of their daily food immediately before each injection to ensure appropriate caloric intake before administration of a full dose of insulin. Semimoist foods are discouraged.

The type of insulin to use is a matter of personal opinion and experience. For dogs, therapy should begin with an intermediate-acting insulin (e.g., NPH, lente). In one study, 53 dogs with uncomplicated diabetes were treated with Vetsulin for 60 days after a variable initial dose determination period. Therapy started once daily and was changed to twice daily as needed. The starting dose was 1 U/kg, with a supplemental dose depending on body weight (dogs below 10 kg received 1 U supplement, 10-11 kg 2 U, 12-20 kg 3 U, and above 20 kg 4 U), as formerly recommended in the package insert. (Note that the dosing scheme was based on the package insert at the time of the study, but recommendations are now different.) Efficacy and safety were evaluated at the end of the dose determination period (time 0) and 30 (time 1) and 60 days (time 2) later. At times 0, 1, and 2, 100%, 66%, and 75% of the dogs, respectively, were judged to be adequately controlled based on blood glucose concentrations and clinical signs. By day 60 66% were receiving twice-daily injections. The median number of days required to achieve adequate glycemic control was 35 (range 5-151). No unexpected side effects were observed, but 22 dogs had signs at some time that could have been caused by hypoglycemia and two died of presumed hypoglycemia. The owners of seven dogs reported swelling or pain (or both) at the injection site, but neither symptom was noted by the investigators.¹³⁸

In cats, good options are glargine, PZI, and lente insulins. Ultralente is no longer available. Prozinc currently is an acceptable insulin choice for cats; detemir (discussed previously) may be a good option for the treatment of diabetic cats in the future, but because of the lack of availability and limited data, it cannot be recommended at this time.

805

One study evaluated use of PZI in 67 diabetic cats. Initial PZI dosage ranged from 0.2 to 0.6 U/kg twice daily. After 45 days, the mean dose was 0.9 U/kg (range 0.2 to 1.8). Mean blood glucose nadir occurred approximately 5 to 7 hours after insulin injection but ranged from 1 to 9 hours.¹³⁹ Overall, 90% of owners believed their cat improved. Clinical hypoglycemia occurred in five cats, and hypoglycemia without clinical signs occurred in another 21 (31%). Ten cats were not controlled by day 45. Whether longer treatment and more dosage adjustments would have achieved control is unknown. In general, cats with newly diagnosed DM had a better response than those with previously treated DM; perhaps the cats that failed previous treatment had an underlying cause of insulin resistance. Most diabetic cats will require PZI twice daily for adequate control, but once-daily injections may suffice in up to 25%. Initial PZI dosage should be low (e.g., 1 U/injection) to prevent hypoglycemia.¹³⁹ The initial reports on Prozinc also support initial low doses with this insulin. In one study one cat was removed because of documented hypoglycemia, and in another study 160 of 690 serial blood glucose curve values documented hypoglycemia in 87 of 139 diabetic cats. The reports do not state whether any episodes of hypoglycemia were clinically apparent.126,127

In diabetic cats, the use of glargine appears extremely promising. Glargine has a long duration of action and predictable blood glucose-lowering effects. In eight newly diagnosed cats treated with a high-protein, low-carbohydrate diet, the DM resolved in all cats within 4 months.¹⁴⁰ Glargine appears to be appropriate for use in any cat, providing control of blood glucose concentrations throughout most of the day. Long-term diabetic cats have been switched to and treated with glargine insulin as well with excellent results;¹⁴¹ remission is less likely after long-term treatment with another insulin, but it may still occur.¹²⁰ In a study evaluating remission rates in diabetic cats initially treated with insulin, 55 diabetic cats were evaluated whose owners followed a highly intensive monitoring and blood glucose regulation (blood glucose concentrations maintained between 50-100mg/dL) protocol using insulin glargine and fed a low-carbohydrate diet. A total of 35 cats (64%) achieved remission. Cats that received glucocorticoid treatment within 6 months before diagnosis of DM, that required a lower maximum insulin dose, or that were intensively managed using glargine within 6 months of diagnosis were more likely to achieve remission, whereas cats with a peripheral neuropathy present at diagnosis (e.g., difficulty climbing stairs or a plantigrade stance) were less likely to do so. Other factors examined that were not predictors of entering remission were age at diagnosis, gender, obesity, evidence of diabetic ketoacidosis at diagnosis, development of azotemia during therapy, concurrent hyperthyroidism, and frequency of asymptotic hypoglycemia.¹⁴² In the authors' opinion, glargine insulin is the current preferred insulin choice for diabetic cats, be they newly diagnosed or long-term diabetics with poor glycemic control on their current insulin regimen. It is also the

only commercially available long-acting insulin that has been extensively studied in diabetic cats.

Cats should be started at a glargine dose of 0.5 U/kg if the blood glucose concentration is above 360 mg/dL or 0.25 U/kg if the blood glucose concentration is below 360 mg/dL. In either case, twice-daily administration is recommended. Compared with other types of insulin, with which dose adjustments are typically made based on the blood glucose nadir, for glargine dose adjustments should be made based on the fasting blood glucose value. Because the doses are typically small, 0.3 mL, low-dose syringes should be used for accurate dosing.

Lente insulin can be used in cats, but because it has a shorter duration of action than glargine or PZI, it almost always, if not always, must be administered twice daily.¹²⁸ A recommended starting dose is 0.25 U/kg twice daily if the blood glucose concentration is 216 to 360 mg/dL or 0.5 U/kg twice daily if the blood glucose concentration is above 360 mg/dL.¹⁴³ Alternatively, a dose of 1 U/cat twice daily for cats weighing less than 4 kg and 1.5 to 2 U/cat twice daily for cats weighing more than 4 kg can be used to initiate therapy.¹⁴⁴

A multicenter study recently assessed the efficacy and safety of porcine lente insulin in 46 diabetic cats.¹⁰² Therapy was initiated twice daily at a dose of 0.25 U/kg if the blood glucose concentration was 270 to 360 mg/dL and 0.5 U/kg if the blood glucose concentration was above 360 mg/dL. All cats were followed for a stabilization period of approximately 16 weeks, and 23 cats were followed for an additional variable period of up to 49 weeks. Diabetic remission was achieved in 15%; all were newly diagnosed diabetics, and time to remission ranged from 2 to 56 weeks. The mean insulin dose both at the end of the stabilization period (week 16) and the end of the study (week 49) was 2 U per cat twice daily. The authors concluded that lente insulin was safe and effective in diabetic cats; achieving diabetic stability with lente may take 3 to 4 months; cats were more likely to go into remission if they were newly diagnosed, compared with previously diagnosed, diabetics; and it could take as long as 56 weeks to achieve remission.

Long-term response to insulin was assessed in 54 diabetic cats that were evaluated numerous times over a minimum of 3 months.¹⁴⁵ Insulins used included beef/pork PZI (n = 14), beef/pork ultralente (n = 26), and beef/pork lente (n = 14). Response was based on resolution of clinical signs and mean blood glucose, with good, mediocre, and poor response considered to be a blood glucose concentration less than 200 mg/dL, between 200 and 300 mg/dL, and greater than 300 mg/dL, respectively. No difference was found among the types of insulin regarding therapeutic success, although this may reflect the small number of animals studied rather than variability of the outcomes.¹⁴⁵

Interestingly, the percentage of cats that were judged to have responded was different depending on which criteria were used: clinical signs versus mean blood glucose concentration. For PZI and ultralente, 14% and 15% of cats achieved good control based on mean blood glucose, whereas no animals were considered well controlled for lente. If using clinical signs as the means to assess control, the percentage of good responders was greater for all treatment groups: 50% for PZI and ultralente and 79% for lente. Improvements in mean blood glucose were considered mediocre in 64% of the PZI group and 50% each for ultralente and lente, whereas improvements in clinical signs were considered mediocre in 50%, 42%, and 21% of the PZI, ultralente, and lente groups, respectively. Glycemic control was significantly better in the cats without concurrent disease compared with cats that did have it. Survival was evaluated in a total of 104 cats. Mean and median survival times in cats with good glycemic control (on the basis of mean blood glucose) for all treatment groups were 24 and 16 months compared with 17 and 20 months for cats with mediocre control, respectively.¹⁴⁵

Monitoring of Therapy and Alteration of Insulin Dose

Marked variation in insulin kinetics—particularly in cats makes monitoring diabetic control crucial. Options include performance of serial glucose curves either in a hospital or at home, measurement of serum glycosylated protein concentrations, monitoring of presence and degree of glycosuria, and assessment of the presence or absence of clinical signs of DM.

Performance of in-hospital blood glucose curves has long been the gold standard for assessing diabetic control. Glucose curves should establish the insulin effectiveness, time to peak effect, duration of effect, glucose nadir, and degree of fluctuation in blood glucose concentration and identify the Somogyi phenomenon (discussed later), if present. To construct a curve, blood glucose concentration is measured in general every 2 hours for one interval between injections (i.e., for 12 hours if insulin is administered twice daily or for 24 hours if insulin is given once daily). When blood glucose concentration is below 125 mg/dL, the concentration should be measured hourly. A normal insulin and feeding schedule *must* be maintained as much as possible. If a patient does not eat the normal amount of the normal food at the usual time, the serial glucose curve should probably not be performed. The patient should be fed its standard diet at the usual time and the insulin given by the owner at home or, if possible, in the hospital so a veterinarian or veterinary technician can assess the owner's injection technique. Obtaining a fasting blood sample for measurement of blood glucose concentration before insulin injection can aid in appraisal of glycemic control, but this may not be possible for the morning value if normal feeding time occurs before the hospital opens. Clearly, cooperation between client and veterinarian is necessary to maximize the information obtained with minimal disturbance to routine.

A curve should be performed the first day insulin therapy is initiated or changed. Glucose concentrations may be lower than expected after the first 24 to 48 hours of insulin therapy, especially in cats as stress hyperglycemia resolves.¹⁴⁶ The first curve is done solely to ensure that hypoglycemia does not occur. If hypoglycemia is found, the insulin dose should be decreased 25% and another curve done the following day to check for hypoglycemia. The insulin dose should not be increased based on the first day's curve. A patient requires 5 to 7 days on a dose of insulin to equilibrate and reach maximal effect. Another blood glucose curve should be

performed 7 to 10 days after discharge. Based on assessment of the curve, the insulin dose can be increased or decreased as necessary.

The pattern of insulin effect should be used to determine dose, interval, and feeding schedule. Ideally, glucose concentrations should reach a nadir (i.e., the lowest point) of 80 to 150 mg/dL. The highest glucose concentration should be close to 200 to 250 g/dL in dogs or 300 mg/dL in cats. The actual nadir and peak concentrations in a patient will probably be lower or higher, respectively, than measured because the exact timing of nadir and peak effects of insulin are not known and can change day to day; therefore blood glucose concentration is not often measured exactly at those times. Changes in insulin dose can usually be made without affecting true (as compared to apparent) duration of effect. The glucose differential is the difference between the nadir and the blood glucose concentration before the next dose and can be a measure of insulin effectiveness.¹⁴⁷ If the curve is relatively flat (e.g., differential of 50 to 100 mg/dL), the insulin may not be having a desired effect. However, the glucose differential should be interpreted in conjunction with the absolute blood glucose concentrations obtained from the curve. If all blood glucose concentrations are less than 200 mg/dL, then the insulin is very effective. However, if all blood glucose concentrations are between 350 and 400 mg/dL, then the insulin is ineffective or stress hyperglycemia is present.

When assessing a glucose curve, whether it is the first curve performed on a patient or the last of many, the clinician should ask three basic questions. First, has the insulin succeeded in lowering the blood glucose? Second, if the insulin has lowered the blood glucose, what was the lowest blood glucose value? Third, how long has the insulin lasted? By answering these questions, logical changes in dosing regimen can be made if necessary. Results of a serial glucose curve should always be interpreted in light of clinical signs. Curves vary from day to day in dogs¹⁴⁸ and cats.¹⁴⁹ Stress hyperglycemia can falsely elevate results, and a patient's refusal to eat while hospitalized can falsely decrease results.¹⁵⁰ If a patient is not polyphagic or polydipsic and polyuric and body weight is stable or increasing, diabetic control is likely good.

The first aim in regulating a diabetic is to achieve an acceptable nadir, with blood glucose concentrations ideally falling between 80 and 150 mg/dL. In general, if an acceptable nadir is not achieved, the insulin dosage should be adjusted depending on the size of the animal and the degree of hypoglycemia or hyperglycemia. Usually, changes of approximately 10% are appropriate. Hypoglycemia should always be avoided. No matter what other blood glucose concentrations are during the day, if the nadir blood glucose concentration is below 80 mg/dL, decrease the dose by 25%. Blood glucose concentrations should be reevaluated 7 to 10 days after an insulin dose adjustment is made if hyperglycemia was the issue. If a dose is lowered because of the presence of hypoglycemia, a curve should be performed the next day to ensure that hypoglycemia does not recur.

Once an acceptable nadir exists, duration of action can be determined by a blood glucose curve. Duration of action is the time from the insulin injection through the lowest glucose concentration until the blood glucose concentration exceeds 200 to 250 mg/dL. If the insulin dose is inadequate and the target glucose nadir has not yet been achieved, the dose must be increased until the nadir is acceptable before duration of effect of the insulin can be determined.

If insulin with too short a duration of activity is used, obtainment of an acceptable glucose nadir may not be possible. In these patients, blood glucose concentration is typically quite high in the morning because control has been inadequate for most of the previous day. A blood glucose curve in this situation shows a noticeable but brief decrease in serum glucose concentration after the insulin injection. Increasing dosing frequency from once to twice a day or changing to a longer-lasting insulin type is indicated.

Based on duration of action, the following general recommendations can be made. If the duration is 22 to 24 hours, once-daily therapy is adequate. If the duration is 16 to 20 hours, a shorter-acting insulin should be used twice daily. If the duration is 13 to 16 hours, twice-daily insulin therapy can be tried, but the evening dose should be lower than the morning dose. If the duration is 10 to 12 hours, the patient should receive insulin twice daily. If the duration appears to be less than 8 hours, a blood glucose nadir higher than 80 mg/dL must be ensured. If blood glucose drops below 60 mg/dL at any time, the Somogyi phenomenon can occur. The Somogyi phenomenon or overswing, also called hypoglycemia-induced hypergly*cemia*, refers to a period of hypoglycemia followed by marked hyperglycemia. The phenomenon results from a normal physiologic response when blood glucose concentrations decline to less than 60 mg/dL in response to an insulin dose that is too high or when blood glucose concentration decreases rapidly regardless of the nadir.95 In either case a number of reflexes are triggered that act to increase blood glucose. Counterregulatory hormones such as epinephrine, cortisol, glucagon, and growth hormone (GH) are secreted. The net effect of these hormones is to increase hepatic glycogenolysis and gluconeogenesis and to decrease peripheral tissue glucose utilization. Hyperglycemia usually occurs rapidly, thus preventing a hypoglycemic seizure. Insulin secretion does not occur in response to the rise in glucose, however, as would occur in normal dogs and cats, and diabetics become extremely hyperglycemic (400 to 800 mg/dL). If the Somogyi phenomenon is observed, the insulin dosage should be decreased so the nadir is above 80 mg/dL; counterregulatory hormones will no longer interfere with the action of the exogenous insulin, and the true duration of effect will become apparent. If the duration of insulin action is truly less than 8 hours, adequate therapy with that type of insulin requires injections more frequently than twice daily, which is impractical for most owners. A switch between different types of intermediate-acting insulin can also be beneficial. For example, a dog or cat may metabolize NPH insulin quickly, resulting in too short an effect, but lente insulin may have a longer duration.

Once control has been achieved, blood glucose curves should be performed every 3 to 6 months to assess adequacy of glycemic control or earlier if clinical signs suggest that control has been lost. The more precarious the control, the more frequently rechecks should be done. As during the initial curves, if the nadir is unacceptable, the insulin dose must be lowered or raised accordingly. If duration of action appears to have changed, then the same modifications as previously discussed can be made.

If using glargine insulin in cats, interpretation of blood glucose curves and dose adjustment is different than for other insulin types. For the first 3 days, 12-hour blood glucose curves should be performed (i.e., the curve should be performed for the interval between the morning and evening dose). The purpose of the blood glucose curve is to detect hypoglycemia, if present, and lower the glargine dose as needed. Many cats require dose reduction within the first 3 days. It is important to note that the insulin dose should not be increased regardless of the appearance of the curves. After the first 3 days, the cat should be sent home and then return for a curve 7 days later. Subsequent blood glucose curves should be performed at 1, 2, and 4 weeks and then as required.

Recommendations for dose adjustments are based on the pre-insulin blood glucose concentration, compared with other insulins for which dose is altered on the basis of the nadir. If at recheck the pre-insulin blood glucose concentration is higher than 290 mg/dL, the glargine dose should be increased by 1 U per cat. The dose should not be changed if the pre-insulin blood glucose concentration is 220 to 290 mg/dL. In either of these first two scenarios, a curve should be done to ensure that hypoglycemia does not occur. The dose should be decreased 0.5 to 1 U/cat if the pre-insulin blood glucose concentration is 80 to 180 mg/dL. If biochemical hypoglycemia is present (i.e., blood glucose concentration is below 80 mg/dL but no clinical signs of hypoglycemia are present), the dose should be decreased by 1 U per cat. If clinical signs of hypoglycemia are present, the glargine dose should be decreased 50%. Administration of glargine should not be discontinued within 2 weeks of starting treatment even if euglycemia is present; the clinician should decrease the dose if needed but should not stop the insulin.151

To determine if a cat is in remission, insulin administration should be continued until the cat is receiving 1 U twice daily. Then, if the pre-insulin blood glucose concentration is below 180 mg/dL, once-daily administration is appropriate. If the next day the pre-insulin blood glucose concentration is still below 180 mg/dL, the clinician should not administer insulin and should do a complete curve. If the pre-insulin blood glucose concentration is above 180 mg/dL when the cat is receiving once-daily insulin, the clinician can go back to twice-daily administration. An attempt to wean the cat can again be made in a couple weeks. Diabetic cats in remission should stay on a low-carbohydrate diet.

If performance of a curve is impossible because of the cat's temperament or the owner's financial constraints, the clinician may start glargine at 0.25 U/kg (with a maximum dose of 2 U/cat) subcutaneously twice daily and have the owner monitor urine glucose concentration or water intake. A cat well regulated on glargine should have trace urine glucose at most, and urine glucose should be negative most of the time. If after

2 weeks of receiving glargine, urine glucose is greater than trace, the dose should be increased 1 U per cat weekly until urine glucose is negative or water intake is below 20 mL/kg in a 24-hour period if the cat is eating canned food and below 60 mL/kg in a 24-hour period if the cat is eating dry food. At this point, the cat should be kept on the same dose for 2 weeks, and then the clinician can start decreasing the dose by 1 U per cat weekly until urine glucose is positive or the insulin has been discontinued.¹⁵²

Performance of blood glucose curves has become controversial, insofar as they are certainly not perfect. Blood glucose curves can be affected by the stress of hospitalization, especially in cats, and deviation from normal routine, and they vary day to day. In one study, glucose curves were performed in diabetic dogs on 2 consecutive days, with all conditions being identical on both days (e.g., type and dose of insulin, amount and type of diet). Parameters such as minimum, maximum, and mean blood glucose concentration; fasting blood glucose concentration before the morning or evening injection (all dogs were treated twice daily); and time from insulin injection to nadir were significantly different between the two curves. In some dogs, the curve showed better control on day 1, whereas others showed better control on day 2. To examine the clinical implications of day-to-day variability of the curves, a theoretical recommendation for adjustment of the dog's insulin dose was based on the results of each curve. The researchers assessed 30 sets of paired 12-hour curves. Opposite theoretical recommendations for adjustment of a dog's insulin dose were made on day 2 compared with day 1 in 27% of occasions. For 17% of the curves, a different but not opposite recommendation resulted. The same dosage adjustment recommendation was made on both days in 57%. Given this variation, predicting the timing of a diabetic's nadir based on previous serial blood glucose curves and obtaining a single sample at that time is unlikely to give a reliable result-in other words, spot-checking does not provide helpful information.148

To avoid some of the problems associated with in-hospital curves, performance of glucose curves at home has taken on new importance. For glucose curves it is not necessary for venous blood to be collected. Capillary blood is suitable,¹⁵³ with the ear being the best site for blood collection. Two types of lancing device are available. If conventional automatic devices designed for pricking human fingertips are used, a device with a variable needle depth should be chosen and the appropriate depth for each patient used.154 Warming of the ear with a hair dryer or a warm, wet washcloth inside a plastic bag may be necessary but not well tolerated, and it may take up to 2 minutes to obtain an adequate sample depending on the size of the drop required.¹⁵⁴ A device that creates a vacuum after the skin is lanced (e.g., Microlet Vaculance, Bayer) does not require warming of the ear and generates an adequate drop of blood within approximately 30 seconds,¹⁵⁴ but mastery may be a bit difficult and require repeated instruction.¹⁵⁵ Glucometers that require minimal amounts of blood as well as those that "sip" the blood into the strip are desirable. Studies support that owners are both willing and able to generate home serial glucose curves, although some owners may require additional demonstrations.¹⁵⁶⁻¹⁵⁸

Unfortunately, home-generated curves have not eliminated all the problems associated with serial glucose curves, because variability remains a problem. Interestingly, a study of diabetic cats compared four serial blood glucose curves generated at home and in the clinic.¹⁵⁸ Owners obtained a 12-hour glucose curve once monthly for 4 months. Within a week of obtaining the at-home curve, the cats were brought to the clinic, where the curve was repeated. The mean glucose concentrations tended to be lower in the clinic than at home. The mean glucose concentrations for each of the four clinic curves compared with the home-generated curves were 336 mg/dL versus 363 mg/dL, 316 mg/dL versus 381 mg/dL, 235 mg/dL versus 307 mg/dL, and 235 mg/dL versus 345 mg/dL. One explanation put forth for these findings was that the cats commonly refused to eat while in clinic. Theoretical treatment recommendations based on nadir glucose concentrations of the home-generated and in-clinic curves were compared, and decisions differed in 38% (14 of 37). In three of these instances, treatment decisions would have been completely contrary.¹⁵⁸ Additionally, day-to-day variability in curves persists, even if home-generated. In seven diabetic cats, paired glucose curves were generated on 2 consecutive days at home or in the clinic. Considerable day-to-day variability existed in both, with no greater agreement between home curves and clinic curves.¹⁵⁶ These findings augment the recommendation that changes in insulin dose be made on the basis of biochemical indicators of glycemic control (e.g., glucose concentration, fructosamine) as well as clinical support of glycemic control (e.g., weight gain, absence of polyuria or polydipsia).

Continuous monitoring of glucose concentrations has also received attention of late.^{149,159,160} The CGMS (Continuous Glucose Monitoring System, MiniMed) is a device that can be strapped onto a patient and a small needle inserted into the subcutaneous tissue. Interstitial glucose concentrations are sampled every 5 minutes for up to 72 hours. Using such a device gives many more data points for evaluation and avoids the stress of multiple venipunctures or catheterization. Furthermore, a patient could wear the device at home if necessary.

The device has been assessed in normal and diabetic dogs and cats. Interstitial and blood glucose concentrations were highly correlated overall.149,159,160 However, postprandial increases in blood glucose concentration may not be detected in the interstitial fluid.¹⁶⁰ Accuracy varied between patients, and the difference between blood and interstitial glucose concentrations was more marked in some patients than others. The greatest discrepancies occurred at higher glucose concentrations.¹⁶⁰ The working range of the CGMS is approximately 40 to 400 mg/dL-that is, blood glucose concentrations outside the range cannot be measured. In fact, if the device repeatedly detects values outside the range, it is interpreted as a machine error and the device shuts off. No irritation resulted from sensor placement.^{149,159,160} Preliminary results suggest that the CGMS is useful for clinical management of insulin therapy.

Measurement of urine glucose concentration at home can aid in monitoring. First, urine glucose levels can be determined as needed to aid in assessment of glycemic control, especially when other data are conflicting. Consistently negative readings on urine glucose may indicate that insulin dosages are either adequate or excessive. A serial glucose curve will differentiate between adequate insulin therapy and use of excessive doses that could result in hypoglycemia. Uniformly high urine glucose readings coupled with unresolved clinical signs indicate that the insulin dose may be inappropriate. Negative urine glucose concentrations in the afternoon, followed by high urine glucose readings the following morning, may be indicative of the Somogyi phenomenon; however, documentation of the Somogyi phenomenon requires performance of a glucose curve. Second, urine glucose concentrations can be determined regularly (at least weekly) to help in the assessment of ongoing control. Changes in urine glucose levels may alert the owner and clinician to loss of glycemic control and the need for reevaluation. If a cat's urine cannot be collected, use of Glucotest (Purina), a product that is sprinkled in a litter box and changes color to reflect the urinary glucose concentration, may help.161

Monitoring of GHb or fructosamine may be helpful. Measurement of glycated proteins alone is probably not adequate for assessment of overall control, but looking at trends can be illuminating. Concentration of either glycated protein should be measured when a diabetic is first diagnosed, and then reassessed with every recheck examination. In general, if the concentration is increasing, control is deteriorating, and if the concentration is decreasing, control is improving. A study of healthy cats infused with intravenous glucose to maintain moderate or marked hyperglycemia (mean glucose 306 mg/dL and 522 mg/dL, respectively) found considerable overlap in fructosamine concentrations between the two groups.¹⁰⁵ Although elevated in the cats with marked hyperglycemia, fructosamine concentrations only intermittently exceeded the reference range in cats with moderate hyperglycemia.¹⁰⁵ Finally, to attribute a change in fructosamine concentration over time to altered glycemic control in the patient and not just inherent variability in the test, a critical difference of more than 33 µmol/L was identified.¹⁰⁵ Thus trends of sufficient magnitude in fructosamine concentrations of individual patients may be the best use of this tool to monitor glycemic control in diabetic patients.

Lastly, home monitoring of clinical signs has been advocated as a useful adjuvant tool in assessing glycemic control. (It should be emphasized, however, that home monitoring of clinical signs alone is not an appropriate means of monitoring a diabetic animal but should be one of several monitoring modalities employed. This is discussed later in this chapter.) One study evaluated the usefulness of a variety of different clinical and biochemical measurements in 23 cats treated with lente insulin.¹⁶² The investigators compared subjective clinical control and water intake to biochemical markers of glycemic control (i.e., serial blood glucose, fructosamine, beta-hydroxybutyrate, cholesterol, triglycerides, glycerol, and urine glucose concentrations). No single measurement best correlated with the level of clinical control identified. The amount of water drunk over 24 hours, maximum blood glucose concentration, mean blood glucose concentration, and urine glucose were the most useful practical indicators of clinical control. Owners were often happy with the level of control in their cats despite not having laboratory evidence of tight glycemic control, emphasizing the importance that the longterm aim of treatment in diabetic cats is to control the clinical signs associated with hyperglycemia.

In one study of 53 dogs, control was judged to be good or poor based on clinical signs, physical examination findings, and body weight. Then, clinical determination of good or poor control was compared with fasting blood glucose, serial glucose curve, and serum fructosamine and GHb concentrations. Although all parameters of glucose control were significantly lower in dogs with good control, considerable overlap existed between the two groups for all. All blood glucose measurements and fructosamine and GHb concentrations were consistent with good glycemic control in 60% of dogs judged to have good clinical control or with poor control in only 39% of dogs judged to have poor clinical control. The initial fasting blood glucose was 100 to 300 mg/dL in 80% of dogs with good clinical control and in 21% of dogs with poor clinical control.¹⁶³

Although the importance of home monitoring of clinical signs cannot be overemphasized, these authors believe that glucose curves should be performed periodically in all diabetic patients (for aggressive animals or those who experience stress hyperglycemia in the hospital, the curves are most appropriately performed at home, if possible). If diabetic control appears inadequate based on clinical signs, the only way to know how to adjust the dose is by performing a curve. Furthermore, hypoglycemia can be clinically nondetectable until a crisis is reached (e.g., the patient begins to have seizures). Performance of curves can demonstrate occurrence of hypoglycemia, and the insulin dose can be changed before clinical signs occur.

Complications of Insulin Therapy

Periods of hyperglycemia in otherwise well-controlled diabetics are difficult to avoid. Evaluation is indicated if hyperglycemia is present most of the time or clinical signs exist. Owner compliance regarding storage, mixing, and administration of insulin should be re-examined first in such a scenario, as well as patient management (e.g., diet, exercise). After these causes of poor control have been eliminated, a glucose curve should be performed to identify causes of poor control such as the Somogyi phenomenon (discussed previously), short duration of insulin action, or insulin resistance.

Interestingly, not every hypoglycemic event triggers the Somogyi phenomenon. The precise reason is not known, but it may have to do with how quickly the blood glucose concentration drops; the Somogyi phenomenon may be more likely to occur with a more rapid decline. Cats, in general, may be less likely to have a Somogyi phenomenon than dogs. In a recent study that evaluated intensive blood glucose control using glargine in 55 diabetic cats,¹⁶⁴ asymptomatic hypoglycemia (blood glucose concentration <50 mg/dL) was measured in most (93%) cats at least once. However, symptomatic hypoglycemia was rare, with only a single event in one cat that had mild signs of restlessness.¹⁶⁴ Despite the high number of hypoglycemic periods, only four single documented Somogyi events occurred in four cats.¹⁶⁵

The Somogyi phenomenon can occur in dogs or cats receiving any insulin dose, but it should be particularly considered as a possibility in patients receiving more than 2.2 U/kg of insulin per dose in the face of persistent glycosuria (>1 g/dL) and clinical signs indicative of poor control (i.e., polyuria, polydipsia, and polyphagia). In addition, it may occur particularly when insulin dose adjustments are made based on early-morning urine glucose concentrations. Diagnosis of the phenomenon is based on documenting nadir and peak glucose concentrations of below 65 mg/dL and above 300 mg/dL, respectively, within a single dosing interval or a rapid decrease in blood glucose concentration followed by a rapid rise and a marked hyperglycemia, regardless of whether hypoglycemia occurred. Because the timing of the blood glucose nadir varies day to day,¹⁴⁸ the presence of the Somogyi phenomenon cannot be documented by measuring blood glucose concentration at a single time point.

Documenting the presence of the Somogyi phenomenon can be challenging. The hormones secreted (e.g., GH, cortisol) may induce insulin resistance that lasts for as long as 72 hours after a hypoglycemic episode. Depending on when a glucose curve is performed, the overswing may be seen; alternatively, if a curve is done on the day after the overswing, only consistently high blood glucose concentrations may be measured. If the presence of glucosuria is monitored, it may be absent or quite elevated, depending on when a sample is collected.

If a Somogyi overswing is present, the daily insulin dose should be decreased by at least 25% and by 50% if clinical signs of hypoglycemia are noted. A glucose curve should be performed immediately after the reduced insulin dose is administered to ensure that hypoglycemia is no longer occurring. Once hypoglycemia has been eliminated, another curve should be performed in approximately 5 to 7 days and the dose adjusted further if necessary. If the cause of the overswing is rapid lowering of blood glucose concentration and not hypoglycemia, a change in insulin type is required.

Rapid metabolism of insulin can result in a clinical situation that looks similar to the Somogyi overswing. With rapid insulin metabolism, the patient may become markedly hyperglycemic before the next insulin dose, but the hyperglycemia is not preceded by hypoglycemia or a rapid decline in blood glucose concentration, as with the Somogyi phenomenon. Morning urine glucose concentrations will be high, and clinical signs of DM generally persist. Increasing the insulin dose will only cause a lower nadir, not prolong duration of action, and hypoglycemia may result. The syndrome can be diagnosed only through construction of a curve. Treatment involves changing to a longer-acting insulin or increasing injection frequency. The vast majority of diabetic dogs require twice-daily insulin therapy for adequate control.¹³⁶ Evaluation of glycemic control should be done approximately 5 to 7 days after initiating a new insulin dose, and further dose adjustments made as needed.

Hypoglycemia. Hypoglycemia is the most common complication of insulin therapy in dogs and cats. Insulin overdose, failure to eat, presence of vomiting, and increased exercise raise the risk of hypoglycemia. Humans can suffer from hypoglycemic unawareness, a condition associated with poorly controlled DM, in which mild hypoglycemia is not sensed and clinical signs of hypoglycemia do not develop until the blood glucose concentration is quite low. Although not documented, the same may occur in dogs and cats.

Clinical signs of hypoglycemia are neurologic, and tissues with the highest metabolic activity are impaired first. Cortical signs include disorientation, weakness, and hunger followed by lethargy and ataxia. Seizures and coma ensue if hypoglycemia persists. Blindness may be a permanent sequela. Death can occur as a result of central respiratory and cardiac depression.

In a retrospective study, the most common clinical signs of hypoglycemia in diabetic dogs were seizures, ataxia, and weakness, occurring at a median of 3 months after initiation of insulin therapy; in cats seizures, recumbency, anorexia, shaking, vomiting, ataxia, and dullness occurred after a median duration of 8 months of therapy. Other clinical signs noted in dogs were anorexia, diarrhea, restlessness, pacing, blindness, and coma; in cats amaurosis, vocalization, circling, lethargy, weakness, diarrhea, urination, stupor, and coma were noted. Obese cats were considered at greater risk for overdosage.¹⁶⁶

The development of hypoglycemia in a previously wellcontrolled animal suggests that a change has occurred either exogenously (e.g., use of an incorrect syringe, overly concentrated insulin because of improper mixing) or endogenously (e.g., DM was transient, patient is vomiting or anorectic, patient has developed maldigestion or malabsorption). Overlap of action of injections should also be considered (i.e., one injection is given when blood glucose concentration is still low from the previous injection).

Treatment of hypoglycemia varies according to the severity of signs. Mild hypoglycemia can be treated by feeding a normal meal; moderate signs may require treatment with sugar or syrup (e.g., Karo syrup) being fed to the animal or rubbed on the buccal membranes. Convulsions require intravenous administration of 50% dextrose. A slow intravenous bolus of 50% dextrose (0.5 g/kg diluted 1:4) should be administered, followed by a continuous-rate infusion of 5% dextrose until the patient can be fed. A single dose of dextrose may not be adequate. Dextrose doses from 0.25 to 19.2 g/kg and 0.2 to 6.3 g/kg were required in dogs and cats, respectively, to attain euglycemia after an insulin overdose, and continuaton of a dextrose drip may be necessary for up to 4 days to maintain normal blood glucose concentrations.¹⁶⁶ Insulin therapy should be discontinued until hyperglycemia is documented. Once the animal is sufficiently conscious, food can be offered.

Insulin resistance. Insulin resistance should be suspected in any pet in which marked hyperglycemia persists throughout the day despite insulin doses of more than 1.5 U/kg per injection or when large doses of insulin (i.e. >2.2 U/kg per injection) are needed to maintain adequate glycemic control. However, use of these doses does not mean that insulin resistance is present. The problem could lie with owner technique of insulin administration, patient management (e.g., exercise, diet), or insulin choice. Lack of response to high doses of one insulin type does not mean all insulins will be ineffective; for example, 20% of cats did not respond to high doses of ultralente insulin but could be effectively managed by twice-daily lente.¹⁶⁷ In addition, longer-acting insulin (PZI) will be more slowly absorbed and less bioavailable than shorter-acting insulin; thus slightly more than 2.2 U/kg of long-acting insulin may be required.

Before a thorough and costly workup for insulin resistance is initiated, factors that mimic insulin resistance should be ruled out. The owner's technique and insulin handling should always be evaluated first. Possible causes for an unsatisfactory response to insulin include inadequate mixing of insulin before withdrawal into the syringe; use of the incorrect syringe (e.g., using a U100 syringe with U40 insulin); misunderstanding of how to read the insulin syringe; problems with insulin injection technique; inactivation of insulin as a result of improper handling; and, if diluted insulin is being used, improper dilution. A bottle of insulin should be discarded after 2 to 3 months of use because activity may begin to decrease. If owner issues are suspected, a glucose curve should be performed after the owner administers insulin using a new, undiluted bottle and while being observed. Second, the owner should be questioned to ensure consistent and appropriate diet and exercise. If hyperglycemia is believed to be due to a postprandial surge from feeding a meal when the insulin's effects are waning, timing of meals should be adjusted. Alternatively, addition of an oral hypoglycemic agent such as acarbose can be considered. Third, if no response is seen to one type of insulin, then another should be tried to see if it might be effective. Fourth, absorption of insulin can vary among subcutaneous sites, so another injection site should be used; the lateral thorax or abdomen is recommended. Lastly, a glucose curve should be performed to eliminate other possible mimics of insulin resistance, such as the Somogyi phenomenon and inadequate duration of insulin action.

Once true insulin resistance has been documented, the following differential diagnoses should be considered.

Insulin antibodies are a commonly discussed cause of insulin resistance. The clinical significance of anti-insulin antibodies (AIAs) remains unclear at this time. Although antibodies may form against exogenous insulin, associated clinical insulin resistance appears rare. AIAs were measured in diabetic subjects after starting therapy with porcine lente insulin (n=100), bovine lente insulin (n=100), or bovine protamine zinc insulin (n=20); 12%, 56%, and 90%, respectively, developed AIA. No association was detected between AIA concentration and insulin dose or fructosamine concentrations.¹³⁵ If AIAs are believed to be a cause of resistance, a commercial assay for measurement of AIAs now exists. Alternatively, in pursuing this diagnosis for insulin resistance, use of a

radioimmunoassay (RIA) for insulin may be helpful.¹⁶⁸ Circulating AIAs can interfere with measurement of serum insulin by RIA, causing spuriously high insulin concentrations, and the artifact can provide evidence of antibody presence. Typically, 24 hours after the last insulin injection in a diabetic pet, serum insulin concentration should be less than 50 μ U/mL. In comparison, apparent serum insulin concentration is above 400 μ U/mL if AIAs are present.¹⁶⁸ If AIAs are believed to be causing insulin resistance, the insulin source should be switched to a different one. Glycemic control should improve within 2 weeks of changing the species of insulin if insulin-binding antibodies are causing resistance.¹⁶⁸

Infection, ketoacidosis, and concurrent illness can cause insulin resistance. The urinary tract and oral cavities are common sites of infection; a urinalysis and urine culture, regardless of urinalysis finding,¹⁶⁹ and complete oral examination should always be performed. Renal disease, hepatic insufficiency, cardiac insufficiency, pancreatitis, and starvation should be considered as possible causes of insulin resistance. Malnutrition can lead to insulin resistance and diminished insulin secretion. Obesity has been linked to glucose intolerance and abnormal insulin secretion in cats and dogs, but its role in creating insulin resistance is unclear insofar as obese diabetic pets generally remain insulin responsive. Hyperthyroidism, hypothyroidism, and hyperadrenocorticism can cause insulin resistance through diverse mechanisms.

Based on data from several recent studies, acromegaly may be a more common cause of insulin resistance in cats than previously recognized, and several reliable methods exist by which a diagnosis may be obtained, especially when the tests are used together. Computed tomography (CT) has proved useful in demonstrating the presence of a mass lesion in the region of the pituitary gland in insulin-resistant diabetic cats suspected of having acromegaly or hyperadrenocorticism, with a mass visualized on CT in all 16 such cats in one study.¹⁷⁰ In another study designed to screen diabetic cats for the presence of acromegaly, serum IGF-1 concentrations were measured in 184 variably controlled diabetic cats. Of the 184 cats screened, 59 had increased serum insulin-like growth factor I (IGF-I) concentrations-that is, greater than 1000ng/mL (reference range 208-443 ng/ mL). Eighteen of the 59 cats underwent further examination, including intracranial CT, contrast-enhanced CT, or magnetic resonance imaging (MRI), and acromegaly was confirmed in 17. Contrast-enhanced CT allowed detection of most, but not all, pituitary masses, and one cat with a postmortem examination diagnosis of acromegaly did not have a visible mass on CT or MRI.¹⁷¹ In another recent study, diabetic cats were screened for concurrent acromegaly by measuring plasma GH and IGF-1 concentrations and examining the pituitary fossa using MRI.¹⁷² Of the 16 cats in the study, six required an insulin dosage at or above 1.5 U/kg per injection and had an enlarged pituitary gland on MRI; one cat receiving less than 1.5 U/kg of insulin per injection had an enlarged pituitary gland. Five of the six cats were diagnosed with acromegaly based on the enlarged pituitary gland on MRI and elevated plasma GH concentrations. Finally, a study evaluating the usefulness of IGF-I concentrations as a screening test for the diagnosis of acromegaly in diabetic cats found that 25.6% (19 of 74) of all diabetic cats and 47.5% (19 of 40) of poorly controlled diabetics had acromegaly.¹⁷³ Currently, no one test appears to be completely effective in diagnosing feline acromegaly, but a combination of serum IGF-1 concentrations, feline GH concentrations where available, and contrast-enhanced CT or MRI are options (see also the section on GH later in this chapter).

Certain drugs can cause insulin resistance, most notably progestogens and glucocorticoids. Although cats are resistant to development of many of the common adverse effects of glucocorticoids, such as polyuria and polydipsia, they may develop glucocorticoid-associated glucose intolerance readily. If possible, use of these medications should be slowly discontinued in diabetic patients. Otherwise, the patients may need to be treated as insulin-resistant. Neoplasia has been associated with insulin resistance in 5% to 10% of diabetic cats and dogs.⁹⁵ Hyperlipidemia should be considered as a possible cause of insulin resistance.

When a cause for insulin resistance is sought, the easiest causes to rule out and the most likely should be eliminated first, proceeding through to the least likely. The following order, in general, has been recommended in cats: concurrent drugs, obesity, concurrent disease (including infection and ketoacidosis), hyperthyroidism, acromegaly, hyperadreno-corticism, and insulin antibodies. The order to use in dogs, in general, is as follows: concurrent drugs, diestrus/acromegaly, obesity, concurrent disease (including infection and ketoacidosis), hyperadrenocorticism, hypothyroidism, hyperlipid-emia, and insulin antibodies.¹⁷⁴ This order is not absolute. If strong evidence exists for a differential diagnosis lower in the order, that possibility should be ruled out first.

Management of insulin resistance requires correcting the underlying disorder, if possible. For causes such as a simple bacterial infection or concurrent administration of diabetogenic medications, eliminating the underlying problem can be relatively easy; other problems, such as acromegaly, may be more difficult to correct. If insulin antibodies are suspected, the insulin can be switched to a less antigenic form.

If the cause cannot be determined or eliminated, the following guidelines are suggested.¹⁷⁴ (1) Administer insulin at least twice daily. (2) Avoid long-acting insulins, unless regular insulin is added. Intermediate-acting insulins are more effective in overcoming insulin resistance and lowering blood glucose concentrations. (3) Consider using mixtures of shortacting and longer-acting insulins. (4) Administer insulin shortly before or at the time of feeding to help control postprandial hyperglycemia. Large insulin doses may be required, but it will be necessary to determine the actual dosage using serial blood glucose curves, as for any diabetic.

Oral Antidiabetic Agents

Oral antidiabetic agents, including the sulfonylureas (e.g., glipizide), biguanides (e.g., metformin), α -glucosidase inhibitors (e.g., acarbose), and the thiazolidinediones (e.g., dar-glitazone), are commonly used to treat human patients with

NIDDM. Mechanisms of action vary and, with the exception of acarbose, are directed toward the underlying abnormalities of type 2 diabetics (Figure 21-5).

Sulfonylureas stimulate pancreatic beta cells to secrete insulin and have been among the most popular oral antidiabetic agents in human medicine. Extrapancreatic effects include decreased hepatic gluconeogenesis and increased tissue sensitivity to insulin. Hypoglycemia is the main adverse effect of sulfonylureas in humans, although it may be least likely to occur with glipizide.¹⁷⁵

Mechanisms of action of metformin, a biguanide, include decreased hepatic gluconeogenesis (perhaps the primary mechanism) and increased insulin sensitivity by hepatic and peripheral tissues.¹⁷⁵ Metformin appears more effective than glipizide in humans in resolving disorders associated with insulin resistance. Side effects occur in up to 20% of human patients and include diarrhea, abdominal discomfort, nausea, and anorexia. Lactic acidosis is a potentially severe adverse effect of biguanide antidiabetic agents in general but occurs rarely with metformin.¹⁷⁵ Among the oral hypoglycemic drugs, metformin is recommended as initial therapy in obese human diabetic patients because it may ameliorate insulin resistance and is less likely to be associated with weight gain.¹⁷⁵ As with glipizide, the initial dose of metformin in humans is low and is progressively increased on the basis of glucose monitoring. Both glipizide and metformin are given with meals in human diabetics.

The alpha-glucosidase inhibitors such as acarbose are complex oligosaccharides of bacterial origin that competitively inhibit small intestinal enzymes responsible for degradation of complex carbohydrates into absorbable monosaccharides.¹⁷⁵ Some of the antihyperglycemic effects of acarbose may be mediated through its effect on thyroid hormones.¹⁷⁶ When acarbose is ingested, the postprandial glucose concentration surge is delayed and diminished. The drug is not absorbed, so systemic effects are uncommon. Flatulence, soft stools, and diarrhea, however, occur because of the osmotic effect and bacterial fermentation of nondigested carbohydrates. The adverse effects appear to be transient, however, and are minimized in humans by starting therapy at a low dose. Acarbose is used in humans primarily to reduce postprandial glucose fluctuations and to improve glycemic stability when response to traditional oral antidiabetic agents is insufficient.¹⁷⁷

The thiazolidinediones (e.g., rosiglitazone, darglitazone) bind to a novel receptor called the peroxisome proliferatoractivated receptor- γ (PPAR- γ) and enhance insulin action and promote tissue glucose utilization. They are referred to as *insulin sensitizers* because they stimulate nuclear receptors that enhance the expression of proteins involved in glucose and lipid metabolism. Like metformin, troglitazone may target disorders associated with insulin resistance.

Clinical Use

Therapy of any disease is ideally aimed toward the underlying abnormality. In type 1 DM, insulin is lacking, so treatment provides an exogenous source. Type 1 diabetic patients do not have the metabolic abnormalities present in type 2 DM that are addressed by oral hypoglycemic agents (i.e., insulin resistance, dysfunctional β cells, and increased hepatic gluconeogenesis). Consequently, administration of these agents to type 1 diabetics is inappropriate, with the exception of acarbose. For type 2 DM, oral hypoglycemic drugs can be used initially, but as type 2 DM progresses, exogenous insulin injections will be required.

Because knowing the type of DM is helpful when choosing therapy, distinguishing between types 1 and 2 in cats and dogs would be extremely helpful. As dogs are mainly type 1 diabetics, oral hypoglycemics have not been used widely in this species. Cats are believed to be mainly type 2, at least initially. However, patients with advanced type 2 DM and glucose toxicity, a population likely to represent the majority of diabetic cats, will have totally lost insulin secretory ability. Accordingly,

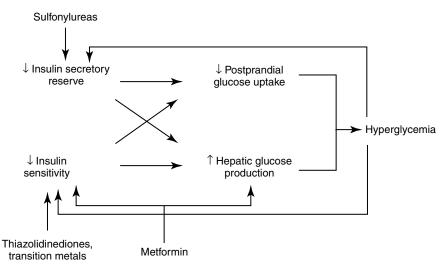

Figure 21-5 Diagram of main metabolic abnormalities underlying type 2 diabetes mellitus and the way they are targeted by the oral hypoglycemic agents. The abnormalities are shown in *red*, along with their accompanying minor abnormalities and consequences. The oral hypoglycemics are noted in *blue*, and the *blue arrows* show which of the main metabolic abnormalities they target.

some diabetic cats will respond to oral hypoglycemic agents, but most will require insulin therapy.

The most studied and used oral hypoglycemic agent in cats is the sulfonylurea glipizide. Because of the mechanism of action, the ability of sulfonylureas to further the progression of DM remains controversial. Beta cells normally co-secrete the hormone amylin with insulin. Amyloid deposits can be found in the pancreatic islets of more than 90% of human patients with type 2 DM and in 65% of diabetic cats, and in diabetic cats the deposits are associated with significant loss of islet beta cells.¹⁷⁸ Amylin is the precursor of the islet amyloid. Although the mechanisms underlying the transformation of amylin into amyloid fibrils are largely unknown, findings in one recent study support the hypothesis that islet amyloidosis results from prolonged beta cell stimulation. In this study, DM was induced in eight healthy domestic cats by a partial pancreatectomy, followed by induction of insulin resistance with corticosteroid and GH treatment. The cats were then treated with either glipizide (n = 4) or insulin (n = 4) for 18 months. All cats were negative for the presence of islet amyloid at the time of pancreatectomy. At the end of the study, all of the glipizide-treated cats and one of the four insulin-treated cats had pancreatic islet amyloid deposits. The glipizide-treated cats had threefold higher basal and fivefold higher glucose-stimulated plasma amylin concentrations than insulin-treated cats, suggesting an association between elevated amylin secretion and islet amyloidosis.¹⁷⁹ Whether this is a positive association between glipizide treatment and development of islet amyloidosis or a negative association between insulin treatment and the development of islet amyloidosis or whether similar events would occur in naturally occurring feline DM remains uncertain.

The long-term success rate with glipizide is estimated to be approximately 35%,^{100,145} but which cats will respond cannot be predicted. The ideal patient for treatment with glipizide is a stable, nonketotic diabetic cat of optimal to obese body weight that has mild clinical signs with no complicating diseases. Patients that are emaciated, dehydrated, or debilitated or that have recently lost 10% or more of their body weight or have concomitant disease are not good candidates. Additionally, glipizide can be tried in any cat whose owners refuse to give injections.

Adverse effects are minimal. Vomiting is most common (approximately 15%).^{99,100} Increased liver enzymes and icterus develop within 4 weeks of initiating therapy in approximately 10%. Hypoglycemia occurs in approximately 12% to 15% of responder cats; usually these cats are transient diabetics. Most cats that respond without continued adverse effects can be treated with glipizide for life, but glipizide loses effectiveness in at least 5% to 10%. The period from initiation of therapy until failure is unpredictable, ranging from weeks to more than 3 years.¹²¹

Glipizide therapy should be instituted at a dosage of 2.5 mg/cat orally twice daily with food, and the cat should be examined after 1 and 2 weeks. A history, complete physical examination, body weight, blood glucose concentration, and urine glucose and ketones test should be evaluated. If no

problems occurred during the first 2 weeks, the dosage should be increased to 5 mg/cat twice daily. If ketonuria is found, the medication should be discontinued and insulin therapy initiated. If vomiting or icterus is present, the drug should be discontinued until the problem resolves. Most cats will tolerate the medication if started at a lower dosage and gradually increased. If hepatic enzyme elevation or icterus occurred, liver enzymes and serum bilirubin concentration should be checked periodically after reinitiation. If problems recur, drug administration should be stopped and the cat placed on insulin.

Once a dosage of 5 mg twice daily has been given for 2 weeks, the previously mentioned parameters and a 10- to 12-hour glucose curve should be checked every 4 weeks.¹²¹ Response to therapy is demonstrated by resolution of clinical signs, blood glucose concentrations during the curve at or below 200 to 300 mg/dL, and lack of glycosuria. Time until response varies, so therapy at the full dosage should continue for 12 weeks unless a contraindication develops.¹²¹

If a cat becomes hypoglycemic while on glipizide therapy, discontinue drug administration and reevaluate the cat, potentially with a glucose curve, to assess if continued glipizide therapy is needed. If the cat becomes hyperglycemic after discontinuation of glipizide treatment, restart therapy with a 50% dose reduction and continue to monitor as described above.

If no response is seen after 12 weeks, glipizide administration should be stopped and insulin therapy instituted. If clinical signs and glycosuria resolve and blood glucose concentrations are at or below 200 mg/dL, glipizide therapy should be stopped and the blood glucose concentration reevaluated in 1 week. If hyperglycemia is present then, glipizide should be reinitiated. If euglycemia is present, no medication is warranted. Glipizide can be used again, however, at any time if hyperglycemia recurs. The patient should be rechecked every 3 months to ensure ongoing control.

Cats that have resolution of clinical signs according to the owner, stable body weight, and normal physical examinations but serial blood glucoses at or above 300 mg/dL present a clinical dilemma. Either the clinical signs have not truly resolved or the hyperglycemia is due to stress. Such cats should ideally be monitored by serum glycated protein concentrations and urine glucose concentrations to determine overall glycemic control. If glycosuria is absent and glycated protein concentrations are at a level or downward trend, glipizide therapy can proceed. If glycosuria is present or glycated protein levels are trending upward, insulin should be used instead.

Biguanides. Metformin doses of 25 to 50 mg/cat twice daily should attain plasma concentrations used for treating human DM,^{180,181} but the use of the drug in diabetic cats is not promising.¹⁸⁰ In the single published study evaluating metformin use in diabetic cats, five newly diagnosed cats received metformin at a gradually increasing dosage, and only one achieved glycemic control after 8 weeks of therapy. In one nonresponder, serum alanine aminotransferase activity was within the reference range at the start of the study but had increased to 1440 U/L at week 7; 3 weeks after discontinuation of the medication, serum alanine aminotransferase activity was 95 U/L. One cat was found dead after 2 weeks, and no response was seen

after 7 to 8 weeks in four cats. The responding cat was treated with 10 mg metformin daily for 1 week, then 10 mg twice daily for 2 weeks, followed by 25 mg twice daily for 5 weeks. Subsequently, the dose was increased to 50 mg twice daily, and 3 weeks later the owner reported resolution of clinical signs of DM. Metformin was used successfully for 4 months until pancreatitis developed, at which time therapy was changed to insulin. The serum insulin concentration was within or greater than the reference range in the responder diabetic cat and was undetectable or at the low end of the reference range in the nonresponders, suggesting that metformin may be beneficial only in diabetic cats with detectable serum insulin concentration at the time treatment is initiated. Adverse effects are common and include inappetence, weight loss, and vomiting. The size of pills commercially available is not amenable to cats, and use of this drug for felines requires compounding.¹⁸⁰

Alpha-glucosidase inhibitors. In five dogs, a combination of acarbose and insulin provided better glycemic control over insulin alone. However, the final conclusion was that because of the expense and adverse effects, acarbose is primarily indicated for poorly controlled diabetic dogs in which the cause for the poor control cannot be identified.¹⁸² Acarbose, in conjunction with a low-carbohydrate diet, was an effective means of decreasing exogenous insulin dependence and improving glycemic control in one group of diabetic cats,¹¹⁸ but how much of the dose reduction in insulin was due to the diet and how much to acarbose is unclear. Acarbose may be helpful in cats with renal disease that cannot be placed on a low-carbohydrate diet because of the high protein content of these diets. Acarbose may be administered at a dosage of 25 to 200 mg/ dog or 12.5 to 25 mg/cat twice daily with meals. Side effects include flatulence, semiformed stools, or diarrhea.

Thiazolidinediones. Although recent work suggests that darglitazone has beneficial effects in obese nondiabetic cats to decrease insulin secretion and glucose concentrations in a glucose tolerance test,¹⁸³ no work has been done in diabetic cats.

Transition metals. Transition metals are insulin mimetic. In healthy nonobese cats, dietary chromium supplementation causes a small but statistically significant, dose-dependent improvement in glucose tolerance.¹⁸⁴ The most commonly reported side effects are mild GI upset. Unfortunately, however, large clinical studies on the effect of vanadium or chromium in diabetic cats are lacking. In one study, chromium had no effect in concert with insulin treatment in diabetic dogs.¹⁸⁵

Acute Metabolic Complications

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is a complex catabolic disorder caused by either relative or absolute insulin deficiency. Diabetogenic hormones (e.g., cortisol, progesterone, GH), probably contribute to its development. Thus any disease that increases the secretion of these stress hormones can predispose diabetic patients to the development of ketoacidosis, and insulin therapy may become ineffective.

Glycogen, protein, and fat, rather than glucose, are used by the body for energy in the absence of insulin. Glycogen is broken down into glucose. As a physiologic survival mechanism

during starvation (insulin deficiency is perceived by the body as a state of starvation because glucose is not available for use by most cells), fatty acids formed from fat breakdown are transported into mitochondria and metabolized to ketone bodies to be used as a fuel source. The ketone bodies are acetone, acetoacetate, and β -hydroxybutyrate. The last is formed from acetoacetate and hydrogen ions. A lack of insulin decreases tissue utilization of ketone bodies. As ketones accumulate, the body's buffering systems become overwhelmed, and metabolic acidosis develops. Glucose formation continues unchecked and even accelerates. Glycosuria that accompanies hyperglycemia causes an osmotic diuresis with subsequent depletion of sodium, chloride, and potassium. If an animal is unable to ingest sufficient water to keep up with ongoing losses, dehydration and prerenal azotemia develop. Severe hyperosmolarity may result. Ketoacidosis can cause vomiting and diarrhea, further complicating acid-base and electrolyte disorders. Production of glucose counterregulatory hormones increases in response to the stress of illness, but the hormones antagonize insulin and worsen the hyperglycemia and ketonemia. Patients with DKA usually are ill when they are brought to the veterinarian, and 6% to 12% are dehydrated. Blood glucose concentration is generally greater than 300 mg/dL, and the patient may be severely acidotic (arterial bicarbonate <11 mEq/L).

Hypokalemia, hypophosphatemia, and hypomagnesemia may accompany DKA. Hypokalemia may develop because of decreased food intake or increased renal loss associated with osmotic diuresis. However, acidosis may cause intracellular potassium ions to shift extracellularly, thus masking total body potassium depletion. Rehydration, correction of acidosis, and insulin therapy may further decrease serum potassium concentrations. The risk of hypophosphatemia is similarly increased by diminished intake, urinary losses, fluid therapy, and translocation after insulin therapy. Energy (adenosine triphosphate [ATP]) depletion becomes evident in high-energy use cells such as skeletal muscle, brain, and red blood cells. Hemolytic anemia is the most common and serious sequela to hypophosphatemia but does not usually occur until serum phosphorus concentration is at or below 1 mg/dL.186 Neuromuscular signs include weakness, ataxia, and seizures as well as anorexia and vomiting secondary to intestinal ileus. Lastly, osmotic diuresis may cause hypomagnesemia, and because of acid-base imbalances, magnesium may shift intracellularly. Clinical signs of hypomagnesemia (e.g., lethargy, anorexia, muscle weakness [including dysphagia and dyspnea], muscle fasciculations, seizures, ataxia, and coma) do not usually occur until serum total magnesium concentration is below 1 mg/dL.186

Diagnosis of DKA includes documentation of the presence of DM, ketone bodies, and acidosis. The existence of ketonuria establishes a diagnosis of ketosis; acidosis must be documented to differentiate ketosis from ketoacidosis. Urine test strips and nitroprusside reagents (e.g., Ketostix) do not detect β -hydroxybutyrate, which can be the predominant ketone present in the acidotic state. If ketoacidosis is suspected but a urine dipstick is negative, other means for detecting ketone bodies, such as Acetest tablets (Ames Division, Miles Laboratories, Elkhart, Ind.) should be used, if available. A commercially available hand-held ketone meter (PrecisionXtra, Abbott, Alameda, Calif.) will detect plasma β -hydroxybutyrate and can be used to aid in the diagnosis of DKA in dogs and cats if urine strips are negative for ketone bodies or urine cannot be obtained.¹⁸⁷

Treatment of ill ketoacidotic patients should be aggressive, with the treatment goals being to restore water and electrolyte imbalances, provide sufficient insulin to begin normalization of metabolism, correct acidosis, identify precipitating factors for the DKA, and provide a carbohydrate substrate when required by the insulin treatment.¹⁸⁶ Care should be taken not to return blood glucose concentrations to normal too rapidly, because biochemical and osmotic problems could be created by overly aggressive therapy, as described in human "fragile" DKA patients that experience rapid changes in serum tonicity and develop cerebral edema. Cerebral cells of diabetic patients may accumulate sorbitol, an osmotically active polyol formed in response to excessive blood glucose concentrations. Thus as a hypertonic patient achieves normal tonicity and euglycemia with treatment, water may move into neurons that have become hypertonic relative to extracellular fluid.

The common use of isotonic, sodium-containing fluids may minimize large osmotic shifts by maintaining serum sodium concentrations as glucose concentrations decrease,¹⁸⁸ so development of cerebral edema may be uncommon, at least in diabetic cats. A recent retrospective study evaluated 13 diabetic ketotic cats treated in an intensive care unit and similarly managed with intravenous constant-rate infusions of regular insulin and 0.9% saline. The median change in glucose concentration was 122% (range 1% to 1230%). In cats with abnormal sodium concentrations, the median change in sodium (irrespective of direction) was 5.4% (range 1.3% to 11.6%). The median percentage change in serum tonicity (irrespective of direction) was only 2.9% (range 1.4% to 5.7%). At all time points examined, sodium was the major determinant of serum tonicity, with only minimal contributions from glucose. If sodium levels had not increased during treatment, the total decrease in serum tonicity owing to glucose alone would have been 13%. The minimal fluctuations in serum tonicity likely explain the low incidence of osmotic-mediated neurologic complications seen during treatment of diabetic cats.188 Caution should still be exercised in treatment, especially of hyperglycemic, hyperosmolar, nonketotic diabetic patients. Blood glucose concentrations in hyperglycemic, hyperosmolar diabetics patients may be elevated to the point that they are a major determinant of serum tonicity; alternatively, a diabetic patient not managed with isotonic sodium-containing fluids may be lacking the sodium concentrations needed to buffer the changes in serum tonicity once measures are initiated to reduce the hyperglycemia. In either case, complications from too rapid a decrease in blood glucose concentrations could occur.

The first step in treating DKA should always be to initiate replacement and maintenance fluid therapy to enhance renal blood flow, promote urinary glucose excretion, and decrease the effects of diabetogenic hormones. Sodium chloride (0.9% saline) containing appropriate potassium supplementation is the fluid of choice. Because of the possible risk of cerebral edema formation, rapid fluid administration is indicated only in life-threatening situations. Fluid administration should be directed at gradually replacing hydration deficits over 24 hours while supplying maintenance fluid needs and matching ongoing losses. Once out of the critical phase, fluid replacement should be decreased in an effort to correct fluid imbalances in a slow but steady manner.¹⁸⁶ When serum sodium concentration is 140 to 155 mEq/L, Ringer's solution should be used; if serum sodium concentration increases to more than 155 mEq/L, 0.45% saline should be administered.

Ideally, potassium supplementation should be based on actual measurement of serum potassium concentration. If measurement is not available, 40 mEq potassium should be added to each liter of intravenous fluids.¹⁸⁶ Potassium supplementation should be adjusted every 6 to 8 hours, again ideally based on actual measurements, until the patient is stable and serum electrolytes are within the reference range. Total hourly potassium administration should not exceed 0.5 mEq/kg body weight. If the serum potassium concentration is greater than 5, 4 to 5.5, 3.5 to 4, 3 to 3.5, 2.5 to 3, 2 to 2.5, or less than 2 mEq/L, then no potassium, 20 to 30, 30 to 40, 40 to 50, 50 to 60, 60 to 80, and 80 mEq of potassium should be added to each liter of fluids administered, respectively.¹⁸⁶

Phosphate therapy is indicated if clinical signs of hypophosphatemia or hemolysis are identified or if the serum phosphorus concentration is below 1.5 mg/dL. An intravenous constant-rate infusion of potassium phosphate (the solution contains 4.4 mEq/mL of potassium and 3 mM/mL of phosphate) should be a given at a rate of 0.03 to 0.12 mM phosphate/kg/hour. Administration of potassium must be taken into account when giving potassium phosphate for correction of hypophosphatemia.¹⁸⁹ Serum phosphate concentration must be measured to assess response and adjust the dose. Because adverse effects of phosphate administration include hypocalcemia, serum calcium concentration, preferably ionized calcium concentration, should also be monitored.

Whether magnesium supplementation is required is controversial. Hypomagnesemia is usually not treated unless persistent lethargy, anorexia, weakness, or refractory hypokalemia or hypocalcemia are encountered after 24 to 48 hours of therapy and another cause for the problem cannot be identified.¹⁸⁶ The initial intravenous dose for the first day is 0.75 to 1 mEq/kg administered by constant-rate infusion in 5% dextrose in water. The supplementation can be continued at half the initial dose for an additional 3 to 5 days if necessary. The dose should be decreased 50% to 75% in azotemic animals. Parenteral magnesium therapy can cause hypocalcemia, cardiac arrhythmias, hypotension, and respiratory depression.¹⁸⁶

Bicarbonate therapy in the management of patients with DKA is contentious. Proponents point to potential deleterious effects of acidosis on cardiac hemodynamics, whereas opponents are concerned by possible creation of paradoxical central nervous system acidosis or a shift in the oxygen-hemoglobin dissociation curve resulting in tissue hypoxia. A prospective trial of human DKA patients with moderate to severe acidosis (pH 6.9 to 7.1) found no difference in outcome in patients treated with bicarbonate and those who were not.¹⁹⁰ Clinical presentation in conjunction with acid–base status should be used to determine the need. If plasma bicarbonate concentration is above 12 mEq/L, bicarbonate therapy is not indicated, especially if the patient is alert;¹⁸⁶ correction of dehydration and insulin administration usually eliminates acidosis. When plasma bicarbonate concentration is below 11 Eq/L (total venous $CO_2 < 12 \text{ mEq/L}$), specific therapy should be initiated. The amount of bicarbonate needed to correct acidosis to 12 mEq/L over 6 hours is calculated as

mEq bicarbonate needed = Body weight(kg) \times 0.4 \times (12 - patient's bicarbonate) \times 0.5

The factor 0.4 corrects for the extracellular fluid space in which bicarbonate is distributed (i.e., 40% of body weight). Using the factor 0.5 means that 50% of the full bicarbonate dose is infused, so a conservative dose is given. The bicarbonate should be infused intravenously over 6 hours (never as a bolus), then the serum bicarbonate concentration reassessed and a new dosage calculated and administered, if needed.¹⁸⁶

Recommendations regarding insulin doses and routes vary for ketoacidotic patients, but authors agree that therapy should begin with low doses. Insulin therapy should be delayed at least 1 to 2 hours after the start of intravenous fluid therapy. At that time serum electrolytes should be measured; if hypokalemia is present, insulin therapy can be delayed an additional 1 to 2 hours to allow fluid therapy to replenish potassium.

The goal of insulin therapy is to lower the blood glucose concentration to 200 to 250 mg/dL over 6 to 10 hours. Regular insulin is used because it is short-acting and more easily regulated compared with longer-acting insulins. Blood glucose concentrations should be monitored hourly. The major risks associated with insulin therapy are hypoglycemia, hypokalemia, and hypophosphatemia.

The three techniques used are hourly intramuscular,¹⁹¹ continuous low-dose intravenous infusion,192 and intermittent intramuscular/subcutaneous.¹⁹³ An intermittent intravenous regimen is discouraged because the biologic effects of regular insulin administered intravenously last only 20 minutes. For the hourly intramuscular technique, an initial loading dose of 0.2 U/kg of regular insulin is given, followed by 0.1 U/kg every 1 to 2 hours. Lower doses can be used at first if hypokalemia is a concern. The rear legs are recommended sites for administration. If the blood glucose concentration declines at a rate greater than 75 mg/dL/hr, the dose should be decreased to 0.05 U/kg/hr. If the decrease is less than 50 mg/dL/hr, the dose should be increased to 0.2 U/kg/hr. When the blood glucose concentration is below 300 mg/dL, regular insulin can be given subcutaneously (0.1 to 0.3 U/kg, every 6 to 8 hours) and the dose altered as required. In addition, when blood glucose concentration is 250 to 300 mg/dL, 100 mL of 50% dextrose should be added to each liter of fluid to achieve a 5% dextrose solution. Blood glucose concentration should be maintained between 150 and 300 mg/dL until the patient is stable and eating. When the patient is no longer receiving fluids, is eating and drinking, has stopped vomiting,

and is no longer ketoacidotic, maintenance insulin therapy with longer-acting insulin can be instituted.

For the constant-rate low-dose infusion technique, regular crystalline insulin (2.2 U/kg for dogs and 1.1 U/kg for cats) is added to 250 mL of 0.9% saline and initially administered at 10 mL/hr in a line separate from that used for fluid administration.¹⁹² The first 50 mL of an insulin-electrolyte mixture run through intravenous tubing should be discarded because of adsorption of insulin to glassware and plastic. An intravenous infusion pump should be used to ensure a constant administration rate. The infusion rate can be slowed for 2 to 3 hours if hypokalemia is a concern and should be altered as needed so that blood glucose concentrations decline by approximately 50 mg/dL/hr. Once the blood glucose concentration reaches 250 mg/dL, the fluid should be changed to 0.45% saline with 2.5% dextrose. The insulin infusion can then be discontinued and regular insulin given every 6 to 8 hours, as previously described. Alternatively, the infusion rate can be slowed to maintain blood glucose concentrations between 150 and 300 mg/dL until the patient is stable enough to institute maintenance insulin therapy. If infusion is used, insulin should be added to the new fluid at the same concentration.

For the intermittent, intramuscular/subcutaneous insulin technique, the initial regular insulin dose is 0.25 U/kg intramuscularly every 4 hours. Once the patient is rehydrated, subcutaneous administration is substituted. Dose is adjusted based on serum glucose concentrations. This technique is not recommended, however. Blood glucose concentrations decrease rapidly, and the risk for hypoglycemia is great.

Hyperglycemic, Hyperosmolar, Nonketotic Syndrome

The true incidence of hyperglycemic, hyperosmolar nonketotic syndrome (HHNS) in the canine and feline diabetic pet population is unknown, but the condition is relatively uncommon. In one retrospective study of diabetic cats, HHNS constituted 6.4% of emergency room visits of diabetic cats.¹⁹⁴ However, it is associated with a high mortality rate in both humans with type 2 DM and feline diabetics.^{194,195}

The pathogenesis of HHNS is not fully understood but may be a result of decreased insulin activity rather than a complete absence. Insulin deficiency causes excess glucagon secretion and decreased glucose use by peripheral tissues. As with DKA, decreased glucose utilization causes muscle and fat breakdown, thus supplying precursors needed for hepatic gluconeogenesis. Insulin deficiency in combination with excess glucagon promotes hepatic gluconeogenesis, and profound hyperglycemia develops. The insulin activity present prevents ketone bodies from forming.

Why some animals develop DKA and others HHNS is unclear. In both disorders patients commonly have concurrent diseases, so insulin resistance is likely to be important in both.¹⁹⁴ Interestingly, certain types of diseases may be more common in HHNS compared with DKA. In one study of cats with HHNS or DKA, overall presence of concurrent disease did not differ between the two groups but presence of specific diseases did. Chronic renal disease occurred in 58.8% of cats with HHNS but only 12.5% of those with DKA, and congestive heart failure was present in 29.4% of the HHNS cats but only 3% of cats with DKA.¹⁹⁴ Thus the presence of certain diseases may predispose one syndrome to develop over another, but this remains to be proven.

The diagnostic criteria for HHNS in veterinary medicine are the presence of severe hyperglycemia (>600 mg/dL) and serum hyperosmolarity (>350 mOsm/L). Severe dehydration causes hyperosmolarity, which leads to the central nervous system abnormalities such as dullness, circling, pacing, or unresponsiveness common with this disorder. Ketones are usually not present, but lactic acidosis often is.¹⁹⁴ The therapeutic goal is to correct the extreme volume depletion and hyperosmolarity. Despite the hyperosmolarity, the initial fluid of choice is isotonic (0.9%) saline.¹⁸⁶ Half the estimated dehydration deficit plus maintenance requirements should be replaced in the first 12 hours and the remainder in the following 24 hours. Potassium and phosphorus supplementation should occur as for patients with DKA. Insulin therapy should be delayed 4 to 6 hours until the positive benefits of fluid therapy are documented (e.g., correction of dehydration, stabilization of blood pressure, and improvement in urine production).¹⁸⁶ Insulin can be administered as for DKA, but the dosages should be decreased by 50% to dampen the decrease in blood glucose concentration and prevent a rapid decrease in extracellular fluid osmolarity.

Prognosis. To some degree, prognosis for a diabetic dog or cat depends on its owner's desire to treat, the presence and severity of underlying disorders, and how well the animal responds to therapy. One must also bear in mind that DM is most commonly diagnosed in the geriatric pet population. The mean survival time for diabetic dogs has been stated to be 3 years after diagnosis, with the highest mortality within the first 6 months.95 A recent study assessing the incidence, survival, and breed distribution of insured dogs in the United Kingdom diagnosed with DM supports this estimation. Median survival time for 686 dogs was 57 days after the first insurance claim; if 223 dogs that survived less than 1 day were excluded from the analysis, median survival was 2 years. For dogs surviving at least 30 days (n=347), the median survival time was not reached by the end of the study.¹⁹⁶ Median survival times in newly diagnosed diabetic cats is reported to be 17 months,145 and the life expectancy of diabetic cats that survive the first 6 months after diagnosis has been estimated to be 5 years.¹²¹

DISEASES OF THE ADRENAL GLANDS

Hypoadrenocorticism

Pathophysiology

Which hormones are deficient in hypoadrenocorticism (Addison's disease) varies according to the underlying pathophysiology. The most common form of hypoadrenocorticism is primary adrenal failure. Glucocorticoids (e.g., cortisol) alone or both glucocorticoids and mineralocorticoids (e.g., aldosterone) may be deficient, depending on which adrenocortical zones have been destroyed. Primary hypoadrenocorticism can be spontaneous or iatrogenic as a result of mitotane, ketoconazole, or trilostane administration. Secondary hypoadrenocorticism is due to pituitary failure to secrete adrenocorticotropic hormone (ACTH). Because ACTH has minimal effects on aldosterone secretion, ACTH deficiency causes isolated glucocorticoid insufficiency. ACTH deficiency can be idiopathic, caused by head trauma or neoplasia, or iatrogenic, secondary to chronic suppression of ACTH caused by administration of glucocorticoids¹⁹⁷ or progestins.^{198,199} Exogenous glucocorticoids of any form, even topical, can feed back and turn off ACTH secretion. With chronic ACTH deficiency, adrenocortical atrophy occurs and cortisol secretion falls. Even though cats are considered to be relatively resistant to most side effects of glucocorticoids, they are just as susceptible as dogs to the adrenal suppressive effects. Administration of megestrol acetate (Ovaban) or other progestins to cats²⁰⁰ can also suppress ACTH secretion. Certain breeds of dogs (e.g., Nova Scotia Duck Tolling retrievers, Standard Poodles, and Bearded Collies) can have a genetic component to development of hypoadrenocorticism.201-203

Hypoadrenocorticism can be a life-threatening condition requiring immediate life-saving therapeutic intervention. The acute life-threatening effects generally reflect mineralocorticoid deficiency and, less commonly, glucocorticoid deficiency. Glucocorticoids affect almost every tissue; many effects are critical to normal homeostasis and become more critical in stressed patients. Glucocorticoids stimulate gluconeogenesis and glycogenolysis by direct hepatic effects and by stimulating protein and fat catabolism peripherally. They also have a permissive effect on adrenergic receptors, enhancing tissue response to alpha- and beta-receptor stimulation. Mineralocorticoids are crucial to maintaining sodium, potassium, and water balance.

Lack of cortisol secretion may cause depression, lethargy, anorexia, vomiting, abdominal pain, shaking or shivering, and weight loss. In severe cases cardiovascular collapse may result. Clinical signs indicative of mineralocorticoid deficiency include collapse and bradyarrhythmias. On routine blood work in patients with mineralocorticoid deficiency, hyponatremia, hyperkalemia, and hypochloremia are usually present. Hypoadrenocorticoid patients often are azotemic. Hypoglycemia will be present due to glucocorticoid deficiency in a small percentage of cases. Hypercalcemia occurs in about 25% of patients. Mild to moderate metabolic acidosis may be present, particularly if mineralocorticoid secretion is impaired.

Diagnosis

Diagnosis of hypoadrenocorticism can be suspected or ruled out on the basis of a baseline cortisol but must be confirmed by performance of an ACTH stimulation test. In one study dogs with basal cortisol concentrations above 55 nmol/L (2 μ g/dL) that were not receiving corticosteroids, mitotane, or ketoconazole were highly unlikely to have hypoadrenocorticism; however, if the basal cortisol concentration was less than 55 nmol/L, an ACTH stimulation test was needed for further evaluation.²⁰⁴ Likely, the same applies to dogs receiving progestins or trilostane. The protocol for performance of an ACTH stimulation test is the same as for diagnosis of hypoadrenocorticism (discussed below). In patients with primary or secondary hypoadrenocorticism, baseline cortisol concentration will be low, with minimal to no response to ACTH stimulation. The test does not distinguish spontaneous from iatrogenic disease and only confirms cortisol insufficiency. In a cortisol-deficient patient, if moderate to marked hyponatremia or hyperkalemia are present, aldosterone is assumed to be lacking as well. Serum aldosterone concentrations can be measured, but this is often not necessary and interpretation can be problematic.²⁰⁵

To differentiate primary from secondary hypoadrenocorticism, plasma endogenous ACTH concentration can be measured, as described below (see section on hyperadrenocorticism). In primary hypoadrenocorticism, negative feedback on the pituitary is lost and endogenous ACTH concentrations will be greatly increased; secondary hypoadrenocorticism, by comparison, is, by definition, a lack of ACTH. Evaluation of endogenous ACTH concentration can be considered if a patient has glucocorticoid deficiency only. If aldosterone secretory ability is impaired, the disease must be primary to the adrenal glands. Distinguishing primary from secondary disease in patients with spontaneous isolated glucocorticoid deficiency can be prognostic. If the disease is primary, aldosterone secretion is likely to be lost in the future and serum electrolyte concentrations should be monitored regularly; if the hypoadrenocorticism is secondary, mineralocorticoid secretion will remain normal.

Therapy

Therapy for hypoadrenocorticism focuses first on acute management of a hypoadrenal crisis, if present, and then on longterm maintenance therapy. The goals of therapy for treatment of a crisis are to replace fluid volume and the needed hormones, correct cardiovascular collapse, and rectify electrolyte and acid–base imbalances. Once the acute crisis is resolved, patients with hypoadrenocorticism can lead normal lives as long as medication is used appropriately.

Before therapy is initiated, if hypoadrenocorticism is suspected and patient status permits, an ACTH stimulation test should be performed for diagnosis. If emergency care that includes glucocorticoid administration is required, dexamethasone is the first choice to use. Exogenous glucocorticoid administration can affect ACTH stimulation testing in two ways. First, certain glucocorticoids-prednisone, prednisolone, methylprednisolone, and hydrocortisone-cross-react on cortisol assays and, if present, will artificially elevate apparent cortisol concentrations. If any of these four glucocorticoids are administered, an ACTH stimulation test should not be performed for 12 hours, whereas if dexamethasone is given, an ACTH stimulation test can still be performed immediately. (If methylprednisolone acetate [e.g., Depo-Medrol] is administered, testing may need to be delayed much longer.) Second, any glucocorticoid can feed back and suppress ACTH and cortisol secretion. The degree of suppression and the length of duration depends on which glucocorticoid was administered, as well as the route, dose, and duration. For example, depending on the dose, a single dexamethasone injection given to treat an Addisonian crisis may, within a few days, completely suppress basal cortisol concentration and suppress post-ACTH cortisol concentrations up to 33%. However, such suppression is easily distinguishable from spontaneous hypoadrenocorticism in which serum cortisol concentration is nondetectable before and after administration of ACTH. Thus, if after a single dexamethasone injection, post-ACTH serum cortisol concentration is nondetectable, a diagnosis of hypoadrenocorticism is made; if the post-ACTH serum cortisol concentration is just below the reference range, the patient's suppressed adrenal function is likely due to administration of an exogenous glucocorticoid, not to hypoadrenocorticism.

For treatment of an Addisonian crisis, fluid therapy is paramount and the primary priority. Although use of 0.9% saline was once advocated, rapid correction of hyponatremia has now been recognized to lead to central nervous system dysfunction.^{206,207} During chronic hyponatremia, the brain adapts to prevent cerebral edema. With rapid correction of serum sodium concentration, osmotic shifts and cerebral dehydration occur, with a possible resultant pontine myelinosis and neurologic signs such as disorientation, dysphagia, weakness, and quadriparesis. Thus, although balanced solutions such as Normosol-R or lactated Ringer's solution contain potassium, they are currently the fluid of choice, with the latter possibly being the best insofar as the sodium is the lowest. Hypertonic saline administration is contraindicated. For treatment of an Addisonian crisis, shock doses of fluids should be given initially and then rehydration corrected over 6 to 24 hours, depending on patient stability. Fluid therapy should be adjusted to increase serum sodium concentration at a rate of 0.5 mEq/L/hr. Frequent measurement of serum sodium concentration is important to ensure that the rate of correction of hyponatremia is appropriate. Fluid type and rate can be adjusted accordingly. If hypoglycemia is present, dextrose should be added to the fluids to make a 5% solution.

A rapid-acting glucocorticoid such as prednisolone sodium succinate (1 to 2 mg/kg over 2 to 4 minutes; can be repeated in 2 to 6 hours), dexamethasone or dexamethasone sodium phosphate (0.5 to 2 mg/kg intravenously, every 2 to 6 hours), or hydrocortisone hemisuccinate or hydrocortisone phosphate (2-4 mg/kg intravenously over 2 to 4 minutes, every 8 hours) should be administered. Alternatively, hydrocortisone sodium succinate can be infused at a rate of 0.5 to 0.625 mg/kg/hr intravenously. Although dexamethasone can be used to replace glucocorticoid deficiency, mineralocorticoid deficiency will not be affected; thus prednisolone, which has some mineralocorticoid activity, might be preferred, at least initially. However, the effect of glucocorticoid administration on diagnostic testing should also be considered (discussed previously). Mineralocorticoid therapy is needed only if aldosterone is deficient and is not recommended until serum sodium concentration is in the reference range or slightly below. Mineralocorticoid administration can correct serum sodium concentration fairly rapidly.

Dilutional effects and increased GFR secondary to fluid administration will begin to correct life-threatening hyperkalemia. Very rarely does hyperkalemia fail to respond rapidly to volume replacement. In such instances, or if the hyperkalemia

is immediately life-threatening, 10% (100 mg/mL) calcium gluconate (0.5-1 mg/kg) can be given intravenously slowly. The calcium protects the myocardium from the effects of the potassium. An electrocardiogram must be monitored during calcium infusion and treatment stopped if new arrhythmias occur or bradycardia worsens. Alternatively, regular insulin (0.06-0.125 U/kg, plus 20 mL of a 10% glucose solution for every unit of insulin given) can be administered. Insulin causes glucose to move intracellularly, and potassium will follow. Glucose is infused in an attempt to prevent hypoglycemia. However, given the abnormal glucose metabolism in hypoadrenocorticism, hypoglycemia still often results. If a patient is already hypoglycemic, just giving dextrose alone is much safer and will also cause intracellular movement of potassium. Lastly, bicarbonate can be given to address acidosis but is rarely required because the other treatments usually resolve the acidosis.

Response to initial therapy of hypoadrenocorticism should occur in 1 or 2 hours in patients suffering from hypoadrenocorticism. In general, cats take longer to respond than dogs. Because sodium deficiency may result in a washout of the medullary interstitium, renal function may not return to normal quickly, and the patient may be diuresing for several days. Care must be taken to balance fluid input with excessive output.

Mineralocorticoid replacement therapy. Maintenance therapy for hypoadrenocorticism begins when vomiting, diarrhea, weakness, and depression have resolved. Mineralocorticoid replacement is needed only for patients that are aldosterone deficient and is available in oral or depot preparations. The initial recommended dose of fludrocortisone in dogs is 0.01 to 0.02 mg/kg orally daily²⁰⁸ and in cats 0.1 mg/cat daily,^{200,209} much higher doses than required in humans. Dosage adjustments, if necessary, are made on the basis of serum electrolyte concentrations. Ideally, sodium and potassium should be within reference ranges. Sodium and potassium should be monitored every 1 to 2 weeks after initiating therapy until a patient is stable. In dogs the daily dosage is adjusted by 0.05 to 0.1 mg increments. Once electrolyte concentrations have stabilized, a patient should be reevaluated monthly for the first 3 to 6 months and every 3 to 6 months thereafter, as long as no clinical signs are apparent. In cats timing of monitoring is the same, and adjustments are made in 0.05-mg increments. In the authors' experience, however, fludrocortisone fails to normalize sodium in a number of patients no matter how high the dose.

In dogs the final required fludrocortisone dose varies greatly between patients; in one study the median final required dose was 0.023 mg/kg/day (range approximately 0.008 to 0.75 mg/kg daily).²¹⁰ Required doses often increase over the initial 6 to 18 months of therapy,^{205,210} possibly as a result of ongoing destruction of the adrenal cortex or changes in drug absorption or metabolism.

Overall, fludrocortisone therapy is effective. In 33 dogs, the response to treatment was considered good to excellent in 78.8%, fair in 9.1%, and poor in 12.1%.²¹¹ The most common side effects are polyuria and polydipsia, but polyphagia,

hair loss, and weight gain may be seen. Most of the adverse effects occur when prednisone and fludrocortisone are administered concurrently and resolve when glucocorticoid therapy is discontinued, but polyuria and polydipsia can be seen with fludrocortisone alone.^{205,210,211} Although fasting hypercholesterolemia and hypertriglyceridemia have been noted with fludrocortisone administration,²¹¹ the significance of these changes remain unknown.

The recommended starting dose of desoxycorticosterone pivalate (DOCP; Percorten, Novartis) for dogs is 2.2 mg/kg intramuscularly every 25 days. For cats the dose of DOCP is 10 to 12.5 mg/cat intramuscularly monthly.²⁰⁹ The subcutaneous route, however, can be used, at least in dogs.²¹² For the majority of dogs, the dosing regimen will be effective. Although one study initiated before a manufacturer's recommended dose was chosen found that some dogs did not need that high a dose, starting at 2.2 mg/kg is safe.^{213,214}

To decrease cost, it may not be necessary to administer DOCP at the full label dose. With DOCP, clinicians typically assume a 28-day interval and start at a dose of 2.2 mg/kg. Electrolytes should be measured on days 14 and 28, and if they are within the reference range on day 28, the DOCP dose can be decreased 10%. When a dose is found that no longer maintains serum sodium and potassium concentrations in the reference range for the full 28 days, the lowest DOCP dose that lasted 28 days can be used. An alternative is to administer 2.2 mg/ kg DOCP, lengthen the interval by 3 days with each injection until the interval is too long, and then use the longest interval during which serum electrolyte concentrations were in the reference range. However, it is probably harder for owners to remember the injections on a long interval, and the authors prefer lowering the dose and maintaining a 28-day interval instead.

A small percentage of dogs, however, do require either injections more frequently than every 25 days or more than 2.2 mg/kg to keep a 25-day or longer interval.^{210,215} If the patient is hyponatremic or hyperkalemic at day 14, the next dose should be increased by 10%. If the electrolytes are normal on day 14 but abnormal on day 28, the interval between injections should be decreased by 2 days²⁰⁵ or the dose increased 10%. In dogs that require DOCP more frequently than every 28 days, clinical signs of Addison's disease may recur before the recheck on day 28. If return of the hypoadrenal state is suspected, the dog should be seen immediately and serum electrolytes measured. If hyponatremia and hyperkalemia are documented, the DOCP injection can be given at that time. If the dosing interval is shortened, the timing of monitoring should be changed accordingly for the next treatment period. Two rechecks should be performed during each dosing interval until good control of the Addison's disease on the last day of the dosing interval is demonstrated.

DOCP is a highly efficacious treatment for hypoadrenocorticism with minimal side effects. Adverse effects reported include depression, polyuria, polydipsia, anorexia, skin and coat changes, diarrhea, vomiting, weakness, weight loss, incontinence, and pain on injection, but all are uncommon. Some of the adverse effects, such as polyuria and polydipsia, are more likely caused by concurrent glucocorticoid administration than by DOCP itself. Treatment failures also occur rarely.

Any recheck, whether monitoring fludrocortisone or DOCP therapy, should include a full physical exam, complete history, and determination of BUN concentration, as well as measurement of electrolytes. If at any recheck the serum electrolyte concentrations are within the reference range but problems, sometimes quite vague, such as anorexia, vomiting, diarrhea, or unwillingness to play exist, glucocorticoid deficiency is the likely cause, and the prednisone dose should be adjusted accordingly. An elevated BUN concentration can be a sign of dehydration caused by insufficient therapy.

Advantages and disadvantages exist with the use of either fludrocortisone or DOCP. For fludrocortisone the major advantage is the ease of diagnosing and adjusting an incorrect dosage because daily administration is easily altered. Daily therapy also constantly reminds owners that their pet is afflicted with a life-threatening disease and needs constant therapy and monitoring. Lastly, the medication is readily available at most pharmacies. However, fludrocortisone can be quite expensive despite the availability of a generic product, especially if higher doses are required; some patients may not be adequately controlled and side effects may occur, even when used without concomitant glucocorticoid therapy. If expense, existence of side effects, or lack of efficacy necessitates discontinuation of fludrocortisone, DOCP becomes the only choice.

For DOCP advantages include a low incidence of adverse effects if used alone, less common treatment failures than with fludrocortisone therapy, and need for infrequent administration. A subcutaneous injection can be given by owners if trained properly, but *great* care should be taken in selection of owners for this task. Missing an injection or giving one inappropriately and not realizing the mistake could be fatal for the patient. Apparent failures may be due to the owner's difficulty in providing injections; improper technique should always be ruled out. If a patient truly does not respond to DOCP, fludrocortisone therapy should be instituted.

Glucocorticoid replacement therapy. For all dogs and cats that have either iatrogenic or spontaneous secondary hypoadrenocorticism or primary Addison's disease without mineralocorticoid deficiency, only glucocorticoid replacement therapy is required. It should be remembered, however, that the disease of animals with primary glucocorticoid deficiency may progress to include mineralocorticoid insufficiency as well, and therapy must be adjusted accordingly. For an animal lacking both types of adrenocortical hormones, the need for daily maintenance glucocorticoid replacement therapy depends in part on which mineralocorticoid supplement is being administered. (For animals with hypoadrenocorticism under stress, excess glucocorticoids are always recommended; this is discussed later at more length.). Fludrocortisone has both glucocorticoid and mineralocorticoid activity, whereas DOCP has only mineralocorticoid properties. Thus approximately 50% of dogs receiving fludorocortisone may not require concomitant exogenous glucocorticoid administration.^{205,208} Although some dogs on DOCP have not received glucocorticoid therapy,^{211,215} this practice is not recommended²⁰⁵ insofar as the patient will be glucocorticoid deficient on a daily basis.

All animals beginning maintenance therapy for spontaneous hypoadrenocorticism should receive prednisone or prednisolone at a "physiologic" dose of 0.1 to 0.22 mg/kg once daily; prednisolone may be the preferred form in cats. If the animal is on fludrocortisone, once a dose that maintains serum electrolyte concentrations within the reference range has been determined, the glucocorticoid can be tapered to alternate days and then discontinued to see whether continued glucocorticoid therapy will be required.²⁰⁸ If the dog or cat is lethargic, dull, or unwilling to exercise or play or if clinical signs of hypocortisolism such as weakness, anorexia, vomiting, and diarrhea are apparent, glucocorticoids should be reinstituted at the lowest dosage that does not produce glucocorticoid-associated adverse effects and keeps the patient free of clinical signs. Patients receiving DOCP should always receive daily glucocorticoid replacement therapy, similarly at the lowest dosage possible. In cats methylprednisolone acetate (Depo-Medrol, 10 mg/month intramuscularly) can be administered if giving them pills is difficult,²⁰⁹ but complications of glucocorticoid therapy such as DM may be more likely.²⁰⁰ Depo-Medrol is not recommended for use in dogs.

In non-Addisonian patients receiving exogenous glucocorticoids chronically, every-other-day administration is recommended to minimize resultant adrenal atrophy. As patients with spontaneous hypoadrenocorticism already have significant adrenocortical destruction or atrophy, atrophy secondary to glucocorticoids is not a concern. Therefore, if a patient with spontaneous hypoadrenocorticism is deemed to need physiologic glucocorticoid replacement therapy, the medication should be given daily to make sure the patient is never glucocorticoid deficient.

During adverse periods such as illness, surgery or trauma, glucocorticoid requirements increase and additional glucocorticoid supplementation at 2 to 10 times the physiologic levels should be administered;²⁰⁸ if the patient does not receive daily glucocorticoid supplementation, it should be given during such times. Working dogs such as hunters and field trial participants should be allowed to complete their usual activities, but owners must be instructed to monitor their pets more closely than normal and discontinue activity if a dog appears unduly fatigued. On days of planned increased exercise or stress, the daily glucocorticoid dose should be doubled,²⁰⁵ or, if the animal is not receiving any glucocorticoids, a dose of 0.1 to 0.2 mg/kg can be given.

If the possibility of complete iatrogenic suppression of adrenal glucocorticoid secretion exists in patients receiving long-term exogenous glucocorticoids, the ideal way to assess adrenal reserve is by performing an ACTH stimulation test. If the response to an injection of ACTH is low, the patient should be tapered off the glucocorticoid supplementation until their adrenal gland function recovers. Once the decision to end steroid therapy is made, the dose of glucocorticoid should be decreased to physiologic doses of prednisone over 1 to 2 weeks.²⁰⁵ If adrenal suppression is secondary to topical

glucocorticoid administration, topical administration should be stopped and oral prednisone initiated at physiologic doses. If this dose of prednisone is tolerated for a week without clinical signs of cortisol deficiency, the dosage schedule should be reduced by administering the drug every other day. After 2 weeks at this dose, the dosage should be further reduced by giving the medication every third day. After 2 to 3 weeks, prednisone most likely can be discontinued.²⁰⁵ Ideally, however, before discontinuation, an ACTH stimulation test should be performed 12 hours after the last dose of prednisone to ensure that the patient has a normal adrenal reserve. Cats should be placed on physiologic doses of prednisolone and tapered off as are dogs.

In older reference sources, salt supplementation was advocated for treatment of patients with mineralocorticoid deficiency,²¹⁶ but this may not be necessary for dogs being fed a standard diet.²⁰⁵ Salt supplementation may still be helpful, however, in an occasional dog that requires large doses of an exogenous mineralocorticoid or that remains hyponatremic despite being normokalemic on an appropriate dose of mineralocorticoid.^{205,210} If salt is administered, the initial dose should be 0.1 mg/kg/day, divided over two or three meals.²¹⁶ After initiating salt supplementation, serum sodium and potassium concentrations should be measured and the sodium chloride dose adjusted accordingly.

Prognosis

Prognosis for patients with Addison's disease is excellent. Median survival is approximately 5 years, and patients typically die as a result of other diseases. The cause of hypoadrenocorticism, the mineralocorticoid used for treatment (i.e., fludrocortisone versus DOPCP), and signalment do not affect survival.²¹⁰ Owners should be aware, however, that their pet has a potentially life-threatening disease when not treated appropriately and continuous, lifelong therapy for spontaneous hypoadrenocorticism and appropriate monitoring are essential. If the disease is iatrogenic, lifelong therapy may not be required, depending on the cause, but therapy is nonetheless important until adrenal function has recovered.

Hyperadrenocorticism

Pathophysiology

Canine and feline hyperadrenocorticism can be either pituitary or adrenal dependent. The pituitary form is more common in dogs and cats than the adrenal form, accounting for approximately 80% to 85% of cases of hyperadrenocorticism. In pituitary-dependent hyperadrenocorticism (PDH), a corticotroph tumor secretes ACTH. The excess ACTH secretion leads to increased release of cortisol from the adrenal glands. In adrenal-dependent hyperadrenocorticism, an adrenal tumor (AT) autonomously secretes cortisol. In dogs and cats, ACTH-secreting pituitary tumors are almost 100% benign, whereas cortisol-secreting ATs are approximately 50% benign and 50% malignant. In either form of the disease, the majority of the clinical signs are caused by hypercortisolemia. The pathophysiology leading to the clinical sequelae is complex because of the large number of body tissues influenced by endogenous glucocorticoids (see chapter on glucocorticoid therapy). Large tumors, either adrenal or pituitary, can also lead to clinical signs because of their mass-occupying effects.

Diagnosis

Diagnosis of hyperadrenocorticism is made on the basis of positive screening test results in patients with the appropriate history, clinical signs, and biochemical test results. Three screening tests are designed to help determine whether a patient has hyperadrenocorticism: the urinary cortisol:creatinine ratio (UCCR), the ACTH stimulation test, and the low-dose dexamethasone suppression test (LDDST). Measurement of a UCCR is a highly sensitive but very nonspecific test. Almost all (>95%) cats and dogs with hyperadrenocorticism have an elevated UCCR, but the ratio is very often elevated in dogs and cats that do not have hyperadrenocorticism (approximately 80% to 85%).²¹⁷ Thus the best use of the UCCR is as a means to rule out the diagnosis of hyperadrenocorticism. If a patient has a normal UCCR, it is highly unlikely to have hyperadrenocorticism; however, because of the very high rate of false-positive results, if a UCCR is elevated, another screening test must be done to confirm the presence of hyperadrenocorticism. One advantage of the UCCR is ease of testing: A single urine sample is required. As even the stress of being in a hospital can elevate a UCCR,^{218,219} it should be measured on a sample collected at home.

The ACTH stimulation test is recommended for patients with minimal clinical signs of hyperadrenocorticism, patients that are receiving phenobarbital, or patients that have a nonadrenal illness present (e.g., a diabetic dog that is also suspected of having hyperadrenocorticism).²¹⁷ In addition, the ACTH stimulation test is the only screening test that can differentiate between spontaneous and iatrogenic hyperadrenocorticism. The recommended form of ACTH is cortrosyn (Cosyntropin, Amphastar Pharmaceuticals, Rancho Cucamonga, Calif.). To perform the test, the clinician injects cortrosyn at a dose in dogs of 5 μ g/kg intravenously²²⁰ or intramuscularly²²¹ or 125 μ g in cats.²²² Blood samples are taken before and 1 hour after injection. In animals with spontaneous hyperadrenocorticism, the response to ACTH should be greater than in healthy patients.

Overall, the ACTH stimulation test will be positive in approximately 80% of dogs and cats with hyperadrenocorticism.^{217,223} If the forms of hyperadrenocorticism are considered separately in dogs, for PDH the sensitivity is 87%, whereas for AT the sensitivity is 61%.²¹⁷ In PDH false-negative results may be attributable to early disease where adrenocortical hyperplasia is minimal. In AT the tumor tissue may not have ACTH receptors and therefore might not respond to an ACTH injection. Nonadrenal illness can affect the ACTH stimulation test in dogs and cats.^{224,225} In one study 14% of dogs with nonadrenal illness had an ACTH stimulation test consistent with hyperadrenocorticismeven although they did not have the disease.²²⁴ Infrequently, a subnormal ACTH response is seen in dogs with AT. A low baseline cortisol concentration with little to no response to exogenous ACTH suggests iatrogenic hyperadrenocorticism. The ACTH test also should be used to monitor patients receiving mitotane, ketoconazole, or trilostane therapy for treatment of hyperadrenocorticism.

Owing to issues related to the cost and availability of cortrosyn, interest has been raised in use of compounded ACTH. Two studies have assessed a total of five compounded forms in dogs. The gels studied appear to be effective in normal dogs.^{226,227} However, the protocols recommended by the manufacturers may not be appropriate, and, if a compounded ACTH gel is being used, samples should be taken before injection and at both 60 and 120 minutes after injection, so the peak response is not missed.²²⁷ Whether the gels are as effective at diagnosing hyperadrenocorticism as is cortrosyn has not been rigorously assessed; they may not be.²²⁶

In normal animals a low dose of dexamethasone suppresses ACTH secretion, and, as a result, blood cortisol concentration decreases. Patients with pituitary- or adrenal-dependent hyperadrenocorticism should continue to secrete cortisol despite being given a low dose of dexamethasone, and suppression will not occur. Overall, the LDDST shows inadequate suppression (i.e., is positive) in approximately 95% of dogs with hyperadrenocorticism.²¹⁷ In general, the LDDST is recommended in patients with moderate to severe clinical signs consistent with hyperadrenocorticism.²¹⁷ A disadvantage of the LDDST in dogs is that nonadrenal illness can cause the test to give false-positive results in a high percentage of dogs. As many as 56% of ill dogs that do not have hyperadrenocorticism may have a positive LDDST test result.²²⁴ In cats 6 weeks of uncontrolled DM does not affect LDDST test results,²²⁸ but whether longer or more severe illness may do so is unknown.

What is considered a "low-dose" test for screening varies between dogs and cats. In both species dexamethasone is administered with blood samples being taken before and 4 and 8 hours after injection. However, in dogs the dose used is 0.01 to 0.015 mg/kg, whereas in cats it is 0.1 mg/kg.

Which test is best, the ACTH stimulation test or LDDST, for diagnosing hyperadrenocorticism in cats is unknown. In one literature review, in cats with hyperadrenocorticism 81% of ACTH stimulation tests were positive (n=37), whereas 79% of cats (n=28) showed inadequate suppression at 8 hours after dexamethasone.²²³ Interestingly, in three cats, two ACTH stimulation tests were performed, with one being negative and one positive. Other reports have not shown as high a sensitivity for the ACTH stimulation, and some authors prefer the LDDST.²²⁹

Once a diagnosis of hyperadrenocorticism is made, the underlying cause—pituitary or adrenal —must be delineated because this provides information on prognosis and treatment options. The UCCR or ACTH stimulation test can never be used to differentiate between PDH and AT. In up to 60% of dogs, the LDDST can provide the differentiation as well as the diagnosis of hyperadrenocorticism.²³⁰ If the 8-hour postdexamethasone concentration is not fully suppressed (check with the laboratory for their definition of suppression; in most labs it is a serum cortisol concentration of less than approximately 30 nmol/L or 1 to 1.5 μ g/dL), the results are consistent with a diagnosis of hyperadrenocorticism. If, in addition, the 4-hour postdexamethasone concentration is fully suppressed or if one

or both postdexamethasone concentrations is less than 50% of baseline, PDH is present.²³⁰ However, if the baseline cortisol is already below 30 nmol/L, these guidelines do not apply.²³¹ If both postdexamethasone concentrations are above 30 nmol/L and neither of these values is less than 50% of baseline, either PDH or AT is possible. In rare cases dogs with an AT may meet one of these criteria for diagnosing PDH.²³¹ Whether differentiation can be done with the LDDST in cats is not known.

If the LDDST was not done as the screening test or did not delineate the form of hyperadrenocorticism present, further tests available to differentiate between PDH and AT are measurement of plasma endogenous ACTH (eACTH) concentration; the high-dose dexamethasone suppression test (HDDST); and imaging such as abdominal ultrasound, CT, and MRI. An advantage of eACTH measurement is that only a single blood sample is required, but special handling is needed. Samples should be collected with EDTA and centrifuged within 15 minutes, and the plasma separated and placed in plastic tubes. Addition of aprotinin facilitates accuracy of measurement²³² as it prevents eACTH degradation. If aprotinin is used, the plasma sample must remain cool only until it arrives at a laboratory; if aprotinin is not used, the sample must remain frozen until analysis.

In dogs with PDH, eACTH concentration should be normal to elevated owing to secretion from the pituitary tumor. In dogs with an AT, the autonomous secretion of cortisol by the tumor will turn off pituitary ACTH secretion so eACTH should be below normal. Values to be used for test interpretation vary with the laboratory and assay used. An advantage of this test is that it can confirm the presence of an AT, whereas the HDDST can never do so. Unfortunately, nondiagnostic values exist. For example, at the Auburn University Endocrine Diagnostic Service, a concentration of less than 10 pg/mL is consistent with an AT, whereas one greater than 15 pg/mL is consistent with PDH. The area between 10 and 15 pg/mL is a "gray zone," in which differentiation is impossible. Although other laboratories may have different cutoffs, a similar gray zone will exist. Gray zone results occur in approximately 18% of canine submissions. However, with repeat testing when the initial result is in the gray zone, a definitive differentiation can be achieved in approximately 96% of dogs.²¹⁷ Unfortunately, there is no way to predict when a blood concentration will be in the diagnostic range.

The basis of the HDDST is that high doses of dexamethasone are generally sufficient to cause pituitary gland tumors to decrease ACTH secretion, and, as a result, cortisol concentration falls. In comparison, ATs secrete cortisol autonomously, and because eACTH concentrations are already low, dexamethasone administration does not suppress serum cortisol concentrations. After collection of a baseline cortisol concentration, 0.1 mg/kg dexamethasone is given intravenously in dogs and 1 mg/kg in cats, and then samples are collected 4 and 8 hours later. Suppression is defined as a 4- or 8-hour cortisol concentration less than approximately 30 nmol/L or 1.0 μ g/dL (check with the laboratory for the specific ranges) or less than 50% of baseline. Because approximately 25% of dogs with PDH do not suppress on a HDDST, lack of suppression does *not* mean a patient has an AT. If the criteria for suppression are met, a patient has PDH. If the criteria are not met, a 50/50 chance still exists that the patient has PDH or AT. Thus the HDDST can *never* confirm the presence of an AT.

Imaging can be helpful in diagnosing hyperadrenocorticism but can never be used as a screening test. Changes associated with hyperadrenocorticism that may be seen on radiographs include hepatomegaly; a pendulous abdomen; calcinosis cutis; osteopenia; and dystrophic mineralization of bronchi, the renal pelvis, liver, gastric mucosa, and abdominal aorta. Abdominal radiography can be helpful in differentiation if an adrenal mass is found. Of 94 ATs in 88 dogs (six dogs had bilateral adenomas or carcinomas), 50 ATs (53%) were detected because of tumoral calcification (n=40) or visualization of a mass (n=17).²¹⁷ ATs can often be visualized by radiography in cats.²²³ Both adenomas and carcinomas can contain mineral densities or appear as a mass cranial to the kidney. Mineralization itself, however, is not definitive for a tumor in either species, and as many as one third of normal cats can have adrenal calcification.

Ultrasonography may have more application as a differentiating tool than radiography because both adrenal glands can be visualized. Small or noncalcified ATs can be detected, and bilateral adrenal enlargement can be visualized in dogs with PDH. Ultrasonography defines location, size, and organ involvement of adrenal masses more precisely than radiography alone, but ATs are not always seen. A small degree of asymmetry exists normally. In 71 dogs, 68 of 79 (86%) tumors were found (eight had bilateral tumors).²¹⁷ Differentiation between an adrenal adenoma and carcinoma is unlikely with ultrasound insofar as they can have a similar appearance. Neither echogenicity nor the presence of mineralization can be used. Lesions suggestive of metastasis may be found, especially in the liver.²³³ Evidence of invasion into the vena cava is suggestive of a carcinoma but can be difficult to judge by ultrasound. With ATs atrophy of the contralateral gland will not always be detectable by ultrasound.

Use of ultrasonography as a screening test for hyperadrenocorticism is not recommended. First, measurements of adrenal gland length and minimum and maximum diameter overlap between dogs with PDH and either dogs with nonendocrine disease or even normal dogs, so ultrasound cannot always distinguish between them. Second, the finding of an AT is not synonymous with hyperadrenocorticism. Ultrasonography cannot distinguish a functional adrenocortical tumor from a nonfunctional tumor, a pheochromocytoma, a metastatic lesion, or a granuloma.

Abdominal CT is an even more sensitive assessment of adrenal gland structure. Standard and dynamic CT can also be used for pituitary evaluation. Dynamic CT is more sensitive than conventional contrast-enhanced CT. If hypophysectomy is being considered for therapy, the extra sensitivity of dynamic CT may be helpful to ensure that the correct treatment is being provided. In other cases dynamic CT may not be warranted. MRI has been used not to differentiate but to assess the size of a pituitary mass in known cases of PDH. Biochemical testing cannot readily differentiate tumor size. Although radiation therapy is not a great means of controlling hyperadrenocorticism,^{234,235} radiation done for local control of a pituitary mass is more effective and provides a better outcome and prognosis the smaller the mass and with no or minimal neurologic signs present.^{234,236} Compared with untreated dogs, radiation therapy for a pituitary mass, with or without the presence of hyperadrenocorticism or with or without the presence of neurologic signs, significantly increased survival. In one study median survival with treatment was not reached, but mean survival was 1405 days versus 359 for those not treated. Radiation also significantly increased control of neurologic signs.²³⁷

The true incidence of pituitary macroadenomas is unknown but has been estimated to be as high as 25% in dogs. The clinical progression of pituitary tumors is also widely unknown. Out of 21 dogs recently diagnosed with but untreated for PDH that had no neurologic signs, 11 had a pituitary mass visible on MRI.²³⁸ At 1 year 13 of the 21 had follow-up imaging. Five had no visible tumor originally, whereas eight did of 4- to 11-mm greatest vertical height. One of the dogs with a visible mass had not been treated, whereas the rest had been treated with mitotane.²³⁹ None of the five dogs with no visible mass originally had neurologic signs at follow-up; two had a visible pituitary tumor.²³⁹ Of the eight dogs that had a visible mass at first imaging, four had no apparent change in their tumor size, whereas in four the tumor had enlarged. The untreated dog was in the latter group. Overall, four developed signs of central nervous system dysfunction (19% of the original 21 and 36% of the 11 dogs with tumors visible at the first scan). Tumor size appeared to correlate with the development of signs, insofar as no dog with a mass smaller than 10 mm had neurologic dysfunction. There was no apparent correlation between pituitary mass size before treatment and increase in size over the year. 239

On the basis of this information, clinical experience, and theoretical considerations, recommendations for routine imaging of the pituitary in patients with hyperadrenocorticism have recently been formulated. With the recognition that the number of dogs studied is small, the suggestions are as follows: All dogs with PDH should have CT or MRI scans at the time of diagnosis. If no mass is visible, medical treatment should be implemented and no follow-up imaging is needed. If a mass 3 to 7 mm in greatest vertical height is seen, medical therapy should be implemented, with a repeat scan in 12 to 18 months. If a mass 8 mm or larger in greatest vertical height is seen, radiation therapy should be done and medical therapy used only if clinical hyperadrenocorticism fails to resolve within 3 to 6 months of finishing radiation. No studies have been performed to date to assess the validity of the guidelines.

Therapy for Canine Hyperadrenocorticism

Surgical and medical options exist for treatment of canine and feline hyperadrenocorticism. By whatever means, the ultimate goal of therapy is to eliminate hypersecretion of cortisol. In the United States, medical therapy is most often used for dogs with PDH. In Europe hypophysectomy is available and has been successful.^{240,241} For cats with PDH, owing to the limited success of medical therapy, bilateral adrenalectomy may be the treatment of choice, followed by lifelong therapy for hypoadrenocorticism.²⁴² For dogs and cats with ATs, surgery is recommended.

Mitotane. Currently, there is no drug therapy that will cure PDH. Lifelong therapy should be anticipated. Mitotane, or o,p'-DDD (Lysodren) has long been the mainstay of medical therapy for canine PDH. A chlorinated hydrocarbon, mitotane is adrenocorticolytic, causing selective necrosis of the zona fasciculata and zona reticularis, the adrenocortical zones that secrete cortisol and sex hormones. The toxin is specific for the adrenal glands, particularly hyperplastic glands, with one exception. In normal animals mitotane has caused fatty degeneration and centrolobular atrophy of the liver, and hepatotoxicity secondary to mitotane therapy for hyperadrenocorticism has occurred.²⁴³ Although the disposition of mitotane has not been well characterized in dogs, safety has been studied in a small number of animals. Normal animals tolerated the drug at 50 mg/kg administered 5 days out of 7 for months with no apparent adverse effects. Adrenocortical function was, however, impaired.

Therapy for hyperadrenocorticism with mitotane occurs in two phases: an induction (loading) phase and a maintenance phase. For treatment of PDH, a starting dose of 40 to 50 mg/kg divided twice daily (i.e., 20 to 25 mg/kg twice daily) and administered orally should be used.²⁴⁴ In smaller dogs division may be impossible because of the 500-mg pill size, and the drug can be given in one dose. Doses higher than 50 mg/kg (administered daily) increase the risk of complete

cortisol deficiency.²⁴⁴ Mitotane should always be given with food because this increases the bioavailability of intact tablets.²⁴⁵ Loading should end when appetite decreases, vomiting or diarrhea occurs, the patient becomes listless, water intake drops to less than 60 mL/kg daily (1 cup = 240 mL and 1 oz = 30 mL) or for a maximum of 8 days (Figure 21-6). Feeding twice-daily during loading allows better assessment of appetite, which may be the most common early sign that control has been achieved. To closely monitor the patient, best judge the endpoint, and impress on an owner the seriousness of overdosing, the clinician may find it helpful to make daily calls to the owner.²⁴² When signs suggest that loading is complete or at the end of 8 days if no changes have occurred, adrenal reserve is assessed by ACTH stimulation testing. If the signs of hyperadrenocorticism have not changed, daily therapy can continue until the results of the ACTH stimulation test are known; otherwise, mitotane should be discontinued while awaiting the laboratory report.242

The goal of the induction phase is to have serum cortisol concentrations before and after administration of ACTH stimulation in the normal resting range (e.g., cortisol concentration of 30 to 150 nmol/L or 1-5 μ g/dL before and after ACTH). Dogs with PDH that continue to have responses to ACTH in the range for normal dogs (e.g., post-ACTH cortisol concentration of 220 to 560 nmol/L or 8 to 20 μ g/dL) tend to have ongoing clinical signs. If pre- and post-ACTH cortisol concentrations are within the ideal range, maintenance therapy should begin. If cortisol concentrations are above the desired range, loading should continue for another 5 days or until clinical signs occur that suggest loading has

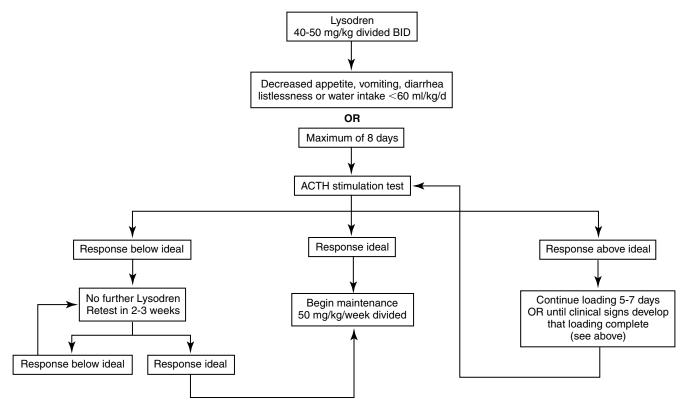

Figure 21-6 Protocol for mitotane induction therapy for canine pituitary-dependent hyperadrenocorticism.

been completed. The mean time required to achieve adequate control is 11 days, but up to 2 months is possible.²⁴⁴ In general, smaller dogs (<12.5 kg) and those receiving phenobarbital may require greater than average induction times. Approximately 33% of dogs will have a serum cortisol concentration less than ideal (e.g., post-ACTH cortisol concentration <30 nmol/L) after induction; mitotane therapy should be discontinued and an ACTH stimulation test performed after 2 weeks to assess adrenal function. Prednisone should be administered at physiologic doses during that time, but none should be given in the 12 hours before performing an ACTH stimulation test. In most dogs serum cortisol concentrations will rise into the ideal range within 2 to 6 weeks, but up to 18 months may be required.²⁴⁴

Special consideration should be given to patients with concomitant hyperadrenocorticism and DM. If a diabetic has insulin resistance secondary to hyperadrenocorticism and requires large doses of insulin for adequate glycemic control, treatment with mitotane removes the cause of insulin resistance and can lead to a rapid decrease in daily insulin requirement. Consequently, insulin overdosage and hypoglycemia may occur if the insulin administration is not adjusted accordingly. To try to slow the return to insulin sensitivity and avoid hypoglycemia, the recommended induction dose for dogs with concurrent hyperadrenocorticism and DM is 25 mg/kg once daily. Furthermore, although administration of prednisone during induction therapy for PDH is discouraged in general by some authors, prednisone (0.4 mg/kg once daily) should be given to diabetics receiving induction phase mitotane, again to help avoid hypoglycemia. Even with these precautions, diabetic patients should be monitored more closely than usual during induction.

Adverse effects of mitotane are generally gastrointestinal or neurologic. One or more adverse effects occur in approximately 25% of dogs with PDH during loading and include weakness, vomiting, anorexia, diarrhea, and ataxia.²⁴⁴ These develop as serum cortisol concentration falls rapidly and typically resolve quickly with appropriate therapy. If adverse effects occur, mitotane administration should be discontinued. Prednisone should be administered (0.2 to 0.5 mg/kg) until the dog can be examined, an ACTH stimulation test performed, and serum electrolytes measured. Most dogs show a clinical response to glucocorticoid administration within 2 to 3 hours. Persistence of apparent adverse effects may signify the presence of another medical problem.

If a dog does not respond to the induction protocol after 14 days, the following factors that could contribute to mitotane resistance should be considered:²⁴² (1) The patient may have an AT, which is more resistant to mitotane. (2) The patient may be inherently resistant to mitotane; some dogs with PDH have required as many as 30 to 60 days of daily therapy or doses of 100 to 150 mg/kg daily. (3) The induction dose is too low. Dogs receiving less than 40 mg/kg daily are less likely to be adequately controlled after 10 days. (4) The drug is not being absorbed well. Ensure that the medication is being given with food, preferably a fatty meal. (5) The diagnosis may be incorrect or the patient is suffering from iatrogenic hyperadrenocorticism. Neither an animal with iatrogenic hyperadrenocorticism nor one that does not have hyperadrenocorticism will respond to mitotane. (6) The owner may not be giving the medication as directed.

Maintenance therapy will be necessary for the remainder of the animal's life, although the dose and frequency vary among patients and can vary in an individual patient over time (Figure 21-7). In the absence of maintenance therapy, the

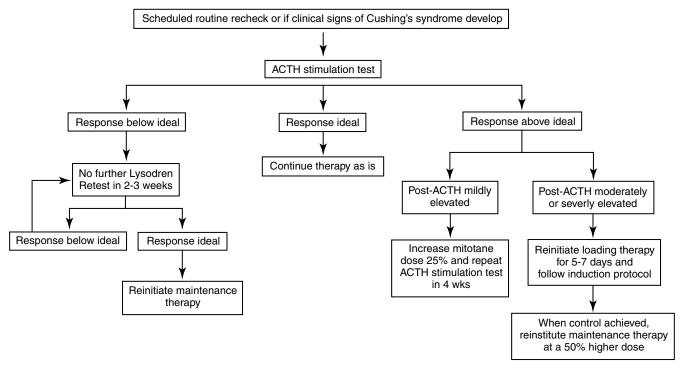

Figure 21-7 Protocol for mitotane maintenance therapy for canine pituitary-dependent hyperadrenocorticism.

adrenal glands will once again become hyperplastic in response to continued ACTH secretion from the pituitary gland. The maintenance phase uses a much lower overall mitotane dose of 50 mg/kg/week orally²⁴⁴ given as 2 to 3 smaller fractions over the course of the week, if division is possible. Because approximately 60% of dogs with PDH on maintenance mitotane therapy, especially those receiving less than 50 mg/kg weekly, relapse within 12 months of starting therapy,²⁴⁴ an ACTH stimulation test should be performed 1, 3, and 6 months after initiating maintenance therapy and approximately every 3 to 6 months thereafter to ensure continued control. If the preand post-ACTH serum cortisol concentrations are in the ideal range, therapy can remain as is. If the post-ACTH cortisol concentrations is mildly elevated (e.g., 150 to 250 nmol/L or 4-9 μ g/dL), the maintenance dose can be increased by 25%, and the dog retested after 1 month to determine if adequate control has been achieved. If so, maintenance therapy should continue at the new dose. If serum cortisol concentrations are still above ideal, reinstitution of daily loading therapy for 5 to 7 days should be considered. If the post-ACTH cortisol concentration is moderately to greatly increased (e.g. greater than 250 nmol/L or 9 μ g/dL), loading therapy should be reinstituted for 5 to 7 days. If induction therapy is reinitiated, the decision to end loading should be based on the same clinical signs as during the initial induction phase or should be done for a maximum of 7 days. Once the serum cortisol levels are again within the ideal range, maintenance therapy should be reinstituted at a 50% higher mitotane dosage.²⁴⁶

In 184 dogs with PDH treated with mitotane for a mean of 2 years, the final maintenance dosage required ranged from 27 to 330 mg/kg weekly, with the two highest doses required by dogs also receiving phenobarbital. Median survival time was 1.7 years (range 10 days to 8.2 years), with the response judged as excellent in 83%, fair in 16%, and poor in 0.6%.²⁴⁴

Approximately 33% of dogs on maintenance mitotane therapy will develop adverse effects including anorexia, vomiting, weakness, diarrhea, and ataxia, typically shortly after initiation of the maintenance dosage or during periods of relapse when daily therapy is reinstituted. If these develop, mitotane therapy should be discontinued, physiologic doses of prednisone administered, an ACTH stimulation test performed, and serum electrolyte concentrations measured. Presence of glucocorticoid deficiency with or without mineralocorticoid deficiency can be documented using these tests and differentiated from direct drug toxicity. If the clinical signs are due either to a hypoadrenal state or to a direct effect of mitotane, they should resolve quickly with prednisone administration. If the signs do not abate, presence of a nonadrenal illness should be suspected. If glucocorticoid deficiency is documented (e.g., before and after ACTH serum cortisol concentration <30 nmol/L or $1 \,\mu g/dL$), mitotane therapy should be discontinued and physiologic prednisone replacement therapy continued until serum cortisol concentrations before and after ACTH increase into the ideal range, which usually requires 2 to 6 weeks. Complete mineralocorticoid and glucocorticoid deficiency is seen in approximately 6% dogs from 1 month to years after initiation of maintenance therapy and is usually permanent.²⁴⁴ If mineralocorticoid and glucocorticoid deficiency is present, the patient needs to be treated for hypoadrenocorticism. Appearance of neurologic signs such as disorientation, dullness, or inappetence may be due to direct drug toxicity or may suggest the presence of a pituitary macroadenoma; CT or MRI is required to confirm the presence of a large tumor. Mitotane dose reduction may be necessary for animals that develop adverse reactions or an alternate dosing scheme can be used (e.g., the dose may be divided into smaller amounts to be given more frequently during the course of the week).

If therapy for hyperadrenocorticism is successful, most clinical signs of the disease or its complications resolve over time. Polyuria, polydipsia, and polyphagia should resolve as soon as cortisol secretion is adequately controlled. Resolution of some clinical signs (e.g., skin manifestations, nonhealing wounds, anestrus) may take 3 to 6 months or longer; calcinosis cutis may never fully resolve. Development of a puppy coat or a change in hair color may occur with mitotane treatment. Resolution of clinical laboratory changes (i.e., elevated liver enzyme activities and serum cholesterol concentration) may take up to 18 months.

An alternative protocol for treating PDH is aimed at nonselective adrenocorticolysis and complete destruction of adrenocortical tissue, with substitution therapy for ensuing adrenocortical insufficiency. Mitotane is given for 25 days at a dosage of 50 to 75 mg/kg daily and up to 100 mg/kg daily for toy breeds, divided into 3 or 4 approximately equal and equally spaced portions and given with food. Lifelong glucocorticoid and mineralocorticoid substitution is begun on the third day of mitotane administration. Prednisone should be initiated at a temporarily high dose of 1 mg/kg twice daily. Fludrocortisone (0.0125 mg/kg daily) and sodium chloride (0.1 mg/kg/ day, divided over 2 or 3 meals) should also be administered.²¹⁶

During the first month, owners should report by telephone at least weekly and as problems arise and should stop mitotane administration if any inappetence develops.²¹⁶ In this regimen appetite change, if seen, is a direct toxic effect of the medication; mild cortisol deficiency is offset by the glucocorticoid replacement therapy and should not cause any adverse effects. If mitotane therapy continues despite a diminished appetite, a hypoadrenocortical crisis can ensue. Glucocorticoid dosage may be increased temporarily if appetite diminishes. Usually, mitotane can be resumed after 4 or 5 days when the appetite returns without further problem.²¹⁶

The first follow-up visit should be 1 week after completion of mitotane administration. Serum electrolytes should be measured to ascertain whether the fludrocortisone and salt doses are correct.²¹⁶ Performance of an ACTH stimulation test may be wise to ensure adequate control of the Cushing's syndrome. The original protocol recommends that patients be treated for hypoadrenocorticism with prednisone (1 mg/kg daily, divided either in 2 equal portions or two thirds in the morning and one third in the evening), fludrocortisone at a dosage that maintains normal serum electrolyte concentrations, and salt.²¹⁶ However, salt may not be necessary; lower prednisone and fludrocortisone doses may be sufficient (discussed later). Furthermore, DOCP may be used as an alternative to fludrocortisone.

The protocol was assessed in 129 dogs.²⁴⁷ In 30% of the dogs, mitotane administration had to be stopped temporarily because of the development of anorexia, vomiting, weakness, neurologic abnormalities, depression, and diarrhea, but it could be resumed within days (median 7 days, range 1 to 63). Convincing signs of partial or complete remission of the hyperadrenocorticism such as hair regrowth, decreased water intake and appetite, and diminished abdominal size were noted in 86%. Relapse occurred in 33%; the median diseasefree interval (time until recurrence, death, or last followup) was 450 days from the day therapy began (range 25 to 1885).²⁴⁷ Adrenal testing (i.e., ACTH stimulation) is recommended only if clinical signs of hyperadrenocorticism recur, but routine measurement of serum urea nitrogen and electrolyte concentrations is required to ensure adequate control of the hypoadrenocorticism. Median survival time was 1.6 years (range 1 day to 6.1 years).²⁴⁷ In another study that used a daily mitotane dose of 75 to 100 mg/kg daily in 46 dogs, median survival was approximately 2 years. Although recurrence rate of hyperadrenocorticism was only 29%, perhaps owing to a higher mitotane dose, 15 dogs suffered an Addisonian crisis at some point during therapy. Overall incidence of side effects was 24%.248

Although treatment of hypoadrenocorticism may appear easier than that of hyperadrenocorticism, two main disadvantages exist for the alternative protocol, and its use has not been strongly recommended. First, treatment of an Addisonian dog can be expensive, and mineralocorticoid with or without glucocorticoid replacement therapy will be required for life. Second, and more important, failure to give medication to an Addisonian patient can be fatal, whereas missing a dose of mitotane will not put a patient in life-threatening danger. ²⁴²

If an AT is being treated, the mitotane protocol used is different from that for PDH; the goal is complete destruction of tumor tissue with serum cortisol concentrations before and after ACTH below the normal resting range (e.g., <10 nmol/L or 0.3 µg/dL on both samples).²⁴⁹ Although approximately 20% of dogs with ATs respond to PDH induction protocols, higher induction dosages and longer induction times are generally required for control of an AT.^{250,251} The cumulative induction dose of mitotane for PDH is usually 400 to 500 mg/kg, whereas that for dogs with an AT is often up to 10 times higher.²⁵⁰Thus initial mitotane induction dosage for treatment of an AT is 50 to 75 mg/kg daily. Because the goal is complete destruction of glucocorticoid-secreting tissue, physiologic doses of prednisone should be administered concurrently.²⁵⁰ The same clinical signs can be used to judge the endpoint of induction as when treating PDH, with a maximum treatment span of 14 days. At the conclusion of a loading period, an ACTH stimulation test should be performed (Figure 21-8).

If a partial response is seen but adequate control has not been achieved (i.e., pre- and post-ACTH cortisol concentration are lower than before treatment but not in the ideal range), mitotane should be continued at the same dosage and an ACTH stimulation test repeated every 10 to 14 days until serum cortisol concentrations fall within the ideal range. If after the initial loading dose the ACTH response is unaltered, the daily mitotane dosage should be increased in 50 mg/ kg increments daily every 10 to 14 days as necessary, until an ACTH stimulation test demonstrates a response to the medication or drug intolerance occurs. Therapy is then continued at the dosage at which a response was seen or at the highest tolerated dosage, and ACTH stimulation testing is again performed every 10 to 14 days or if clinical signs suggest an endpoint

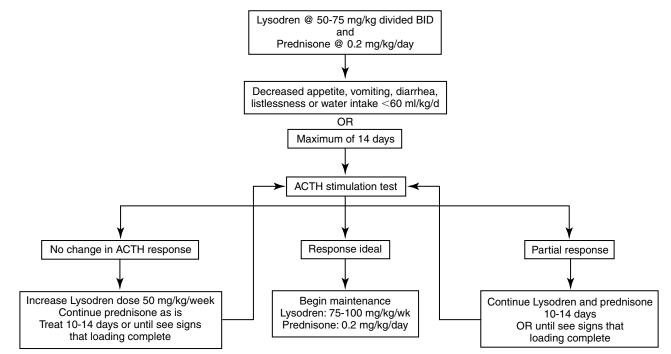

Figure 21-8 Protocol for mitotane induction therapy for canine adrenal-dependent hyperadrenocorticism.

has been reached. In 31 dogs with an AT, total induction time ranged from 10 days to 11 weeks with a mean of 24 days.²⁵⁰

Once cortisol concentrations before and after ACTH administration are within the ideal range, maintenance therapy should begin at an initial mitotane dosage of 75-100 mg/ kg/week.²⁵⁰ Daily physiological doses of prednisone should also be administered, as these dogs have subnormal basal serum cortisol concentrations. An ACTH stimulation test should be performed after 1 month of maintenance therapy to determine whether serum cortisol concentrations have remained adequately suppressed. If pre- or post-ACTH cortisol levels are within the normal resting range (i.e., 10 to 160 nmol/L or 1 to 4 μ g/dL), the mitotane maintenance dose should be increased 50% and the dog retested in 1 month. If the cortisol levels are still above the resting range at that time, induction therapy should be reinstituted; once ideal cortisol levels are again achieved, maintenance should be restarted at a 50% higher dosage than previously used. An ACTH stimulation test should again be performed 1 month after a dose adjustment to assess control (Figure 21-9). Once ongoing successful therapy is documented, an ACTH stimulation test should be done every 3 to 6 months or if clinical signs recur. Relapse occurs during maintenance in approximately 66% of cases, usually because of either too low an initial maintenance dose or tumor growth.²⁵⁰

As are induction doses, maintenance doses required for adequate control of an AT are higher than for PDH. In 32 dogs with an AT, the final mean maintenance dose required was 159 mg/kg weekly, slightly more than double the average maintenance dose required to control PDH. Approximately 25% of dogs with ATs require maintenance doses greater than 150 mg/kg weekly. Adverse effects, as previously described, occur in approximately 60% of dogs with ATs treated with mitotane. They can develop as long as 16 months after initiation of therapy, are more common during the maintenance rather than the induction phase, and are due either to direct toxicity of medication or to adrenocortical insufficiency, with the former being approximately twice as likely.²⁵⁰

If severe side effects occur, mitotane should be stopped, the prednisone dose increased to 0.4 mg/kg daily, and the dog reevaluated as soon as possible with an ACTH stimulation test and measurement of serum electrolyte concentrations to determine whether complete mineralocorticoid and glucocorticoid deficiency exists. If serum electrolytes are normal but pre- and post-ACTH serum cortisol concentrations are below 10 nmol/L, it is likely that only glucocorticoids are deficient. Mitotane therapy should be restarted, and prednisone administration continued at a dosage of 0.4 mg/kg daily to exclude cortisol deficiency as the cause of the side effects. If adverse effects recur when mitotane is reinstituted despite an increased glucocorticoid dosage, direct drug toxicity is likely. If the adverse effects are due to the mitotane, its administration can be temporarily discontinued and then reinstituted at a 25% to 50% lower dosage once signs of toxicosis have resolved. If hyponatremia, hyperkalemia, and subnormal cortisol concentrations are present, both mineralocorticoids and glucocorticoids are deficient. Loss of both types of adrenocortical hormones is likely to be permanent. Replacement therapy for both hormones should be instituted, and mitotane should not be administered until adrenal recovery can be documented by an ACTH stimulation test.

Treatment of AT with mitotane can provide good results. Of 32 dogs with an AT treated with mitotane, 66%, 28%, and 6% were judged by their owners to have a good to excellent, fair, and poor response, respectively. Mitotane does not appear to arrest metastatic tumor growth, and the response in dogs without evidence of metastatic disease is better than that in dogs with metastases. Mean survival time of dogs with ATs treated with mitotane is approximately 16 months, with a reported range of 20 days to 5.1 years.²⁵⁰

Ketoconazole. Ketoconazole is a triazole antifungal drug widely used for the treatment of disseminated fungal diseases. The drug inhibits cytochrome P450 enzymes responsible for synthesis of gonadal and adrenal steroids and has been used to treat hyperadrenocorticism in people. In addition, ketoconazole may antagonize glucocorticoid receptors. In normal dogs

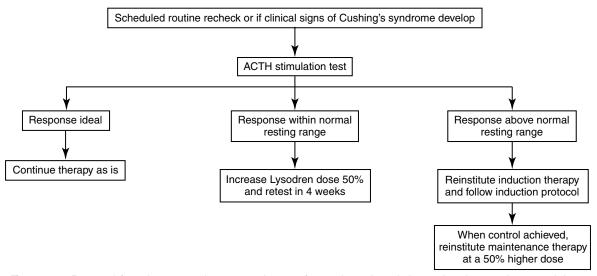

Figure 21-9 Protocol for mitotane maintenance therapy for canine adrenal-dependent hyperadrenocorticism.

ketoconazole administration decreases serum cortisol and testosterone, but not mineralocorticoid, concentrations.^{252,253}

Dosing of ketoconazole should be initiated at 5 mg/kg orally twice daily for 7 days, a low dosage to allow an evaluation period for development of side effects such as gastroenteritis or hepatitis. Light feeding may ameliorate gastritis resulting from ketoconazole administration. If no ill effects are observed during the first week, the dosage should be increased to 10 mg/kg orally twice daily for 14 days, after which an ACTH stimulation test should be performed. The ideal ranges for serum cortisol concentrations before and after ACTH administration are the same as when mitotane is used. If serum cortisol concentrations are above ideal, the ketoconazole dosage should be increased to 15 mg/kg orally twice daily and the dog monitored every 14 to 60 days.²⁵⁴ Dosages equal to or greater than 20 mg/kg twice daily may be required.^{255,256} If no response is seen or the disease progresses despite therapy, ketoconazole should be discontinued and alternative therapy begun.

The efficacy of ketoconazole may be less than that of mitotane. After ketoconazole therapy, basal and post-ACTH cortisol concentrations may actually be higher than those pretreatment in some dogs.²⁴² Of 132 veterinary internists and dermatologists surveyed, specialists likely to treat Cushing's syndrome, 52% considered ketoconazole to be effective in less than 25% of cases, 19% reported effectiveness in 25% to 49% of cases, and 14% each believed ketoconazole to be efficacious in 50% to 74% and 75% to 100% of cases. 256 A recent report suggested a higher efficacy of 70% in 48 dogs,²⁵⁷ but the followup on treated dogs was inconsistent and the ideal post-ACTH cortisol concentration was not as low as recommended by most authors. Thus, although ketoconazole may lower serum cortisol concentration in dogs with PDH and clinical improvement can be seen,^{254,257} whether therapy is truly adequate in such a high percentage is unclear.

Ketoconazole appears to be relatively safe, with a low incidence of side effects. When seen, adverse effects may include anorexia, vomiting, elevated liver enzymes, diarrhea, and icterus.^{256,257} Side effects believed to occur secondary to ketoconazole administration in a small number of cases include depression; weakness; lethargy and trembling; liver failure; polyuria and polydipsia; thrombocytopenia; and dermatologic changes such as altered coat color, poor coat condition, and scaling.²⁵⁶ Lightening of the hair coat may also occur. The effect of ketoconazole on reproductive status has not been addressed, but it does decrease testosterone synthesis in healthy dogs²⁵² and should be used cautiously in male dogs intended for breeding.

Despite possibly limited efficacy and high cost compared with mitotane, ketoconazole therapy may occasionally be warranted. First, ketoconazole can be used in dogs that cannot tolerate mitotane. Second, it may be used as a diagnostic aid when the diagnosis of hyperadrenocorticism is unclear. If an ACTH stimulation test shows that ketoconazole therapy has adequately controlled cortisol secretion, then any clinical signs present that were caused by hyperadrenocorticism should resolve. If the disease is placed in remission and the diagnosis thus confirmed, mitotane treatment can be initiated instead. If no resolution of clinical signs is seen, hyperadrenocorticism can be ruled out as a diagnosis and ketoconazole discontinued. Ketoconazole provides a better alternative to trial therapy than mitotane or trilostane because the adrenolytic effects of mitotane or trilostane may be irreversible, whereas cortisol levels normalize within 24 hours of discontinuing ketoconazole.²⁵⁴ Third, because ATs may be mitotane-resistant or the high doses of mitotane required to treat an AT may cause unacceptable side effects, ketoconazole may be used for medical treatment of ATs or before an adrenalectomy to prepare the patient for surgery. However, no study has evaluated ketoconazole efficacy in a large number of dogs with ATs.

Bromocriptine and selegiline. Dopamine clearly affects ACTH secretion from the pituitary; both elevated dopamine levels and dopamine agonism suppress ACTH secretion, at least from the intermediate lobe of the pituitary. Thus increasing dopamine concentrations or activity may inhibit ACTH oversecretion (Figure 21-10) and be useful for treatment of PDH. Raising dopamine levels can be effective only for PDH, however. Because endogenous ACTH secretion is suppressed in patients with an AT, dopamine agonism or alteration of dopamine metabolism would have little, if any, further effect on ACTH release. Moreover, because ATs function autonomously of ACTH, lowering ACTH levels would not alter cortisol secretion.

Bromocriptine, a dopamine agonist, has met with limited success for treating PDH. In one study bromocriptine was administered to seven dogs with PDH,²⁵⁸ and 40 dogs were included in another.²⁵⁹ Vomiting was a limiting side effect and cause for treatment discontinuation in a large proportion, and only 1 of the 47 responded clinically. Thus bromocriptine is not recommended for treatment of canine PDH.

Monoamine oxidase inhibitors, including selegiline (l-deprenyl), inhibit degradation of biogenic amines, most notably dopamine, and are used to treat dopamine-deficient conditions such as human Parkinson's disease. Unlike other monoamine oxidase inhibitors, selegiline is specific for cerebral forms (i.e., monoamine oxidase B). An important question in treating canine PDH, however, is whether the ACTH-lowering effect of dopamine is on the anterior or intermediate lobe of the pituitary (or both). If dopamine inhibits only intermediate lobe ACTH secretion, as is generally believed, then selegiline use would be efficacious only in cases of PDH caused by intermediate lobe tumors (i.e., approximately 20% of canine PDH cases). Indeed, one study of 10 dogs suggested a 20% response rate.²⁶⁰ Unfortunately, only histopathology can differentiate anterior and pituitary lobe tumors. Furthermore, a more recent study found selegiline to be ineffective for treatment of PDH.261

If selegiline is used to treat PDH, as with other drugs, therapy must be for the lifetime of the animal.²⁶² Treatment should begin at 1 mg/kg orally once daily for 30 days. If no response is seen, the dose should be doubled for an additional 30 days. Failure to respond at that time indicates the need for an alternative therapy. Selegiline therapy is relatively safe. Side effects are uncommon and usually mild, including vomiting, diarrhea, and ptyalism.^{260,261} Severe neurologic disturbances

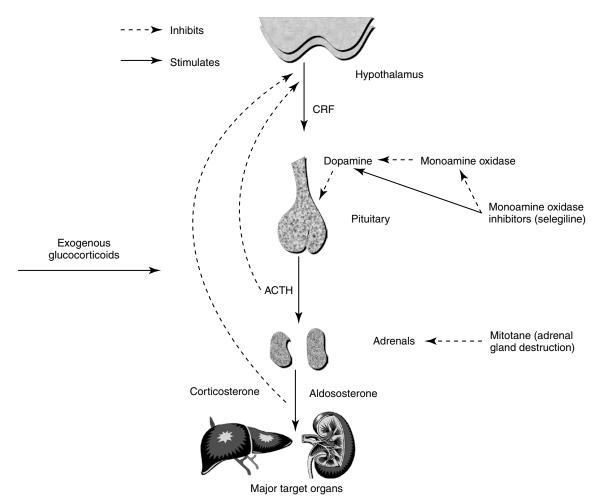

Figure 21-10 Diagram of the hypothalamic-pituitary-adrenal axis and its relationship to medications that affect the axis.

and pancreatitis possibly have been caused by selegiline therapy,²⁶⁰ but the neurologic problems also may have been due to the presence of a large pituitary mass. Chronic selegiline therapy does not result in glucocorticoid insufficiency²⁶³ and, based on its mechanism of action, would not be expected to affect aldosterone secretion. One disadvantage of selegiline is cost. Several generic versions are available, but although the bioequivalency of the generic preparations is the same among themselves, they are less bioavailable than the original product, l-deprenyl (Eldepryl); comparisons with the animal product Anipryl are not available. Thus, it may be wise to avoid the generic products until studies have established the appropriate canine dose. Another disadvantage of using selegiline for treating PDH is that monitoring of efficacy is based solely on relatively subjective findings. The results of the ACTH stimulation test do not change while dogs are receiving selegiline. Thus other objective measures of effect, such as quantification of water intake or measurement of urine specific gravity, should be used.

In general, use of selegiline to treat PDH is not recommended because of its low efficacy, but it could be tried in dogs with PDH that cannot tolerate mitotane and trilostane or as a diagnostic aid, as with ketoconazole. However, trial therapy with selegiline would be hard to judge. The sole measure by which to judge efficacy of therapy is resolution of clinical signs. If an animal does not respond clinically, it would be impossible to tell if the dog did not have hyperadrenocorticism or had an AT or l-deprenyl-resistant PDH. With ketoconazole therapy the ACTH stimulation test provides an objective measure of when adequate biochemical control has been achieved. If cortisol secretion is suppressed by ketoconazole and clinical signs continue, the diagnosis of hyperadrenocorticism can be ruled out.

Trilostane. Trilostane (Vetoryl) has been used to treat hyperadrenocorticism for a number of years in Europe and is now approved by the Food and Drug Administration for treatment of canine hyperadrenocorticism in the United States. A synthetic steroid analog that inhibits the adrenal enzyme 3β -hydroxysteroid dehydrogenase, trilostane suppresses production of progesterone and its end products, including cortisol and aldosterone. Additional enzymes such as 11β -hydroxylase and 11β -hydroxysteroid dehydrogenase may also be affected.²⁶⁴ Trilostane appears to be highly effective in suppressing cortisol secretion and controlling clinical signs in the majority of patients.^{248,265-270} As with mitotane, clinical signs of hyperadrenocorticism typically quickly resolve with control of cortisol concentrations, but certain ones such as dermatologic abnormalities can take up to 3 months. Other abnormalities such as calcinosis cutis or pseudomyotonia may not fully resolve. However, a small proportion of dogs with PDH (<10%) are not well controlled with trilostane.^{267,270,271}

Trilostane is available as 10-, 30- and 60-mg capsules in the United States and may need to be compounded for smaller dogs. In approximately 50% of dogs, dosage adjustments, either up or down, will be required during the course of treatment. Authors of one study noted that in most dogs an initial sensitivity to the drug existed followed by a need for a dose increase. After time, the dose required often hit a plateau.²⁶⁷ Interestingly, the final dose required for control has varied greatly between studies. Part of the discrepancy may relate to the differences in what was considered the ideal post-ACTH serum cortisol concentration. However, in one study the median final dose was 6.1 mg/kg,²⁷⁰ and in another study it was 16 to 19 mg/kg.²⁶⁷ In any case, each dog should be started on the recommended dose, and then the dose should be adjusted according to ACTH stimulation test results. The duration of survival is at least as good as that achieved with mitotane therapy.268

Reported adverse effects for the most part are relatively mild, including lethargy and vomiting, but fatality has occurred.^{267,270,271} Although some studies found relatively low incidence of side effects, one non-peer-reviewed report described mild, self-limiting side effects such as diarrhea, vomiting, and lethargy in 63% of treated dogs.²⁷² Safety has not been evaluated in lactating dogs and males intended for breeding. Trilostane should not be given to pregnant females.

As with mitotane therapy, excessive adrenal gland suppression can occur and warrants discontinuing medication temporarily (discussed later) and lowering the dose. Trilostane can affect aldosterone secretion as well as cortisol, so a hypoadrenocortical crisis can occur. Caution should be used in administering trilostane with an angiotensin-converting enzyme inhibitor or an aldosterone antagonist (e.g., spironolactone) because the suppressive effect on serum aldosterone concentration may be cumulative.

Although, in theory, the effects of trilostane as an enzyme inhibitor should be rapidly reversible (e.g., within a couple days), suppression can last weeks to years.^{266,267,273} One dog developed hypocortisolism after only 3 doses of trilostane; glucocorticoid replacement therapy was needed for at least 1 year.²⁷³ Surprisingly, adrenal necrosis can occur secondary to trilostane administration as well.²⁷⁴ The hypoadrenocorticism reported after complete adrenocortical necrosis in one dog lasted for at least 3 months but likely would be permanent.²⁷⁴ How often acute iatrogenic hypoadrenocorticism will occur in dogs treated with trilostane is unknown but is likely more common than originally believed. In one study four of six dogs with PDH and one of one with AT treated with trilostane had some degree of adrenal necrosis at necropsy. In two dogs the damage was sufficiently severe to cause hypoadrenocorticism. Both dogs had received therapy with mitotane before trilostane but had been on trilostane for 15 and 22 months.²⁷⁵ Thus the contribution of each drug is unclear. Adrenal rupture, possibly secondary to adrenal necrosis, may have occurred (see Vetoryl package insert).

Current guidelines are for a lower starting dose than previously recommended. The package insert states that therapy should be initiated at 2.2 to 6.7 mg/kg once daily with food. These authors recommend starting as close to the low end of the range as possible. If minor side effects are seen, drug administration should be stopped for 3 to 5 days until side effects resolve and then restarted, giving trilostane every other day for 1 week before continuing with the initial dosing scheme. It is important to differentiate minor adverse effects from hypocortisolism, and ACTH stimulation testing may be needed.

Postpill timing is crucial for dogs receiving trilostane, and the test should be initiated at 4 to 6 hours after the pill was administered. Keeping the timing consistent for each patient may also be important. The first scheduled recheck should be after 10 to 14 days of therapy. Lately, recommendations are being made to not increase the trilostane dose for at least 4 weeks after initiating therapy. An initial ACTH stimulation test should be performed after 10-14 days of therapy to ensure hypocortisolemia is not present. If at any time the post-ACTH cortisol concentration is below 40 nmol/L (1.45 µg/dL), the trilostane should be suspended and restarted at a decreased dose after 3 to 7 days (see package insert) or, ideally in the authors' opinion, after recovery of adrenocortical function has been demonstrated. At the 2-week recheck, the dose should only be raised in cases where the owner reports that no improvement has been seen, the clinical signs are still striking, and the post-ACTH cortisol concentration is markedly above ideal. Then, in such cases at 2 weeks or if waiting until the 4-week recheck, if the post-ACTH cortisol concentration is 40 to 150 nmol/L (1.45-5.4 μ g/dL), the dose should continue as is. If the post-ACTH cortisol is 150 to 250 nmol/L (5.4-9.1 µg/dL), the dose can be continued if the dog is doing well clinically; if not, twice-daily therapy should be used. The same dose that was given once daily should be given twice (e.g., if the regimen is 60 mg once daily, it can be doubled to 60 mg twice daily), or a lower dose can be given in the evening (e.g., from 60 mg once daily to 60 mg in the morning and 30 mg in the evening). If the post-ACTH serum cortisol concentration is above 250 nmol/L (9.1 μ g/dL), the trilostane dose should be increased. An ACTH stimulation test should be performed 10 to 14 days after every dose adjustment. Once the clinical condition of the dog and the dose have stabilized, an ACTH stimulation test should be performed 30 and 90 days later and then every 3 months thereafter. Size of dosage adjustment, either up or down, will likely be dictated by available capsule size but ideally should be approximately 25%.

Despite recommendations in the package insert for oncedaily dosing, trilostane may begin to lose effectiveness 8 to 10 hours after the pill is given.^{265,276,277} Indeed, trilostane has been administered twice daily.^{248,265,266} In one study of 44 dogs with PDH, the initial dose of trilostane was 15 mg orally twice daily for dogs less than 5 kg, 30 mg twice daily for dogs 5 to 20 kg, 60 mg in the morning and 30 mg in the evening for dogs 20 to 40 kg, and 60 mg twice daily for dogs larger than 40 kg. At the first recheck (day 7), an ACTH stimulation test was performed starting at 4 to 6 hours after the pill was given. Good control was judged on the basis of clinical signs and a serum cortisol concentration before and after ACTH administration of 30 to 110 nmol/L. Dose was adjusted in 25% to 50% increments. On further rechecks, the ACTH stimulation test was initiated 8 to 12 hours after the pill was given. Good control was believed to be a post-ACTH cortisol concentration of 30 to 250 nmol/L.²⁶⁶

Mean initial dose of trilostane was 6.2 mg/kg (range 2.4 to 15) divided into twice-daily doses. The dose was not changed over the course of the study in 10 dogs, increased in 19, reduced in 5, and both increased and reduced at different times in 10. At all rechecks the mean dose was between 6 and 8 mg/ kg divided into twice-daily doses, but the range was approximately 2 to 20. Adverse reactions were seen in 25% of cases related to low cortisol concentration. In 11% trilostane therapy was discontinued because of prolonged suppression of serum cortisol concentration. In four dogs adrenal function returned to normal and no further treatment was needed; one dog was treated as an Addisonian.²⁶⁶Another study using the same protocol found high efficacy with relatively few side effects, and survival times were longer compared with those of dogs treated with a nonselective adrenocorticolytic protocol.²⁴⁸

Special consideration should be given to twice-daily dosing in dogs in which breaks in control of the hyperadrenocorticism could be detrimental (e.g., in dogs with concurrent DM or dogs with pulmonary thromboembolism secondary to hyperadrenocorticism). The recommended starting dose is 1 mg/kg twice-daily. If using twice-daily therapy, although one study recommended performing an ACTH stimulation test 8-12 hrs post-pill,²⁶⁶ such timing has not been critically evaluated.

An early paper suggested that monitoring of the urine cortisol:creatinine ratio (UCCR) before a trilostane dose could be an indication of duration of action.²⁶¹ However, two studies yielded conflicting results. In 22 dogs with HAC, a morning UCCR pre-dose was lower in dogs with good control compared to those with poor control (14.8 vs. 47.5); however, overlap existed between the 2 groups.²⁶⁵ On the other hand, in 18 PDH dogs, the UCCR was measured in samples collected before or 6 hours after trilostane administration; a pair of urine samples was collected once weekly for 4 weeks. Although basal UCCRs were significantly higher than the 6-hour values, neither the basal nor the 6-hour samples were significantly different between dogs with adequate vs. inadequate control. Post-ACTH cortisol concentrations did not correlate with UCCR. Basal UCCRs in 13 dogs and 6 hours post-trilostane UCCRs in 12 were still above the reference range 8 weeks after the dose was judged to be optimal.^{265a}

Interestingly, in one study, of 6 dogs that had UCCRs within the reference range most of the times, three developed hypocortisolism and in three hypocortisolism was suspected based on clinical signs but was not confirmed. The hypocortisolism was documented or suspected between 16 weeks and 21 months after the trilostane dose was judged to be optimal.^{265a}

How best to switch a dog from mitotane to trilostane is unknown. According to the Vetoryl package insert, a post-ACTH cortisol concentration should be above 250 nmol/L $(9.1 \ \mu g/dL)$ before giving trilostane. It may be ideal to wait at least 30 days after discontinuing mitotane, but if the clinical signs of hyperadrenocorticism are severe, trilostane can be started sooner as long as the post-ACTH cortisol concentration is high enough. Dogs previously treated with mitotane may have greater response to trilostane, so careful monitoring of adrenal function is required.

833

Trilostane has been used to treat five dogs with ATs.²⁷⁸⁻²⁸⁰ Insufficient information is available to ascertain whether the treatment protocol or efficacy varies if treating dogs with PDH versus those with an AT. One dog did receive a maximum dose of 17.2 mg/kg.280 Clinical signs were controlled, at least transiently, and survival prolonged. Survival in one dog was only 117 days.²⁷⁸ In the other four dogs survival was at least 10 to 18 months; interestingly, in three trilostane therapy was initiated when an AT accompanied by pulmonary metastases was identified.^{279,280} Response of ATs to trilostane, at least in these five dogs, compares favorably to that achieved with mitotane. However, in dogs with ATs mitotane theoretically may be the preferred treatment. Mitotane is truly a chemotherapeutic drug in this instance, killing primary neoplastic cells and, perhaps, metastatic cells as well. Trilostane simply would control tumoral secretion, not growth. In fact, in dogs with PDH and in one dog with an AT treated with trilostane, the size of the adrenal glands increased.275,281

Retinoic acid. 9-*cis* Retinoic acid has been used to treat a total of 27 dogs with PDH in two studies. Unfortunately, endogenous ACTH and α -melanocyte-stimulating hormone concentrations and UCCR were used to evaluate treatment, which makes the results difficult to interpret insofar as these tests are not typically used to monitor therapy. Interestingly, pituitary tumor size significantly decreased in 14 dogs that were treated for 180 days.^{282,283} Although results were promising, much more work is necessary before retinoic acid therapy can be recommended, especially when proven therapies such as mitotane or trilostane are available. In addition, retinoic acid at the doses used in the study would likely be cost prohibitive to most owners.

Therapy for Feline Hyperadrenocorticism

Hypercortisolism. Medical therapy for feline classic hyperadrenocorticism (i.e., excessive cortisol as compared to excess of other adrenocortical hormones), appears not to be as successful as in dogs; however, very little information has been published. Unilateral adrenalectomy is the treatment of choice for an AT. Given the limited success of medical therapy, some authors believe bilateral adrenalectomy with subsequent lifelong therapy for hypoadrenocorticism is the treatment of choice for feline PDH. However, cats with severe hyperadrenocorticism may not be good surgical candidates because of the debilitating effects of the disease (e.g., thin skin, immunosuppression, poor wound healing), and medical control for stabilization before surgery would be ideal. Although not available in the United States, transsphenoidal hypophysectomy has been reported for treatment of PDH in seven cats.²⁸⁴ Radiation therapy may be effective for aiding in the control of feline PDH.²⁸⁵ (See also the section on acromegaly later in this chapter.)

Early reports suggested mitotane was not highly effective in cats at doses of 25 mg/kg or 50 mg/kg for up to 90 days,²⁸⁶⁻²⁸⁸ but one case report suggested that mitotane therapy may be successful with higher doses and longer induction periods. A cat was treated with mitotane at 25 mg/kg once daily for 18 days with little effect. At 69 days, after a dose increase to 37.5 mg/kg once daily, there was still minimal effect, but by day 111 the hyperadrenocorticism was controlled.²⁸⁹

In one cat with an adrenocortical carcinoma, ketoconazole caused transient (3.5 months) resolution of polyuria and polydipsia and a reduction in the insulin dose required to control concurrent DM. Interestingly, although basal serum cortisol concentrations decreased during treatment, adrenocortical response to ACTH stimulation was not altered.²⁹⁰ Other mechanisms of action of ketoconazole, such as antagonism of glucocorticoid receptors, may account for the clinical improvement, or it may have been coincidental. In four other cats with hyperadrenocorticism, two responded to ketoconazole doses of 5 mg/kg twice daily for 7 days, followed by 10 mg/kg twice daily indefinitely; one had no response after 2 months; and one developed severe thrombocytopenia after 7 days of treatment, necessitating withdrawal of therapy.²⁹¹

Metyrapone affects cortisol synthesis by inhibiting the adrenal enzyme 11-β-hydroxylase. Clinical response without side effects other than hypoglycemia has been achieved in six cats using 30 to 70 mg/kg twice daily.^{288,292,293} In two cats treated with an unknown dose, one had a slight clinical improvement (partial hair regrowth and slight resolution of polyuria and polydipsia) after 6 months, whereas the other showed no improvement after 1 month.²⁹⁴ Although doses as high as 65 mg/kg three times daily have been used, a maximum of 70 mg/kg twice daily has been recommended to avoid gastrointestinal complications.²⁸⁸ The ACTH stimulation test should be used to ensure adequate control of cortisol secretion with the same goal as for dogs treated with mitotane for PDH. Interestingly, however, one cat had clinical improvement without marked reduction in cortisol concentrations.²⁹² However, the availability of metyrapone varies.

In a total of six cats with PDH, trilostane administration reduced clinical signs and improved endocrine test results, but all continued to have some signs of hypercortisolemia, especially dermal changes.^{295,296} In cats with PDH and DM treated by other means, the DM resolved in about 50% of cases;²²³ however, insulin requirements did not change in four cats with PDH and DM treated with trilostane.295,296 Thus trilostane ameliorates clinical signs of feline hyperadrenocorticism, but more research is needed before it can be recommended for treatment. Whether a higher dosage or longer duration of therapy will improve efficacy remains unclear.²⁹⁵Additionally, the ideal ranges for basal and post-ACTH serum cortisol concentrations and testing time (i.e., performance of ACTH stimulation tests beginning 4 to 6 hours after administration of the pill) for dogs were used. The pharmacokinetics and pharmacodynamics of trilostane are unknown in cats, and it may be necessary to optimize the testing protocols for cats.

Sex hormone excess. Progesterone-secreting adrenal masses have been reported in three cats.^{288,297,298} Clinical signs are

as those for hypercortisolism. With such a mass, the cortisol response to an ACTH stimulation test is blunted, suggestive of iatrogenic hypoadrenocorticism despite a lack of a history of exogenous glucocorticoid administration. Suppression is due to the ability of progestins to feed back on the pituitary and inhibit ACTH secretion as do glucocorticoids.¹⁹⁹ Measurement of sex steroids before and after ACTH stimulation should reveal marked hyperprogesteronemia. Abdominal ultrasonography may reveal an adrenal mass. Treatment of choice is unilateral adrenalectomy. Two cats with progesterone-secreting adrenal tumors were treated with aminoglutethimide, an inhibitor of adrenocortical steroid synthesis, preoperatively. One cat showed improvement at 2 weeks, but the response had diminished by week 6.298 The second cat improved dramatically at first, but significant mammary gland enlargement ensued and aminoglutethimide administration was discontinued; the rapid decrease in progesterone potentially stimulated prolactin secretion.²⁸⁸

One spayed female cat with an AT secreting estradiol and testosterone has been identified, with the most notable clinical signs being aggression and male-type behavior, malodorous urine, and vulvar hyperplasia. Therapy with trilostane (30 mg once daily) was effective in reducing clinical signs; partial improvement was seen by day 28 and almost complete resolution by day 84. Interestingly, basal concentrations of both hormones as well as that of 17-hydroxyprogesterone and progesterone increased with therapy. Clinical signs returned by day 174 despite continued therapy. The reason for clinical improvement in the face of increased measured hormone concentrations is unknown.²⁹⁹ Possibilities include a placebo effect (believed unlikely by the authors of the case report), false elevations of the apparent concentrations of the measured hormones by hormones that cross-react on the assays used,²⁹⁹ or another nonmeasured hormone that did decrease in response to therapy and was responsible for causing the clinical signs. Although unlikely, the sex hormone elevations may have been false-positive test results for a state of excessive sex hormone secretion.

Hyperaldosteronism. Primary hyperaldosteronism can occur in cats from an aldosterone-secreting tumor or from idiopathic non-tumorous secretion of excess aldosterone. Although aldosterone-secreting AT were previously believed to be rare, the incidence may be increasing.³⁰⁰ Affected cats are middle-aged to older, with no sex or breed predisposition. Clinical symptoms of hyperaldosteronism are typically nonspecific and result from potassium depletion, mainly causing hypokalemic myopathy. Historical complaints and physical examination findings include polyuria and polydipsia, nocturia, generalized weakness, collapse, anorexia, weight loss, a pendulous abdomen, and blindness.³⁰⁰⁻³⁰³ One cat presented with respiratory distress; the respiratory failure was believed to be a manifestation of hypokalemic polymyopathy.³⁰⁴ Some cats have bilateral retinal detachments and hypertension.^{300,301} Adrenocortical tumors secreting more than one hormone (e.g., aldosterone and progesterone) have been reported,³⁰⁵ and clinical signs associated with the other hormone (i.e., hyperprogesteronism) may also be present.

The hallmark of primary hyperaldosteronism is hypokalemia with an elevated serum aldosterone concentration but a normal or subnormal plasma renin activity. Measurement of an elevated serum aldosterone concentration alone is not truly adequate, but a feline plasma renin activity assay is not currently commercially available. In humans serum aldosterone concentration is measured after dietary intake of a specific sodium amount. Whether such standardization is necessary in veterinary medicine is unknown, making diagnosis of primary hyperaldosteronism more difficult. The presence of renal failure presents a particular dilemma, insofar as renal failure in and of itself can lead to hypokalemia and hyperaldosteronemia. The magnitude of aldosterone elevation may be the key. With primary hyperaldosteronism, serum concentrations were approximately 3000 pg/mL in two cats,³⁰¹ whereas it was a maximum of 518 pg/mL in azotemic cats.³⁰⁶ Identification of an AT by radiography or ultrasonography in cats with appropriate clinical signs and laboratory results would also be highly suggestive of primary hyperaldosteronism. Until a feline plasma renin assay is available, diagnosis of primary hyperaldosteronism requires that all secondary causes of hyperaldosteronism (e.g., states associated with peripheral edema or liver failure) be ruled out.

Initial treatment of primary hyperaldosteronism is directed at controlling hypokalemia or hypertension (or both). Potassium supplementation using oral potassium gluconate at doses of 2 to 6 mmols twice daily has been used, and intravenous potassium chloride may be required in more severely hypokalemic cases. Amlodipine besylate (0.625 to 1.25 mg per cat once daily) is the initial treatment of choice for hypertension while test results are pending.³⁰⁷ Spironolactone, a competitive aldosterone receptor antagonist, is also recommended (2 to 4 mg/kg once daily), assisting in the control of both hypokalemia and hypertension. Severe facial dermatitis has been reported in Maine Coon cats receiving spironolactone for management of hypertrophic cardiomyopathy.³⁰⁸ Medical management may not be successful long-term or for normalization of serum potassium concentration. The role of antineoplastic chemotherapy has yet to be determined.

Treatment of choice for an AT is adrenalectomy. Given that these tumors are malignant in approximately 50% of cases, surgery may not be curative. In addition, the procedure has been associated with high perioperative mortality; approximately 33% of reported cases died intraoperatively or postoperatively, most commonly as a result of severe acute hemorrhage from the caudal vena cava.³⁰⁷ Medical therapy preoperatively to stabilize a patient is ideal, especially if the tumor is secreting another hormone such as cortisol or progesterone that can create complications such as poor wound healing. A detailed description of perioperative and intraoperative management of an aldosterone-secreting adrenocortical carcinoma with attached caval thrombus has been recently reported.³⁰⁹ Approximately 5% of human patients develop postoperative hyperkalemia, requiring transient administration of fludrocortisone; although not reported in the literature, the same may occur in cats.³⁰⁷

With medical management with combinations of potassium supplementation, amlodipine, and spironolactone, reported survival times in four of five cats with aldosterone-secreting AT ranged from 7 months to 984 days, with cats most commonly succumbing to chronic renal failure or a thromboembolic episode.³⁰⁷ Poor response in the fifth cat may have been due to owner compliance issues. In some cases hypertension becomes refractory to medical management. For cases that undergo adrenalectomy and survive the immediate perioperative and postoperative periods, the prognosis is good; 8 of 17 adrenalectomized cats survived for at least 1 year, and two cats were alive 3.5 and 5 years postoperatively.³⁰⁰ Cats with malignant tumors can do well; one cat with a carcinoma survived 1045 days after adrenalectomy.

An alternate form of hyperaldosteronism now recognized in cats is similar to the idiopathic or bilateral hyperplasia form in humans.³¹⁰ Clinical presentation is similar to the tumorous form with respect to signalment and presenting complaints, but retinal detachment and blindness, perhaps due to the presence of higher blood pressures in general, is more common with idiopathic hyperaldosteronism. Ultrasonography or CT examination of the adrenal glands reveals no changes or only subtle abnormalities such as an increase in adrenal echogenicity or areas of calcification and thickening or rounding of one pole of one or both adrenal glands. Therapy consists of medical management (as discussed previously), and affected cats tend to respond well.³⁰⁷

DISORDERS OF THE PITUITARY GLAND

Disorders of Growth Hormone

Normal Physiology

The primary function of GH is promotion of linear growth. The growth-promoting effects of GH are mediated by IGF-1 or somatomedin C. Growth hormone also stimulates protein synthesis. On the other hand, GH tends to decrease protein catabolism by directly promoting lipolysis and antagonizing the effects of insulin. In excess, GH decreases carbohydrate utilization and impairs cellular glucose uptake. The net effect is promotion of hyperglycemia; carbohydrate intolerance; and, with sustained increases in plasma GH, development of DM, which quickly becomes resistant to insulin treatment.³¹¹

Secretion of GH from the pituitary gland is controlled by releasing (GH-releasing hormone) and inhibiting (somatostatin) factors secreted by the hypothalamus in response to complex neurohumoral regulatory mechanisms. Other stimulators of GH release include the following: other hormones such as ghrelin;³¹² neurogenic stimuli, including α -adrenergic, dopaminergic, and cholinergic factors such as clonidine and xylazine; and metabolic factors such as the presence of certain nutrient metabolites and hypoglycemia. Secretion of GH results in feedback inhibition to and subsequent release of somatostatin from the pituitary gland.

Hyposomatotropism

Conditions associated with GH deficiency include pituitary dwarfism and GH-responsive dermatosis. Congenital GH deficiency in dogs is most often encountered in German Shepherd dogs but has also been reported in cats and other canine breeds. In German Shepherd dogs, the defect is inherited through a simple autosomal recessive pattern, but the gene has yet to be identified.³¹³

Clinical signs. Clinical signs of congenital GH deficiency include abnormal growth (i.e., proportional dwarfism), bilaterally symmetric truncal alopecia, and severe cutaneous hyperpigmentation. In adults with acquired hyposomatotropism, manifestations are purely dermatologic.

Diagnosis. Diagnosis of congenital pituitary dwarfism is made on the basis of signalment, history, physical examination, endocrine testing, and ruling out of other causes of small stature. Measurement of changes in GH concentrations in response to stimulation (e.g., administration of xylazine, clonidine, or ghrelin) can be used to diagnose disorders of GH secretion and would be ideal. In German Shepherd dogs, ghrelin-induced plasma GH concentrations above 5 µg/L likely exclude a GH deficiency. However, false-negative results may be encountered,³¹² and validated GH assays are not commercially available in the United States. An alternative method of diagnosis of congenital GH deficiency is measurement of serum IGF-1 concentration, which should be low. Interpretation of results, however, must take into account the size of the breed, because smaller dogs have lower normal IGF-1 concentrations than larger breeds. Pituitary dwarves may also be hypothyroid, so appropriate testing should be undertaken.

Clinical manifestations of adult-onset GH deficiency are typically confined to the skin, causing bilaterally symmetric alopecia and hyperpigmentation. Hyposomatotropism may develop in adults in rare cases owing to pituitary gland destruction by inflammatory, traumatic, vascular, or neoplastic disorders.³¹¹ An idiopathic form of acquired hyposomatotropism termed adult-onset, GH-responsive dermatosis was previously believed to occur in dogs, but its existence is now questioned. Dogs previously receiving this diagnosis likely had an idiopathic condition currently called *Alopecia X*. In addition, many other disorders can cause a similar clinical appearance (e.g., hyperadrenocorticism, Sertoli cell neoplasia, castration-responsive dermatosis, hyperestrogenism of intact female dogs, estrogen-responsive dermatosis of spayed female dogs, testosterone-responsive dermatosis, and telogen defluxion) and should be ruled out before a diagnosis of GH deficiency is sought in an alopecic dog. Although hair regrowth may occur with exogenous GH therapy, it is likely a nonspecific pharmacologic effect, and response to therapy does not prove a GH deficiency existed.

Therapy. Therapy for pituitary dwarfism relies on obtaining adequate serum GH concentrations, but no effective exogenous GH product is readily available for use in dogs. Recombinant human GH is expensive and can induce antibody formation that interferes with its effectiveness.³¹⁴ Although porcine and canine GH are structurally identical, the availability of porcine GH is variable. If obtainable, the recommended initial dose of porcine GH is 0.1 IU/kg subcutaneously 3 times weekly. Subsequent adjustments in dosage and administration frequency should be based on clinical response and plasma IGF-1 concentrations. The therapeutic goal is to maintain plasma IGF-1 concentration within the reference range for the breed. Hypersensitivity reactions, carbohydrate intolerance,

and DM are the primary adverse effects; DM may become permanent if not detected early and the GH administration discontinued.³¹¹

Because progestins can cause mammary gland production and secretion of GH in dogs,^{315,316} their administration is a potential therapy for canine GH deficiency. Two pituitary dwarves treated with medroxyprogesterone acetate (2.5 to 5 mg/kg initially at 3-week intervals and then at 6-week intervals) had an increased body size and growth of a complete adult hair coat. However, pruritic pyoderma, cystic endometrial hyperplasia with mucometra, and signs of acromegaly were noted in one or both dogs. The dogs were alive and healthy for at least 3 years after starting therapy.³¹⁷ Another three dogs were treated with proligestone (10 mg/kg subcutaneously every 3 weeks) and growth, increased IGF-1 levels, and improvement in hair coat were seen, but complications included development of clinical features of acromegaly, mammary development, and vulvar discharge in one intact female.³¹⁸ The dose of progestin used to treat GH deficiency must be altered to avoid side effects while maintaining a clinical response. Progestins can cause DM, however, as can GH, so appropriate monitoring must be done.

If treating GH-responsive dermatosis, if porcine GH is available, the recommended dose is 0.1 IU (0.05 mg)/kg subcutaneously 3 times per week for 4 to 6 weeks. Hypersensitivity reactions, carbohydrate intolerance, and overt DM are the primary adverse reactions. Hair regrowth and thickening of the skin are measures used to assess therapeutic response. The hair coat should improve within 4 to 6 weeks of the start of therapy. The hair that grows back consists primarily of secondary hairs, with variable regrowth of primary, or guard, hairs.³¹¹ Duration of clinical remission in dogs that respond to therapy varies but may be up to 3 years. A 1-week course of GH treatment should be given if clinical signs begin to recur.³¹¹ Some dogs with suspected GH-responsive dermatosis fail to respond adequately to GH treatment. A misdiagnosis, inactive GH, or the presence of GH antibodies should be considered.311

Hypersomatotropism

Acromegaly is caused by excessive GH secretion. Canine acromegaly is almost exclusively seen in intact bitches or in dogs receiving progestin therapy. In dogs progestins can induce GH production in foci of hyperplastic ductular mammary glandepithelium.^{315,316} The progestin-induced mammary glandderived protein is identical to GH from the pituitary gland and is biologically active.³¹⁵ In dogs a single case each of a GH-secreting pituitary tumor³¹⁹ and elevated serum GH concentrations secondary to an astrocytoma in a young dog have been reported.³²⁰ Progestins do not cause GH secretion in cats. Feline acromegaly is due to GH-secreting pituitary tumors, predominantly in older, male castrated cats.

Clinical signs. Clinical signs of acromegaly reflect either anabolic or catabolic abnormalities. The most common in dogs is inspiratory stridor (due to soft tissue accumulation in the pharynx) and its accompanying sequelae. Increased body size can also be seen as a result of proliferation of connective

tissues and flat-bone growth, particularly of the feet, head, and abdomen. Organomegaly is often present. Thickening of the skin and widening of interdental spaces may occur. In cats the most common observed clinical signs are organomegaly, prognathia inferior, broad facial features, and respiratory stridor, although some cats may not grossly appear to have any abnormalities.¹⁷¹ Catabolic effects cause insulin antagonism; indeed, the presence of DM may be the first clinical problem noted. Cardiovascular abnormalities associated with acromegaly include the presence of systolic murmurs or gallop rhythms; radiographic evidence of cardiomegaly; echocardiographic changes such as left ventricular wall hypertrophy, intraventricular wall hypertrophy, and left or right (or both) atrial enlargement, and systolic anterior motion of the mitral valve;and, late in the course of the disease, congestive heart failure.^{311,321} Lastly, in cases of acromegaly due to a pituitary tumor, neurologic signs may be observed.

Diagnosis. The diagnosis of acromegaly can be made on the basis of signalment, history, physical examination, and measurement of serum IGF-1 or GH concentrations. In dogs the vast majority of cases are due to progestin exposure, so they occur in middle-aged to older intact females or dogs receiving exogenous progestin therapy. In most cats the diagnosis is ultimately based on identification of conformational alterations (e.g., increased body size, large head, prognathia inferior, organomegaly) in a cat with insulin-resistant DM, a persistent increase rather than decrease in body weight in the face of poorly controlled DM, an increase in serum IGF-1 concentration in the face of insulin-resistant DM, and documentation of a pituitary mass by CT or MRI. Although nonacromegalic diabetic cats can have elevated IGF-1 concentrations,^{322,323} measurement of IGF-1 is still helpful in diagnosis. The IGFlassay is performed at only one laboratory in the United States (Michigan State University). The reference range for feline serum IGF-1 concentration is 5 to 70 nmol/L. An IGF-1 concentration above 100 nmol/L is consistent with acromegaly in cats with the appropriate clinical features; a concentration of 70 to 100 nmol/L is nondiagnostic. However, measurements repeated in 3 to 6 months are usually diagnostic as acromegalic or not.³¹¹ An ovine GH assay was recently validated for measurement of feline GH, but it is not currently commercially available in the United States. Concentrations of GH ranged from 1.87 to 6.33 μ g/L in healthy cats and from 8.45 to 33.2 µg/L in acromegalic cats.³²⁴ Also, most cats have a tumor visible on CT or MRI at the time acromegaly is tentatively diagnosed.311

Therapy. Treatment for acromegaly caused by a pituitary tumor is aimed at decreasing tumor size as well as diminishing GH secretion. Transsphenoidal cryohypophysectomy has been described.³²⁵ An effective medical option has not been reported; neither octreotide³²¹ nor l-deprenyl³²⁶ has been successful in decreasing GH secretion or improving insulin sensitivity.

Radiation therapy is currently considered the best treatment option for feline acromegaly. In one study, eight cats with pituitary tumors were treated with radiation therapy.³²⁷ Four cats had hyperadrenocorticism, three had acromegaly, and one tumor was nonsecretory. In six cats no acute adverse effects developed; in two cats transient early-delayed brain effects occurred in one and acute aural effects in the other. Reported late adverse effects included suspected radiation-induced hearing loss in two cats (mild in one, complete in another), bilateral cataracts 13 months after therapy in one, blindness in another (not clearly related to the radiation), and pharyngeal squamous cell carcinoma 16 months after radiation therapy in one. Other side effects of radiation therapy comprised transient, mild epilation and hair depigmentation in the treatment field. Clinical signs improved in all cats, but endocrine testing normalized in only one.³²⁷ In another study of 14 acromegalic cats, adverse effects included personality change and seizures in one each and weight loss in two.³²⁸

Radiation therapy can help decrease insulin doses and improve insulin sensitivity. In six cats treated with radiation, three each with acromegaly and PDH, all had insulin-resistant DM before radiation therapy and became insulin sensitive after therapy. However, five required exogenous insulin administration for the rest of their lives.³²⁷ In two cats with acromegaly, one had a slight reduction in insulin dose, and in the other the dose decreased 50%.329 In 14 cats with acromegaly, 13 had improved diabetic control after radiation therapy that was sustained for variable, unpredictable lengths of time up to 60 months. Seven cats responded while still receiving radiation, but the mean time until improved control occurred was 5 weeks after therapy. Remission was achieved in six cats, at a mean of 3.6 months after therapy; three cats did not require insulin for at least 32 months, and three relapsed after 3, 17, and 24 months. In two cats, DM began to progress after 19 and 21 months. Interestingly, changes in IGF-1 concentrations did not appear to correlate with glycemic control.³²⁸

Of eight cats treated with radiation therapy, median survival time for all cats, those with an adenoma (n=6), and those with a carcinoma (n = 2) were 523, 587, and 252 days, respectively. For those with an adenoma, six were alive at 1 year and three at 2 years. In 14 cats, median survival was 28 months (approximately 840 days).³²⁸ Euthanasia or death is often not related to the pituitary tumor, but in a few cases poor diabetic control can be a contributing factor.³²⁷⁻³²⁹

If acromegaly is due to progestin therapy in a dog, administration should be discontinued. Intact bitches should be spayed. With elimination of the endogenous or exogenous progestin exposure, the anabolically induced clinical signs (e.g., increased soft tissue mass) should resolve when GH concentrations return to normal.³¹¹ On the other hand, if β cell activity of the pancreas has become impaired, DM may be permanent.

Despite lack of treatment options, prognosis is still good, given that GH-secreting tumors typically grows slowly. The concomitant DM, however, is ultimately very difficult to control because GH causes profound insulin resistance.

Diabetes Insipidus

Normally, vasopressin (antidiuretic hormone [ADH]) is secreted, along with oxytocin, from the posterior pituitary. The major stimuli for vasopressin release are an increase in plasma osmolality ($\geq 2\%$) and volume depletion, but other stimuli such as nausea, pain, and hypoglycemia will stimulate its release.³³⁰ Vasopressin has both pressor and antidiuretic effects. Arginine vasopressin is the predominant hormone in most animals (lysine vasopressin exists in pigs) and is associated with strong pressor actions. Vasopressin binds to the V₂ receptor on the basolateral surface of the principal cell of distal renal nephrons, causing increased water reabsorption. The binding leads to an increase in intracellular cAMP and activation of a cAMP-dependent protein kinase. The protein kinase phosphorylates a serine residue on vesicles containing water channels (aquaporins [AQPs]), beneath the luminal membrane. Ultimately, the AQPs fuse with the luminal membrane and increase tubular water permeability, allowing water and solutes to follow the concentration gradient into the hyperosmotic renal medullary concentrating gradient surrounding the ducts.^{330,331} Up to 90% of the fluid filtered by the glomerulus that is not absorbed in the proximal nephron will be reabsorbed in the distal tubules under the presence of ADH. In the absence of ADH, the distal and collecting tubules become impermeable to movement of water or solutes (most notably urea). The hypotonic filtrate formed in the proximal nephron is eliminated unchanged, resulting in a water diuresis that is characterized by a large volume of urine with a low osmolality.

Diabetes insipidus results from either a complete or partial deficiency in ADH secretion (i.e., central diabetes insipidus [CDI]), or ADH interaction with its target receptors in the distal and collecting renal tubules (i.e., nephrogenic diabetes insipidus [NDI]). Causes of CDI include trauma, neoplasia, and hypothalamic-pituitary malformations or it may be idiopathic. Additionally, CDI is reported as a potential complication of transsphenoidal hypophysectomy in dogs.²⁴¹ NDI may be congenital or secondary to an acquired disease. In humans congenital NDI is most often secondary to an X-linked genetic mutation in a V₂ receptor gene that results in a mutation in the receptor.³³² Congenital NDI is rare in veterinary medicine and is not known to be a heritable defect. There are few published case reports of NDI in young dogs;^{333,334} it has never been reported in cats. Documented causes of acquired NDI include drugs, such as amphotericin B; infections such as pyometra, neoplasia, hypercalcemia, and hypokalemia; endocrine disorders such as hyperadrenocorticism and hyperthyroidism; renal failure; and pregnancy.335-337 Aging, in humans and rodents, is a cause of acquired NDI, likely mediated through interference with the aquaporin-2 water channels of the renal collecting ducts.338,339

Clinical signs. Polyuria and polydipsia are the clinical signs that tend to catch the attention of pet owners. Polyuria and polydipsia can also lead to worsening of urinary incontinence in dogs that are already are or predisposed to be incontinent and the incontinence may be the cause of presentation to a veterinarian. In patients with CDI secondary to a pituitary tumor, which may account for approximately 40% of cases of acquired canine CDI, neurologic signs may also be present.

Diagnosis. The modified water deprivation test is used to distinguish between CDI, NDI, and psychogenic polydipsia.

The reader is referred elsewhere for an in-depth discussion on how to perform the test.³³⁰ In working up dogs or cats with polyuria and polydipsia, the clinician should perform the modified water deprivation test *last*. All other causes of polyuria and polydipsia other than CDI, NDI, and psychogenic polydipsia should be ruled out before the test is performed.

Response to 1-deamino-(8-D-arginine) vasopressin (DDAVP) may be used diagnostically by evaluating response to therapy.^{330,340} Although easier to perform than a modified water deprivation test, the results can be difficult to interpret. The patient's 24-hour water intake for 2 or 3 days should be measured while the patient is allowed free-choice water. A urine sample should also be collected at a given time each day to check urine osmolality and specific gravity. After these initial days, the patient should be treated with DDAVP by administering the intranasal preparation (1 to 4 drops placed in conjunctival sac) or the oral tablets (0.1 mg) every 12 hours for 5 to 7 days.³⁴¹ Water intake is monitored and a urine sample obtained on the fifth to seventh day of treatment at the same time of day as before treatment. A dramatic reduction in water intake or an increase in urine concentration (i.e. >50%) provides strong evidence for CDI. Moderate response is consistent with partial CDI.³³⁰ A mild response is suggestive of psychogenic polydipsia. If no response is seen, NDI is present. Medullary washout initially may decrease response to DDAVP, but urine output should decrease nonetheless if CDI is the cause of the polyuria/polydipsia. Water intoxication is possible. Failure to respond to DDAVP indicates that treatment with DDAVP will not be successful.330

Therapy. In the ADH molecule, substitution of D-arginine for L-arginine (at amino acid 8) and modification of cysteine yields a powerful antidiuretic, DDAVP. Whereas AVP interacts with receptors in vascular smooth muscle (V_1 phosphatidylinositol-dependent receptors), thereby increasing blood pressure, and renal epithelial cells (V_2 , c-AMP-dependent receptors), for the antidiuretic effects, DDAVP primarily interacts with V_2 receptors.

DDAVP is commercially available (Desmopressin) as a product approved for use in humans in three preparations: parenteral injection, nasal drops, or oral tablets. Because these products target primarily V_2 receptors, effects are essentially renal in action, with two exceptions. DDAVP can cause peripheral resistance and blood pressure to decrease.

For patients with complete CDI, the only therapeutic option is replacement therapy with DDAVP. This can be used for patients with partial CDI as well. If the intranasal drops available for humans are being used, administration may be more easily accomplished by transferring the nasal spray to a sterile eye-dropper bottle and placing the drops into the conjunctival sac. Duration of action of DDAVP is 8 to 24 hours, but it can vary even in the same individual, possibly because of discrepancies in drop size. The dose must be titrated to effect. Dosages in the range of 1 to 4 drops every 12 to 24 hours typically suffice,^{342,343} but administration three times daily may be required.^{340,344} Alternatively, DDAVP can be administered subcutaneously at 0.5 to 2 µg daily to twice daily.³³⁰ Because nasal drops are less expensive than the parenteral preparation,

subcutaneous administration of the intranasal drops has been reported. If the intranasal formulation is used, it should be passed through a bacteriostatic filter before injection. Lastly, oral DDAVP can be administered. A dose of 0.1 mg every 8 hours has been recommended, with a gradual increase as needed to effect if unacceptable polyuria and polydipsia persist 1 week after initiating therapy. Once clinical response is seen, a decrease in frequency to twice daily can be tried.³³⁰ It should be noted that no controlled studies on efficacy or dose of oral DDAVP have been reported in veterinary medicine, and the recommendations are anecdotal.

DDAVP administration appears safe. Conjunctival irritation occasionally occurs because the solution is acidic.³³⁰ In theory, water intoxication is a potential, serious complication. Given this possibility, it is recommended that DDAVP be administered only after polyuria and polydipsia recurs or only at night, when the need for control of polyuria and polydipsia is typically greatest so as to avoid nocturia. If DDAVP is given before polyuria and polydipsia is seen, the pet should ideally not be allowed free access to water immediately after each dose to prevent consumption of large amounts of water that the animal will not be able to excrete owing to the DDAVP effects. Although most owners do not do this, water intoxication has not been reported.

DDAVP therapy can be expensive. As an alternative, DDAVP may be administered only when polyuria and polydipsia is objectionable (e.g., to prevent nocturia or when guests are expected). As long as the pet always has unlimited access to water and an appropriate area for urination, therapy can be discontinued. A low-salt diet should be fed.³³⁰

Chlorpropamide is an oral hypoglycemic agent discovered to reduce urine output by 30% to 70% in humans with CDI. The exact mechanism of action is unknown, but chlorpropamide may raise the sensitivity of the renal collecting duct epithelium to low concentrations of ADH. Thus chlorpropamide is probably useful only for partial CDI in which the neurohypophysis has some residual secretory capacity.^{330,344} Chlorpropamide has not been highly successful in veterinary medicine. No success was seen at 10 to 40 mg/kg in several cases, and severe hypoglycemia occurred in one patient.³⁴⁴ Clinical signs resolved in one cat for 7.5 months (40 mg/ day orally) until the cat died suddenly. Although the death was not believed to be due to the medication, the cause was unknown.345 No adverse effects have been reported other than hypoglycemia. To prevent hypoglycemia, regular feeding schedules must be used.330

Paradoxically, thiazide diuretics are advocated for treatment of CDI and NDI. By inhibiting sodium reabsorption in the ascending loop of Henle, thiazides reduce total body sodium concentration, causing contraction of extracellular fluid volume and increasing salt and water reabsorption in the proximal tubule. As a result, the fluid reaching the distal renal tubule has a lower sodium concentration and exerts less osmotic pressure. The net effect is a slight increase in urine osmolality with a proportionate reduction in urine volume. Depending on sodium intake, polyuria is reduced by 30% to 50% in humans.³³⁰ No published reports exist for use of thiazide diuretics in dogs with CDI. Hydrochlorothiazide (2.5-5.0 mg/kg twice daily) and chlorothiazide (20-40 mg/kg twice daily) can be tried.³⁴⁶ In two cats hydrochlorothiazide (12.5 mg/cat twice daily) and a sodium-restricted diet decreased water intake 35%.^{340,347} A low-salt diet should be fed.³³⁰ For spontaneous NDI, therapy is restricted to thiazide diuretics or a low-sodium diet (or both). In one dog chlorothiazide (approximately 35 mg/kg twice daily orally) and a low-sodium diet decreased water intake approximately fourfold, although it was still approximately 2 times normal.³³³

Dermatologic Therapy

Robert A. Kennis and Dawn Merton Boothe

Chapter Outline

ANATOMY AND PHYSIOLOGY OF THE SKIN AS THEY	TRANSDERMAL DELIVERY OF DRUGS
RELATE TO DRUG THERAPY	TREATMENT OF SPECIFIC DERMATOLOGIC
PRINCIPLES OF TOPICAL DRUG THERAPY	DISORDERS
Drug Movement and the Skin	Chronic Pruritus
Vehicles	Drug Therapy
Classes of Topical Drugs	Acral Lick Dermatitis
SYSTEMIC DERMATOLOGIC THERAPY	Canine Seborrhea
Antimicrobials	Generalized Demodicosis
Antiinflammatory and Antipruritic Agents	Dermatophytosis
Antiparasitic Drugs	Canine Perianal Fistulae (Anal Furunculosis)
Immunomodulators	

A major advantage of treating diseases of the skin is easy access to the site of disease. Drug delivery can be facilitated by topical therapy, and response can be based on visual examination (clinical signs) rather than solely on supportive diagnostic aids. The advent of topical drug therapy has also, however, led to a plethora of systems designed to deliver drug to the skin; its upper layers; through the skin; and, in some instances, into systemic circulation. The result is an innumerable list of products that vary in active and inactive ingredients. This chapter approaches treatment of skin diseases by first discussing drugs that are intended for topical administration and then drugs intended for systemic therapy. Finally, specific skin diseases are addressed.

KEY POINT 22-1 Successful dermatologic therapy is based on myriad factors. Dosages and frequency of administration should be modified to meet the needs of the individual patient.

ANATOMY AND PHYSIOLOGY OF THE SKIN AS THEY RELATE TO DRUG THERAPY

The skin is the largest organ of the body, accounting for 12% of body weight in the adult dog and 24% in the puppy.¹ Although structurally canine and feline skin markedly varies from human skin, some similarity is maintained among the species. Generally, skin is thickest on the head, dorsum, and plantar and palmar surfaces of the feet; thinner on the ventral abdomen, medial aspects of the limbs, and inner pinnae; and thinnest on the scrotum.² The skin is perforated by several appendages, the number and structure of which varies among

the species. In cats and dogs, these include hair follicles, sebaceous and sweat glands, and nails.

Histologically, the skin is composed of the epidermis and dermis. Dermis is essentially composed of connective tissue, including collagen, elastin, and reticular fibers, and amorphous ground substance. It can be roughly separated into a dense, deeper reticular layer that connects the dermis to the hypodermis (composed mostly of fat) and a more superficial, loosely packed papillary layer. The dermis contains an arterial and venous network that provides nutrients to the epidermis and receives topically administered drugs able to penetrate this region, which distribute to the rest of the body.² Cutaneous blood flow rates can affect percutaneous absorption of drugs. Cutaneous blood flow in the dog and cat is greatest in the skin of the ventral abdomen and pinnea.² This fact, coupled with skin thickness, leads to these regions serving as the site of drug delivery for many topically applied drugs intended to have systemic effects.

The epidermis is composed of stratified squamous keratinized epithelium that undergoes sequential superficial differentiation. Five layers of the epidermis exist, with the stratum basale being deepest, followed by the stratum spinosum, stratum granulosum, stratum lucidum, and the stratum corneum (the most superficial layer). Among these layers the stratum corneum is the most important to topical drug therapy because it is the primary barrier. The stratum corneum consists of several layers of dead cells, which present a significant lipid barrier to drug penetration. The thickness varies with the area of the body. The cells are aligned to minimize water loss and are surrounded by a plasma membrane that serves as a barrier to movement into or out of the skin.²

The epidermis is anaerobic² because of the absence of capillaries that directly provide oxygen to the cells.² Despite the fact that 80% of the total energy requirements of the skin occur by anaerobic glycolysis, the skin is metabolically active. Drugs that are able to pass through the stratum corneum potentially are subjected to drug-metabolizing enzymes similar to those in the liver. The skin has a great capacity to synthesize lipids, which are located in the extracellular (intercellular) material, the primary barrier to drug penetration in this region of the epidermis.² Lipids are important to intercellular cohesion, permeability (barrier), function, and normal desquamation of mature corneocytes.³ Epidermal lipids include both free and esterified fatty acids, sphingolipids, free and esterified cholesterol, and phospholipids.³ The lipids form a bilipid layer, with the hydrophobic and hydrophilic ends aligning within themselves.² As the epidermis differentiates, the fatty acid component tends to increase. Alterations in the lipid layer result in the release of arachidonic acid and the subsequent formation of inflammatory mediators. Keratin is the major protein of the skin and is the foundation of the hair.²

PRINCIPLES OF TOPICAL DRUG THERAPY

Topical drug therapy is indicated as initial therapy until a definitive diagnosis can be made (i.e., while waiting for results from diagnostic tests), as an adjunct to systemic therapy, and as sole treatment for selected specific dermatologic diseases. A definitive diagnosis of the cause of the skin disease should be made if possible before any masking treatments have been initiated. Therapy may be based on the morphology of skin lesions if further diagnostics yield no useful data. The clinician must be able to distinguish between primary and secondary lesions. Primary lesions develop as a direct result of the underlying disease. Secondary lesions may evolve from the primary lesion, trauma (e.g., scratching) induced by patient response to the lesion, or medications. The clinician must also be able to recognize or discriminate between acute versus chronic, deep versus superficial, and benign versus malignant lesions.

Clinicians should be very familiar with one or two drugs from each class (e.g., one keratolytic, two topical antifungals). Lesions should be evaluated frequently to assess therapy and the need to modify treatment because of treatment failure or adverse effects. The clinician must know the adverse effects of each drug and anticipate and look for evidence of these effects. Clients must be well educated regarding topical drug agents and the need for compliance. Several principles can guide effective use of dermatologic agents.

Drug Movement and the Skin

The skin functions as a barrier to prevent loss of water, electrolytes, and macromolecules and to exclude external agents (chemical, physical, and microbiologic) from the internal environment. The stratum corneum is the layer of the epidermis that is primarily responsible for this physical barrier because of the abundance of keratin and the configuration and content of the intercellular lipids. Topically applied drugs can be absorbed by three routes; they are, in order of importance or magnitude, the stratum corneum (between rather than through the cells), hair follicles, and sweat or sebaceous glands that open into the hair follicle. Movement of drug through the stratum corneum occurs by passive diffusion. Only a very small proportion of topically applied drug penetrates the stratum corneum. Despite the alignment of the lipid layer, both lipid-soluble and water-soluble drugs can pass through the stratum corneum, although passage may occur through the appendages. In general, permeability of lipophilic drugs through intact skin is generally greater than that of polar drugs.⁴ More drug is likely to pass through the skin of heavily haired animals because of the larger number of hair follicles.

Before a drug can move through the stratum corneum, it must first move out of the vehicle. Thus factors that affect percutaneous absorption are not limited to the drug but include factors involving the vehicle. Drug movement through the skin has been mathematically described (Fick's law)² to be directly proportional to the partition coefficient between the vehicle and the stratum corneum, the concentration of drug dissolved in the vehicle, the diffusion coefficient, and the surface area of the skin to which the drug is applied. Percutaneous absorption is inversely proportional to the depth of the stratum corneum (and additional layers). The driving force for absorption, as with any drug movement, is concentration of diffusible drug. The higher the concentration of the dissolved drug in the barrier (stratum corneum), the greater the diffusion "gradient." Drugs with a high degree of lipid solubility achieve higher concentrations in the stratum corneum because it is lipophilic. Large drug molecules are absorbed less readily.

Vehicles

A vehicle is a substance used in a medicinal preparation as the agent for carrying the active ingredient. Occasionally, the vehicle is therapeutic, but usually it is inactive. The vehicle of a topical agent can profoundly affect movement of drug into the skin. Two topical medications may have the same active ingredient at the same concentration but have different vehicles and thus markedly differ in efficacy. A drug must be sufficiently soluble in a vehicle such that it can distribute throughout the vehicle and thus come in contact with the skin in diffusible form. It cannot, however, be so soluble in the vehicle that it does not leave the vehicle and thus penetrate the skin. Vehicle selection is critical to effective topical therapy. A vehicle not only acts as a carrier but also can have a direct impact on the skin and thus on drug movement.

Characteristics of a Vehicle

The physical and chemical characteristics of the vehicle and the drug largely determine drug movement. The partition coefficient describes the relative affinity of a hydrophobic phase and a hydrophilic phase. The greater the partition coefficient, the greater the affinity between the drug and the lipid phase of the skin, which generally results in an increase in percutaneous absorption of the drug. Once the skin is penetrated, however, the drug must be able to leave the lipid phase of the skin if it is to reach systemic circulation. Drugs with very high partition coefficients tend to remain in the lipid layer, causing a reservoir effect. A partition coefficient of 1 is desired for topical medicaments.²

The rate of vehicle penetration through the stratum corneum also influences percutaneous absorption. If vehicle penetration of the stratum corneum is more rapid than penetration of the skin, the concentration of drug in the vehicle on the surface of the skin increases, perhaps to the point of precipitation, slowing absorption. Evaporation of the vehicle will cause the same effect.² Some vehicles are used to facilitate drug movement into the skin. For example, dimethylsulfoxide (DMSO) is so hygroscopic that it readily moves through the skin, carrying many drugs with it. The vehicle may contain ingredients (e.g., Tween) intended to facilitate percutaneous drug absorption by altering the integrity of the stratum corneum. Disruption of the composition or lipid orientation of the stratum corneum enhances drug penetrability. A vehicle that hydrates the corneum facilitates drug penetration. Occlusion of the skin increases hydration; vehicles can occlude by preventing skin transpiration, the passage of water vapor from the skin. Occlusive bandages also can be used to facilitate drug absorption. Water associated with hydration alters the compact structure of the corneum, decreasing resistance to drug movement. Dehydration of the stratum corneum decreases drug absorption; rehydration might be indicated before drug application.

Other patient factors that influence drug movement include the integrity of the barrier presented by the stratum corneum. Drug absorption dramatically increases if the skin has been traumatized, leading to the disruption of the stratum corneum. Absorption may also be enhanced by rubbing a medicament vigorously onto the skin. Prior removal of debris on the surface of the skin (e.g., dirt, blood, hair) can increase drug absorption, as can increasing the temperature of the skin (with sweats or water). Enhanced blood flow to the area might force drug into the hair follicles and through the stratum corneum. A warmer environmental temperature also might increase drug movement into the skin.

Many vehicles are represented in the commercial products for veterinary use. Compounding of dermatologic products is a relatively common practice in veterinary medicine. Although this can often provide a safe and effective therapeutic agent, it is important to remember that the effect of the vehicle on bioavailability of the active ingredient(s) can be profound. The resulting product may be entirely ineffective because of lack of absorption, or it may cause toxicity as a result of systemic absorption.

Types of Vehicles

Water itself can be therapeutic. Bathing with water vehicles (especially shampoos) contributes to dermatologic therapy by removing debris, including potential allergens, bacteria, and other organisms, from the skin surface and rehydrating and cooling the skin (if cool water is used).⁵ The addition of other drugs (shampoos, soaks, and dips or rinses) to water, forming an aqueous solution, suspension, or lotion, can create other therapeutic effects. Aqueous medications are often the topical treatment of choice for acute exudative dermatoses.

Shampoos, a type of water vehicle, can be very effective adjuvants for the control of dermatoses.^{5,6} In general, contact time should be at least 10 minutes. Shampoos generally are applied once to twice weekly. Examples of shampoos with therapeutic intent include hypoallergenic shampoos, which are cleansing and moisturizing; antipruritic shampoos, which often contain colloidal oatmeal along with antihistamines, anesthetics (pramoxine hydrochloride), or cortisone 1%; and insecticidal shampoos containing compounds such as pyrethrins, carbaryl, and permethrin. Application of rinses, sprays, or lotions can enhance the residual effect of shampoos.

Rinses generally are applied after a shampoo and are not necessarily intended to be completely rinsed from the coat. Incomplete rinses may increase the residual effect of the drug but also may leave the coat greasy to the touch and dull (especially on long-haired coats). Rinses include cream rinses (generally rinsed off the animal) and aqueous rinses (generally not rinsed off). Aqueous rinses also can be applied as a soak, which should last at least 10 to 15 minutes. Powders (colloidal oatmeal) intended to be applied as soaks can be placed in cheesecloth or nylon stockings before placement in water. Humectants such as Humilac (Virbac U.S.) may be applied as a spray directly onto the skin or diluted with water and applied as a rinse. Humectants are oil-free products that help draw moisture to the stratum corneum.

Lotions are liquid or semiliquid combinations of active ingredient with a water, alcohol, glycerin, or propylene glycol base. Often the liquid base evaporates, and a thin film of powder remains on the skin. For this reason lotions may have a drying effect on the skin. Examples include calamine lotion and the antifungal Resizole (Virbac U.S.). Lotions also are available with a variety of antipruritic and parasitic medications.

Both aerosol and pump sprays are available for many veterinary products. Those with alcohol bases may be drying to the target area. Clipping animals may be necessary to facilitate penetration of the hair coat. Foams consist of a mixture of finely divided gas bubbles interspersed in a liquid. These preparations provide an effective way of spreading a small amount of liquid over a large surface area. A potential drawback of sprays is the noise of the application, which may frighten the patient. Both sprays and lotions may be easier to use than creams and ointments, especially for dogs with long hair coats.

Creams and ointments are mixtures of grease or oil and water that are blended together into an emulsion. In general, ointments are greasy to the touch and form an occlusive layer over the skin, reducing water loss. Creams are smooth to the touch and, once applied to the skin, are rapidly absorbed or evaporate (i.e., there is no occlusive layer left on the surface of the skin). In general, ointments are contraindicated in exudative areas. Examples include triple antibiotic ointments and creams and hydrocortisone ointments and creams. Hydrocarbon bases are emollient, being composed of vegetable oils and animal fats. Examples include oleic acid, paraffin, petrolatum, and wax. They generally are hydrophobic and occlusive, causing the stratum corneum to hydrate. They are greasy, however, and cannot be washed off. Anhydrous absorption bases contain little to no water but readily accept large amounts of water while maintaining a thick consistency. Examples include hydrophilic petrolatum and anhydrous lanolin.

Emulsions are oil and water combinations. Water-oil emulsion bases are water-washable bases that are easily removed from the skin surface. The oil phase generally is petrolatum with an alcohol; the aqueous phase may be water, propylene glycol, polyethylene glycol, or glycerin. Oil-water emulsion bases are composed of an aqueous phase that is greater than the oil component. These tend to be water washable, nongreasy, and nonocclusive. Finally, water-soluble-based ointments have no hydrophobic lipid base. They are completely water soluble, do not hydrolyze, and do not support the growth of microorganism contaminants in the product. If the preparation is in a gelled medium, the product is a gel (e.g., a combination of propylene glycol, propylene gallate, methylcellulose, polyethylene glycol, and others). DMSO is commonly prepared as a gel.² Gels are clear, colorless, and water miscible. Gels are becoming more popular because they can be rubbed into the skin to completely disappear and do not leave a sticky feeling. Examples of gels in veterinary medicine are KeraSoly, OxyDex and Pyoben.

DMSO has the ability to allow some substances ordinarily unable to penetrate the skin to be carried through it. DMSO is a waste product of wood processing that has been used in a large number of topical medicaments. In addition to its hydrophilic actions, DMSO is characterized by bacteriostatic, antiinflammatory, fibrinolytic, and vasodilatory actions. Topical analgesia may reflect a thermal effect, which occurs with direct application.² At concentrations greater than 70%, however, DMSO can cause skin irritation. In concentrations greater than 50%, DMSO has been shown to enhance the percutaneous absorption of a large number of drugs, including glucocorticoids, antibiotics, hormones, and antiinflammatory agents. Absorption increases as DMSO concentration reaches 100%.² DMSO increases percutaneous absorption of fluocinolone (a potent glucocorticoid) by a factor of five and other compounds by as much as a factor of 25. DMSO is approved for use only in the horse (for traumatic musculoskeletal injuries) and in the dog (in Synotic, a commercial steroid ear preparation). Any other use for DMSO is considered extralabel use. Toxic effects that should be considered when DMSO is used include teratogenicity (contraindicated in pregnant animals); potential for inducing degranulation of mast cells in underlying skin; and, in cats, hemolysis with hemoglobinuria and methemoglobinuria. DMSO has been shown to induce lenticular changes in animals and humans. Rubber gloves should be worn when DMSO is handled.

Adsorbents act to bind potentially noxious agents, keeping them from damaging the skin. Protectants provide an occlusive layer that physically protects the skin from the external environment. Together these two classes of vehicles are represented by dusting powders and mechanical protectives (kaolin, lanolin, mineral oil, petrolatum, zinc stearate). Dusting powders generally are inert, composed of starch, calcium carbonate, talc, titanium dioxide, zinc oxide, and boric acid. Smoothsurfaced powders prevent friction, protecting abraded and raw skin. Rough or porous powder surfaces absorb water, tending to occlude the skin surface when wetted. Rough powders should be avoided on moist or exudative lesions because of the risk of secondary bacterial or fungal infections. Care should be taken to make sure that powders, and in particular talc, are not used within a body cavity because of the potential for a massive granulomatous response.

Demulcents are high-molecular-weight water-soluble compounds that reduce irritation. Like protectants, they can coat the surface of damaged skin, protecting the stratum corneum and its underlying structures, and they inherently reduce irritation. Examples include mucilages, gums, dextrins, starches, methylcelluloses, and polyvinyl alcohol.² Among those most commonly used in veterinary medicine are glycerin, propylene glycol, and polyethylene glycols. Glycerin, when used in high concentrations on the skin, can dehydrate and irritate it by increasing transepidermal water loss. Propylene glycol is miscible with water. Like glycerin, it is hygroscopic, is not occlusive, and also is bacteriostatic and fungistatic. As such, it might be considered the ideal vehicle. It spreads easily on the skin surface, has a low evaporation rate, is not greasy, and may hydrate rather than dehydrate the skin.² A mixture of one part propylene glycol to one part water has been used to treat canine sebaceous adenitis. Topical hypersensitivity occurs occasionally. Several polyethylene glycols are available. They differ markedly in molecular weight, with the number directly correlating with size and viscosity. Polyethylene glycols that are 900 or above tend to be semihard to waxy solids at room temperature; lower-molecular-weight products are liquid. These compounds are not easily hydrolyzed but are very water soluble and nontoxic.²

Astringents cause precipitation of proteins and prevent exudation. Because of their inability to penetrate the skin, their action is predominantly on the surface. Many astringents are also antiseptic. Astringents can arrest hemorrhage by coagulating plasma proteins (ferric chloride, silver nitrate). Burow's solution is available commercially as Domeboro (aluminum acetate powder or tablets) for use as an astringent in exudative dermatoses. Commercially available otic products containing Burow's solution (Bur-Otic, Virbac U.S.)) can be used to treat dogs that spend a lot of time in the water or after bathing to reduce the risk of secondary infection. Magnesium sulfate (Epsom salt) is not an astringent but acts to dehydrate or "draw" water from the tissues.

Emollients are fatty or oleaginous substances that soften, protect, and soothe the skin. They are often used to make the cream or ointment vehicle in many dermatologic preparations. Examples include mineral oil, petrolatum, glycerin, and vegetable and animal oils. In veterinary medicine emollients are commonly used as cream rinses after baths. Most of these chemicals have a characteristic medicinal odor that appeals to owners. Active ingredients can be added (pramoxine hydrochloride) to enhance therapeutic effect.

Classes of Topical Drugs

Many topical products are commercially available, and many have multiple effects. Some of these agents are also discussed in other chapters (e.g., those on parasitology, antibacterials, and antifungals).

Antiseborrheics

Antiseborrheic drugs include keratolytics and keratoplastics. The appropriate antiseborrheic depends on the patient's condition (seborrhea sicca versus seborrhea oleosa).

Sulfur is keratolytic (keratolytics hydrate and soften the stratum corneum, promoting its mechanical removal) and keratoplastic (keratoplastics normalize cornification). It has a mild follicular flushing action but is not a good degreaser. It also has antibacterial and antipruritic effects. Its keratolytic effects may reflect inflammation that ultimately causes sloughing of the stratum corneum. Keratoplastic effects probably reflect cytostatic effects.² Many commercially available products containing sulfur are available. Shampoo products containing sulfur may have additional active ingredients for enhanced therapy. Lime sulfur (LymDip) is used for its antifungal, antipruritic, and antiprasitic effects.

Salicylic acid is keratoplastic, bacteriostatic, and mildly antipruritic. It is frequently used in combination with sulfur products, including most of the sulfur products listed previously. When salicylic acid is combined with sulfur, a synergistic effect results. In stronger concentrations (6%) it acts as a keratolytic.

Coal tar is keratolytic and keratoplastic and has good degreasing action. It is also frequently used in combination with sulfur and salicylic acid. Commercial shampoos are frequently used in veterinary medicine and include Lytar, Allerseb-T, and Mycodex Tar & Sulfur. Straight tar lotions should not be used in veterinary medicine. Coal tar is toxic to cats. Coal tar preparations are potentially irritating, photosensitizing, carcinogenic, and staining. In general, these products are reserved for severe seborrheic disorders.

Benzoyl peroxide (2% to 5%) is keratolytic, bactericidal, degreasing, and follicular flushing. It also is a strong oxidizer, free radical generator (and therefore antibacterial), and antimicrobial.² Benzoyl peroxide is metabolized by viable epidermal cells in the skin to benzoic acid. In high concentrations it can irritate the skin. It may be too drying for some patients with seborrhea sicca. These products are not well tolerated by cats and should not be used on them. Commercial products available for veterinary patients include Oxydex, Pyoben, Derma Ben SS, and Benzoyl-Plus shampoos. A gel form of 5% is available for veterinary use, primarily for treatment of chin acne.⁷ Other uses include fold pyodermas and local superficial or deep pyodermas. Benzoyl peroxide will bleach clothing.

Resorcinol is a keratolytic agent that also has bactericidal and fungicidal effects. It is a protein precipitant that promotes keratin hydration, acting as a keratolytic.² It often is combined with another keratolytic (e.g., sulfur, salicylic acid).²

Selenium sulfide is antiseborrheic, keratolytic, and keratoplastic by virtue of its antimitotic effects. Cell proliferation and sebum formation are slowed. It tends to be irritating, however, and can stain hair. Mucous membrane irritation may result if accidental contact occurs. A product for human beings is Selsun Blue. Fatty acids (e.g., undecylenic acid [Desenex]) are also keratolytic.

Retinoids

Retinoids are natural or synthetic derivatives of retinol (vitamin A) that exhibit vitamin A activity (Figure 22-1).8 Dermatologic effects of vitamin A include epithelial differentiation. Vitamin A deficiency causes metaplasia of glandular epithelia; excessive vitamin A causes keratinizing epithelia to differentiate into a secretory epithelia.9 The antikeratinizing effects are the target of drug therapy.9 Retinoids tend to "normalize" the skin. Although natural retinoids have proved to be too toxic for clinical use, the synthetic products are characterized by specific effectiveness with decreased toxicity. They tend to vary in bioavailability, in metabolism to active versus inactive metabolites, and in tissue distribution patterns. First-generation compounds include retinol and its derivatives tretinoin and isotretinoin. The second-generation products are synthetic and include etretinate and acitretin, approved for treatment of human acne and psoriasis, respectively. The third-generation compounds, arytenoids, are in development.8

The effects of the retinoids include cellular proliferation and differentiation, immunomodulation, inflammation, and production of sebum. Their actions are mediated by retinoic acid receptors, members of the thyroid/steroid receptors.⁸ Retinoids may influence genomic expression of cells by altering RNA synthesis, typical of other steroids. Tretinoin increases dermal thickness and granular layer thickness, decreases melanocytic activity, and increases the secretion of a polysulfated glycosaminoglycan intercellular matrix. In humans wrinkling is reduced. It is formulated as a 0.01% to 0.1% topical preparation. Therapy begins with lower concentrations and gradually increases. Adverse effects include erythema, peeling, burning, and stinging, which tend to decrease with time and are less likely to occur when the drug is prepared as an emollient.

Isotretinoin normalizes keratinization of the follicular epithelium and reduces sebum synthesis and, in human beings, *Proprionobacterium acnes*. It is administered orally, however, with cumulative doses being important to efficacy. Toxicity is manifested in the skin and mucous membranes; is dose dependent; and, in humans, may facilitate the growth of *Staphylococcus aureus*. Dermatologic manifestations include epistaxis, dry eyes, blepharoconjunctivitis, erythematous eruptions,

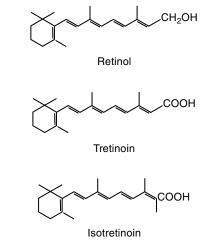

Figure 22-1 Stuctures of synthetic retinoids.

and dry mucous membranes.⁸ Systemic manifestations can be minimized with short-term therapy and include increased liver enzymes, myalgia, and arthralgia. Teratogenicity occurs with all retinoids; the drugs generally are contraindicated in pregnancy. Isotretinoin was studied in dogs.¹⁰ Four of 29 developed conjunctivitis, which resolved once therapy was discontinued. Cats may have a higher incidence of side effects, including periocular erythema, epiphora, and blepharospasm. The potential veterinary applications of isotretinoin include selected abnormalities of sebum production such as primary idiopathic seborrhea and comedo syndromes.

Etretinate is a synthetic aromatic retinoid that is effective for the treatment of inflammatory psoriasis. The retinoids are highly potent aromatic analogs of retinoic acid and represent the third generation. Etretinate is extremely lipophilic and is stored in adipose tissue. Accumulation is sufficient to allow detection of the drug in humans 2 to 3 years after its use is discontinued. It normalizes keratin expression in epidermal cells, suppresses chemotaxis, decreases stratum corneum cohesiveness, and may impair cytokine function.⁸ It is less likely than isotretinoin to cause conjunctivitis, but hair loss, cutaneous exfoliation, bruising, and liver dysfunction are more common. Collection of a baseline minimum database is recommended for humans before its use. Its teratogenicity precludes use by women of childbearing age; owners of animals using the drug should be warned of its contraindications.8 The drug may no longer be available because of its adverse effects. Acitretin has now replaced etretinate in the U.S. market. A dose of 0.5 to 1 mg/kg orally per day was suggested.¹¹

The use of retinoids in clinical veterinary medicine has not been well established. Animals are not afflicted by skin diseases typical of those for which retinoids are indicated in human patients (e.g., psoriasis, acne). Use is limited by lack of known effects and indications, cost, and the risk of side effects. Dogs, however, appear to be more tolerant of the retinoids than human beings.^{10,12} Side effects that have been reported in dogs include inappetence, vomiting, diarrhea, thirst, pruritis, conjunctivitis, cheilitis, stiffness, and hyperactivity.¹² Keratoconjunctivitis has been reported in dogs.^{10,12} Tear composition is changed, leading to more rapid evaporation. Schirmer's tear test should be monitored monthly for the first 6 months of therapy. Clinical pathology changes are rare, but monitoring before and 30 days after the start of therapy is recommended for dogs receiving synthetic retinoid therapy.¹² In cats the most common side effect is anorexia. Teratogenicity is a likely problem, particularly with etretinate, when used for intact females.

The most common use of synthetic retinoids in dogs has been for treatment of keratinization disorders of dogs, particularly primary seborrhea of cocker spaniels. Etretinate has been evaluated in spaniels with idiopathic seborrheic dermatitis (approximately 10 mg or 0.75 to 1 mg/kg orally per day). Animals generally respond well with a decrease in scaling, a softening and thinning of seborrheic plaques, decreased pruritis, and reduction in odor. Response occurs within 2 months, and improvement continues for at least 2 more months.¹² The more severe the syndrome, the slower the time to response; discontinuation of therapy is likely to result in recrudescence of clinical signs within 3 to 12 weeks.⁹ The drug was minimally effective in the treatment of ceruminous otitis associated with seborrhea.¹² Maintenance therapy ranges from 10 mg every other day to 10 mg daily, alternating 30 days on and 30 days off. Isotretinoin (1 and 3 mg/kg per day) appears to be much less effective.9 Neither isotretinoin nor etretinate has proved to be effective in West Highland White Terriers, and etretinate was ineffective in Basset Hounds. Both etretinate and isotretinoin have proved effective in the treatment of Schnauzer comedo syndrome9,12 and canine ichthyosis. Newer applications of the synthetic retinoids include hair follicle dysplasia (etretinate), which should respond in approximately 30 days, and selected dermatologic cancers. These include solarinduced squamous cell carcinoma (etretinate 2 mg/kg divided or once daily for 6 months), mycosis fungoides (etretinate or isotretinoin 3 to 4 mg/kg divided or once daily), and selected benign cutaneous neoplasms (multiple sebaceous adenomas, epidermal cysts, inverted papillomas, and infundibular keratinizing acanthomas).¹²

Isotretinoin for the treatment of disorders of the sebaceous glands has been variably successful; success may be breed dependent. It was proved effective in sebaceous adenitis of standard poodles in one study but ineffective in another.⁹ A higher dose (2 to 3 mg/kg) has been recommended. Hair growth in poodles that do respond is abnormal, however, in that kinks are lost. Vizslas appear to respond to isotretinoin very well.⁹ In contrast, neither isotretinoin nor etretinate appears to be effective in sebaceous adenitis of Akitas.

Retinoids appear to be safe for cats but do not appear to be effective for solar-induced squamous cell carcinoma. Either isotretinoin or etretinate (2 to 2.5 mg/kg) can, however, be beneficial for preneoplastic actinic disease. Cats tolerate retinoids well, although anorexia is more common in cats than in dogs.¹² Reducing treatment to every other day or every other week may limit this side effect. Topical tretinoin (0.025% cream) may be efficacious for treatment of feline acne. The product must be used very sparingly, however, so as not to incur severe tissue irritation.¹²

Although there are no reports of either acute or chronic toxicity in animals receiving retinoids, animals nonetheless should be closely monitored. Monitoring should begin with a physical examination before implementation of therapy, including measurement of tear production. These tests should be repeated at 4- to 6-month intervals. A complete blood count and serum chemistries, including triglycerides, should be monitored at baseline, at 1 and 2 months of therapy, and then every 4 to 6 months during therapy. Care should be taken to counsel clients regarding the cost, importance of compliance, and risk of accidental human ingestion.

Ceruminolytics

Ceruminolytics are topical products that emulsify, soften, and break up waxy debris and exudate. Generally, they are detergents or surfactants used for cleaning or flushing the ear. Examples include dioctyl sodium sulfosuccinate, which is water soluble (and perhaps less messy); squalene, which is an oil-based product; propylene glycol; glycerin; and oil. Carbamide peroxide differs from most other ceruminolytics in that it is a humectant, releasing urea and oxygen to cause its foaming action. Ceruminolytics and drying products are often combined with alpha hydroxy acid such as lactic, salicylic, benzoic, and malic acids. These acids have the added advantage of decreasing local pH and are mildly antibacterial and antifungal, along with their keratolytic effects. These products need to be placed in the ear 3 to 15 minutes before flushing with water or saline.

Antipruritics

Antipruritics (topical)⁵ are used to provide temporary relief of itching, but their efficacy is debatable. In general, antipruritics relieve itching by four mechanisms. (1) The itching sensation can be substituted with another sensation (such as heat or cold). Examples of agents with this mechanism of action include menthol, camphor, warm soaks or baths, and ice packs. (2) The skin can be protected from external factors such as scratching, biting, irritants, and changes in humidity or temperature. This can be accomplished with bandages or impermeable protective agents. (3) Peripheral sensory nerves can be anesthetized by local anesthetics (benzocaine, lidocaine). These drugs may, however, cause allergic sensitization. A new product in this category for small animals is pramoxine (Dermacool). (4) Biochemical agents used topically to treat pruritus include glucocorticoids and antihistamines. Despite the fact that the skin contains large numbers of mast cells, topical antihistamines do not seem to be efficacious. Systemic antihistamines, on the other hand, may be useful.

Topical glucocorticoids may not be as potent as their oral or injectable counterparts.¹³ Like systemic glucocorticoids, however, the active ingredients vary in potency and risk of side effects. For topical glucocorticoids ointments provide greater efficacy than creams. Topical glucocorticoids can be absorbed through the skin and cause systemic effects. This is more likely to be a problem with the potent fluorinated agents (betamethasone, dexamethasone, triamcinolone, flumethasone, and flucinolone) and when combined with DMSO (Synotic). Gloves should be worn to apply these drugs. There are many forms of glucocorticoids available for topical use, including use on extensions of the skin such as the external ear canal and anal sacs. Once absorbed through the skin, topical corticosteroids are handled by the body in the same capacity as systemically administered glucocorticoids. The extent of percutaneous absorption of topical glucocorticoids depends on factors such as the vehicle, the ester form of the steroid (greater lipid solubility enhances percutaneous absorption), duration of exposure, surface area, and integrity of the epidermal barrier. A new product containing 0.015% triamcinolone (Genesis spray, Virbac U.S.) has been formulated to be applied topically to the entire skin surface for its antipruritic effect.¹¹ This product may also be used for spot treatment of pruritic regions. Ointment bases are occlusive and are therefore more likely to increase percutaneous absorption of the same glucocorticoid in a cream base. Highly potent preparations in any form should not be used on abraded skin.

Irritants

A number of products are used to inflame or irritate the skin to various degrees. Examples include those that cause hyperemia (rubefacients), inflammation (irritants), and cutaneous blisters (vesicants). Caustics are corrosive agents that destroy tissue after one or more applications. Examples include camphor, coal tar, creosote, menthol, methyl salicylate, iodine, mercuric iodide, alcohols, and pine tar. Among these, only coal tar is used to any degree in veterinary medicine. It is a by-product of bituminous coal distillation and, as an irritant, decreases epidermal synthesis of DNA.² Escharotics also are corrosives that precipitate proteins, causing the formation of a scab and eventually a scar. Examples include glacial acetic acid, aluminum chloride, gentian violet, phenol, salicylic acid, and silver nitrate. The uses in veterinary medicine are few.² Irritant products have been used empirically for many centuries. Their proposed mode of action is masking of moderate to severe pain by milder pain caused by the application. Another desired effect of irritants is to induce a healing action on chronic wounds. The idea is to heal chronic inflammation by converting it to acute inflammation. Chemicals used include phenol, formalin, mercuric iodide, and camphor. Menthol-containing products are sometimes used to treat acral lick dermatitis ("lick granuloma") in dogs but may be painful upon initial application. Capsaicin has been used topically on human beings for relieving arthritis pain. It also has been used to treat acral lick dermatitis in dogs.

Antimicrobials

Alcohols, iodine, chlorhexidine, iodophors, and hexachlorophene can be effective in the treatment of infectious skin diseases (see Chapters 10, 11, and 13).

Benzoyl peroxide, discussed with the antiseborrheics, is a potent broad-spectrum antibacterial agent. It is an excellent adjunctive treatment for pyoderma. In a clinical trial of four antibacterial shampoos (containing 3% benzoyl peroxide, 0.5% chlorhexidine, 1% available iodine in a povidone complex, and 0.5% triclosan combined with 2% salicylic acid and 2% sulfur), although each was effective prophylactically, the product containing benzoyl peroxide was most effective.¹⁴ Use of the veterinary products (as opposed to the human proprietary products) is strongly recommended. Benzoyl peroxide is very irritating to cats and should be avoided.

Many antibiotics are available in topical form as ointments. Examples include neomycin, bacitracin, polymyxin B, gramicidin, and nitrofurazone. Often these drugs are available in combination with each other or with steroids.

Mupirocin is a compound produced by *Pseudomonas fluorescens* that is effective against superficial (topical) infections caused by *Staphylococcus* species. It is less active against gram-negative organisms and in humans is not active against normal skin flora. It inhibits protein synthesis by binding to bacterial tRNA synthetase. Prepared as an ointment, it often is used for prophylaxis of superficial infections resulting from wounds and injuries.⁸ Veterinary products containing mupirocin recently have become available (Muricin ointment 2%, Dechra). Treatment of otitis externa often involves a topical antibiotic-steroid combination such as Tresaderm or Panalog. Any of the agents contained in these products, neomycin in particular, can cause allergic sensitization or irritation. Cats appear to be more sensitive to topically applied otics than dogs.

In general, topical therapy of dermatophytoses in dogs and cats is not highly effective because of the thick hair coat and the location of the organisms deep in the hair follicle. The drugs are often unable to reach the site of the infection in adequate concentrations. Gentle clipping of the affected area(s) may aid in topical application, but whole body clipping is generally not recommended. Amphotericin B (Fungizone), available as 3% cream, lotion, or ointment, can be used for Candida infections. Chlorhexidine is a mild antifungal as well as antibacterial and is available as a rinse or shampoo (1% to 4% recommended). By itself it is not very effective for the treatment of dermatophytosis. New formulations combined with miconazole (Malaseb rinse, shampoo and spray DVM) or ketoconazole (Ketochlor, Virbac US)) shampoo can be used for Malassezia dermatitis or adjunct therapy for dermatophytosis. Clotrimazole 1% (Lotrimin, Veltrim) is effective against dermatophytes, Candida, and Malassezia. It may cause mild irritation. Miconazole is available as a 2% cream or 1% lotion (Conofite and Resizole 2%) and shampoo (Dermazole) and is effective against dermatophytes, Malassezia, and Candida. Nystatin (Panalog ointment or cream, nystatin cream) is effective against some yeast and some dermatophytes but not Malassezia species. Sulfur is effective against dermatophytes and therefore may be used for localized or generalized dermatophytosis (LymDyp, DVM). Cats may become ill if they groom after treatment so it is recommended that they wear an Elizabethan collar until the product is dry. Lime sulfur dip is also antiparasitic and antipruritc and very cost effective compared with other topical treatments. Lime sulfur dip may stain fabric and can tarnish jewelry. It is a very efficacious product, but because of the strong odor, owner compliance may be weak. Thiabendazole is effective for dermatophytes and some yeast, including Malassezia. Products including thiabendazole include Tresaderm, a combination product with neomycin and dexamethasone, which is best used for local lesions. In general, the use of a topical agent containing corticosteroid is not recommended when treating dermatophytosis.

Antiparasitics

Drug delivery systems. Antiparasitics are available as sprays, powders, shampoos, foams, spot-ons, tablets, and dips. The use of parasiticides is discussed in Chapter 15. Spot-on products are commonly used as broad-spectrum antiparasitic agents. Their ease of use and efficacy make them a preferred product for many circumstances. Powders are the safest formulation but must be frequently applied. They often are messy and must be applied deep into the coat to be effective. Sprays may have little residual effect depending on the active ingredient and concentration of the product, and the noise made during application often frightens the animal. Efficacy can be enhanced by ensuring adequate penetration of the skin so that the spray

can reach the skin. The face can be treated by spraying into a glove and then rubbing the face. A water-based spray may cause less drooling than an alcohol-based spray.

Shampoos have little residual effect and must stay on the skin at least 10 minutes to kill fleas and ticks. The active ingredients (pyrethrin, pyrethroids, carbaryl) in these preparations are not intended to be absorbed systemically. Any factor that would increase the absorption of these drugs (see earlier discussion) may result in system toxicity. Because cats are especially susceptible to the toxicities of certain parasiticides, only those products specifically intended for use on cats should be used. Flea shampoos should not be used more than once weekly to avoid drying of the skin. A humectant rinse may help compensate for the drying effects. Shampoos remove flea eggs, flea feces, and other debris, facilitating other topical therapy and making the animal look and feel better. Highconcentration pyrethrins may be effective as repellents for fleas and ticks. They are rapidly destroyed by ultraviolet light. Toxicity can follow ingestion (grooming) or percutaneous absorption. Toxicity is manifested as salivation, tremors, and seizures. Treatment is symptomatic but should include bathing.

A number of spot-on products act as adulticides and some are effective against the juvenile stages as well. They are applied to the infrascapular area from where they diffuse over the body. Some products are intended to be systemically absorbed for their antiparasitic effects. They can cause contact allergy and irritation. Examples include imidacloprid (Advantage, Bayer), fipronil (Frontline, Merial) selemectin (Revolution, Pfizer), metaflumazone (ProMeris, Fort Dodge), and dinotefuran (Vectra 3D, Summit).

In most cases flea collars have limited efficacy. Collars containing carbaryl, pyrethrin, or organophosphates are readily available in stores. Besides having limited efficacy, collars occasionally cause irritation reactions. Collars containing methoprene (Ovitrol) act to "sterilize" the fleas and are helpful in flea eradication. To keep clients from being disappointed with the results, clinicians should inform them that these products do not kill adult fleas. Collars containing amitraz (Preventic) are effective against ticks but not fleas. The feeding ticks will detach and die. Recent studies demonstrate that the tick will be killed before being able to transmit borreliosis, but other tick-borne diseases were not evaluated. This collar will not affect nonfeeding ticks. Ingestion of the collar is associated with acute toxicity. Yohimbine can be an effective antidote. Even though the active ingredient is amitraz, it has been shown to have many beneficial effects for the treatment of demodicosis.

Active ingredients. Pyrethrins are extracts from the chrysanthemum flower. Their mechanism of action involves disrupting neurologic function by prolonging Na⁺ in nerve membranes. They rapidly kill fleas, flies, lice, cheyletiella, otodectes, and mosquitoes but have little residual activity. Although among the safest products for use in cats, only those products approved for cats should be used. Pyrethrincontaining products are available in many formulations. Both pyrethrins and permethrins have repellent properties, but their residual effects are not well documented. Pyrethroids are synthetic analogs of pyrethrins with the same mechanism of action but greater ultraviolet stability and thus longer action. Microencapsulation of pyrethroids provides further residual activity. They have a slower knockdown than pyrethrins, and thus they are often combined with them. Toxicity and treatment thereof is the same as for pyrethrins. Permethrins are available as 0.05% to 25% flea sprays but also up to 65% as spot flea and tick products. A relatively new product (K9 Advantix) combines imidacloprid with permethrin for increased efficacy against ticks. Toxicities have been seen with this product when it was inadvertently applied to a cat.

Chlorinated hydrocarbons should not be used (if there happens to be any still on the market). There are two types of cholinesterase inhibitors available: carbamates and organophosphates.

Carbamates such as carbaryl are available in sprays, dips, collars, and premise-control sprays, and they are safe for dogs and cats. Toxicity of carbamates as well as organophosphates reflects overstimulation of the parasympathetic system and should be treated with atropine and 2-pyridine aldoxime methylchloride.

Organophosphates are the most toxic insecticides used in veterinary medicine. With one exception, these agents should not be used around cats. Care should be taken to avoid cumulative exposure if animals are exposed to this class of insecticide in lawn and garden preparations. Examples of commonly used organophosphates are chlorpyrifos (Dursban, Duratrol), used for flea sprays and dips; diazinon, used for environmental flea and tick control; malathion, used on both cats and dogs and often combined with other insecticides (noncholinesterase inhibitors); phosmet (Paramite Dip), useful for flea control and sometimes used for scabies; cythioate (Proban), a systemic insecticide; and fenthion (Pro-Spot), topically applied for a systemic effect. Organophosphates are disappearing from the market because of concerns of safety of animals and human beings.

Fipronil (Frontline) is a new synthetic molecule in the phenylpyrazole family. It acts at gamma-aminobutyric acid (GABA) receptors and inhibits GABA-regulated chloride flux into the nerve cell. It is a flea adulticide and has efficacy against ticks. It may also be effective in preventing scabies mite infestation. Preliminary studies indicate good residual activity even after bathing. This product is available as an on-animal spray or as a spot-on product. Frontline Plus contains fipronil and methoprene for its ovicidal properties.

Imidacloprid (Advantage and K9 Advantix) is a spot-on application product that kills adult fleas. It works by preventing postsynaptic binding of acetylcholine, leading to respiratory paralysis of the flea. This product may be removed by frequent bathing but is labeled as waterproof. It must be applied every 30 days to be effective. Advantage may be applied as frequently as every 7 days if needed to treat severe infestations of fleas. The addition of permethrin to the K9 Advantix provides efficacy against ticks and mosquitoes and repellent properties against mosquitoes and other parasites. Again, this product is to be used only on dogs.

A combination product containing imidacloprid and moxidectin (Advantage Multi) is available in a spot-on formulation for dogs and cats. The age restriction is 7 weeks and 9 weeks, respectively. This product is used to treat for fleas, heartworm prevention, intestinal worms, and ear mites. It is not approved for use in the United States for the treatment of sarcoptes (scabies) or demodicosis but may prove to be efficacious.

Selamectin (Revolution, Pfizer) is available as a spot-on formulation. It is approved for the treatment of fleas, heartworm prevention, tick (*Dermacentor* sp.) infestations, sarcoptes (scabies), and otodectes (ear mites) for dogs. The age restriction is 6 weeks. The formulation for cats has an age restriction of 8 weeks. It is approved for the treatment of fleas, heartworm prevention, otodectes, roundworms, and hookworms. Anecdotal reports indicate efficacy for feline scabies mites, Notoedres, though not approved for this use.

Nitenpyram (Capstar, Novartis) is an oral medication for the treatment of flea infestations in dogs and cats. The age restriction is 4 weeks, and the animal's body weight must be greater than 2 pounds. This product may be given daily but is often used in conjunction with other flea medications on an as-needed basis. Rapid and complete kill of adult fleas is the main reason for using this product. Anectotal reports indicate efficacy when inserted rectally (i.e., during a surgical procedure when fleas are discovered). It has also been used to treat subcutaneous maggot infestations of dogs and cats. Neither of these uses are licensed or approved by the Food and Drug Administration.

Amitraz (Mitaban) is a monoamine oxidase inhibitor. It is the only licensed product for treatment of generalized demodicosis. Mitaban is also efficacious against scabies and ticks, but this is considered an off-label use. This product rapidly oxidizes on exposure to light and air, and the breakdown product is more toxic than the parent compound. Mitaban should be mixed fresh each time, and the entire contents should be used to avoid toxicity. Side effects include sedation and lethargy (sometimes for 24 hours), pruritus, bradycardia, hypothermia, hypotension, and hyperglycemia. Hyperexcitability is an uncommon side effect. Amitraz is not appropriate for epileptic dogs and animals receiving behavior-modifying drugs. Yohimbine works as a reversing agent. The large animal form of amitraz (Taktic) should not be used on dogs. ProMeris for dogs (Fort Dodge) is a spot-on formulation containing amitraz and metaflumazone. It has recently been approved to treat localized and generalized demodicosis in dogs greater than 8 weeks of age. The recommended application rate is every 14 days until remission. Potential side effects include those associated with amitraz application. Anecdotal skin reactions have been noted.

Ivermectin (Ivomec 1%) is a GABA agonist that leads to parasite paralysis. In mammals GABA in the central nervous system is protected by the blood-brain barrier. Ivermectin is a large molecule that cannot pass the blood-brain barrier except in certain breeds. It is efficacious against scabies, lice, otodectes (ear mites), and cheyletiella. It is *not* approved for use in small animals for treatment of parasites other than as a heartworm preventive. Ivomec is rapidly absorbed orally or subcutaneously. The administration into the ear canal is not recommended except for the 0.01% ivermectin product Acarex. It should not be used in Collies, Border Collies, Shetland Sheepdogs, Australian Shepherds, Old English Sheepdogs, or any dog that looks like a Collie. Also, it is not recommended for any animal younger than 12 weeks of age. Daily ivermectin has been used to treat demodicosis. Enzodiazepines are contraindicated for concurrent use. Treatment of ivermectin toxicity is symptomatic and supportive. There is no good antagonist available.

Milbemycin (Interceptor) has a similar action to ivermectin. Its use in dermatology is confined to daily oral administration for the treatment of refractory demodicosis. Therapy may take 6 to 9 months, and relapses are common. Cost is a limiting factor. This drug is not approved for use for demodex treatment. Although not contraindicated in Collies and Collielike dogs, caution is advised for side effects. A new otic product containing milbemycin (Milbemite) is a very effective treatment for ear mites in dogs and cats.

Spinosad is the active ingredient in Comfortis (Eli Lilly). This is an oral tablet that is given monthly to control fleas on dogs only. The age restriction is 14 weeks. Safety in pregnant animals is not evaluated. Side effects have been noted when this medication has been used in conjunction with off-label usage of ivermectin; this is not recommended. This product has no efficacy against ticks. Vomiting was the most common adverse reaction noted. Absorption of the medication is adequate after 1 hour.

A combination product containing dinotefuran, permethrin, and pyriproxyfen (Vectra 3D, Summit VetPharm) has been approved for use on dogs older than 7 weeks of age. This spot-on product is effective against fleas and ticks and will repel and kill mosquitoes. It is recommended to apply this product monthly. The feline formulation does not contain permethrin. The age restriction is 8 weeks for kittens.

A combination product containing metaflumizone and amitraz (ProMeris, Fort Dodge) is a spot-on product approved for dogs older than 8 weeks of age. It is effective for fleas and ticks and has recently been approved for the treatment of localized and generalized demodicosis. ProMeris for cats (8 weeks or older) does not contain amitraz and is for the treatment of fleas only.

Flea insect growth regulators (IGRs) are endogenous chemicals in insects that control the early stages of their metabolism, morphogenesis, and reproduction. Synthetic compounds mimic the effects of the natural chemicals. Because IGRs maintain high levels of these chemicals during maturation and development of larvae, insects are prevented from developing. Natural levels decrease over time and allow normal maturation. IGRs have no effects on mammals and are very safe. They are combined with pyrethrins or pyrethroidsor fipronil to increase the spectrum of activity to include adults. Several products are available: Methoprene (Ovitrol spray) is a juvenile hormone analog available for on-animal and environmental use. It is degraded by ultraviolet light and hormone esterase. Pyriproxifen (Nylar) is a juvenile hormone mimetic for fleas. Preliminary studies indicate very long residual activity even when the animal is bathed and excellent environmental stability. This ingredient is available mixed with 2.5% permethrin (KnockOut spray) and is a very effective treatment for canine flea allergy. The high concentration of pemethrin precludes its use on cats. Pyriproxifen is also included in Vectra 3D (Summit Labs).

Lufenuron (Program) is a benzoylphenylurea that inhibits synthesis and deposition of chitin within the ova and larval exoskeleton of developing fleas. It is strongly lipophilic and stored in adipose tissue with slow release into the blood vasculature, providing long residual activity from a single dose. It does not affect adult fleas. Lufenuron is taken up by the feeding flea and incorporated into the developing egg. It is excreted in the flea feces. If the flea larvae consume flea feces containing lufenuron, they will be unable to mature into the pupal stage. Because of the slow absorption from the gastrointestinal tract, this product is given with food. Cats do not absorb this product as well as dogs, and therefore a higher dosage on a per-pound basis is needed for the same efficacy and duration of effect. This product is very safe and carries no contraindications.

Miscellaneous. Pennyroyal oil is a volatile oil extracted from plants in the mint family. Because of its limited efficacy and evidence of hepatotoxicity, this product is not recommended. D-limonene is from oils of citrus fruits. Toxicities have been noted in the cat, especially depression, ataxia, and toxic epidermal necrolysis. This product is not recommended. Tea tree oil contains various monoterpenes. Toxicities with this oil have been reported, and there is no scientific evidence to support claims of its efficacy as an antiparasitic agent.

SYSTEMIC DERMATOLOGIC THERAPY

Systemic dermatologic therapy is indicated for diffuse, serious, or chronic conditions (Table 22-1).

Antimicrobials

Antimicrobials indicated for the treatment of dermatologic disorders are discussed in Chapters 10 and 11. A number of antimicrobials are effective for the treatment of bacterial skin diseases (pyoderma). Care should be taken when using sulfonamides, often selected as first-choice therapy, because of their ability to suppress the synthesis of thyroid hormones (see Chapter 32). A study in 20 dogs receiving sulfamethoxazole (with trimethoprim) at 30 mg/kg every 12 hours for 6 weeks found marked suppression of thyronine concentrations and response to thyroid-stimulating hormone. Suppression did not occur with 15 mg/kg of sulfadiazine (trimethoprim) once daily for 4 weeks.¹⁵ Thyroid function returned to normal within 3 weeks of discontinuing therapy. Suppression may result from inhibition of thyroid peroxidase by the amino group in the sulfonamide. The effect of sulfonamides on feline thyroid function has not been reported.

Antiinflammatory and Antipruritic Agents Glucocorticoids

Glucocorticoids are discussed in Chapter 30. Glucocorticoids continue to be overused and abused for treatment of dermatologic diseases.^{13,16} Scott¹³ noted that more than 50% of

his referral cases are complicated by the excessive use of the drugs. Yet glucocorticoids remain an important and legitimate component of both acute and chronic treatment of a variety of skin diseases associated with pruritus or inflammation resulting from allergic diseases (e.g., atopy, flea bite, other insect- and arachnid-mediated hypersensitivity, food hypersensitivity, contact dermatitis), pyotraumatic dermatitis ("hot spots"), and acral lick dermatitis.¹³ Note that glucocorticoids for acral lick dermatitis may largely be replaced with behavior-modifying drugs for this syndrome. Glucocorticoids also remain the cornerstone of therapy for many of the autoimmune diseases affecting the skin, including the eosinophilic granuloma complex, pemphigus complex, systemic lupus erythematosus, and discoid lupus erythematosus. Optimal therapy of each of these diseases varies, insofar as some may respond to glucocorticoids alone and some may require a combination of glucocorticoids and alternative immunosuppressive drugs such as azathioprine, chlorambucil, cyclosporine, or cyclophosphamide. Routes of administration vary with lesion and intent and include oral, topical, intralesional, and systemic (intravenous, subcutaneous, intramuscular). The use of topical glucocorticoids was previously discussed; note that side effects of glucocorticoids will not necessarily be prevented by limiting therapy to topical application. In general, oral administration is preferred for its convenience and ability to regulate dosage safely (including rapid withdrawal relative to other routes). Although some animals may appear to respond better to injectable rather than oral drugs, differences in response may reflect an insufficient oral dose. This is particularly likely to occur if the oral drug is one that is less potent than the injectable drug.¹³

The choice of glucocorticoid should be based on desired potency (e.g., dexamethasone is more potent than prednisolone and may be preferred for acute needs) balanced with avoidance of side effects (prednisolone is characterized by a smaller tendency to affect the hypothalamic–pituitary–adrenal axis negatively; see Chapter 30).¹⁶ Personal preference among clinicians ultimately also will determine the selection of specific drugs: Whereas prednisolone may be efficacious for some situations, it may not be for others. In addition, an animal may develop intolerable side effects with one glucocorticoid but not another. The development of steroid tachyphylaxis may lead to deselection of a steroid that previously was efficacious.¹³ Remission in the case of acute exacerbation of clinical signs might respond to a pulse-dose approach using the original antiinflammatory dose.¹⁶

Dermatologic conditions requiring glucocorticoid therapy range from mild to serious. Dermatoses associated with lifethreatening conditions generally are limited to diseases that also are accompanied by diseases of multiple organs (e.g., immune-mediated disease). In such cases glucocorticoid therapy should be aggressive, with doses sufficiently high to control disease. Regardless of the indication of glucocorticoids, alternate-day therapy should be a goal of maintenance.¹⁶ Not all conditions will, however, be sufficiently controlled with alternate-day therapy.¹³ Because high doses of glucocorticoids are often required to adequately treat immune-mediated diseases, adverse effects are likely to occur. Concurrent administration of additional immunosuppressive drugs (azathioprine, chlorambucil, cyclosporine, or cyclophosphamide) may allow the glucocorticoid dose to be decreased. Dose reduction for patients with autoimmune diseases should be conducted gradually and should occur for at least 2 weeks (longer if time to clinical remission was prolonged), and the actual dose should be decreased by no more than half. Relapse may occur if the dosage is decreased too rapidly. Clinical reassessment should continue until a minimally effective dose is established for maintenance therapy.

Chronic inflammatory disorders (e.g., atopy or flea allergy dermatitis) should be treated less aggressively. A minimum effective dose should be determined by trial and error and reevaluated such that the dose is reduced when possible. Agents that are amenable to alternate-day administration include the first-choice drugs prednisone and prednisolone and the second-choice drug methylprednisolone.¹⁶ The ideal alternate-day dose for these drugs is 0.22 to 0.55 mg/kg.¹⁶ The durations of action of hydrocortisone and cortisone may be too short for effective alternate-day therapy. Although triam-cinolone's duration of antiinflammatory action is longer than that of prednisolone and methylprednisolone, suppression of the hypothalamic–pituitary–adrenal axis is more likely but less typical of the long-acting agents such as dexamethasone and betamethasone.

All patients receiving long-term glucocorticoids should be monitored, with physical examinations occurring at least twice yearly. Urinalysis is recommended with a urine culture because of the risk of subclinical urinary tract infection.¹⁶ In cases of relapse, the animal should be reevaluated for complicating diseases or conditions such as pyoderma, dermatophyte infection, and demodicosis.^{13,16} Glucocorticoids should be discontinued whenever possible; however, discontinuation may not be possible for immune-mediated disorders.^{13,16} Concurrent treatment with nonglucocorticoid antipruritics such as antihistamines or fatty acid supplements, either systemically or topically, should be attempted to reduce the glucocorticoid dose¹⁶ Other agents being studied include misoprostol and cyclosporine.

Cyclosporine

Cyclosporine may be used to control pruritus in dogs and cats with atopic dermatitis.^{17,18} It appears to be quite effective at 5 mg/kg orally once daily, and doses range from 2.5 to 6 mg/kg daily. Initially it should be given with food to decrease the likelihood of vomiting, but it is best given on an empty stomach for improved absorption. Food decreased the bioavailability by 22%.¹⁹ The water-soluble forms should be selected (Atopica, Neoral). Long-term use of cyclosporine for the treatment of canine atopic dermatitis has been reviewed.²⁰ Laboratory abnormalities were detected in 25% of the dogs; 0.039% developed oral growths, and 0.058 % developed hirsutism. Many dogs were tapered to 2 to 3 times per week to control clinical signs. Interestingly, 24% of the dogs did not require ongoing therapy when cyclosporine was discontinued. In another report approximately 40% of dogs treated with cyclosporine for 4 months did not relapse during a 2-month follow-up.¹⁹ There appears to be good evidence to support the beneficial response to cyclosporine therapy in atopic dogs.²¹ A poor response to therapy, not due to side effects of cyclosporine, may indicate secondary skin infections, ectoparasitism, or non-atopy-related causes of the pruritus. Cyclosporine has also been used for treating canine perianal fistulae, erythema multiforme, sterile granuloma, pemphigus complex disease, and occasionally sebaceous adenitis.²² Tacrolimus ointment (Protopic 0.1%) applied topically once daily for 4 weeks led to clinical improvement of localized lesions associated with atopic dermatitis in the dog.23 Improvement was not noted in dogs with generalized lesions. Tacrolimus ointment may also be used for the treatment of autoimmune diseases with localized severity such as discoid lupus erythematosus confined to the planum nasale. This potent immunosuppressive agent is still in its infancy with respect to the uses in veterinary dermatology.

Dapsone

Dapsone is a sulfone product that has been used dermatologically for its antiinflammatory effects.⁸ Prevention of myeloperoxidase respiratory burst impairs white blood cell activity, and blocking of integrin-mediated adherence impairs neutrophil migration. Antibody adherence to neutrophils also is blocked. Dapsone is approved for use in humans for a number of immune-mediated diseases. Dapsone is metabolized to a toxic compound (dapsone hydroxylamine) that depletes glutathione in cells with a glucose-6-phosphate dehydrogenase deficiency in people; the importance of this effect has not been documented in animals. The metabolite, however, causes rapid hemolysis. Cimetidine can be used to minimize toxicity by competing for drug-metabolizing enzymes.⁸

Antihistamines

Despite structural differences, all classes of H₁ antihistamines have similar antiinflammatory actions and side effects. The primary mechanism of action of these drugs reflects competitive inhibition of histamine at the receptor. Newer H_1 antagonists also block histamine release and have proved effective for treatment of atopy in humans (see the discussion of antihistamines in Chapter 31). However, differences in response among drugs, species, or disorders might also reflect impaired histamine release from mast cells or altered T-cell function. Side effects of these drugs also vary with the product and include gastrointestinal upset and neurologic manifestations, including drowsiness (the most common side effect) and hyperexcitability. Contraindications include central nervous system disorders (including epilepsy), glaucoma, and smooth muscle motility disorders such as might occur in the gastrointestinal or urinary tract. These products are generally used safely in human pregnancy, although safety has not been established in the pregnant or nursing cat and dog. Products with antihistamine activity only generally have fewer contraindications; the particular product should be reviewed before use and those with other pharmacologic effects avoided when appropriate.

Antihistaminergics can be beneficial in some cases of pruritus in dogs and cats. Because of varying effects among the drugs, each antihistaminergic should be tried for at least 1 week before an alternative medication is sought. Among the drugs tested in clinical trials, clemastine appears to be the most effective in stopping itching associated with pruritus in dogs and cats and is the antihistamine of choice.²⁴ Cost, however, can be prohibitive. A recent study found that after oral administration of clemastine, bioavailability was only 1% to 6%. It may be necessary to modify dose regimens for greater systemic effect.²⁵ Chlorpheniramine should be considered next for both dogs and cats.7 The bitter taste of chlorpheniramine might be avoided by use of time-release capsules, which need to be administered only once daily. Diphenhydramine and hydroxyzine may be less efficacious; in addition, hyperexcitability may limit use in cats. A minimally effective dose may reduce the incidence of side effects. Astemizole is another recently approved human product. Although it appears safe (1 mg/kg), its efficacy has not been established in animals. In human medicine a combination of H_1 (the traditional antihistaminergic selection) and H₂ blockers has been recommended. The immunomodulating effects of H₂ blockers may benefit the dermatologic patient.⁸ Newer H₁-blocking drugs (loratadine) do not cause anticholinergic effects and are not sedating. Caution should be taken when combining these products with H₂ receptors, however, because of an increased risk of cardiac arrhythmias, probably due to inhibition of drug-metabolizing enzymes.8 Antihistamines may act synergistically with misoprostol in controlling pruritus. There is fair evidence for its efficacy in controlling pruritus in dogs with atopy²¹; studies currently are under way.

Omega-3 (Omega-6) Polyunsaturated Fatty Acids

Body fats are stored as either adipose tissue or structural fat. Adipose tissue is rich in triglycerides, which are composed of a glycerol backbone and three fatty acids. Structural fats are represented by phospholipids, also composed of a glycerol backbone; two fatty acids (at the 1 and 2 positions); and a phosphate group (at the 3 position). Fatty acids can be released from glycerol by phospholipase. Saturated fatty acids have no double bonds. Unsaturated fatty acids (UFAs) include monounsaturated fatty acids, which have one double bond, and polyunsaturated fatty acids (PUFAs), which have two or more double bonds. The shorthand identification system of PUFA reflects the number of carbon atoms, the number (n) of double bonds, and the position of the first double bond from the terminal or omega methyl group end of the molecule.³ For example, the formula for linoleic acid, an essential fatty acid for mammals, is 18:2n-6; it contains 18 carbons and two double bonds, with the first double bond located between the sixth and seventh carbon. Alpha-linolenic acid (ALA) (18:3n-3) also contains 18 carbons but has three double bonds, with the first located between the third and fourth carbon (Figure 22-2).

Essential fatty acids (EFAs) are those fatty acids required for normal physiologic function that cannot be synthesized by the animal and thus must be obtained in the diet.³ Among the functions of EFAs are serving as a structural component of cell

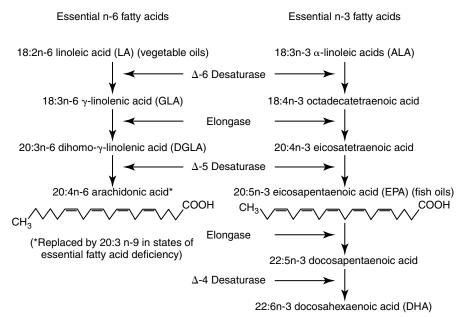

Figure 22-2 The three families of fatty acids are the plant-derived (α -linolenic acid) and fish oil-derived (eicosapentaenoic acid) n-3 family, the plant-derived n-6 family, and the de novo (nonessential) fatty acid family. Fatty acid biosynthesis includes desaturation, wherein a double bond is added, and elongation, wherein two carbon atoms are added. The same enzymes are used for fatty acid biosynthesis; the fatty acids in different families are not interconvertible.

membranes, primarily as arachidonic acid and in specialized tissues (retina and brain) as eicosapentaenoic acid (EPA) and docosahexaenoic acid.³ The PUFA component is important in determining fluidity of the membrane, rendering it more stable, and maintaining cellular permeability. The epidermal water barrier of the skin depends on linoleic acid (LA) lipids located in the intercellular lamellar granules at the level of the stratum granulosum–corneum interface. EFAs are also the source of eicosanoids, from which are derived prostaglandins, leukotrienes, platelet-activating factor, and related compounds. Prostaglandins are notable for their protective effects in many body systems; both classes of eicosanoids also are potent inflammagens (see Chapter 16).

Two families of UFAs are essential for mammals (see Figure 22-2). Fatty acids of the n-3 (omega-3) series include ALA; EPA (20:5n-3) is a metabolic product of ALA found in fish oil. Fatty acids of the n-6 (omega-6) family include LA, the precursor to arachidonic acid (AA), a fundamental component of cell membranes and thus the most important of the EFAs in mammals.³ Gamma-linolenic acid (GLA) is a product of LA found in certain plant oils. It is elongated to dihomo-gamma-linolenic acid, which is then converted to AA. Of the omega-3 series, ALA is elongated to EPA and then docosahexaenoic acid (DHA) (see Figure 22-2). Because of the absence of microsomal desaturase enzymes necessary to make double bonds, mammals are unable to synthesize LA and ALA.³ Most mammals are, however, able to synthesize AA from dietary sources of LA, EPA, and DHA from dietary sources of ALA. Thus, although LA and ALA are EFAs, their products and end products are conditionally essential because their synthesis requires the precursor. However, cats cannot synthesize AA.³ In addition, enzymes necessary for conversion of LA to AA apparently are not present; thus AA must be consumed in their diet. Dietary supplements contain

PUFAs rich in LA and GLA (plant sources) and EPA (fish oil), although the quantity or ratio of plant and animal oils varies with the source (Table 22-2).

After ingestion from the diet, and metabolism and restructuring in the body, the end products of n-3 and n-6 PUFAs are EPA and AA, respectively. Both of these products are inserted as components of phospholipids into cell membranes. When the membrane is damaged, both EPA and AA are released into the cell, where they are converted by lipoxygenase and cyclooxygenase to various eicosanoid (leukotriene and prostaglandin) end products (see Chapter 16). The activities of these end products vary with the fatty acid: Those formed from EPA are much less inflammogenic than those formed from AA. The composition of PUFA in cell membranes can be nutritionally modified by replacing AA with either EPA or GLA.³ These nutritional modifications can result in changes in inflammagen mediators. Inclusion of GLA (an n-6 EFA) in the diet specifically should reduce the formation of two inflammatory eicosanoids found in skin: leukotriene B_4 (LTB₄) and prostaglandin E_2 (PGE₂) because GLA may be elongated to DGLA, apparently increasing the concentrations of PGE₁, an antiinflammatory prostaglandin.³ In addition, DGLA has a higher affinity for lipoxygenases than AA.

Inclusion of EPA and DHA (n-3 EFA) causes replacement of AA in the cell membrane; increasing the proportion of EPA or ALA also can decrease inflammatory responses by the cell. Because EPA has a high affinity for but is a poor substrate for cyclooxygenase, the generation of inflammatory prostaglandins is inhibited.³ In addition, LTB₅, a leukotriene that is less chemotactic than LTB₄, is preferentially formed. Immunologic reactivity also may be modulated with fatty acid supplementation. Mobility of cell surface receptors and movement of materials between the inside and outside might be affected. The cell-mediated response can be reduced, especially at high doses.²⁶ Combinations of EFA of the n-3 (EPA) and n-6 (GLA) series appear to enhance control of inflammation, and the two should be given in combination for maximum effects.³ Several combinations are available in commercial preparations (see Table 22-2). The most appropriate combination of n-3 versus n-6 fatty acids has not, however, been documented, but a ratio of 5 to 10:1 has been suggested on the basis of a study that found a decrease in LTB₄ and an increase in LTB₅ in the skin of dogs whose diets were supplemented with these ratios.³

Current therapeutic indications for EFA include pruritus caused by atopy and other disorders and keratinization disorders. EFAs may have steroid-sparing effects, but these products may take 12 weeks or longer for full therapeutic effect.²⁷ Newer inflammatory conditions being studied include lupus erythematosus, rheumatoid arthritis, hypothyroidism, and cancer cachexia and neoplasia.³

Noninflammatory prostaglandins also are affected by replacement of AA with EPA. The normal role of prostaglandins (reviewed in Chapter 16) can be modified with fatty acid supplementation, and this can account for some of their side effects. Side effects reported in humans include nose bleeds and hemoptysis; gastrointestinal distress; and decreased serum vitamin E, which could increase inflammation owing to increased oxygen radical. Side effects reported in dogs include lethargy, pruritus, vomiting, diarrhea, and urticaria. Use of fatty acids may increase the incidence of pancreatitis in dogs prone to that disease; fatty acid supplementation should begin with a low dose that is gradually increased over several weeks.

Behavior Modifiers

Tricyclic and other antidepressant drugs are used to treat stereotypic behaviors, including those resulting in skin lesions (see Chapter 25). The most common behaviors are related to grooming, such as acral lick dermatitis (lick granuloma) and hair chewing. Pruritus has also become a common indication for antidepressant therapy. Most behavior modifiers (psychotropic drugs) have the ability to alter multiple central nervous system neurotransmitters. Most notably affected are the biogenic amines, including serotonin and dopamine (and, to a lesser degree, epinephrine). Acetylcholine and histamine may also be affected. Because these neurotransmitters are affected centrally, they can affect many physiologic behaviors, including control of the endocrine system, motor control, appetite, and so forth. Because physiology varies markedly among animals, adverse reactions to the drugs should be anticipated on account of differences in response (i.e., pharmacodynamics) and differences in drug disposition. The behavior-modifying drugs should be used cautiously, and their use is best based on previous studies or experiences noted in the veterinary literature. Antidepressants interact with cholinergic, histaminergic, and α-adrenergic receptors and thus are associated with a variety of adverse effects. Adverse reactions have been noted in cats (central nervous system signs, gastrointestinal upset). Amitriptyline, imipramine, and clomipramine are tricyclic antidepressants that have been used in dogs and cats. Doxepin is a tricyclic antidepressant with potent antihistaminergic (H_1) effects that has also been used to treat pruritus. Fluoxetine is a nontricyclic antidepressant that specifically binds serotonergic receptors.

The behavioral aspects of the self-mutilation syndrome of acral lick dermatitis have been treated with tricyclic antidepressants, fluoxetine (Prozac), and narcotic antagonists. Narcotic antagonists are reportedly effective for humans and animals for the control of certain behavioral disorders. The mechanism of action of these drugs is unknown. Increased release of endogenous opioids has, however, been detected in self-mutilative behaviors in experimental animals. The use of chemical antagonists may be a reasonable alternative to the plethora of treatments recommended by various authors for this syndrome. Other postulated benefits of the opioid antagonists include eradication of endorphin-mediated "self-reward" and analgesia. Like naloxone, naltrexone appears to be a pure opioid antagonist. Naltrexone is, however, characterized by a higher oral efficacy and longer duration of action. The success of treatment with naltrexone varies; if there has been no response after 10 days, the dose is doubled. Treatment for 1 to 2 months will cause remission in up to 60% of animals with lick granulomas, although relapses are likely in some when the drug is discontinued. Response has also been reported with hydrocodone bitartrate (Hycodan).

Antiparasitic Drugs

A limited number of agents are administered systemically (orally or by injection) for control of dermatologic parasites. Milbemycin and lufenuron are two examples. These drugs are discussed in greater depth in Chapter 15.

Macrolide Antibiotics

lvermectin. Ivermectin is used to treat a number of parasitic dermatoses in animals. The drug stimulates the release of the inhibitory neurotransmitter GABA at peripheral neuronal synapses, resulting in paralysis and death of the parasite (see Chapter 15). Selective activity in animals reflects a difference in the peripheral role (nematodes and arthropods) versus central role (mammals) of this neurotransmitter. In most mammals ivermectin does not penetrate the blood-brain barrier in sufficient concentrations to cause side effects. The drug is administered orally and parenterally; up to 3 weeks may elapse before the drug is totally eliminated in feces. The primary indication for ivermectin in small animals is mite infestation: feline and canine scabies, cheyletiellosis, and ear mites. The drug has also been used for mite infestations of guinea pigs and birds. Although clinical response may occur in several weeks, animals may remain skin-scrape positive for several to many months. Adverse reactions are idiosyncratic and have been reported primarily in herding breeds (Collies, Border Collies, Shetland Sheepdogs, Old English Sheepdogs, Australian Shepherds). Adverse reactions are associated with a mutation in the MDR1 gene. Testing is available at Washington State University for this mutation to help identify dogs at risk for life-threatening reactions. Reactions have ranged from mydriasis to tremors, hypersalivation, ataxia, coma, and death. The 1% bovine product may be diluted with propylene glycol to allow more accurate dosing in small animals. Ivermectin can be used (off-label) for the treatment of generalized canine demodicosis. Treatment is usually started at 0.1 mg/ kg daily and gradually increased. The commonly used dosage ranges from 0.2 mg/kg daily to 0.6 mg/kg daily, but some clinicians recommend dosages as high as 0.8 mg/kg/day. Careful patient monitoring for side effects and response to therapy is warranted.

Milbemycin. Like ivermectin, milbemycin at 1.5 to 2 mg/kg daily is effective for the treatment of demodectic mange. Cost may be a limiting factor. Response to treatment is lengthy, and relapses may occur. The dosage may be modified if an inadequate response is seen after 1 month of therapy. Also like ivermectin, milbemycin can cause toxicity, particularly in Collie-type dogs, although this drug is slightly safer than ivermectin. Moxidectin also may be efficacious; Collies also appear to be more sensitive to its adverse effects. Moxidectin is not approved for the treatment of canine demodicosis in the United States.

Immunomodulators

Immunomodulators (biologic response modifiers) potentiate some facet of the immune response (see Chapter 19). Many compounds described as immunomodulators have been used to treat a variety of dermatologic conditions. Immunosuppressants used to treat immune-mediated dermatologic disorders include glucocorticoids, cytotoxic (antineoplastic) drugs, and selected hormones. Immunostimulants tend to be less effective (see Chapter 19).

Staphylococcus aureus phage lysate (Staphage Lysate) is a vaccine containing parts of *S. aureus*, a bacteriophage, and culture medium ingredients. It is indicated for treatment of canine staphylococcal pyoderma. Vaccination is intended to result in stimulation of antibacterial antibodies. There may also be a hyposensitizing effect. Concomitant antimicrobial therapy should be used for the initial 4 to 6 weeks. Staphage Lysate is administered subcutaneously once a week initially, and then the dosage interval is lengthened. The vaccine is relatively expensive. Possible side effects include allergic reactions and local redness and swelling at the injection site. This

vaccine should be reserved for patients with recurrent staphylococcal pyoderma that responds to antimicrobial therapy but recurs when therapy is discontinued. It is extremely important that other causes of pyoderma (e.g., allergies, ectoparasites, endocrinopathies) are identified and treated.

Propionibacterium acnes killed suspension (Immuno-Regulin) is available as an adjunct to antimicrobial therapy in the treatment of canine pyoderma. It has been shown to induce cell-mediated immunity. This bacterium is the species associated with human acne. Treatment with Immuno-Regulin involves intravenous injections twice weekly initially and then once weekly. Potential adverse effects include anaphylactic reactions. Disadvantages include expense and the need for intravenous injections (client cannot administer at home). It is the author's opinion that use of this agent should be reserved for patients in which all other forms of therapy have failed.

Hyposensitization involves parenteral administration of allergens (antigens) in allergic patients. Although the mechanism of action of this therapy is unknown, the most appealing theory is that repeated exposure to the allergen may result in reduced cellular sensitivity (tolerance). Hyposensitization is one of best therapies for long-term management of the dog and cat. Patient and client selection are critical for success because therapy generally lasts as long as the patient is alive. Hyposensitization solutions may be based on intradermal allergy testing or serum allergy testing. Many protocols are available insofar as patient response may be quite variable.

TRANSDERMAL DELIVERY OF DRUGS

Most drugs in human and veterinary medicine that are applied to the skin are intended to provide their pharmacologic effect where they are applied. Systemic absorption is intended to be minimal so that systemic effects will not be encountered. There are, however, a small number of drug products that are designed to be applied to the skin and absorbed transdermally, whereupon they attain sufficiently high plasma concentrations to produce systemic effects. The same factors mentioned in the discussion of the principles of topical drug therapy affect drug absorption from cutaneous sites.

Transdermal drug delivery offers several advantages. It is easier to administer drugs transdermally, and drug delivery can be sustained, thus ensuring continued therapeutic effects. Drug input might be more precisely controlled over oral therapy because there are fewer factors complicating transdermal drug absorption, such as first-pass hepatic metabolism.

Not all drugs may be administered transdermally. The drug should not be irritating to the skin and should be transdermally bioavailable. Effective transdermal drug delivery formulations are very difficult to design, which is probably why so few products are available. Some products used in veterinary medicine, although not intended for transdermal absorption, can result in systemic absorption in the person treating the animal. Such drugs should be handled with nonpermeable gloves (e.g., DMSO, all anticancer drugs, nitroglycerin ointment, all antiparasitics [dips and shampoos], and altrenogest [Regu-Mate]). Gloves might also be used when administering chloramphenicol, although percutaneous absorption in association with oral medication of small animals has not been documented.

Several products are used in veterinary medicine with the intent of achieving systemic therapeutic effects. Nitroglycerin ointment relaxes vascular smooth muscle primarily on the venous side and is used for dogs and cats to treat cardiogenic edema. The ointment is applied to glabrous areas (i.e., axillary, inguinal, or inside the ears). Onset of action is approximately 1 hour. Selemectin (Revolution, Fort Dodge) and other systemic insecticides (discussed previously) are applied topically. Scopolamine, nitroglycerin, and clonidine transdermal patches are available for use in human patients to treat motion sickness, angina, and hypertension, respectively. Fentanyl, a narcotic analgesic available in transdermal patches, has proved to be an effective and safe alternative to injectable opioid delivery for control of pain in dogs and cats (see Chapter 28).

TREATMENT OF SPECIFIC DERMATOLOGIC DISORDERS

Selected skin diseases are discussed in other chapters. Otitis externa, pyoderma, and other bacterial infections of the skin are discussed in Chapter 8. Fungal disorders are additionally discussed in Chapter 9, external parasites are additionally discussed in Chapter 13, immune-mediated diseases of the skin are discussed in Chapter 31, behavioral disorders of the skin are discussed in Chapter 26, and endocrinopathies affecting the skin are addressed in Chapter 21.

Chronic Pruritus

Pathophysiology

Pruritus is a cutaneous sensation that leads the animal to resolve the feeling by scratching, rubbing, licking, or chewing. The cause of the sensation is complex, as can be its resolution. Ideally, the underlying cause of the sensation is identified and treated, ultimately leading to resolution of the pruritus. Discussion of or even provision of a comprehensive list of the causes of pruritus is beyond the scope of this chapter.

Like pain, the sensation of pruritus consists of a peripheral signal, originating in the skin, and central perception, ending at the sensory cortex. A number of chemicals are responsible for signal generation and transmission in the skin, although the precise types that predominate in the dog and cat are not known. The chemicals largely are the same as those generating the inflammatory response and include both preformed chemicals (histamine, serotonin) and those synthesized in situ (prostaglandins, leukotrienes, proteases). The signal generated at the level of the skin can be modified by emotional, biochemical, or central factors, leading to behavior that appears to be disproportionate to the inciting cause (i.e., skin trauma induced in response to a single flea bite).²⁸ Drugs oriented toward control of pruritus can target either peripheral or central transmission. For chronic pruritus drugs with systemic effects generally are more effective.

Drug Therapy

Topical Therapy

A number of nonglucocorticoid topical preparations may control pruritus.^{5,13} Care should be taken to select products that are not irritating or drying. Shampoos generally should be applied once to twice weekly. Cool water may be effective in some animals; antipruritic efficacy can be enhanced by the addition of moisturizing agents, colloids, antiinflammatories, or anesthetics. Preparations that can be applied in "spots" include Dermacool (hamamelis extract and menthol.¹³ ResiSoothe (Virbac U.S.) and Relief cream rinse (DVM) are lotions that are also effective for spot treatment.

Other medications available in sprays that might be helpful for control of pruritus include local anesthetics such as lidocaine (Dermacool) or promaxine (with colloidal oatmeal: Relief Spray), 2% benzyl alcohol with 0.05% benzalkonium chloride, and hamamelis distillate (PTD). In addition to anthistaminergic medications, sprays also may contain glucocorticoids for treatment of localized pruritus such as pyotraumatic pruritus and allergic dermatitis.⁵ More potent sprays intended for acute management contain 0.1% triamcinolone, 0.025% fluocinolone, or 0.1% betamethasone; "milder" glucocorticoid sprays for long-term maintenance contain 0.5% to 2.5% hydrocortisone. Sprays can be applied two to three times per day.5 Sprays should be applied every 12 hours until inflammation and pruritus are controlled and then tapered to an asneeded basis. Systemic side effects may be seen with extended use. Localized adverse effects such as the development of thin skin or alopecia may also occur.

Glucocorticoid ointments and creams may be difficult to use because of lack of penetration through the hair coat into the skin. A hydrocortisone lotion that is not greasy or staining may be useful for treatment of large areas with some residual activity.⁵ ResiCort (1% hydrocortisone) lotion (Virbac U.S.) is a formulation that is easier to apply to the skin surface than ointments and creams.

Total body application of moisturizing and hypoallergenic shampoos, or colloidal oatmeal soaks or shampoos with or without antihistamines, local anesthetics (Relief Shampoo DVM), or hydrocortisone (Cortisoothe, Virbac U.S.) are indicated for patients with generalized pruritus.^{6,13} Colloidal shampoos containing pyrethrins, carbaryl, or pyrethrins and permethrin will facilitate control of pruritus associated with fleas.⁵ Application of a rinse, spray, or lotion after a shampoo will provide some residual effect.⁵ Cream rinses containing colloidal oatmeal with (pramoxine) or without a local anesthetic are available for control of pruritus. Incomplete rinsing of a cream rinse may facilitate residual activity in dogs with short hair coats (coats of long hair become greasy). Antipruritic cream rinses might also be applied locally for control of localized pyoderma (e.g., Relief lotion).⁵ Several aqueous rinses also are available for control of pruritus. These include 100% colloidal oatmeal (Aveeno), oilated oatmeal with 43% colloid (Aveeno Oilated Bath) (for very dry skin and hair coats, also applied as a soak), and moisturizing bath oils or humectants (Humilac spray, Virbac U.S.). Aqueous rinses generally

also can be applied as sprays, although efficacy is greater as a total body rinse.⁵

Topical shampoo therapy is an important component of treatment or prevention of superficial and deep pyodermas. Antibacterial shampoos containing benzoyl peroxide, chlorhexidine, or ethyl lactate are indicated as adjuvant therapy for pruritus associated with pyoderma (see Chapter 8). Those most effective contain benzoyl peroxide or chlorhexidine.⁶ Following the shampoo with a chlorhexidine rinse (dilution of a 2% solution to 0.5%) further enhances antibacterial activity. Maximum ChlorhexiDerm HC shampoo (DVM), a new product containing 4% chlorhexidine and 1% hydrocortisone, has been developed to treat secondary pyoderma associated with an underlying pruritic disorder. Very few controlled and blinded studies exist to guide the selection and use of drugs for treatment of chronic pruritus in dogs or cats. In general, those that have provided support for selected drugs define success or response as a reduction in pruritus by 50%. There is good evidence, however, that glucocorticoids and cyclosporine are beneficial for the treatment of canine atopy.²¹

Antibiotics

Antibiotics may be indicated to control secondary infection (generally *Staphylococcus*) that can contribute to pruritus. The use of antibiotics for treatment of dermatologic disorders is discussed in Chapter 8. For some animals antibiotic therapy may be the sole therapy needed to control pruritus. Some antibiotics (e.g., erythromycin, tetracyclines) directly provide some relief from pruritus (rather than by controlling infection).²⁹ Tetracyclines in general are not, however, effective for treating pyoderma associated with staphylococcal infections. Erythromycin can be effective against *Staphylococcus* species, but it can cause gastrointestinal upset.

Glucocorticoids

Glucocorticoids remain the most effective drugs for control of chronic pruritus associated with allergies.^{13,28} The principles of glucocorticoid therapy (see Chapter 30) must be closely observed when a glucocorticoid is used to control pruritus. Injectable products should be avoided when possible. Miller and coworkers²⁸ suggest that injections may be acceptable for animals in which a single injection provides pruritic relief for 3 to 4 months or more. The temptation to increase the frequency of administration of an injectable product to less than 3-month intervals should be resisted. Prednisone and prednisolone (0.55 to 1.1 mg/kg per day [dog]; 2.2 mg/kg per day [cat]) remain the glucocorticoids most commonly used for long-term treatment. The dose can be divided and given twice or once daily. The dose is titrated to a minimum effective dose defined by the point at which the animal is "tolerably itchy"that is, the itch does not disrupt the animal's (or owner's) life or cause secondary trauma to the skin.²⁸ The lack of pruritus suggests that the dose is too high. Many animals cannot tolerate even an alternate-day regimen of glucocorticoids; other animals remain pruritic at doses associated with marked side effects. Long-term side effects will be seen with continued use. It has been suggested that alternative therapies should be

sought for animals that require glucorticoid therapy for more than 3 months out of the year.

Some clinicians find glucocorticoids devoid of mineralocorticoid to be less frequently associated with polyuria and polydipsia²⁸; however, the rationale behind this observation is not clear because this side effect is related to anti-antidiuretic hormone effects rather than to increased mineralocorticoid effects. Nevertheless, an alternative glucocorticoid might be tried; however, triamcinolone and dexamethasone have increasingly longer biologic effect times, and the risk of hypothalamic-pituitary-adrenal suppression increases with continued use. Methylprednisolone may be a viable alternative. If undesirable side effects occur with glucocorticoid use, combination therapy might be tried (e.g., antihistamines, bathing, fatty acid therapy) in an attempt to decrease the dose of glucocorticoids. In some animals, however, only continued use of glucocorticoids in the face of side effects will control pruritus sufficiently. In such patients the risk of therapy must be weighed carefully against the disadvantages of continued pruritus. Glucocorticoid-sparing drugs should be attempted before selecting glucocorticoids. If proved effective as sole drug therapy, then combined use should be considered to reduce the dose and thus likelihood of side effects. These include antihistamines, misoprostol, and omega series fatty acids.

Antihistamines

Antihistamines traditionally have been considered ineffective as a sole therapy for controlling pruritus in dogs or cats. However, with the advent of newer drugs and modification of the goal of therapy (e.g., reduction in the glucocorticoid dose), the following approaches may enhance the use of antihistamine therapy for control of pruritus. The clinician should wait at least 1 week before evaluating efficacy. If one drug does not work, an alternative should be tried. The clinician also should aim to reduce the itching sensation rather than eradicate it. The antihistamine also can be combined with other drugs that might decrease itching (e.g., fatty acids). Drugs most likely to be useful include diphenhydramine (Benadryl), hydroxyzine, chlorpheniramine, and clemastine. Cyproheptadine, also an antiserotinergic, and the tricyclic antidepressants amitriptyline and doxepine (both with antihistaminergic effects) also may be useful. It may be necessary to increase the dosage of doxepin to as high as 5 mg/kg for it to be effective in some dogs.

Few studies have properly evaluated the use of antihistamines for the treatment of pruritus in dogs. One study³⁰ provided support for a reduction in pruritus in allergic dogs treated with one of three antihistamines. In general, however, response occurred in at most 25% of animals treated. Thus response rates tend to be low. Response to chlorpheniramine was best, followed by diphenhydramine or hydroxyzine. Follow-up studies^{28,31} found clemastine to be much more effective than astemizole or trimeprazine. Thus, of the antihistamines studied in clinical patients, clemastine appears to be the most effective. Because of low bioavailability when clemastine is given orally, a higher dose (1 mg/kg twice daily) may be more clinically effective.³² Misoprostol may enhance the efficacy of antihistamines used to treat pruritus.

Cats appear to respond to antihistamines better than dogs. Chlorpheniramine can be used to treat cats without causing the excitement that often occurs with diphenhydramine (the latter effect probably reflects overdosing). One study found response to chlorpheniramine to be excellent in 73% of cats when dosed at 2 mg every 12 hours within 2 weeks. Other reports consistently have been favorable with doses of 2 to 4 mg/cat twice daily. Occasionally, a 24-hour dosing interval may be effective. The 8-mg time-release capsule (sprinkling one fourth to one half of the contents on food) may prove easier to administer than the bitter-tasting tablets. Alternatively, the 4-mg tablet can be broken in half and dipped in tuna fish.⁷ It is generally recommended that the 4-mg tablet be administered unbroken, however. An over-the-counter solution is also available. Side effects reported in cats include vomiting, diarrhea, and hyperexcitability. Hydroxyzine and amitriptyline can cause adverse reactions in cats. Clemastine (0.34 to 0.68 mg every 12 hours orally) may be effective.

A combination of both H_1 and H_2 receptor antagonists has been recommended but has not proved useful in animals thus far.²⁸

Fatty Acid Supplements

Studies that focus on the effects of dietary supplementation of EFA on canine atopy vary. Interpretation among clinical trials is complicated by the quantity and source of the PUFAs (GLA, EPA, and DHA), the lack of tissue fatty acid analysis, the duration of therapy (which probably was not sufficiently long), and differences in outcome measures and adjuvant therapy. In addition, many of the studies were not controlled or blinded.

White³ provides a summary of the results of selected clinical trials implemented by various dermatologists. A study evaluating LA, linolenic acid, and EPA in dogs with atopy, flea allergy, and idiopathic pruritus (nonseasonal) found the response rate to the PUFA to be low (20% or fewer being controlled well; another 36% responding by a 50% reduction in pruritus). An open comparison of evening primrose oil, marine fish oil, and EFA products administered for 2 weeks found response in 25% of animals, but no product appeared more effective than the others. Responders worsened when supplementation was removed. Comparison of evening primrose oil alone or combined with marine fish oil found significant improvement with the sole product and increased (but not significant) efficacy with the combined product. A double-blind placebo-controlled crossover study with olive oil (placebo) or evening primrose administered for 9 weeks found clinical improvement with evening primrose oil. Two recent blinded studies have reported the benefits of EFA (EPA 180 mg and DHA 120 mg per 4.55 mg/kg) supplementation when administered for 6 weeks. Eleven of 16 dogs responded to fish oil, 3 of 16 responded better to corn oil, and 2 of 16 dogs responded to neither oil. A parallel study of 28 dogs supplemented with high doses of GLA (350 mg), EPA (250 mg), or linolenic acid (250 mg) and EPA (50 mg) found a benefit with all three supplements, suggesting that higher doses may be important to efficacy.

Cats seem to respond better than dogs, with up to 40% efficacy reported by some authors.²⁸ Again, however, results of clinical trials tend to be conflicting. Pruritic cats with miliary dermatitis and other nonlesional causes of pruritus responded to 2 and 6 weeks of therapy of a linolenic acid-EPA supplement. In contrast, 12 weeks of therapy with evening primrose oil (3.7 mg linolenic acid/kg) or olive oil did not improve feline skin disease in another study. A 6-week course of evening primrose alone or when combined with marine fish oil resulted in improvement in feline pruritus and dermatitis; in contrast, marine fish oil by itself caused worsening of the skin disease. A 12-week course of therapy with evening primrose and sunflower oil also improved the skin and coat of cats with miliary dermatitis.³ White³ suggests that atopy should be most responsive to EFAs that are low in LA and high in linolenic acid and/or EPA/DHA. Addition of vitamins to the EFA supplement may facilitate efficacy of the EFA product. The appropriate ratio (n-6:n-3) is not clear, nor is the duration of therapy. A ratio of 5 to 10:1 has been suggested on the basis of a study that found a decrease in LTB₄ and an increase in LTB₅ in the skin of dogs supplemented with diets containing these ratios.3 Response has been reported in as few as 7 to 14 days or as many as 9 to 12 weeks.

The most appropriate use of EFA for control of pruritus may be in combination with antihistamines or glucocorticoids.³ Success with fatty acid supplements also is most likely if an alternative product is tried if and when the first fails, adequate time is allowed to elapse before clinical assessment is complete, the goal is reduction rather than eradication of pruritus, or the goal is reduction of the dose of other drugs associated with adverse effects (e.g., glucocorticoids).

Behavior-Modifying Drugs

The use of behavior-modifying drugs is increasingly popular; the proper use and side effects associated with these drugs are discussed in Chapter 25. Among the behavior-modifying drugs, those that are characterized by antihistaminergic effects might be preferred (e.g., doxepin or amitriptyline).

Behavior-modifying drugs have been used to treat feline pruritus, particularly those associated with psychogenic alopecia.⁷ Psychogenic alopecia also has responded to naloxone (1 mg/kg subcutaneously, one dose), although time to recurrence of the abnormal behavior ranged from as short as 1 week to as long as 6 months.⁷ The dopamine antagonist haloperidol (2 mg/kg intravenously) did not appear very useful long term when compared with a control for treatment of psychogenic alopecia.⁷ Cats did, however, respond within 48 hours. Buspirone does not appear to be effective for control of psychogenic alopecia.⁷ Fluoxetine has been useful for chronic, idiopathic licking in cats.

Combination Therapy

Combinations of drugs that alter the sensation or response to the sensation through different mechanisms of action should be considered. The combinations that appear to be most effective include fatty acid supplements (Dermcaps) with glucocorticoids (leading to a 25% to 50% reduction in the glucocorticoid dose)²⁸; antihistamines (trimeprazine) and glucocorticoids (an increase from 50% improvement with glucocorticoids alone to 76% improvement with the combination, with a 50% to 75% reduction in the glucocorticoid dose)³³; and fatty acid supplements with antihistamines (chlorpheniramine and Dermcaps in combination caused a 35% response in animals that responded to neither drug alone).²⁸ Combination of misoprostol with antihistamines is being investigated. Assessment at weekly intervals should be accompanied by a change in therapy if response has not been sufficient.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs should be avoided in pruritic skin diseases. Inhibition of prostaglandin formation may result in greater synthesis of leukotriene and related compounds. Newer lipoxygenase-specific inhibitors (approved for use in the treatment of human bronchial asthma) may be beneficial, but these drugs have not been studied with the intent of controlling pruritus.

Future Therapies

Future therapies may focus on biologic response modifiers.³⁴ Products with potential efficacy for human patients with atopy include interferon-γ, thymopentin (an active pentapeptide of a thymic hormone that promotes differentiation of mature T lymphocytes), and interleukin-2.

Acral Lick Dermatitis

Acral lick dermatitis (lick granuloma) is a self-traumatizing syndrome that afflicts dogs, occurring almost exclusively in larger breeds. The cause is not known, but it has patterns similar to an obsessive-compulsive disorder. It is often considered psychogenic in origin; suggested behavioral causes include boredom, loneliness, and confinement.³⁵ Underlying bony pathology or allergy may also be the cause of the lesions. Chronic lesions are frequently infected with bacteria or fungal organisms, which can also contribute to the pruritic stimulation. Local irritation has, however, been suggested as a provoking cause. Not surprisingly, drugs used to treat obsessive-compulsive disorders in humans have proved effective. The proper use of these drugs is discussed in Chapter 26. In one clinical trial with 43 dogs, the drugs most effective were those that increase serotonin at the neurotransmitter. This is not surprising because the serotonin system has been implicated in a variety of abnormal behaviors.³⁵ Dose ranges of the drugs (orally per day) proven successful in clinical trials³⁶ include clomipramine (2.4 to 3.6 mg/kg),³⁶ fluoxetine (0.55 to 1.36 mg/kg), and sertraline (2.7 to 4.3 mg/kg). Of these, clomipramine followed by fluoxetine appeared to be most effective, causing response (50% or more reduction in behavior) in close to 50% of animals studied. Clinical response was not evident until the second week of therapy and continued to decline through the 5 weeks of one study.³⁵ Adverse effects occurred in approximately 25% of dogs in each treatment group, but they tended to be mild and subsided with time. Discontinuation of the behavior-modifying drug may cause recrudescence of clinical signs. Drugs to which there was little

response included desipramine and fenfluramine. In most cases, secondary infection is present and must be treated. Glucocorticoid therapy is usually indicated in the early stage of treatment to decrease the inflammation. Antiinflammatory dosages rather than immunosuppressive dosages are recommended. Oral prednisone or prednisolone are the favored products. Additional topical therapy with Synotic applied twice daily may be selected instead of oral glucocorticoid therapy. Appropriate antibiotic therapy based on culture and susceptibility is indicated.

Both naloxone and naltrexone, both pure narcotic antagonists, have been used to resolve abnormal behavior in dogs with lick granulomas. Increased release of endogenous opioids has been detected in self-mutilating behaviors in experimental animals. Opioid antagonists may eradicate endorphinmediated self-reward and analgesia. Like naloxone, naltrexone is a pure opioid antagonist but is characterized by a higher oral efficacy and longer duration of action. An uncontrolled study of the use of naltrexone in dogs with acral lick dermatitis reported a 64% success rate.³⁷ A dose of 2.2 mg/kg orally once daily (1 mg/kg subcutaneously) was increased to 2.2 mg/kg orally twice daily when there was no response after 10 days. Dogs were treated for 1 month; lesions returned when the drug was discontinued, and time of recurrence varied from 1 week to 3 years after the drug was discontinued. One animal that failed to respond to naltrexone responded to nalmefene, another narcotic antagonist. Chronic cases or those with a poor response to therapy should be biopsied to rule out neoplasia and cultured for infectious agents.

Canine Seborrhea

Canine idiopathic seborrhea is an inherited disorder of keratinization characterized by pruritus, epidermal thickening, and formation of dry or greasy crusts and seborrheic plaques.^{3,38} The pathophysiology is not well understood, but hyperproliferation of the epidermis, hair follicle infundibulum, and sebaceous glands have been reported. Renewal time for the epidermis is reduced from 22 to 8 days.³⁸ Increased cutaneous concentrations of AA have been measured in affected dogs. Treatment controls but generally does not cure the condition. The production of increased scale can be caused by myriad diseases and problems. The search for the cause of the scale is more important than symptomatic therapy. Primary idiopathic seborrhea as a diagnosis is fairly uncommon.

Therapy for seborrhea oleosa should include shampoos that are keratolytic, keratoplastic, and degreasing. Ingredients that serve this purpose contain sulfur; salicylic acid; benzoyl peroxide; or, less commonly, coal tar. Among these, benzoyl peroxide is probably the preferred ingredient, although a sulfur salicylic shampoo might be tried first. Benzoyl peroxide activity is enhanced with the addition of sulfur (SulfOxydex, DVM). In general, products for human beings should not be used on dogs. Products also can be alternated.

Animals should be bathed twice a week until scaling, greasiness, and odor are controlled; the frequency of bathing is then decreased to the minimum necessary to control clinical signs. Contact with the shampoo (completely lathered) must occur for at least 10 minutes. For animals with an extremely thickened accumulation, bathing with a mild cleanser such as D-Basic (DVM) before a medicated shampoo is used may prove beneficial and will be sparing of the more expensive products. PUFAs have recently been used for treatment of seborrhea. Supplementation should begin as topical therapy is started. Corn, sunflower, or safflower oil (1.5 mL/kg every 24 hours orally) or commercial EFA products can be used.³⁸ It is possible that the skin of affected dogs cannot obtain or metabolize LA, suggesting that topical administration.³

Generalized Demodicosis

Therapy for generalized demodicosis should be accompanied by proper nutrition, minimization of stress, and control of accompanying pyoderma. Self-cure can be expected in 50% of dogs younger than 12 months of age, although no factors appear to be predictive of self-cure.³⁹ The most efficacious treatment for generalized demodicosis appears to vary in the literature. No single drug will cure all cases; up to 10% cannot be cured.³⁹ Amitraz (Mitaban)19.9%, and amitraz in ProMeris (Fort Dodge) are the only drugs approved by the Food and Drug Administration for treatment of demodicosis, although an Environmental Protection Agency-registered solution is available (Taktic). Amitraz (Mitaban)is labeled for treatment at 2-week intervals (diluted to 250 ppm or 10.6 mL in 7.6 L). Original reports regarding its efficacy using the approved protocol apparently were inappropriately optimistic (90% predicted cure rates). Long-term cure rates according to the approved treatment regimen range from as little as 0% to 50% (0.025% or 250 ppm dip).⁴⁰ Follow-up studies at greater concentrations have more favorable results.

Concentrations of 500 ppm (double strength) may be used for refractory cases. Weekly dips of 250 to 500 ppm are curative in 75% to 80% of cases, respectively.⁴⁰ Long hair coats should be clipped and animals bathed first. Treatment should continue until two dips have occurred after two negative skin scrapings, regardless of how many dips must occur. Weekly application may be implemented if biweekly therapy is not successful. Oral vitamin E therapy at 200 IU/dog five times daily may enhance efficacy of amitraz, although this has not been proved.⁴⁰ ProMeris (Fort Dodge) is to be applied every 14 days until a remission is reached. Adverse side effects similar to the those of of Mitaban have been reported. Immunomodulators such as Staphage Lysate, ImmunoRegulin, and levamisole appear to be ineffective.⁴⁰

Should amitraz fail, a macrolide antibiotic should be considered. Milbemycin at 1 and 2 mg/kg daily appears to cure 50% to 90% of dogs, respectively. Duration of therapy in one study ranged from 90 to 300 days; treatment should occur for 60 days past multiple negative skin scrapings. Side effects should be limited as long as 2.5 mg/kg is not exceeded.³⁹ Ivermectin at 0.3 to 0.6 mg/kg per day orally (but not 0.2 to 0.4 mg/kg per week subcutaneously) also may be efficacious, with treatments being necessary for as long as 210 days. Because the drug is very bitter, administration in vanilla ice cream or apple sauce is recommended.⁴⁰ This dosing regimen is not safe for Collies and related breeds. Testing for reaction to ivermectin involves administration of 0.125 mg/kg per day for 7 days. Alternatively, hospitalization might occur for the initial period during which a starting dose of 0.1 mg/kg is gradually increased to the maintenance dose. Signs of pending toxicity include mydriasis and excessive salivation. Neurologic signs are also possible. Testing for the MDR1 gene mutation is available through Washington State University. This test will help identify those dogs that are sensitive to ivermectin toxicity.

Should relapse occur within 3 months, inadequate treatment is the most likely cause,³⁹ and the therapeutic protocol can be repeated but for a longer duration. Later relapses probably reflect recurrence; repetition of the initial treatment protocol is not likely to be effective,³⁹ and an alternative protocol should be selected. It is essential to resolve any complicating skin infections and to search for an underlying cause of refractory demodicosis. Also, underlying allergic disorders must be addressed.

Dermatophytosis

Treatment of dermatophytes is also addressed in Chapter 9. Establishment of the efficacy of selected treatment regimens is handicapped by the often self-resolving nature of the infection. Moriello⁴¹ emphasizes that, as with pyoderma, topical therapy alone is not sufficient for effective treatment of dermatophytosis. Indeed, several disadvantages are associated with topical therapy. Hairs protect spores; in addition, many commonly used topical antifungal solutions and shampoos are not sporicidal. Among the more efficacious are lime sulfur (1:16) and enilconazole (bottle dilution, but not licensed for use in the United States).⁴¹ Unfortunately, both of these topical products are associated with side effects: Enilconazole has caused death in some cats, and lime sulfur can be very irritating. Grooming after topical treatment increases the risk of toxicity in cats if they are allowed to groom while the product is wet. Pet owners are exposed to topical agents, increasing their risk. Occasionally, topical agents worsen infection, perhaps because of damage to the skin (mechanical scrubbing) during shampooing. The efficacy of topical ointments, creams, and gels is questionable. Among the topical ointments and creams, bifonazole is more effective than miconazole, but its efficacy also is questionable, particularly if infection involves haired skin. In addition, topical agents tend to be messy, are groomed by the animal, and encourage "spot" therapy. Nonetheless, topical therapy is an important adjuvant for treatment of dermatophytosis. Topical therapy will limit environmental contamination and contagion if spores on the hair coat are killed. The preferred topical product⁴¹ is lime sulfur (4 to 8 oz/gallon); higher concentrations are potentially irritating and cause exfoliation. Gauze sponges should be used to pat, not rub, the dip onto the skin. An Elizabethan collar should reduce the risk of ingestion.

Five drugs are used to systemically treat dermatophytosis: griseofulvin, ketoconazole, itraconazole, and fluconazole and terbinafine (see Chapter 9). Even in infections that will be self-resolving (self-cure generally occurs in 60 to 100 days), systemic antifungal therapy will hasten the time to recovery and thus is beneficial, limiting environmental contamination and exposure to human beings. Griseofulvin remains the drug of choice because it is licensed and approved for use in dogs and cats. Either the microsize dose (25 to 50 mg/kg divided or once every 24 hours) or the ultramicrosize dose (5 to 10 mg/kg orally once daily) can be administered. Because many animals are intolerant to ketoconazole, itraconazole is the second drug of choice should an animal not tolerate griseofulvin therapy or fail to respond to it. Ketoconazole is significantly less expensive than itraconazole and is a reasonable choice for dogs. Although improvement should be evident within 2 to 3 weeks of therapy, several weeks (generally 30 to 70 days) must lapse before a cure is achieved. A comparison study in kittens infected with Microsporum canis found that time to resolution with griseofulvin (50 mg/kg orally divided or once every 24 hours) was 70 days versus 56 days with itraconazole (10 mg/ kg orally once daily); the control group remained positive at 100 days. Therapy should be monitored by fungal cultures biweekly after 4 to 6 weeks of therapy and treatment continued until two or three consecutive weekly cultures are negative. Note that false-positive fungal cultures can occur after clinical recovery because of environmental contamination. Cats with questionable positive results should be isolated from the environment for 3 to 5 days and subsequently recultured. Griseofulvin should not be used in pregnant animals, those younger than 12 weeks of age, or those that test positive for feline immunodeficiency virus. This drug should be discontinued immediately if the cat becomes anorexic or lethargic or if gastrointestinal signs are seen. Terbinafine, a systemic antifungal approved for use in human beings for treatment of dermatophytosis, has not been studied for efficacy or safety in animals. However, an unpublished pharmacokinetic study with cats (in Europe) indicates that a dose of 10 mg/kg once daily is appropriate; 10 to 30 mg/kg orally once daily has been suggested in Internet resources. Fluconazole may also be effective when other treatments fail or are associated with side effects. The recent change to a generic drug has reduced the cost dramatically. Terbinafine has been shown to be effective for treating Malassezia and may be an alternative antidermatophyte treatment.

Cleansing of the environment is obviously critical in a cattery or kennel situation but can also be important in a singleanimal household. Undiluted bleach and 1% formalin are the most effective products for resolving environmental contamination.⁴¹ This regimen is likely to kill 100% of spores; residual activity is likely to be greatest with undiluted bleach, followed by 1% formalin, enilconazole (not available in the United States), and common household bleach diluted 1:10. Common household bleach is not as efficacious in killing spores as the other two products, but it is the least expensive and most readily available. Aqueous chlorhexidine is ineffective.

Canine Perianal Fistulae (Anal Furunculosis)

Very little has been written on the topic of canine perianal fistulae. Nonsurgical management is the new standard of therapy.⁴² Cyclosporine orally at 5 mg/kg twice daily until a remission is reached is the treatment of choice. The available

water-soluble forms should be selected (Neoral, Atopica).⁴³ Vomiting and diarrhea are common side effects. Additional side effects can include gingival hyperplasia and secondary infections. Tacrolimus ointment (protopic 0.1%) is a topical analog of cyclosporine. It has been shown anecdotally to be effective for the treatment of perianal fistulae when used as a sole treatment. In the author's experience, this product alone is not beneficial. Cyclosporine orally with or without tacrolimus ointment appears to be the current treatment of choice. Treatment may take several weeks to induce a remission before tapering off the dosage to every other day. Relapses are common. Secondary infections are common and should be treated on the basis of culture and susceptibility testing.

Rational Use of Reproductive Hormones

23

Autumn P. Davidson, Janice L. Cain, and Sophie A. Grundy

Chapter Outline

PHYSIOLOGIC PRINCIPLES OF REPRODUCTIVE	Treatment of Vaginal Hyperplasia and Prolapse
HORMONES	Diagnosis and Treatment of Premature Labor
Hypothalamic Hormones	Prevention or Termination of Estrus
Pituitary Gonadotropins	Prolongation of Interestrus Intervals in the Bitch
Gonadal Steroids	Treatment of Clinically Significant Pseudocyesis
Inhibitors of Gonadal Steroids	Pyometra and Postpartum Metritis
Autacoids	Pregnancy Termination
COMMERCIAL AVAILABILITY OF REPRODUCTIVE	Medical Management of Dystocia
HORMONES	Adjunct Therapy for Mammary Gland Carcinoma
Gonadotropin-Releasing Hormone And Its Analogs	Urinary Incontinence in Spayed or Neutered Dogs
Gonadotropins	Cryptorchidism
Dopamine Agonists	Benign Prostatic Hyperplasia
Gonadal Steroids	Hypogonadism
Inhibitors of Gonadal Steroids	Management of Retrograde Ejaculation; Improvement
Antiprogestins	of Ejaculate
Miscellaneous	MISUSES OF REPRODUCTIVE HORMONES
INDICATIONS FOR THE RATIONAL (EVIDENCE-	Treatment of Idiopathic Infertility
BASED) USE OF REPRODUCTIVE HORMONES	Treatment of Mismating and Pregnancy Termination
Estrus Induction	Treatment of Benign Prostatic Hyperplasia
Induction of Ovulation	
Treatment of Follicular and Luteal Ovarian Cysts in	
Bitches	

The use of reproductive hormones as pharmaceuticals should be based on knowledge of both the reproductive physiology of the species under treatment and the pathophysiology of the disorder being treated. Too often, the use of hormonal therapies in small animal reproduction is based on their documented action in other species. Hormonal therapies are also used when the underlying reproductive disorder has not been fully studied nor understood in small animals. Although there are specific indications for the rational (evidence-based) use of reproductive hormones in small animal theriogenology, they are commonly used inappropriately. This chapter includes a review of the basic physiology of hormones used therapeutically in small animal theriogenology, a discussion of their clinical availability, their appropriate applications, and common misuses.

PHYSIOLOGIC PRINCIPLES OF REPRODUCTIVE HORMONES

Hypothalamic Hormones

Gonadotropin-Releasing Hormone and Its Analogs

Gonadotropin-releasing hormone (GnRH) is a highly conserved hypothalamic decapeptide with the same amino acid sequence in all mammals. After puberty GnRH is released in a pulsatile manner from the hypothalamus, traverses the hypothalamic-hypophyseal portal system, and activates anterior pituitary gonadotroph receptors. The pituitary responds by releasing luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in a pulsatile pattern.¹ Stimulation of the pituitary by GnRH must be in pulsatile form for repeated release of LH and FSH; after receptor activation, GnRH is rapidly deactivated and cleared. The frequency and amplitude of GnRH pulses vary depending on the phase of the reproductive cycle. The frequency of GnRH pulsatile release in primates during folliculogenesis is every 70 to 90 minutes.² It is this natural pulsatile secretion of GnRH and its short biological half-life that cause difficulties when attempting to use GnRH as a pharmaceutical. Investigations with specialized infusion devices for pulsatile delivery have successfully augmented fertility in a variety of species,³⁻⁵ but the clinical application of such a method lacks practicality for routine use in small animal patients.

GnRH analogs are synthetically prepared substances that differ from GnRH by various amino acid substitutions in the peptide sequence. Analogs with a few amino acid substitutions can act as GnRH agonists because of their increased binding affinity and decreased clearance compared with GnRH. Heavily substituted analogs can cause receptor blockade and have an antagonist function. The result is a suppressive effect on the pituitary–gonadal axis. This axis is easily downregulated such that frequent or high dosing of a GnRH agonist will suppress the release of LH and FSH also.⁶ GnRH agonists and antagonists thus may have the same ultimate physiologic effect.

Oxytocin

A nonapeptide hormone synthesized by neurons in the hypothalamus, oxytocin is transported axonally to the posterior pituitary, where it is stored. This peptide hormone is released from the posterior pituitary into the general circulation after appropriate neural stimulation. Its primary effects are on mammary tissue and the myometrium. The effects of oxytocin on the milk let-down reflex and parturition have been well described.⁷ The ability of oxytocin to induce myometrial contraction is enhanced by prior estrogen sensitization to "prime" the myometrium for maximal response.8 The half-life of oxytocin in the blood is short, approximately 1.5 minutes; thus secretion pulse frequency and amplitude are important for its physiologic effects. The release of neurotransmitters may alter the amplitude and frequency of oxytocin release; for example, dopamine enhances burst frequency and amplitude, whereas cholinergic antagonists may be inhibitory.9

Pituitary Gonadotropins

Luteinizing Hormone and Follicle-Stimulating Hormone

The pituitary gonadotropins LH and FSH are relatively large glycoproteins, each consisting of two covalently bound structural subunits (α and β). Within a species the amino acid sequence of the α -subunits are identical for all anterior pituitary glycoproteins, with high sequence homology existing across species. The β -subunits are specific for individual hormones (i.e., thyroid-stimulating hormone) and provide the functional specificity of each. The overall size of these glycoproteins precludes economic synthetic production of these hormones.⁸

The secretion patterns of these hormones differ depending on the species and the phase of the ovarian cycle. A unique pattern of LH secretion in the bitch has been documented¹⁰ (Figure 23-1). Serum concentration of LH is at basal levels during anestrus. Significant increases in both the amplitude and frequency of LH pulsatile release occur before proestrus. The frequency of LH pulsatile release during anestrus is 3 to 7 hours; before proestrus LH pulse frequency is 60 to 120 minutes.¹¹ This increase in LH release before the onset of proestrus is likely involved with termination of the anestrus phase.¹ The factors that lead to the LH increase at that time are unknown. Serum estrogen concentration at that time also decreases; estrogen production inhibits LH release. What causes the relative decrease in estrogen production at that time is also unknown.

Serum LH concentration returns to basal levels for most of proestrus (i.e., folliculogenesis). The increase in serum estrogen concentration during folliculogenesis contributes to an inhibition of LH release during that phase.¹ When estrogen

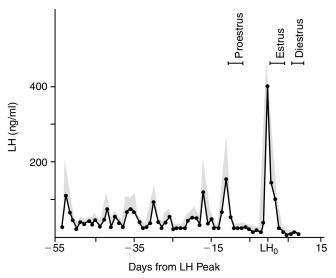

Figure 23-1 Concentrations of luteinizing (LH) hormone in canine serum throughout late anestrus, proestrus, estrus, and early diestrus. *Stippled area* is the standard error of the mean (*bars* indicate ranges of proestrus, estrus, and diestrus). (From Olson PN, Bowen RA, Behrendt MD et al: Concentrations of reproductive hormones in canine serum throughout late anestrus, proestrus, and estrus, *Biol Reprod* 27:1196, 1982.)

production decreases, the inhibition of LH release is discontinued. At that time a preovulatory surge in LH release (the preovulatory LH peak) occurs and is thought to trigger ovulation. The duration of the preovulatory LH peak is 1 to 3 days, after which LH secretion returns to a basal state in early diestrus. Additionally, LH is luteotrophic throughout most of the luteal phase in the bitch.

Similar to the pattern of LH secretion, FSH secretion also appears to be inhibited by relatively high concentrations of estrogen during proestrus. Inhibin, a modulary hormone released from the ovary during folliculogenesis, also inhibits FSH release during this phase. When estrogen secretion declines in late proestrus, FSH secretion surges to maximal levels before ovulation, in concert with the preovulatory LH peak^{1,10} (Figure 23-2). After this FSH surge, serum FSH concentration remains relatively high during diestrus and pregnancy. Interestingly, the bitch is also unique with regard to the pattern of FSH secretion during anestrus. During anestrus serum FSH concentration can be 50% to 100% of the concentration found at the preovulatory FSH peak and is 5 to 10 times higher than during proestrus.¹ It is unclear why FSH produced during anestrus is unable to stimulate folliculogenesis. It has been postulated that perhaps the FSH measured during anestrus is in a biologically inactive form.¹

The patterns of LH and FSH secretion in the queen have not been clearly determined. It has been documented that after adequate copulation LH release begins within minutes. Queens are induced ovulators; thus this response is expected. Apparent spontaneous ovulation, without copulation or other tactile stimulation, has been reported in the queen.¹² The pattern of LH secretion during the apparent spontaneous ovulation has not been determined, however.

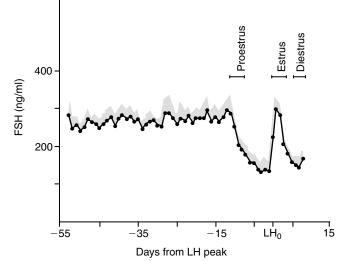

Figure 23-2 Concentrations of follicle-stimulating hormone (FSH) in canine serum throughout late anestrus, proestrus, and early diestrus. *Stippled area* is the standard error of the mean (*bars* indicate ranges of proestrus, estrus, and diestrus). (From Olson PN, Bowen RA, Behrendt MD et al: Concentrations of reproductive hormones in canine serum throughout late anestrus, proestrus, and estrus, *Biol Reprod* 27:1196, 1982.)

The release of LH and FSH is also pulsatile in response to GnRH in the male. Both glycoprotein hormones are necessary for spermatogenesis. Testicular interstitial cells bind LH and respond by increasing testosterone production. Activation of receptors on Sertoli cells by FSH promotes spermatogenesis and produces inhibin, a hormone that, as in the female, regulates FSH release by the pituitary. After neutering the loss of negative feedback inhibition causes serum FSH concentrations to increase dramatically.¹³ This has also been documented in cases of infertility resulting from primary testicular degeneration.¹⁴ Postcastration elevations in LH serum concentrations also occur, but overlap in measured values between intact and neutered dogs is possible.¹³

Some species also produce placental gonadotropins. A luteotrophic gonadotropin produced by the human placenta (human chorionic gonadotropin [hCG]) has a potent LH-like effect in many species. A gonadotropin produced by fetal trophoblastic cells in horses is referred to as equine *chorionic gonadotropin (eCG)* or *pregnant mare serum gonadotropin (pmSG)*. In most species eCG has a combination of FSH and LH activity. Additionally, eCG products commonly contain components of equine serum that can be antigenic when used as a pharmaceutical in another species.

Prolactin

A relatively large polypeptide produced by the anterior pituitary, prolactin is luteotrophic in the bitch and queen.^{15,16} It is suspected that prolactin is also involved in the maintenance of the anestrus phase in the bitch.¹ Prolactin is under negative control by dopamine such that the administration of a dopamine agonist will inhibit prolactin secretion. Inhibition of prolactin secretion can promote luteolysis during the second half of diestrus or pregnancy in the bitch¹⁵ and queen.¹⁶ Various dopamine agonists have been investigated for inducing abortion and shortening anestrus (i.e., estrus induction). Bromocriptine is a dopaminergic drug that has been used in various protocols. Its use has not gained acceptance, however, because it commonly causes vomiting and diarrhea. The highly potent dopamine agonists cabergoline and metergoline have fewer or no apparent side effects, respectively. The effect of metergoline to decrease prolactin secretion may primarily result from blockade of central serotonin receptors and may function as a dopamine agonist only at higher doses.¹⁷ Metoclopramide, more commonly used as a central serotonin antagonist, may be used to enhance prolactin release in the bitch and queen, and thus enhance milk let-down, through its central dopamine (D_2) agonist effects.

Gonadal Steroids

Estrogen

Produced by the ovary during folliculogenesis, estrogens affect target tissues, causing vulvar edema, vaginal mucosal hyperplasia, sanguineous vulvar discharge in the bitch, and sexual attraction in both the bitch and queen. The bitch uniquely exhibits sexual receptivity when estrogen production decreases; serum concentration of estrogen peaks 1 to 2 days before the end of proestrus. A concurrent increase in progesterone is required for complete expression of sexual receptivity. Estrogen acts synergistically with progesterone to stimulate growth of endometrial and mammary glands, and estrogen priming may be important before the natural effect of oxytocin on the myometrium during parturition.⁸ Male production of estrogen occurs in both the Leydig and Sertoli cells, by way of de novo steroidogenesis in the Leydig cell and P450 aromatase conversion of testosterone alone in the Sertoli cell. Considerable interspecies variation occurs with respect to the relative ratios of estrogen produced by each cell. Excessive production of estrogens by Sertoli cell tumors and, less commonly, by other testicular or adrenal tumors results in male feminizing syndrome. Estrogens are involved in receptor sensitivity and feedback influence on the hypothalamicpituitary-gonadal axis.

The adverse effects of estrogen (i.e., bone marrow aplasia, cystic endometrial hyperplasia/pyometra, infertility) have been documented in dogs after administration of any estrogen preparation.^{18,19} The unique sensitivity of dogs to estrogen toxicity may be due to the relatively weak binding affinity of sex-steroid binding proteins for estrogen in the dog. The result is a decrease in the inherent buffering mechanism that would otherwise regulate the amount of free hormone available to penetrate cell membranes. Estrogen toxicity can occur with exogenous or endogenous estrogens (e.g., Sertoli cell tumors, ovarian follicular cysts, and ovarian neoplasia).

Progesterone

As the main progestational hormone in both bitches and queens, progesterone is produced by corpora lutea just before and after ovulation. The bitch continues to produce

progesterone during nonpregnant diestrus; serum concentrations of progesterone are indistinguishable in concentration or duration of production from that of pregnancy. The decline of progesterone and increase in prolactin production at the termination of diestrus cause the clinical manifestations of pseudopregnancy in the nonpregnant bitch. This is a demonstration of a normal physiologic occurrence that should not be confused with a pathologic state and in fact suggests normal ovarian function. There is some variation among bitches regarding the maximum amount of progesterone produced in midgestation (or mid-diestrus), with levels reaching 80 to 100 ng/mL in some individuals. The minimum serum progesterone concentration necessary to maintain pregnancy appears to be 2 ng/mL.²⁰ The minimum amount of progesterone required to sustain pregnancy in the queen has not been determined; however, serum progesterone concentrations of less than 1 ng/mL for several days occurred before termination of pregnancy were observed in one study.¹⁶

Placental production of progesterone by the queen during the latter half of pregnancy had been suggested as a requirement to maintain pregnancy. It has been learned, however, that corpora lutea of the queen are necessary for progesterone production throughout pregnancy.²¹ During pseudopregnancy in queens (i.e., nonfertile ovulation), peak luteal activity appears to occur at days 10 to 15 and then declines to basal values by days 35 to 40.²²

In the bitch progesterone is produced before ovulation by follicular luteinization, approximately concurrent with the preovulatory LH peak. Serial evaluations of serum progesterone concentrations during proestrus and estrus can be used to indirectly determine the preovulatory LH peak and thus determine the time of ovulation in the bitch. This methodology, known as *ovulation timing*, is used to improve breeding management. The bitch typically exhibits sexual receptivity (behavioral estrus) when the serum concentration of estrogen is decreasing and progesterone is increasing.

Synthetic progestational compounds (progestagens) are commercially available. Megestrol acetate has been marketed as a drug to suppress estrus or inhibit ovulation, depending on the time and dose of administration. The method by which progestagens inhibit folliculogenesis and ovulation is not precisely understood. It appears that although megestrol acetate will not decrease the serum concentration of LH that is already at low basal levels, it may be able to prevent the increases in LH that normally occur at the end of anestrus.¹

Testosterone

Produced by the interstitial cells of the testes, testosterone is necessary for gonadal development, spermatogenesis, and libido in the male. The normal function of Sertoli cells to promote spermatogenesis depends on an intratesticular testosterone concentration that greatly exceeds circulatory levels.⁸ Pharmacologic administration of androgens, including testosterone, can induce infertility by negative inhibition of LH and FSH release, which are necessary for spermatogenesis. Testosterone is converted in the prostate to dihydrotestosterone (DHT), which promotes development of this gland and the eventually contributes to the anticipated formation of benign prostatic hyperplasia in mature dogs. DHT is an androgen with greater biological activity than testosterone.

Testosterone and the androgenic steroid mibolerone have been used to suppress ovarian activity and thereby prevent estrus cycles in the bitch. Mibolerone was specifically approved for this use, although the duration of time from discontinuing administration to the occurrence of the next estrous cycle was variable. Silent heats following mibolerone therapy were common. Persistent anestrus (i.e., lack of return to estrous cycles) has been a problem in some Greyhound bitches treated with injectable testosterone to prevent estrus cycles during racing.

Inhibitors of Gonadal Steroids

Tamoxifen is both an estrogen agonist and antagonist that has been used as adjunctive therapy for women with mammary carcinoma. The nature of its effect depends on tissue estrogen receptor type. Tamoxifen appears to have, at least in part, a direct estrogenic effect in the bitch. Some bitches treated with tamoxifen had observable vulvar edema; sanguineous vaginal discharge; and, in some cases, pyometra of the uterine stump.²³ Tamoxifen and clomiphene, another antiestrogenic compound, have been used to promote superovulation in women, possibly by promoting an increase in endogenous FSH release. Tamoxifen has been used in the bitch as a mismate therapy but was associated with pyometra, endometritis, and cystic ovaries in a high percentage of bitches; was reliably effective only when given during the first 14 days of diestrus; and is not advised.²⁴

Antigestagens are agents that inhibit the effect of progesterone by binding to and altering the progesterone receptor and have been investigated as abortion agents in humans (i.e., mifepristone, RU-486). Preliminary studies have documented the effectiveness of mifepristone to terminate pregnancy in bitches.²⁵

Finasteride is another useful inhibitor of gonadal steroids. Testosterone is converted to DHT in the prostate by the action of the enzyme 5α -reductase. Trophic in its effect, DHT induces benign prostatic hyperplasia as a dog ages. Finasteride inhibits the action of 5α -reductase, thereby reducing DHT concentrations in the prostate. Finasteride may also alter prostatic angiogenesis and reduce hemospermia through a change in microvessel density. Developed for use in men with prostatic hyperplasia, finasteride has been investigated for successful similar use in dogs.²⁶ Benign prostatic hyperplasia causing hemospermia can be detrimental to efforts to successfully freeze and thaw canine semen; otherwise, it is minimally problematic in the dog unless accompanied by infection or neoplasia.

Autacoids

Prostaglandin F_{2α}

Prostaglandins, potent autacoids, have therapeutic indications in small animal theriogenology. Administration of prostaglandin $F_{2\alpha}(PGF_{2\alpha})$ induces a direct luteolytic effect in bitches and queens during pregnancy or diestrus. Induction of luteolysis depends on dose, frequency of drug administration, and stage of diestrus that the drug is administered. After day 30 of diestrus, PGF_{2α} is reliably luteolytic in both the bitch²⁷ and queen.²² Corpora lutea are relatively resistant to luteolysis by PGF₂-alpha during the first 5 days of diestrus in the bitch.²⁸ There is evidence that PGF_{2α} will cause either a transient decrease in progesterone production or complete luteolysis when administered during early diestrus after day 6.²⁸ In addition to a direct luteolytic effect, PGF_{2α} also has a stimulatory action on the myometrium, promoting evacuation of uterine luminal contents. The drug is therefore effective as an abortifacient and for the treatment of open cervix pyometra in the bitch and queen.

Additional effects of PGF_2 -alpha administration include panting, nausea, vomiting, diarrhea, hypersalivation, and tachycardia in dogs and vocalization, mydriasis, and possibly vomition and diarrhea in cats. These adverse clinical signs usually stop within 20 to 30 minutes of drug administration. The drug is preferably administered after fasting in the dog and cat to decrease the incidence of vomiting. The adverse effects of $PGF_{2\alpha}$ are potentially dose related, although there is individual sensitivity, and signs usually abate after repeated dosing. Although extremely rare, cardiovascular collapse after PGF_2 -alpha administration is possible.

Most protocols using $PGF_{2\alpha}$ are based on the formulation of dinoprost tromethamine. This product is not approved for use in dogs or cats in the United States. Informed owner consent is advised, although the use of $PGF_{2\alpha}$ is established in the veterinary literature. The more potent synthetic $PGF_{2\alpha}$ analogs (cloprostenol and fluprostenol) are now used clinically in both the dog and the cat; studies regarding the use of these compounds indicate efficacy with fewer side effects, owing to the increased specificity of the compounds for uterine smooth muscle.

KEY POINT 23-1 Both natural and synthetic hormonal products are available for the treatment of small animal reproductive conditions; the clinician should weigh the benefits of both before selecting therapy.

COMMERCIAL AVAILABILITY OF REPRODUCTIVE HORMONES

Gonadotropin-Releasing Hormone And Its Analogs

Lack of availability is a major hindrance to widespread use of GnRH analogs to control reproduction in humans and animals. Analogs are expensive to produce and are often available only as investigational products for research studies; availability also varies throughout the United States. One marketed GnRH analog (an antagonist) is leuprolide (Lupron, TAP Pharmaceuticals, Deerfield, Ill.). The native GnRH hormone (gonadorelin, Rhone Merieux) is commercially available (Cystorelin, or Factrel, Fort Dodge Laboratories, Fort Dodge, Iowa). Implant formulations of GnRH agonists such as deslorelin have been shown to be effective for reversible long-term suppression of reproductive function in the male and female dog and estrus suppression in the queen^{29,30} and have been manipulated for estrus induction in the bitch.³¹

Gonadotropins

Currently, FSH is not available in the United States; hCG is readily available (Chorulon, chorionic gonadotropin, Butler, Columbus, Ohio). In the United States eCG is not commercially available but may be available in Canada (Equinex, Ayerst Laboratories, Quebec) and in some European countries. Purified canine LH is not commercially available, but human LH can be purchased in a 1:1 ratio with human FSH in a product used to treat human infertility (Repronex, menotropin, Serono Laboratories, Norwell, Mass.). Additionally, purified human FSH is available (Metrodin, Bravelle, Serono Laboratories). The use of human menotropins has not been extensively studied in small animal medicine, and these products are likely to be too costly for routine use.

Dopamine Agonists

Bromocriptine (Parlodel, Sandoz Pharmaceuticals, East Hanover, NJ) is available, as is the newer dopamine agonist cabergoline (Dostinex, Pharmacia and Upjohn); metergoline (Virbac Laboratories, Carros, France) is available in Europe.

Gonadal Steroids

Other than antigestagens, which are not available in the United States, gonadal steroids and their inhibitors are widely available in many formulations. Some hormones are available in repositol formulation (i.e., medroxyprogesterone acetate, Depo-Provera, Upjohn, Kalamazoo, Mich.), and others are available in esters that exert a more potent effect (i.e., esters of estradiol). Some commonly available products include compounded diethylstilbestrol (DES), progesterone in oil (Eli Lilly), and testosterone propionate (Steris Laboratories, Phoenix, Ariz.).

Inhibitors of Gonadal Steroids

Tamoxifen (Nolvadex, Zeneca Pharmaceuticals, Wilmington, Del.) and finasteride (Proscar, Merck and Co., West Point, Pa.) are commonly available through pharmacies for humans. One product that is available (but not recommended on account of the side effects of progesterone administration in intact bitches) for contraception (heat prevention) in bitches is megestrol acetate (Ovaban, Schering-Plough).

Antiprogestins

Progesterone-receptor blockers (antiprogestins), such as mifepristone and aglepristone, are clinically available for use only in humans, and they are not available in the United States at this time.

Miscellaneous

Other products commonly available include oxytocin (Butler), natural prostaglandin $F_{2\alpha}$ (Lutalyse, Upjohn), Cloprostenol (Estrumate, Cayman Pharma), misoprostol, and PGE, (Cytotec, G. D. Searle & Co., Chicago, Ill.).

INDICATIONS FOR THE RATIONAL (EVIDENCE-BASED) USE OF REPRODUCTIVE HORMONES

Some reproductive disorders are common and well described in the literature (e.g., pyometra, dystocia). Others are either incompletely understood or are less common (e.g., estrus induction, luteal insufficiency) such that information can be difficult for the practicing veterinarian to obtain. The discussion presented here is intended to provide an overview of several reproductive problems of dogs and cats that commonly require veterinary intervention (Table 23-1). Many of these disorders are topics of current research, which is needed to better understand and manage them.

KEY POINT 23-2 Medical management of reproductive conditions best treated surgically (i.e., neutering) should be reserved for individuals with good reproductive potential.

Estrus Induction

Induction of Estrus in the Bitch

A reliable, practical method to successfully induce fertile estrus in the bitch has long been sought. Protocols that are successful in other species usually do not produce the same effect in the bitch. This is primarily because of the unique reproductive physiology of the bitch and a lack of understanding of all the factors that initiate a new estrous cycle. Various protocols have been tested using all classes of reproductive hormones: GnRH, GnRH analogs, gonadotropins, dopamine agonists, and DES (Table 23-2). Some relatively successful protocols use compounds that are not commercially available at this time. It is important to thoroughly evaluate all potential causes of reproductive failure before estrus induction is attempted and realize that protocols are designed and tested using bitches that are reproductively normal. The outcome of estrus induction in bitches that have reproductive pathology is not known.

Investigation into the use of GnRH as an agent to induce estrus in the bitch resulted in seven of eight Beagle bitches that ovulated and conceived (GnRH 140 μ g/kg per pulse every 90 minutes intravenously for 11 to 13 days).⁵ This protocol used a programmable, portable pulsatile infusion device (Pulsamat, Ferring Laboratories, Ridgewood, N.J.) that delivered the GnRH from a reservoir within the pump to a jugular intravenous catheter. The pump, attached to a harness worn by the bitch, was well tolerated by laboratory Beagles. The pump and harness were not well tolerated by privately owned Labrador Retriever bitches, however. The fragility of the pump and its expense preclude its routine use in veterinary medicine.

Indication	Hormone Used	Considerations		
Estrus induction	See Table 23-3			
Induction of ovulation				
Ovulatory failure	hCG or GnRH to induce ovulation	Difficult to accurately determine follicular maturity to administer at correct time		
Ovarian cysts	hCG or GnRH to induce luteinization	Often ineffective, may require ovariectomy need to differentiate neoplasia		
Vaginal hyperplasia	hCG or GnRH to hasten ovulation	Not proven to shorten time for spontaneous recovery		
Luteal insufficiency	Progesterone to maintain gestation	Potentially teratogenic, inhibits lactation development, luteal insufficiency is rare; need diagnosis before treatment attempted		
Estrus prevention	Mibolerone or megestrol acetate GnRH analogs (implant)	Mibolerone: unpredictable and unavailable, irregular return to estrus after withdrawal; megestrol acetate: potential for infertility, pyometra; requires compounding GnRH analogs are not available in all states		
Signs of pseudocyesis, galactostasis, mastitis	Cabergoline	Mild GI side effects		
Pyometra/postpartum metritis	tra/postpartum metritis PGF ₂ , cloprostenol Transient side effects of PGF ₂ , need carefu supportive clinical care			
Pregnancy termination	PGF ₂ , cloprostenol, dopamine agonists, dexamethasone.	Transient side effects of PGF ₂ ; unavailability of some dopamine agonists, steroid side effects (transient)		
Dystocia	Oxytocin 10 μ/ml	Can induce uterine tetany and fetal demise if overdosage occurs Use less concentrated solution		
Mammary gland carcinoma	Tamoxifen	Controversy as to efficacy, possibly exacerbates condition		
Urinary incontinence	DES	Phenylpropanolamine can be synergistic if ineffective alone		
Cryptorchidism	hCG or GnRH	Ethical concerns, not proven to be effective		
Benign prostatic hyperplasia	Finasteride	Costly, requires compounding in small dogs		
Hypogonadism	Gonadotropins	Rare condition, difficult to document		

hCG, Human chorionic gonadotropin; GnRH, gonadotropin-releasing hormone; PGF₂, prostaglandin F₂; DES, diethylstilbestrol.

GnRH analogs, many of which are not currently commercially available, have been investigated as agents to induce estrus in bitches. The advantage of GnRH analogs is their relatively longer bioavailability and increased potency. Concannon³² reported the use of [D-Trp⁶NmeLeu⁷Pro⁹NEt] GnRH administered by a constant-rate infusion device. Twenty-four bitches received 1.7 to 2.5 µg/kg/day subcutaneously for 14 days; nine bitches ovulated and whelped litters. In a preliminary report, the use of [D-Trp⁶Pro⁹NEt] GnRH was administered to bitches (1 µg/kg subcutaneously every 8 hours) by the following protocol: every 8 hours subcutaneous injections until the observation of behavioral estrus, after which treatment was continued for another 3 days at half the original dose (i.e., 0.5 µg/kg subcutaneously every 8 hours).³³ Four of six bitches treated with this protocol whelped litters as a result of an induced estrus.

Deslorelin implants have also been used successfully as vulval implants for 10 days to induce estrus in the bitch.³¹ They must be removed before downregulation occurs.

The gonadotropins FSH and LH have been investigated with numerous protocols as agents to induce estrus in the bitch. Most protocols use either eCG or FSH to stimulate folliculogenesis and hCG to induce ovulation. Some protocols additionally use DES administered before gonadotropins; estrogen can increase the responsiveness to gonadotropins. Gonadotropin protocols are largely unreliable and can induce adverse effects (e.g., ovarian hyperstimulation with hyperestrogenism), and with some protocols an abnormal luteal phase was detected.³⁴ One report indicated great success with the currently unavailable product PLH (Burns-Biotech),³⁵ although it is unknown what the relative biopotency of FSH and LH was in the product marketed as PLH. That protocol was investigated using Greyhound bitches that had previously received testosterone to suppress estrus during racing. Those bitches had not received testosterone during the 12 months before inclusion in the study, and none of the bitches had an observed proestrus or estrus during that period of time.

The protocol was as follows: DES was administered (5 mg/ bitch per day orally) until proestrus was evident and then for 2 days thereafter. If no signs of proestrus were observed by day 7 of DES treatment, the dose was doubled (10 mg/bitch per day orally) until a response was elicited (not to exceed 7 additional days of DES therapy). On day 5 of proestrus, PLH was administered (5 mg/bitch intramuscularly), and on days 9 and 11 of proestrus FSH was administered (10 mg/bitch intramuscularly).³⁵ All seven bitches in this report became pregnant when bred during an induced estrus. This method used gonadotropin administration in a reverse sequence to that of other reported studies. Because the LH used in this study was no longer available, an attempt to modify the protocol using hCG in place of LH was attempted, but results were disappointing.³⁶

Subsequent studies into the use of DES as a sole agent to induce estrus may indicate that the DES used in other protocols was the primary active agent, and perhaps the administration of additional hormone products decreases the response. Fertile estrus has been induced in bitches by the sole administration of oral DES. In a preliminary report DES (5 mg/bitch orally) was administered daily until proestrus was observed and then for 2 days thereafter.³⁷ The DES therapy continued for 6 to 9 days and resulted in an induced proestrus lasting 0 to 2 days (range) and an estrus duration of 15 to 26 days (range). The preovulatory LH peak occurred 13.5 ± 3.7 days after the last day of DES treatment, although one treated bitch did not have a detectable preovulatory LH peak. All five treated bitches in this study became pregnant, four bitches whelped at term, and one bitch aborted. The lengths of proestrus and estrus and the sizes of the litters did not significantly differ between treated and control groups (n = 5 in each group). The bitches used in this study were treated during a defined

Table 23-2 Hormones Used to Induce Estrus in Bitches			
Hormone Classification	Considerations	Drawbacks	
GnRH	Leaves normal feedback mechanisms intact; drug is available, not expensive	Requires expensive, cumbersome pump for drug delivery	
GnRH analogs	Success in preliminary reports; subcutaneous administration or delivery by implanted infusion devices	Leuprolide, lutrelin, deslorelin, lupron	
Gonadotropins	Many different protocols proposed	Most successful protocol used PLH, which is no longer commercially available. Hormones that are available (eCG, hCG, FSH, LH) are less unsuccessful. Can cause hyperstimulation and hyperestrogenism	
Estrogen	Oral administration of DES, readily available compounded	Reliably induces signs of proestrus, ovulation less predictable. Informa- tion available based on one study at this time. Better protocols exist.	
Dopamine agonists	Shortened interestrous interval	Cost of the newer dopamine agonist cabergoline, which has decreased adverse effects, but usually requires compounding; bromocriptine available but associated with vomiting and diarrhea. Must allow 8 week anestrus period.	

GnRH, Gonadotropin-releasing hormone; eCG, equine chorionic gonadotopin (also known as pregnant mare's serum gonadotropin [PMSG]); hCG, human chorionic gonadotropin; FSH, follicle-stimulating hormone; DES, diethylstilbestrol. period of anestrus (95 to 129 days; mean 107 ± 13 days), which resulted in a shorter period of anestrus than is normal for the colony (175 ± 87 days). Additional investigation into the use of DES as an agent to induce fertile estrus is needed before clientowned bitches are treated. The optimum dosage schedule and potential for toxicity must be assessed. It may be necessary to adjust the dose in smaller bitches to avoid toxicity.

Another method to shorten the naturally long interestrus interval in the bitch is by the administration of a dopamine agonist to decrease prolactin secretion. Prolactin secretion may alter ovarian responsiveness to gonadotropins; the continued presence of prolactin during anestrus may be responsible for the duration of this phase of the estrous cycle. Decrease in prolactin secretion can shorten the length of anestrus and can induce estrus if treatment occurs during late anestrus. Recent work indicates that the effect of bromocriptine causing shortening of anestrus is due to a yet-undefined action other than its lowering of plasma prolactin concentration and can shorten either diestrus or anestrus to have this effect.³⁸ Bromocriptine (20 μ g/kg twice daily administered 112 ± 4 days after the last onset of proestrus) was used in one study to decrease the interestrus interval in bitches.³⁹ Bromocriptine causes vomiting, and investigation into its use has been largely replaced by the dopaminergic drugs cabergoline and metergoline. Termination of anestrus and induction of fertile estrus with minimal side effects has been reported by several authors in dogs using cabergoline.^{40,41} One protocol uses cabergoline at 5 µg/ kg/day until the second cytologic day of proestrus. Treatment for up to 40 days has been reported as effective in inducing fertile estrus in 70% to 90% of normal bitches when started in late anestrus.⁴² Ovulation timing and appropriate breeding management result in normal pregnancies. Two protocols using metergoline were reported in one study.⁴³ Bitches were treated with metergoline (12.5 mg/bitch intramuscularly every 3 days) until the onset of proestrus. Response to therapy was considered positive if proestrus was observed within 40 days after the first day of treatment; 18 of 20 bitches so responded. Ten of these bitches received no additional treatment and were bred, and nine produced litters. Eight other bitches responding to metergoline were additionally treated with hCG (500 IU/bitch intramuscularly) during late proestrus. Six of these bitches ovulated, and four achieved pregnancy. Overall, the metergoline protocol without hCG was more effective in producing pregnancy.

The administration of $PGF_{2\alpha}$ can also shorten the interestrus interval if administered during diestrus. Diestrus normally has a duration of 65 to 70 days in the bitch, and luteolytic therapy with $PGF_{2\alpha}$ abbreviates this phase of the estrous cycle. Bitches that have undergone luteolytic therapy will still enter a phase of anestrus for a variable period, but the return to proestrus or estrus can be sooner than expected, by 1 to 2 months.

Induction of Estrus in the Queen

The domestic cat has been used as a model for reproductive techniques that can apply to preservation of the nondomestic large felines.⁴⁴ Queens are apparently sensitive to effects of gonadotropins administered to induce folliculogenesis, but

production of anovulatory follicles or cysts can result. The administration of eCG as a single bolus (100 IU) to anestrus queens, followed in 5 to 7 days by a single injection of hCG (50 IU), resulted in a pregnancy rate that was comparable with that produced by natural matings.⁴⁵ Daily administration of FSH-P (2 mg/queen per day intramuscularly) for 5 to 7 days results in 72% of queens that will mate and deliver normal offspring.⁴⁶

Induction of Ovulation

Ovulatory Failure in the Bitch

Ovulation failure is rare in the bitch. Too often, bitches are suspected of ovulatory failure when they have seemingly long proestrous and estrous phases, produce small litters, or fail to conceive. Bitches can have signs of estrus, and a fully cornified vaginal smear, for up to 21 days before natural spontaneous ovulation. Also, bitches can have a split estrus: signs of proestrus or estrus without ovulation, a period of anestrus for several weeks, and then return to proestrus. Often the second estrus will be ovulatory and fertile. Split estrus is more common in pubertal bitches but can occur in mature bitches.

Ovulation can be reliably detected with ultrasonography but requires thrice-daily monitoring during the ovulatory period and technical expertise. Direct visualization by laparoscopy is not possible because of the ovarian bursa (it requires bursal resection and is done only experimentally); thus the determination of ovulation is usually attempted indirectly. Serum progesterone concentration can be measured in bitches that historically fail to conceive. The timing of the progesterone measurement is important. It is recommended to evaluate progesterone during the first few weeks of diestrus. Serum concentration of progesterone should be in excess of 5 ng/mL (and generally in excess of 20 ng/mL) at this time. A progesterone level of less than 2 mg/mL indicates either ovulation failure or luteal insufficiency. Values between 2 and 5 ng/mL are suspect and can indicate ovulatory failure, luteal insufficiency, or an uncommonly low progesterone production during diestrus.

Bitches that have normal proestrus and estrus but apparently do not ovulate can be given hormonal products in an attempt to induce ovulation. To mimic the preovulatory LH peak, either GnRH or hCG can be administered at the point of follicular maturation. The determination of follicular maturity is difficult. Incorrect administration (i.e., inappropriate timing) of either preparation can cause preovulatory luteinization of follicles without ovulation or the ovulation of immature, nonviable ova. It has been recommended to administer either GnRH (50 µg/bitch intramuscularly) or hCG (500 to 1000 IU/bitch intramuscularly) on either the day before or the day after the first breeding.⁴⁷ Bitches can begin sexual receptivity several days before or after spontaneous ovulation; therefore this protocol is questionable and not documented. It may be advisable to measure serum LH concentration daily during proestrus and estrus and administer either GnRH or hCG on the day of the natural preovulatory LH peak. This presumes that the bitch produces enough LH to measure a peak but either does not produce enough LH to cause ovulation or has another factor inhibiting ovulation. Bitches that fail to ovulate may not produce a measurable LH peak, in which case this recommendation would also fail. Clearly, more investigation is needed in this area.

Ovulatory Failure in the Queen

Queens can be sexually receptive before follicular maturation; sexual receptivity may not correlate with follicular development because estrogen may not return to baseline. Limited mating before the third to fourth day of estrus can result in an attenuated LH secretion and ovulatory failure.⁴⁸ Additionally, although an LH response after one effective mating will occur, a maximal LH response ensuring ovulation of all mature ova will more likely occur if numerous matings over a several-day period is allowed. In one report 10 of 48 queens ovulated after a single mating, whereas 30 of 36 ovulated after multiple matings.⁴⁹ Optimal breeding management includes mating three times per day at 4-hour intervals throughout estrus. Matings starting on the third day of estrus are advised.

If it is determined that a queen fails to ovulate despite appropriate management, induction of ovulation can be attempted. Protocols with either hCG or GnRH have been reported as follows: hCG 500 IU/queen intramuscularly on day 1 of estrus⁵⁰ and GnRH 25 µg/queen intramuscularly on day 2 of estrus.⁵¹

Treatment of Follicular and Luteal Ovarian Cysts in Bitches

Estrogen-producing follicular cysts can cause prolonged proestrus, nymphomania, estrogen toxicity, and resultant infertility. A luteinized follicular cyst producing progesterone can cause persistent diestrus and resultant infertility. Nonfunctional ovarian cysts can prevent normal cycling and result in infertility. Ovarian cysts are often detected during ovariohysterectomy of older bitches as incidental findings. The detection of a cystic ovarian structure by ultrasonography can be a significant finding. Normal ovarian follicles, luteal structures, and subepithelial cysts should be ruled out, often by sequential ultrasonographic examinations in concert with serum hormone (estradiol and progesterone) measurements. The possibility of a cystic ovarian neoplasm, which can produce clinical signs identical to those of benign cysts, must be considered and is more likely in bitches older than 5 years of age. The measurement of estrogen and progesterone concentrations from the fluid of percutaneously aspirated ovarian cysts can assist the diagnosis of a functional cyst; this will not, however, differentiate between a cyst and neoplasm.

Whether to attempt therapeutic pharmacologic intervention when an ovarian cyst is detected is controversial; ovarian cysts can spontaneously regress.⁵² Estrogen-producing follicular cysts can be luteinized with GnRH (50 μ g/bitch intramuscularly) or hCG (500 to 1000 IU/bitch intramuscularly). Either treatment can be used as a single injection or repeated daily for three treatments. Response to therapy is a termination of estrous behavior or decrease of estrogen and increase of progesterone serum concentrations. Efficacy of these regimens has not been reported, and surgical removal of the cyst by unilateral ovariectomy is usually required if aggressive intervention is deemed necessary. Similarly, lysis of luteal ovarian cysts with PGF_2 -alpha can be attempted but is usually unrewarding in the authors' experience. Ovariectomy permitting histopathologic evaluation of both follicular and luteal ovarian cystic disorders is advised. Ultrasound-guided aspiration of follicular cysts has been advocated as a successful method of terminating prolonged proestrus or estrus in the bitch and deserves further controlled evaluation.

Treatment of Vaginal Hyperplasia and Prolapse

Estrogen produced during folliculogenesis normally causes a hyperplastic response of the vaginal mucosal epithelium and cornification of the vaginal epithelial cells, in preparation for the copulatory lock. The estrogen response can induce a hyperplastic vaginal periurethral papillary mass in some bitches that can prolapse through the vulvar cleft. Follicular luteinization can be attempted to prematurely decrease estrogen production with GnRH (50 µg/bitch intramuscularly) or hCG (500 to 1000 IU/bitch intramuscularly). It is doubtful that medical intervention is of benefit given that most bitches resolve this condition after ovulation. Successful surgical methods of amputating the hyperplastic tissues have been reported; the condition resolves in normal bitches when estrogen levels fall.53 Prolonged vaginal hyperplasia or prolapse most commonly occurs with ovarian pathology (follicular ovarian cysts), requiring ovariectomy for resolution.

Diagnosis and Treatment of Premature Labor

Corpora lutea in both the queen and bitch produce progesterone during gestation. Evidence of spontaneous abortion or fetal reabsorption associated with serum progesterone concentrations below 1 to 2 ng/mL can suggest luteal insufficiency, which is usually associated with inappropriate myometrial contractility. By the time fetal death is observed clinically, progesterone secretion has likely decreased secondarily.⁵⁴ Also, a serum progesterone concentration below 1 to 2 ng/mL after estrus can indicate lack of ovulation rather than luteal insufficiency. Primary luteal insufficiency has not yet been documented in the bitch and queen.

Bitches with a documented history of fetal reabsorption (i.e., ultrasonographic confirmation with no other associated pathology) should be evaluated after the next breeding with both uterine monitoring, ultrasonography, and serum progesterone concentrations.55 If inappropriate uterine contractility is determined with no contributory pathology evident, tocolytic therapy can be considered (terbutaline 0.03 mg/ kg orally every 8 to 12 hours to effect). Serum progesterone concentration should be evaluated; if it is less than 3 to 5 ng/ mL and viable fetal vesicles are detected, progesterone supplementation can be considered. Because excessive or inappropriate progesterone administration during pregnancy can cause masculinization of female fetuses and interfere with lactogenesis, it should be undertaken only when indicated (i.e., when tocolytic therapy alone is not effective). Progesterone administration will also prevent normal spontaneous parturition; therefore treatment must be discontinued 3 days before the calculated date of parturition. Therapeutic intervention in suspected hypoluteoidism can be accomplished with the administration of injectable natural progesterone or oral synthetic progestagens. Total serum levels of progesterone can be monitored only when supplemented with the natural product. Progesterone in oil is given intramuscularly at 2 mg/kg every 72 hours.⁵⁶ Altrenogest (Regu-Mate, Hoechst-Roussel), a synthetic progestagen manufactured for use in the mare, is dosed orally at 0.088 mg/kg every 24 hours.⁵⁷ Both forms of supplementation must be discontinued in a timely fashion so as not to interfere with normal parturition, within 24 hours of the due date with the oral synthetic product, and within 72 hours with the natural, injectable depot form. This requires accurate identification of gestational length using prior ovulation timing (parturition is expected to occur 64 to 66 days from the LH surge or initial rise in progesterone or 56 to 58 days from the first day of cytologic diestrus). Less accurate identification of gestational length can be made from breeding dates (58 to 72 days from the first breeding), radiography, or ultrasound.

Luteal insufficiency is also uncommon in the queen, although it is frequently suspected in queens that experience late-term abortion (i.e., day 50 to 55 of gestation). As in the bitch, luteal insufficiency is diagnosed by determination of viable pregnancy and inadequate progesterone secretion.

Evaluation of such queens early in gestation for inappropriate myometrial activity is advisable. Evaluation of protocols designed to cause medical abortion in queens has determined that a measured serum progesterone concentration of 1 ng/ mL may be sufficient to support pregnancy, at least for a short time.¹⁶ The criteria to diagnose luteal insufficiency in the queen, therefore, remains undetermined. Premature labor in an otherwise benign uterus can be effectively treated with tocolytics (terbutaline 0.03 mg/kg orally as needed), the exact dose based on response to therapy, as evaluated by uterine monitoring.

Prevention or Termination of Estrus

Megestrol acetate is the only substance currently licensed in the United States to delay or suppress estrus in bitches. There are no products currently licensed for this purpose in the queen. It is advised not to use progestational products to delay or suppress estrus in bitches intended for future breeding because of the predictable side effects of progesterone in the intact bitch. A progestagen hormone, megestrol acetate, promotes the development of endometrial gland proliferation and suppresses the local uterine immune response. These effects can increase the incidence of pyometra and infertility. Progestagens can cause pathologic changes in mammary glands, the endocrine pancreas, and prolactin-producing and growth hormone–producing cells of the pituitary gland.⁵⁸ The drug is contraindicated in cases of previous uterine or mammary gland disease or diabetes mellitus.

If megestrol acetate therapy is chosen despite potential adverse effects, the treatment protocol depends on the stage of the estrous cycle in which treatment is begun. To prevent estrus, megestrol acetate (0.55 mg/kg per day orally for 32 days) is given beginning at least 7 days before the onset of proestrus. After discontinuation of therapy, the bitch will likely begin an estrous cycle. Alternatively, megestrol acetate (2.2 mg/kg per day orally for 8 days) administration can be started during proestrus to abbreviate the signs of estrus and prevent ovulation. In addition to a dose-related effect, this high-dose protocol can be potentially more deleterious than the low-dose protocol because the uterine effects of megestrol acetate can be enhanced by endogenous estrogens increased during proestrus.

Although not yet commercially available in most of the United States, GnRH analogues in a repository form offer good options for preventing estrous cycles for approximately 6 months resulting from down regulation.

Prolongation of Interestrus Intervals in the Bitch

Synthetic androgen (previously available as mibolerone, the availability of which is currently variable) therapy was recommended as a therapeutic protocol to delay estrus in bitches that have interestrus intervals of less than 4 months and are infertile as a result of an abbreviated anestrus. Frequent ovulatory estrous cycles may not allow sufficient time for the endometrium to recover from the trophic influences of progesterone during a nonpregnant diestrus.⁵⁹ Synthetic androgen suppression of ovarian activity for 6 to 9 months was previously recommended after ruling out other causes of infertility in bitches with short interestrus intervals.⁵⁴ Fertility rates after the use of mibolerone for this purpose have not been reported; the benefit of this protocol have never been proved. As there is no documented effective therapy for abbreviated anestrus, breeding affected bitches at the earliest opportunity, before progesterone-mediated changes in the endometrium have occurred, is advised. The heritability of this tendency has not been established. Because of problems with human abuse of androgenic substances, the availability of such compounds is variable.

Treatment of Clinically Significant Pseudocyesis

The decrease in serum progesterone and increase in serum prolactin concentrations at the end of diestrus can cause overt signs of pseudocyesis (e.g., nesting, galactorrhea, reclusiveness, and possibly aggression) in some bitches. Because this is a normal phenomenon, clinical signs rarely warrant therapeutic intervention. Rarely, mastitis occurs during pseudocyesis. Cabergoline, a prolactin inhibitor, at 5 μ g/kg orally every 24 hours for 3 to 5 days, alleviates the signs of pseudopregnancy if problematic.

Pyometra and Postpartum Metritis

The pathophysiology and diagnostic criteria of pyometra and postpartum metritis are well described.^{54,60} Case selection must be considered carefully because medical therapy should be reserved for animals that are medically stable and have future reproductive potential. Ovariohysterectomy, after appropriate medical stabilization, remains the treatment of choice for bitches or queens older than 6 to 7 years of age or if signs of systemic sepsis are present.

Many protocols have been proposed for the effective treatment of open-cervix pyometra and postpartum metritis in the bitch and queen using PGF₂. These protocols use the natural hormone dinoprost tromethamine, marketed as Lutalyse or Prostin (Upjohn). Dosage recommendations range from 0.1 to 0.2 mg/kg body weight every 12 to 24 hours for 5 to 7 days. Alternatively, the synthetic prostaglandin cloprostenol has fewer side effects and appears to be equally effective, using doses of 1 to 3 μ g/kg subcutaneously every 12 to 24 hours, to effect. Monitoring with ultrasonography aids in the documentation of disease resolution. Some individuals may require repeated or prolonged treatment if the initial regimen is unsuccessful. The administration of concurrent appropriate systemic antimicrobial therapy, either broad spectrum in anticipation of or based on culture and sensitivity results from a guarded sample of the cranial vaginal vault, is indicated.

Similar management of closed-cervix pyometra is problematic. Treatment can be attempted in the bitch with closed-cervix pyometra that is medically stable and carefully monitored during the treatment process. The use of a PGE_1 analog (misoprostol) intravaginally in conjunction with $PGF_{2\alpha}$ has been advocated as a method of establishing cervical patency.⁶¹ Failure to respond to therapy or worsening of clinical signs indicates the need for ovariohysterectomy.

Pregnancy Termination

There are now several options for the management of an unwanted breeding (i.e., misalliance or mismating) of a bitch that has future reproductive potential. The administration of estrogen is no longer recommended because of potential toxicity, induction of a pyometra, or future infertility (see additional information in the later discussion of misuses of reproductive hormones). Besides allowing the pregnancy to proceed to term or performing an ovariohysterectomy during early gestation, there are safe, reliable methods to induce medical abortion in the bitch and queen.

Early Diestrus Protocol

Administration of $PGF_{2\alpha}$ (dinoprost tromethamine) to bitches in early diestrus can result in transient or permanent luteolysis and thus prevent continuation of pregnancy.²⁸ Fetal contents are reabsorbed, and outward signs of abortion are not detected. In one study the following protocol was successful for all 25 bitches treated with $PGF_{2\alpha}$: 0.25 mg/kg subcutaneously twice daily for 4 days between days 5 and 19 of diestrus.²⁸ Clinicians are advised to determine the onset of diestrus cytologically by evaluating sequential vaginal cytology after the mismating. The major drawback to this regimen is that treatment occurs before documentation of pregnancy can be performed. Because many mismatings (60%) do not result in pregnancy, bitches can be unnecessarily treated with this protocol.²⁷ This regimen can be performed on an outpatient basis, and its relatively short treatment period (i.e., 4 days) is favorable.

Midgestation Protocols

After day 30 of gestation, $PGF_{2\alpha}$ therapy induces luteolysis and myometrial contractions, resulting in fetal expulsion. Treatment is begun after documentation of pregnancy by ultrasonography. Ultrasonography is repeated during the treatment period to determine the end point of therapy because some bitches can partially abort their litter and carry the remaining pups to term. The following protocol has been reliably successful in bitches treated after day 30 of gestation: $PGF_{2\alpha} 0.1 \text{ mg/kg}$ subcutaneously every 8 hours for 2 days and then increasing the dose to 0.2 mg/kg subcutaneously every 8 hours until the abortion is complete.²⁷ The range of therapy is from 3 to 9 days, with excellent subsequent reproductive capability in treated bitches. Queens have also been similarly treated with good results.⁵⁴ Cloprostenol can be substituted for $PGF_{2\alpha}$ with fewer undesirable physical side effects.

An adjunctive therapy to $PGF_{2\alpha}$ has been proposed to hasten the treatment period (i.e., the duration of treatment needed to produce effect). Administration of misoprostol, a prostaglandin E compound, intravaginally daily (1 to 3 µg/kg) concurrently with the previously described $PGF_{2\alpha}$ protocol was found to decrease the treatment period by 1 to 2 days.⁶¹ The proposed action of the misoprostol in this regimen is to soften and open the cervix, thus permitting evacuation of uterine contents.

Dexamethasone has been used successfully to induce abortion and resorption in the bitch.²⁴ Dexamethasone administered at 0.2 mg/kg orally twice daily for 10 days initially is advised and effective. Pregnancies of less than 40 days generally are resorbed with minimal vaginal discharge. Successful pregnancy was reported in 18 of 20 bitches bred at the subsequent estrus. It is imperative that ultrasonographic evaluation of the pregnancy take place after the 10-day treatment period, insofar as fetal death occurs between 8 and 12 days, and additional days of treatment may be needed to complete termination. Progesterone levels, when measured, were below 1 ng/mL, suggesting luteolysis. Side effects include polydipsia, polyuria, polyphagia, and panting, which were tolerable for the treatment period and resolved when the drug was discontinued. Dexamethasone-induced abortion permits outpatient treatment of unwanted pregnancy with minimal expense.

Abortion can be induced in bitches and queens by the antiprolactin effect of dopamine agonists. Because bromocriptine is not well tolerated, studies investigating the use of cabergoline and metergoline to terminate pregnancy in the bitch and queen have been conducted.^{15,16} Pregnancy termination with a dopamine agonist results in fetal reabsorption more commonly than the uterine evacuation that occurs with the PGF_{2α} regimen. The protocols appear to be effective and well tolerated; the availability and expense of the latter generation dopamine agonists are the major drawback.

Medical Management of Dystocia

Oxytocin is the most commonly used reproductive hormone in general veterinary practice. Its use in the medical management of uterine inertia has been well described elsewhere.⁵⁴ It is important to accurately assess the indication for the use of oxytocin and ensure that fetal malposition or obstruction is not present. Additionally, overuse of oxytocin can result in a tetanic uterus and can impede fetal (placental) blood supply and cause fetal compromise.⁵⁵ Judicious use of oxytocin to treat uterine inertia can be beneficial. Dose ranges are lower than previously reported, from 0.25 to 2 units subcutaneously or intramuscularly per dose, and can be repeated every 30 minutes to effect. Previously suggested doses of more than 1U/kg are superphysiologic and contraindicated because they may induce tetanic contractions, compromise fetal (placental) blood supply, and cause uterine rupture. It has been recommended to administer calcium gluconate subcutaneously 10 to 15 minutes before the oxytocin therapy despite the typical eucalcemic status of bitches experiencing dystocia, suggesting that the benefit of exogenous calcium occurs at the cellular level. Calcium improves strength of uterine contractions, whereas oxytocin increases their frequency.⁵⁵ The use of uterine and fetal monitoring systems permitting insightful mediation (WhelpWise) is strongly advocated during the management of labor.

Adjunct Therapy for Mammary Gland Carcinoma

The use of the antiestrogen tamoxifen has been investigated as an adjunct in the treatment of mammary gland adenocarcinoma in the bitch.⁶² Although the bitch exhibits direct estrogenic effects to the reproductive tract (i.e., vulvar edema, stump pyometra) after the administration of tamoxifen, this drug may have an antiestrogenic effect on mammary tissue. In one report tamoxifen therapy (mean dose 0.42 mg/kg orally twice daily) was effective for five of seven bitches with nonresectable or metastatic mammary carcinoma.⁶² In another study tamoxifen was administered (0.7 mg/kg every 24 hours orally for 4 to 8 weeks) but had no observable effect in 10 bitches that had advanced mammary cancer.⁶² The use of tamoxifen as an adjunct in the treatment plan for mammary neoplasia requires more investigation before it can be advised routinely.

Urinary Incontinence in Spayed or Neutered Dogs

Supplementation with reproductive hormones can be considered when a diagnostic evaluation for chronic urinary incontinence in a neutered dog detects decreased urethral sphincter tone with no other pathology evident. Supplementation with DES or testosterone in ovariectomized bitches or castrated dogs, respectively, can enhance the sensitivity of α -adrenergic receptors to endogenous *a*-agonists. Oral treatment with DES can be started at 0.1 to 1 mg/bitch per day for 7 days, after which the frequency is diminished to the lowest effective dose. If signs cannot be controlled with infrequent therapy (i.e., 1 mg or less every 3 to 5 days in a 30-kg bitch), alternative or adjunctive drug therapy with phenylpropanolamine should be considered. Potential side effects of DES treatment include estrogen-induced bone marrow toxicity (not reported with oral diethylstilbesterol), attraction of male dogs, and dermatologic disorders. Supplementation of incontinent male dogs with testosterone (testosterone cypionate 2.2 mg/kg intramuscularly every 30 days) can be considered.⁶³ Adverse effects include prostatic hyperplasia and behavioral changes such as inappropriate urination, aggression, and sexual excitability. When treating idiopathic urinary incontinence in either the neutered female or male dog, the clinician may prefer to consider a compounded α -agonist phenylpropanolamine. Essentially no side effects are expected with this type of therapy, but the owner may need to administer the drug multiple times per day for a consistent effect. The role of gonatotropins in idiopathic incontinence has been reported; a depot administration of GnRH has been used for the treatment of urinary sphincter incompetence in the bitch with good results, suggesting a future role for adjunct therapy of urethral sphincter incompetence in the bitch.⁶⁴

Cryptorchidism

Cryptorchidism is an inherited congenital disorder for which bilateral castration is recommended. Medical treatment to cause descent of a retained testicle is unethical if performed for the purpose of enabling the dog to be shown or bred and likely ineffective. Alternatively, descent of a retained testicle before castration will allow a prescrotal surgical approach. Protocols using either GnRH or hCG have been recommended, although no controlled studies to document efficacy have been published. The precise method of action of these hormones to induce testicular descent is unknown. One protocol for GnRH is 50 to 100 µg/dog subcutaneously or intramuscularly, repeated after 4 to 6 days if no improvement is observed. An alternative protocol is to administer hCG 100 to 1000 IU/dog intramuscularly 4 times spaced over a 2-week period.55 This protocol has been unsuccessful when used in dogs older than 16 weeks of age, and no actual controls existed in the study describing its use.54

Cryptorchidism is uncommon in cats. To the authors' knowledge, the medical treatment of this disorder in cats has not been investigated.

Benign Prostatic Hyperplasia

Chronic administration of a GnRH analog can cause downregulation, and serum testosterone concentrations can decline to castrate levels. This is the basis of therapy for the administration of leuprolide (a GnRH analog) to men with prostatic carcinoma. Prostatic carcinoma occurs with equal frequency in dogs castrated before puberty as in intact dogs, indicating that testicular androgens are not the sole inciting factor in the development of prostatic neoplasia in the dog.⁶⁵ Adrenal androgens may play a role in the development of prostatic neoplasia in dogs and in men refractory to downregulation therapy.

It is possible that downregulation therapy could successfully treat other androgen-dependent conditions in the dog (e.g., perianal adenoma, perineal hernia formation, benign prostatic hyperplasia). Factors such as cost, lack of appropriate dosing information, and the routine acceptance of surgical castration in the dog make treatment with GnRH analogs for such cases unlikely. The advantage of medical treatment versus surgical castration is the potential reversibility of infertility with cessation of downregulation therapy, although the androgen-dependent disorder would likely recur.

Successful treatment of benign prostatic hyperplasia using finasteride has been reported.²⁶ The advantage of finasteride administration is the maintenance of spermatogenesis,

because finasteride decreases intraprostatic DHT concentrations and does not affect intratesticular or circulating testosterone concentrations. Recommendations have been to administer finasteride to dogs at the dosage currently used for men: 5 mg/dog orally once daily. Whether a lower or less frequent dosing regimen is possible remains to be investigated. The disadvantage of finasteride administration in men, as a potentially teratogen, is not of concern in dogs because of the minimal exposure associated with typical breedings. One problem resulting from the long-term use of finasteride is a reduction in the volume of the prostatic fraction of the ejaculate, perhaps necessitating the use of semen extenders. The impact of this lack of prostatic fluid on natural breedings (in which the volume of prostatic fluid forces semen into the uterus) is not known. The use of progestagens (i.e., medroxyprogesterone and megestrol acetate) has also been reported as a method to decrease prostatic hypertrophy and maintain sperm production. The potential adverse systemic effects of these compounds (i.e., effects on growth hormone production, liver function, insulin secretion, mammary gland disease) make this treatment less appealing.

Hypogonadism

Hypogonadotropic hypogonadism, a congenital condition in which the pituitary fails to produce gonadotopins, occurs in men. Affected men can respond to gonadotropin replacement therapy with resultant fertility. Hypothalamic or hypogonadotropic hypogonadism has not been documented to occur in a congenital form in dogs. Acquired pituitary dysfunction can occur in dogs with space-occupying neoplasms, but the diagnosis of hypogonadism is difficult. Lack of negative feedback inhibition causes dogs with primary testicular degeneration or atrophy to have high serum LH and FSH concentrations. If primary pituitary failure was the cause of azoospermia, the serum FSH and LH concentrations would be low. At present, FSH and LH assays are not readily available for the dog; a semiquantitative LH kit is available (Synbiotics). Because of the nature of LH secretion, challenge testing is recommended to evaluate pituitary function.

Treatment of this form of infertility depends on the etiology of the pituitary disease; fertility may be unimportant in view of the dog's general health. Although the prognosis for return to fertility is guarded, one protocol using gonadotropin replacement therapy is to administer 500 IU hCG biweekly (subcutaneously or intramuscularly) and FSH at either 1 mg/ kg intramuscularly every 48 hours or 25 mg/dog subcutaneously once weekly.⁵⁴ Because spermatogenesis and spermatozoa maturation requires approximately 77 days in the dog, therapy must be continued for 3 months before the effectiveness of this protocol can be evaluated.

Management of Retrograde Ejaculation; Improvement of Ejaculate

Retrograde ejaculation causes semen to flow into the urinary bladder, reducing the effective ejaculate. Retrograde ejaculation is treated with pseudoephedrine hydrochloride (3 to 5 mg/kg given 3 hours and 1 hour before collection) or phenyl-propanolamine (3 mg/kg every 12 hours).⁴²

It is often desirable to increase the sperm quantity in an ejaculate to optimize the sample for freezing for shipping. In the dog it has been theorized that GnRH administration before ejaculation will induce an LH surge with a primary increase in testosterone and thus improve the total spermatozoa per ejaculate; however, a recent study evaluating eight mature mixed-breed dogs showed no objective improvement in semen parameters or libido. Interestingly, administration of PGF₂-alpha (0.1 mg/kg 15 minutes before collection) significantly increased the total number of sperm per ejaculate compared with control dogs and dogs receiving oxytocin and GnRH before collection. It is thought that administration of PGF₂-alpha before ejaculation facilitates the movement of spermatozoa from the epididymis to the ductus deferens, thus enhancing the ejaculatory output.⁶⁶

MISUSES OF REPRODUCTIVE HORMONES

Some reproductive hormones have been misused for many years (Table 23-3). Assumptions based on incomplete information about canine reproductive physiology led to the development of these protocols in the past. Current knowledge and other alternatives (i.e., for mismating in bitches) have resulted in the discontinuation of these practices, which are now considered inappropriate.⁶⁷

Table 23-3 Misuses of Reproductive Hormones			
Disorder	Hormone Misused	Considerations	Alternatives
Female infertility	GnRH, gonadotropins	Alteration of feedback loop decreases fertility	Appropriate diagnostic evaluation; ovulation timing and optimal breeding management
Male infertility	GnRH, gonadotropins, testosterone	Lack of effect or decreased fertility; testosterone decreases spermatogenesis	Appropriate diagnostic evaluation
Mismating	Estrogens (DES or ECP)	Can cause bone marrow toxicity, infertility, pyometra	Early or late diestrus treatment with $PGF_{2\alpha}$, cabergoline, dexamethasone.
Benign prostatic hyperplasia	Estrogen (DES)	Can cause squamous metaplasia and increased risk of bacteria prostatitis	Castration; treatment with finasteride

GnRH, gonadotropin-releasing hormone; DES, diethylstilbestrol; ECP, estradiol cypionate; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$.

Treatment of Idiopathic Infertility

Infertility in the Bitch

Physiologic processes that control folliculogenesis in the bitch are complex and involve precise, minute amounts of hypothalamic and pituitary hormones that are sensitively controlled by the ovarian feedback loop. To interrupt the hypothalamicpituitary-ovarian axis pharmacologically leads to dysfunction, rather than an augmentation, of the system. The rational administration of GnRH requires pulsatile administration, the use of GnRH analogs results in downregulation, and the use of gonadotropins is largely unsuccessful to induce fertile estrus in *known* fertile bitches. There is no evidence to support the use of these hormones in bitches with a history of infertility or decreased fecundity. Careful evaluation of the underlying causes of infertility and optimal breeding management and husbandry with ovulation timing (i.e., serial evaluation of measured parameters to determine the time of ovulation) is recommended.

Infertility in the Stud Dog

Decreased production of sperm is usually the result of primary testicular degeneration and atrophy. Gonadotropin secretion is increased as a result of the lack of negative feedback inhibition. The administration of GnRH or gonadotropins in such cases is therefore inappropriate. Careful investigation to determine the cause of infertility (e.g., testicular atrophy, bacterial prostatitis, infectious or immune-mediated orchitis, spermatic tubular obstruction) is recommended.

As is true of GnRH and gonadotropins, the use of gonadal steroids to enhance fertility is contraindicated. The most common misuse of gonadal steroids to potentiate fertility is the administration of testosterone to heighten libido. Pharmacologic administration of testosterone inhibits steroidogenesis by interruption of the sensitive feedback mechanisms of the hypothalamic–pituitary–gonadal axis. The concentration of testosterone within the seminiferous tubules normally exceeds that found in circulation. An increase of circulating testosterone will serve to decrease output of FSH and LH and thereby decrease spermatogenesis. Additionally, many dogs with low libido have normal concentrations of serum testosterone but have a decrease in libido for other reasons (e.g., prostatic disease, behavioral issues).

Treatment of Mismating and Pregnancy Termination

Estrogens, in the form of either estradiol cypionate (ECP) or DES, have been used historically to prevent pregnancy after mismating in the bitch. The administration of estrogen in any form is no longer recommended for this condition because estrogens are either ineffective or unsafe to use. All bitches treated with estrogens are at risk for the development of bone marrow aplasia, pyometra, or infertility. Although most cases of estrogen-induced bone marrow toxicity have been associated with ECP administered at high doses (i.e., >1 mg), aplastic anemia has been observed in bitches receiving a lower dose. One study determining the efficacy of estrogens to

prevent pregnancy found that DES (75 μ g/kg orally for 7 days) was ineffective when treatment began in proestrus, estrus, or day 2 of diestrus.¹⁹ Also, ECP (22 μ g/kg intramuscularly) was ineffective when administered once during proestrus or estrus, preventing pregnancy in only 50% of treated bitches.¹⁹ The administration of estrogens during diestrus increases the risk of the development of pyometra because the progester-one effect on the uterus to promote glandular secretion and decrease local uterine immunity is enhanced in the presence of estrogen. To prevent pregnancy in mismated bitches, protocols using PGF_{2a}, dexamethasone, or dopamine agonists should be considered.

Treatment of Benign Prostatic Hyperplasia

The use of estrogens to treat benign prostatic hyperplasia in dogs is not recommended. In addition to potential toxicity with the administration of estrogens, estrogen-induced squamous metaplasia of the prostate gland may increase the risk of bacterial prostatitis and cyst formation.

KEY POINT 23-3 Hormonal therapy for reproductive conditions is best limited to protocols for which specific studies exist in the dog and cat; interspecific extrapolations are not reliable.

Anesthetic Agents

Elizabeth A. Martinez

Chapter Outline

PREANESTHETIC MEDICATIONS Anticholinergics Tranquilizers Opioids Alpha₂-Adrenergic Agents INJECTABLE ANESTHETICS Barbiturates

Dissociative Agents

Propofol Etomidate INHALANT ANESTHETICS Nitrous Oxide Isoflurane Sevoflurane Desflurane

PREANESTHETIC MEDICATIONS

The use of preanesthetic medications before general anesthesia in dogs and cats has several advantages. The advantages include helping to decrease stress and anxiety, providing analgesia, decreasing the amount of subsequent anesthetic drugs used, and minimizing the cardiopulmonary depression associated with the commonly used anesthetic agents. Additionally, certain preanesthetic medications will facilitate recovery from anethesia.

The preanesthetic medications used routinely in dogs and cats include the anticholinergics, phenothiazine and benzodiazepine tranquilizers, opioids, and alpha₂-adrenergic agonists. Certain drugs discussed in this chapter are not labeled for use in dogs or cats or for the dose and route of administration suggested. Decisions regarding extralabel use should be based on the judgment of the veterinarian and the current laws governing extralabel use of drugs.

KEY POINT 24-1 Selecting an appropriate anesthetic regimen for the small animal patient requires a thorough understanding of the commonly used anesthetic premedication, induction, and maintainence agents, including their indications, contraindications, and potential adverse effects.

Anticholinergics

General Pharmacology

Anticholinergics competitively antagonize acetylcholine at postganglionic terminations of cholinergic fibers in the autonomic nervous system. They are used as preanesthetic medications to decrease salivary secretions, decrease gastric fluid acidity, and inhibit the bradycardic effects of vagal stimulation. Other effects include mydriasis, decreased tear formation, decreased intestinal motility, and bronchodilation. Atropine and glycopyrrolate are the two anticholinergic drugs used in dogs and cats.

22

Atropine Sulfate

Atropine sulfate (0.02 to 0.04 mg/kg) can be administered intramuscularly, subcutaneously, or intravenously. The duration of action is 60 to 90 minutes. Atropine may stimulate vagal nuclei in the medulla and cause an initial bradycardia before the desired effect is seen, particularly when the drug is administered intravenously. Other central effects of atropine include depression, restlessness, and delirium. Atropine administration may cause cardiac arrhythmias and sinus tachycardia. Atropine does cross the placental barrier and may lead to central and peripheral anticholinergic effects in the fetus when administered to the dam. Arrhythmias are more common after intravenous administration and include second-degree atrioventricular block, unifocal ventricular premature contractions, and ventricular bigeminy.¹ Atropine is contraindicated in animals with preexisting tachycardia.

Glycopyrrolate

Glycopyrrolate is a synthetic quaternary ammonium anticholinergic. Glycopyrrolate may be given intramuscularly, subcutaneously, or intravenously at a dose of 0.011 mg/kg. The duration of action of vagal inhibition is 2 to 4 hours, significantly longer than with atropine. The antisialagogue effect may persist for up to 7 hours. The cardiovascular effects of glycopyrrolate are similar to those of atropine. Because of its large structure, glycopyrrolate does not cross the blood–brain or placental barrier readily and therefore has minimal central or fetal effects.²

Tranquilizers

Acepromazine

Acepromazine (0.05 to 0.1 mg/kg intravenously, intramuscularly, or subcutaneously, not to exceed a total dose of 3 mg; oral dose is 1 to 2 mg/kg), a phenothiazine tranquilizer, is used commonly as a premedication before general anesthesia in dogs and cats to relieve anxiety. Through depression of the reticular activating system and antidopaminergic actions in the central nervous system (CNS), acepromazine produces mental calming, decreased motor activity, and increased threshold for responding to external stimuli. Acepromazine does not produce analgesia but may act synergistically when administered concurrently with other drugs with analgesic activity. Administration of acepromazine will decrease the dose of subsequent anesthetic agents. Other effects include antiemetic activity and antihistaminergic properties. Hypotension and hypothermia can result from depression of vasomotor reflexes. Acepromazine is metabolized by the liver and should not be used in patients with liver disease. Because of the potential for hypotension, acepromazine should be used cautiously in compromised patients, particularly those with significant cardiovascular disease. Acepromazine may inhibit platelet function and should be avoided in patients with coagulopathies.²

In many veterinary textbooks, authors cautioned against the use of acepromazine in animals at risk for seizures. Recently, this caution is being questioned on account of a lack of references. In two retrospective studies, no evidence was found that acepromazine lowered the seizure threshold in dogs with a history of seizure disorders.^{3,4} It was further concluded that a controlled prospective study is necessary for a more thorough evaluation of the use of acepromazine both in this patient population and in the general canine population.

Diazepam

Diazepam (0.1 to 0.2 mg/kg intravenously) is a benzodiazepine tranquilizer that possesses muscle relaxant and anticonvulsant properties. Benzodiazepines exert their effect by enhancing the CNS inhibitory neurotransmitters gammaaminobutyric acid (GABA) and glycine and by combining with CNS benzodiazepine receptors.¹ Diazepam may produce a mild calming effect in some patients, but agitation and excitement can also occur. Diazepam is solubilized by mixing with propylene glycol. Diazepam has minimal cardiovascular effects; bradycardia and hypotension may be seen after rapid intravenous administration. Propylene glycol is associated with pain on injection and incompatibility when mixed in the same syringe with other drugs. Clinical uses of diazepam in small animal anesthesia include providing muscle relaxation when given concurrently with dissociative anesthetics and as a co-induction agent with injectable anesthetics (thiopental, propofol, etomidate) to decrease their doses or side effects (or both). The effects of diazepam can be reversed with the benzodiazepine antagonist flumazenil.

Midazolam

Midazolam (0.1 to 0.2 mg/kg intravenously and intramuscularly) is a benzodiazepine tranquilizer with behavioral effects and clinical uses similar to those of diazepam. Midazolam is more potent and has a shorter duration of action than diazepam. Midazolam is water soluble at a pH of 3.5. At a pH above 4, the chemical structure changes to become lipid soluble.⁵ Unlike diazepam, midazolam can be mixed with other anesthetic agents and can be administered intramuscularly without causing irritation. Flumazenil can be used to antagonize the effects of midazolam.

Midazolam is often used as a component of a total intravenous anesthetic technique (TIVA). The advantage of TIVA is that general anesthesia can be maintained without the use of inhalant agents, which can cause significant cardiovascular depression in certain high-risk patients. Midazolam, 8 µg/kg/ min, combined with fentanyl, 0.8 µg/kg/min, are delivered as a constant-rate infusion (CRI) after induction of anesthesia. The dose can be adjusted as needed to produce a desirable level of anesthesia. Typically, the dose is lowered periodically during the anesthetic period, based on the judgment of the level of anesthesia. This technique makes recovery less prolonged. In certain patients a low concentration of inhalant (e.g., sevoflurane) may be added if the TIVA is inadequate to maintain a desirable level of anesthesia. This is particularly true in animals that are alert and active preoperatively. These patients have significant cardiovascular disease precluding a primary inhalant regimen but are asymptomatic or well-compensated. Examples include young dogs with valvular stenosis or patent ductus arteriosis without evidence of heart failure.

Opioids

Opioids act by combining with one or more specific receptors in the brain and spinal cord to produce analgesia, sedation, euphoria, dysphoria, and excitement. The mu receptors are thought to mediate supraspinal analgesia, respiratory depression, and euphoria. Kappa receptors mediate spinal analgesia, miosis, dysphoria, and sedation; the sigma receptors mediate hallucinations, psychomimetic activity, and respiratory and vasomotor stimulation. Delta receptors are thought to primarily modify mu receptor activity.¹ Opioids are classified as agonists, agonist–antagonists, or antagonists according to their receptor activity.

Opioids, agonists or agonist-antagonists, are used before, during, and after surgery in dogs and cats to provide analgesia. Certain opioids may produce sedation in some patients. The antagonists are used to reverse the effects of the agonists or agonist-antagonists. The opioid chosen is based on the degree and duration of expected pain and physical status of the patient. Understanding the differences between the commonly used opioids and their possible side effects are also important when choosing which drug to use. Dose, route, classification, and duration of action of the commonly used opioids in dogs and cats during the perioperative period are shown in Table 24-1.

The most common side effects of opioids preanesthesia include bradycardia and second-degree atrioventricular

Table 24-1 Commonly Used Opioids for Dogs and Cats				
Opioid	Dose, mg/kg	Route	Duration of Action	Classification
Morphine	0.05-1.0	IM, SC	4 hrs	Agonist
Hydromorphone	0.1-0.2	IV, IM, SC	4 hrs	Agonist
Butorphanol	0.2-0.4	IV, IM, SC	2 hrs	Agonist-antagonist
Buprenorphine	0.005-0.020	IV, IM, SC	6-8 hrs	Agonist-antagonist
Fentanyl	0.005-0.01	IV, IM	20-40 min	Agonist
Nalbuphine*	1	IV to effect	NA	Agonist-antagonist
Naloxone	0.04-0.06	IV to effect	NA	Antagonist

IM, Intramuscular; *SC*, subcutaneous; *IV*, intravenous; *NA*, not applicable.

*Nalbuphine is used to reverse the sedative effects of opioid agonists, without affecting analgesia

blockade. These effects may be prevented or treated with an anticholinergic agent. When given as a preanesthetic medication, certain opioids may cause vomiting. It is more commonly seen after administration of a mu agonist (morphine, hydromorphone). Respiratory depression can also occur, especially at high doses. The respiratory depressant effects may be additive to those caused by inhalant anesthetic agents. The user should be prepared to assist or control ventilation if necessary. This is especially crucial in patients with suspected spaceoccupying masses or lesions of the brain. Hypercapnia resulting from respiratory depression causes cerebral vasodilation and can lead to a life-threatening increase in intracranial pressure. The opioids can cause histamine release and should not be used before intradermal skin testing for allergies.

CRIs of many of the opioids can be used both intraoperatively and postoperatively to provide analgesia and decrease the amount of inhalant anesthetic agent required. Fentanyl (2 to 5 μ g/kg/hr intravenously), morphine (0.1 to 0.2 mg/kg/hr intravenously), hydromorphone (0.02 to 0.05 mg/kg/hr), and butorphanol (0.1 to 0.2 mg/kg/hr intravenously) will provide acceptable analgesia for most patients. Remifentanil (18 to 36 μ g/kg/hr intravenously) is unique in that it is undergoes rapid hydrolysis by nonspecific tissue and plasma esterases. Therefore it has a rapid onset and offset and is noncumulative, and clearance is unaffected by decreased hepatic function.

Alpha₂-Adrenergic Agents

The alpha₂-adrenergic agonists are used to produce sedation, muscle relaxation, and analgesia in dogs and cats by stimulating presynaptic alpha2-adrenoreceptors and causing a decrease in norepinephrine release both centrally and peripherally. This action leads to a decrease in both CNS sympathetic outflow and circulating catecholamines.² Cardiopulmonary effects can be significant with these drugs and include respiratory depression, bradycardia, first- or second-degree atrioventricular blockade, decreased cardiac output, and increased peripheral vascular resistance. Because of these effects, careful patient monitoring should be employed after administering these drugs in dogs and cats. Alpha2-adrenergic agonists should not be used in compromised patients. Other effects seen with the use of alpha₂-adrenergic agonists include vomiting, hyperglycemia, decreased gut motility, and dieresis. The commonly used drugs are xylazine, medetomidine, and dexmedetomidine.

Xylazine

Xylazine (0.2 to 1 mg/kg intravenously and intramuscularly) can be given as a premedication agent alone or in combination with opioids to facilitate intravenous catheter placement and decrease dose requirements of subsequent injectable and inhalant anesthetic agents. It is also used commonly as an adjuvant with dissociative anesthetic agents to improve muscle relaxation and provide visceral analgesia for short surgical procedures.

Medetomidine

Medetomidine is an alpha₂-adrenergic agonist approved for use in dogs. Although the clinical effects are similar, medetomidine is more potent and possesses a higher alpha₂ receptor selectivity profile than xylazine. The preanesthetic dose in dogs is 5 to 10 µg/kg, intravenously and intramuscularly and up to 20 µg/kg for sedation. Medetomidine is not approved for use in cats. However, it has been used successfully, either alone or in combination with an opioid or dissociative agent, for immobilization or surgical anesthesia. The preanesthetic dose in cats is 10 to 15 μ g/kg, but a dose range up to 40 to 80 μ g/kg intramuscularly is reported.⁶ This author recommends using the lowest dose needed to produce the desired effect. Combining medetomidine with an opioid may have a synergistic effect, allowing a lower dose of each drug to be used. The use of medetomidine (20 µg/kg intramuscularly) in feline hypertrophic cardiomyopathy patients with concurrent left ventricular outflow obstruction has been shown to improve the hemodynamics of these patients.7

When medetomidine is used as a preanesthetic medication, the dose of subsequent anesthetic agents will be markedly reduced. This includes both induction and inhalational agent requirements. The patients should be monitored carefully throughout the anesthetic period. Profound bradycardia is common after medetomidine administration but can be minimized by preemptive treatment with an anticholinergic agent. If severe bradycardia or hypotension occurs, the medetomidine can be reversed with atipamezole.

Failure to achieve adequate sedation, or no effect at all, can occur in stressed, agitated animals because of high levels of endogenous catecholamines. These animals should be allowed to rest before medetomidine is given. Repeat dosing is not recommended in dogs that do not respond satisfactorily to medetomidine. It is important to remember that sudden arousal and the potential for biting after minimal stimulation or handling can occur. To prevent harm, the user is warned against a false sense of security when handling animals sedated with medetomidine.⁸

Dexmedetomidine

Dexmedetomidine is the active, dextrorotary enantiomer of the racemic mixture medetomidine. The same indications for medetomidine apply to the clinical use of dexmedetomidine at equal pharmacologic doses. Dexmedetomidine has approximately twice the potency as medetomidine; therefore it is dosed at one half the amount of medetomidine to achieve the same level of sedation and analgesia. The pharmacologically inactive enantiomer levomedetomidine has no sedative, analgesic, or cardiorespiratory effects, but its absence may influence the pharmacokinetic and pharmacodynamic effects of dexmedetomidine. Differences would be expected in the drug metabolism of dexmedetomidine compared with medetomidine given that only half of the racemic mixture is administered and subsequently metabolized. One study in cats comparing medetomidine and dexmedetomidine before ketamine anesthesia reported that cats premedicated with dexmedetomidine recovered more quickly that the cats receiving medetomidine.9

Romifidine

Romifidine is the newest $alpha_2$ -adrenergic agonist to be evaluated for use in small animal veterinary patients. It is not approved for use in small animals in the United States. Compared with xylazine, the onset of action is slower and the duration of action is longer. At equipotent doses the cardiovascular effects are similar to those of xylazine. In healthy dogs 10 to 20 µg/kg administered intramuscularly produced mild to moderate sedation with limited effects on cardiovascular function.¹⁰ In healthy cats 40 µg/kg adminisered intramuscularly produced moderate sedation.¹¹

Alpha₂-Adrenergic Antagonists

Reversal of the clinical effects of xylazine and medetomidine can be accomplished with specific $alpha_2$ -adrenergic antagonists. Yohimbine (0.1 mg/kg intravenously), tolazoline (2 mg/kg IV), and atipamezole are most commonly used in dogs and cats. Atipamezole is used to reverse the effects of medetomidine. The dose of atipamezole is determined by the amount of the agonist given and the time elapsed since the agonist was administered. To prevent neurologic (excitement and muscle tremors), cardiovascular (hypotension and tachycardia), and gastrointestinal (salivation and diarrhea) side effects, atipamezole should be given intramuscularly and at the lowest dose needed to produce reversal of the CNS and cardiovascular effects of medetomidine.

INJECTABLE ANESTHETICS

Injectable anesthetic agents are used to rapidly produce unconsciousness. They usually are given before maintenance of general anesthesia with an inhalant anesthetic agent but may also be administered by repeated injection or infusion, alone or in combination with other injectable agents, to maintain anesthesia. The major disadvantage of injectable agents once administered is that the effects are not immediately eliminated, including any unwanted cardiopulmonary changes. The injectable agents used in veterinary patients include the barbiturates, dissociative agents, propofol, and etomidate.

Barbiturates

The barbiturates cause depression of the CNS by interfering with passage of impulses to the cerebral cortex. Barbiturates are categorized according to their duration of action. The ultrashort-acting barbiturates thiopental and methohexital are the two most commonly used in dogs and cats to produce a rapid induction of anesthesia. The transition to inhalant anesthesia is smooth, and recovery is relatively rapid because of redistribution. Methohexital is cleared from the body at a faster rate and is preferred in sighthounds, which have a more prolonged recovery with the thiobarbiturates.

The barbiturates decrease cerebral blood flow, cerebral metabolic rate of oxygen, and electrical activity of the brain.² Because of these CNS effects, anesthetic induction using a barbiturate is preferred in patients with certain neurologic diseases (seizure disorders, space-occupying lesion of the brain). Other organ system effects include cardiovascular and respiratory depression that is dependent on the dose and rate of administration. Cardiac arrhythmias may occur, with ventricular extrasystoles and bigeminy being the most common.²

Maximal effect from an intravenous injection of an ultrashort-acting thiobarbiturate is reached within 30 seconds. The duration of action depends on redistribution to lean body tissues. Barbiturates are primarily metabolized by the liver and eliminated by renal excretion. Care should be taken when administering barbiturates to patients with liver disease because the duration of action may be prolonged.

Thiopental

Thiopental can be used as a 2% to 5% solution in dogs and cats. More concentrated solutions may cause severe tissue damage if accidentally administered perivascularly. For induction of anesthesia, thiopental is administered in small increments, 2 to 6 mg/kg intravenously, until the desired effect is reached. A total dose of 10-12 mg/kg is usually sufficient for induction, before intubation and maintenance with an inhalant agent. Repeated injections of thiopental for maintenance of anesthesia have a cumulative effect and can cause a prolonged recovery.

Methohexital

Methohexital is similar in its effects to thiopental, except it is more rapidly metabolized and is not cumulative.² Methohexital is reconstituted as a 2.5% solution, and a calculated dose of 6 to 10 mg/kg is drawn up in a syringe. One half is administered initially and the remainder given to the desired effect. In patients that have not been premedicated, involuntary excitement or emergence delirium can be seen during the recovery period. Treatment is accomplished with intravenous administration of diazepam, 0.2 mg/kg.

Dissociative Agents

Dissociative anesthesia is an anesthetic state caused from interruption of ascending transmission from the unconscious to conscious parts of the brain.¹² This group includes ketamine and tiletamine. Tiletamine is a component of Telazol. Dissociative anesthesia is characterized by a catalepsy; somatic analgesia; and intact ocular, laryngeal, and pharyngeal reflexes. Because control of the airway may not be complete, intubation with a cuffed endotracheal tube is recommended. Visceral analgesia is poor. Muscle rigidity or reflexive skeletal muscle movements can also occur. Dissociative agents are commonly used for induction and maintenance of anesthesia in cats and dogs.

Ketamine

Both ketamine and tiletamine increase cerebral blood flow and intracranial pressure and therefore should be avoided in patients in which these effects could be detrimental.¹² Seizure activity may be seen particularly in dogs. As a result of sympathetic stimulation, the cardiovascular effects include an increase in heart rate and arterial blood pressure. The myocardium becomes sensitized to catecholamine-induced arrhythmias. Although ventilation and arterial oxygenation generally remain adequate, an apneustic or irregular breathing pattern may be observed after administration of a dissociative agent. Transient apnea may be seen after rapid intravenous administration. Excessive salivation may occur and is controlled by administration of an anticholinergic. Hallucinatory behavior, emergence delirium, or CNS excitement may be observed during the recovery period. Prior administration of a tranquilizer will attenuate these effects.

Whereas ketamine is metabolized primarily by the liver in the dog, it is excreted intact by the kidneys in the cat. Ketamine should be used with caution in animals with hepatic or renal disease. In cats with urethral obstruction, ketamine can be used if renal disease is absent and the obstruction is relieved. Tiletamine is excreted predominantly by the kidneys. Telazol is contraindicated in patients with pancreatic disease or impairment of renal function.

Ketamine can be administered intravenously (1-2 mg/kg) or intramuscularly (2-20 mg/kg) for induction or maintenance of anesthesia in cats and dogs. Intravenous administration is used for induction before intubation and maintenance with an inhalant agent or for anesthesia for short procedures. Intramuscular administration, in combination with agents providing analgesia and muscle relaxation (e.g., dexmedetomidine), is used for maintenance of anesthesia for surgical procedures. Duration of action is dose dependent. Recovery from large intramuscular doses of ketamine may be associated with prolonged recoveries. Ketamine should be combined with a tranquilizer, muscle relaxant, or opioid to provide muscle relaxation and additional analgesia and to smooth the recovery period. Using adjuvants is important when administering ketamine to dogs because when it is used alone, extreme muscle tone, spontaneous movements, violent recovery, and convulsions can occur.

Ketamine may also be administered as an intravenous CRI both intraoperatively and postoperatively to provide analgesia. At subanesthetic doses, ketamine blocks the *N*-methyl-D-aspartate (NMDA) receptor responsible for the transmission of painful stimuli from the peripheral nervous system to the CNS. Low-dose ketamine administered as a CRI helps to prevent "wind-up," an exaggerated and prolonged response to pain caused by NMDA receptor activation. In dogs undergoing forelimb amputation, an initial bolus of 0.5 mg/kg of ketamine administered intravenously, followed by a CRI dose of 10 µg/kg/min intraoperatively and 2 µg/kg/min for 18 hours after surgery, resulted in lower pain scores that dogs receiving saline infusions. Both groups also received a fentanyl CRI (1 to 5 µg/kg/hr) during the 18-hour postoperative period.¹³

Telazol

Telazol is a combination of tiletamine and zolazepam. Tiletamine has a longer duration of action and greater analgesic effect than ketamine. Zolazepam, a benzodiazepine tranquilizer, provides muscle relaxation and is an effective anticonvulsant. Telazol has been used intramuscularly (4 to 15 mg/kg), alone or in combination with xylazine or an opioid, for induction and maintenance of anesthesia for surgical procedures. Lower doses (2 to 4 mg/kg) can be given intravenously for induction before intubation and maintenance with an inhalant agent. Adverse responses to Telazol can occur during the recovery period, particularly in dogs. These responses include muscle rigidity, convulsions, and emergence delirium. Using the lowest dose of Telazol possible and treatment with a tranquilizer will minimize these effects.

Propofol

Propofol (2,6-diisopropylphenol) is classified as a nonbarbiturate sedative–hypnotic agent. It is an alkylphenol, poorly soluble in water, and is solubilized in a lecithin-containing emulsion (Intralipid). Because propofol emulsion is capable of supporting microbial growth, any unused propofol, in either an ampule or vial, should be discarded within 6 hours. The advantage of propofol over other injectable anesthetic agents is its rapid recovery profile.¹⁴

Propofol causes a decrease in both intracranial and cerebral perfusion pressures and therefore can be used in patients with neurologic disease. Propofol has cardiovascular effects similar to those of the thiobarbiturates, including a dose-dependent decrease of arterial blood pressure, cardiac output, and systemic vascular resistance. Heart rate may remain unchanged or increased. Ventricular arrhythmias may also be observed. Propofol should be used with caution in patients with severe cardiovascular disease. Propofol does cause a dose-dependent respiratory depression and may also cause transient apnea. Methods for ventilatory support should be available.

Propofol is noncumulative. Termination of the anesthetic effects from propofol is due to redistribution from vessel-rich tissues followed by rapid biotransformation by the liver. Propofol is rapidly cleared from the body by hepatic and extrahepatic metabolism.

Propofol can be administered as an intravenous bolus (4 to 6 mg/kg) for induction of anesthesia as well as maintenance of anesthesia by a CRI (0.4 mg/kg/min intravenously).

Propofol does not provide analgesia; therefore painful procedures should not be performed when given alone. Premedication with an opioid or alpha₂ agonist will provide analgesia, but dose requirements for propofol will be lowered. Propofol allows for a rapid recovery with little to no hangover effect compared with the thiobarbiturates. Side effects include excitement during induction or recovery in patients that have not been premedicated, pain on injection, and occasional muscle tremors or myoclonic activity.¹⁵ The main disadvantages of propofol are cost and limited shelf-life.

Etomidate

Etomidate is an imidazole derivative classified as a rapidacting, nonbarbiturate anesthetic agent.¹⁶ Etomidate is not a good analgesic. Etomidate (1 to 3 mg/kg) is used as an intravenous induction agent before intubation and maintenance with an inhalant agent. The main advantage of etomidate over other injectable induction agents is its minimal cardiopulmonary depressant effects; therefore it is very useful in severely compromised patients.

Etomidate is a good induction agent for neurologic procedures insofar as it depresses cerebral blood flow and cerebral metabolic rate of oxygen. Administration of etomidate produces little change in heart rate, arterial blood pressure, and cardiac output. Transient apnea may be observed after induction. In patients that have not been premedicated, administration of etomidate may be associated with pain on injection, involuntary muscle movements, gagging, or retching.¹⁶ Premedication with a tranquilizer or opioid will attenuate these effects. Etomidate causes transient adrenocortical suppression.¹⁷ The effect may be seen for 2 to 3 hours after a single intravenous bolus. Although it is believed that this suppression is not clinically significant after a single dose, long-term infusion with etomidate is not recommended. Etomidate is noncumulative, is rapidly redistributed, and undergoes some ester hydrolysis.

INHALANT ANESTHETICS

Inhalant anesthetic agents are used to produce general anesthesia in dogs and cats. These drugs produce unconsciousness, muscle relaxation, and analgesia. Inhalant anesthetic agents are administered directly to the respiratory system, absorbed from the alveoli into the bloodstream, and passed to the brain. The advantage of using inhalant agents instead of injectable agents for maintenance of general anesthesia is the ability to adjust the depth of anesthesia by increasing or decreasing the amount of inhalant delivered to the patient. Also, the commonly used inhalant agents permit a rapid induction and recovery from anesthesia because of its elimination through the lungs. Delivering inhalant anesthetic agents requires the use of an anesthetic machine. A proper machine consists of a vaporizer for drug delivery, a source of oxygen, a patient breathing circuit, and methods for eliminating carbon dioxide and scavenging waste gases. Additionally, the patient is often intubated; therefore ventilation can be supported if necessary, and arterial oxygenation is improved because of the high levels of oxygen present in the breathing circuit.

Potency of inhalant anesthetic agents is expressed by its MAC value, which is the minimum alveolar concentration of anesthetic that produces no responses in 50% of patients exposed to a painful stimulus. MAC is measured as the endtidal concentration of anesthetic. The lower the MAC value of the inhalant agent, the greater its potency. Surgical anesthesia is approximately 1.5 to 2 times the MAC. Several factors control the partial pressure of inhalant anesthetic in the brain. The brain tension mirrors the alveolar concentration of anesthetic agent, which depends on the amount delivered to the lungs and uptake from the lungs. Several factors determine uptake of anesthetic from the lungs. These include solubility (blood-gas partition coefficient), cardiac output, the alveolar-venous anesthetic tension difference, and the presence of shunts or any pathologic change in the alveoli that may cause a diffusion barrier. Elimination of inhalants is primarily by the lungs. Some anesthetic agents undergo varying degrees of biotransformation by the liver. Toxic metabolites are formed by several of the inhalant anesthetic agents. The most commonly used inhalant anesthetic agents in dogs and cats are nitrous oxide, isoflurane, and sevoflurane. Another inhalant agent, which is not used routinely in dogs and cats, is desflurane.

Nitrous Oxide

Nitrous oxide has a MAC value of greater than 100% in the dog and cat.¹⁸ It is used as a mild analgesic or to add to the effects of other inhalant anesthetic agents. As it crosses the alveolar membranes, it will speed the uptake of the primary inhalant agent (second gas effect). A period of denitrogenation with 100% oxygen should be performed before nitrous oxide is introduced into the breathing circuit. Up to 70% nitrous oxide is then administered to the patient. Typically, nitrous oxide is administered as 1:1 or 2:1 N₂O:O₂ ratio. Care must be taken to prevent hypoxia by delivering a minimum of 30% oxygen and, when nitrous oxide is discontinued, delivering 100% oxygen for a minimum of 5 minutes before allowing the patient to breather room air. Nitrous oxide is eliminated through the lungs rapidly after its discontinuation.

Nitrous oxide has minimal effects on the cardiopulmonary system. Because nitrous oxide is 30 times more soluble in blood than nitrogen, it diffuses into air containing cavities faster than nitrogen diffuses out. Therefore the administration of nitrous oxide is contraindicated in patients with pneumothorax, obstructed bowel, or other closed-air cavities. Nitrous oxide should not be used with closed-circuit or low-flow anesthesia because of the significant risk that a hypoxic mixture will be delivered.

Isoflurane

The MAC value for isoflurane is 1.28% in the dog and 1.63% in the cat.¹⁹ Although isoflurane causes a dose-dependent increase in intracranial pressure, it can be used safely in patients with neurologic disease if less than 1 MAC is delivered and hypoventilation is avoided. Vasodilation caused by increased muscle and skin blood flow can be significant and

result in hypotension. Isoflurane is a respiratory depressant; therefore it may be necessary to assist ventilation at higher anesthetic depths. Less than 1% of isoflurane undergoes biodegradation. The majority is eliminated unchanged by the lungs. The rapid recovery produced by isoflurane in patients that have not been premedicated may lead to emergence delirium. Treatment with a tranquilizer such as acepromazine may be required. Opioids are strongly recommended if the animal is thought to be in pain. Isoflurane is an excellent choice for either induction or maintenance of anesthesia in most small animal patients. As with any anesthetic technique, vigilant monitoring of the cardiopulmonary system is encouraged.

Sevoflurane

The MAC value of sevoflurane is 2.36% in the dog²⁰ and 2.58% in the cat.²¹ The principle advantage of sevoflurane over isoflurane is its extremely rapid induction and recovery times. The cardiovascular and respiratory effects are similar to those produced by isoflurane. Sevoflurane does not sensitize the myocardium to catecholamine-induced arrhythmias. Sevoflurane undergoes minimal metabolism by the liver; the majority is eliminated unchanged by the lungs. Sevoflurane reacts with carbon dioxide absorbents and decomposes to compound A. Compound A is a vinyl halide that has been shown to be nephrotoxic in laboratory rats. There have been no case reports of compound A-associated renal injury in human or veterinary patients. Although compound A formation is an area of controversy among researchers, sevoflurane should not be used during low-flow or closed-circuit anesthesia to prevent the accumulation of the potentially nephrotoxic substance.

Because of its low lipid solubility, sevoflurane produces a rapid and smooth induction and a rapid recovery. As with isoflurane, patients that have not been premedicated may experience emergence delirium. Sevoflurane may be advantageous for outpatient procedures in which a rapid surgery-to-discharge time is desired. During the anesthetic management of critically ill patients, wherein it may be necessary to make rapid changes in the depth of anesthesia, sevoflurane may be preferred over isoflurane. Also, sevoflurane is preferred for maintenance of anesthesia for cesarean sections because the neonates, if ventilating adequately, will quickly eliminate residual inhalant agent. The primary disadvantages of using sevoflurane is the higher cost compared with isoflurane.

Desflurane

The MAC value of desflurane is approximately 7.2% in the dog²² and 9.79% in the cat.²³ Desflurane has an extremely low blood–gas partition coefficient allowing for a very rapid induction and recovery from general anesthesia. A dose-dependent respiratory depression is seen. The cardiovascular depressant effects are similar to isoflurane. Desflurane is very pungent, which may make mask inductions difficult in some patients. Desflurane is eliminated from the lungs and has not been

reported to cause hepatic or renal toxicity. Desflurane requires a special, electrically heated vaporizer for delivery because of its high vapor pressure. Desflurane is not used routinely in veterinary patients at this time.

Muscle Relaxants

Elizabeth A. Martinez

Chapter Outline

NEUROMUSCULAR BLOCKING AGENTS

Anatomy and Physiology of the Neuromuscular Junction Pharmacology Individual Agents Monitoring Neuromuscular Blockade

Muscle relaxants may be chosen for use in veterinary patients for several reasons. Because of their muscle-relaxing effects, they are used during certain surgical procedures. Orthopedic procedures such as dislocation and fracture reductions can be performed more easily because of abolished skeletal muscle tone.¹ When a balanced anesthesia technique is used that combines opioids, nitrous oxide, and low-dose inhalant agents, muscle relaxation is greatly improved if a neuromuscular blocking agent is given. This technique is especially beneficial for critically ill patients in which high doses of inhalant agents may lead to unwanted cardiovascular depression.² During intraocular procedures or for patients with penetrating eye injuries requiring surgery, muscle relaxants may be beneficial by producing a central pupil, motionless eye, and soft globe. When used during induction and intubation, they can help prevent an increase in intraocular pressure that can occur during coughing or vomiting.²

KEY POINT 25-1 The use of muscle relaxants in anesthetized small animal patients can help facilitate the procedure being performed, but it is important to remember that these drugs do not provide analgesia or analgesia.

When using a muscle relaxant, the clinician must remember that these agents do not provide either anesthesia or analgesia. The patient must be adequately anesthetized, which may be even more difficult to determine because some of the usual indicators of depth of anesthesia is abolished. These indicators include purposeful movement, palpebral response, and degree of jaw tone. Owing to paralysis of the muscles of respiration, ventilation must also be controlled until neuromuscular function is restored.

NEUROMUSCULAR BLOCKING AGENTS

Anatomy and Physiology of the Neuromuscular Junction

The components of the skeletal neuromuscular junction include the somatic motor nerve terminal, synaptic cleft, and the motor end plate of the muscle fiber. The cell bodies of the REVERSAL OF NEUROMUSCULAR BLOCKADE SKELETAL MUSCLE RELAXANTS Physiology Pharmacology Individual Agents

somatic motor neurons are located within the spinal cord. The axon divides into multiple branches, each of which innervates a single muscle fiber in mammalian species. At each neuromuscular junction, the terminal portion of the axon loses its myelin sheath and forms an arborization that lies in close proximity to the motor end plate of the muscle fiber (Figure 25-1). The site of action of neuromuscular blocking agents is at the nicotinic cholinergic receptors located at the motor end plate of the muscle fiber.

The nicotinic receptors at the neuromuscular junction bind and respond to the endogenous neurotransmitter, acetylcholine (ACh). ACh is synthesized from the acetylation of choline by the enzyme choline acetyl transferase, using acetyl coenzyme A as the source of the acetyl groups. ACh is then packaged at high concentrations into synaptic vesicles by carrier-mediated transport. When a motor nerve is stimulated and action potential subsequently generated reaches the nerve terminal, ACh is released rapidly into the synaptic cleft by way of calcium-mediated exocytosis. One presynaptic nerve impulse releases 100 to 500 vesicles or approximately 3 million ACh molecules. ACh then diffuses across the synaptic cleft and, upon binding with a nicotinic cholinergic receptor, stimulates opening of an ion channel located on the muscle fiber membrane. This allows sodium ions to move and allow sufficient current through them that the resting membrane potential is shifted toward threshold, generating an action potential that triggers muscle contraction. Unbound ACh within the synaptic cleft is rapidly hydrolyzed by the enzyme acetylcholinesterase to choline and acetate. The choline is taken up by the nerve terminal and recycled for continued synthesis of ACh (this is the rate-limiting step in ACh synthesis).

Pharmacology

Neuromuscular blocking agents exert their effects by interfering with the postsynaptic action of ACh. They can be divided into two classes, depolarizing and nondepolarizing neuromuscular blocking agents. Nondepolarizing drugs produce muscle relaxation by preventing ACh from binding to its receptors on

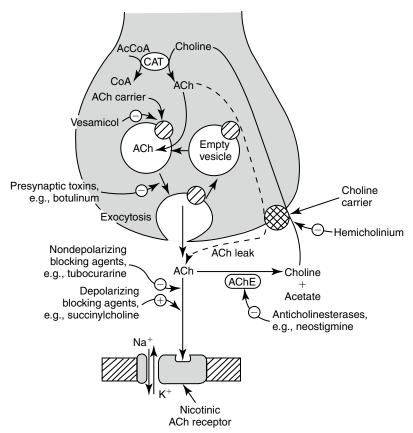

Figure 25-1 Neuromuscular junction with sites of drug action. *AcCoA*, Acetyl coenzyme A; *ACh*, acetylcholine; *AChE*, acetylcholinesterase; *CAT*, catecholamine; *CoA*, coenzyme A. (From Rang HP, Dale MM, Ritter JM et al: *Pharmacology*, New York, 1995, Churchill Livingstone.)

the motor end plate. As a result of this competitive antagonism, the ion channels will not open, no shift in the resting membrane potential will occur, the motor end plate will not depolarize, and the muscle becomes flaccid. Complete neuromuscular blockade will occur when approximately 90% to 95% of the receptors are occupied.³

Depolarizing drugs elicit their pharmacologic effect by binding to the ACh receptor in the same way ACh does, causing transient muscle fasciculations. Because these drugs are not immediately metabolized by acetylcholinesterase, however, they bind for a much longer period than ACh does, causing persistent depolarization of the muscle fiber endplate. In mammals the result of this maintained depolarization is a loss of electrical excitability by the postsynaptic muscle fiber, producing neuromuscular blockade.

Individual Agents

The development of newer muscle relaxants has given the practitioner many options when selecting which agent to use. These drugs differ in their onset and duration of action, recovery time, cardiovascular effects, and route of elimination. When making the decision on which muscle relaxant to use, it is important to consider the reason for neuromuscular blockade, the desired duration of action, and the physical status of the patient. Organ dysfunction and concurrent drug administration may alter the clinical effect of muscle relaxants. Doses

for depolarizing and nondepolarizing neuromuscular blocking agents for dogs and cats are listed in Table 25-1.

Depolarizing Agents

Succinylcholine. Succinylcholine is the only depolarizing neuromuscular blocking agent in clinical use today. Succinylcholine has a rapid onset of action, and its short duration of action is primarily due to rapid hydrolysis by plasma cholinesterase.⁴ For these reasons succinylcholine is used routinely to facilitate endotracheal intubation in human patients. Its use in small animal patients has been limited because the larynx of the dog and cat is easily visualized and does not routinely exhibit excessive laryngospasm, making neuromuscular blockade unnecessary for intubation.⁵

Because of the short duration of action of succinylcholine, frequent redosing or a constant-rate infusion is required if long-term neuromuscular blockade is desired. This may lead to tachyphylaxis (increased dose requirement) and change the character of the initial block (phase I block) to one similar to that produced with nondepolarizing blocking agents (phase II block), which may increase recovery time and require the use of a reversal agent (anticholinesterase therapy).⁶

Use of succinylcholine may be associated with significant side effects. A transient increase in serum potassium concentration occurs because of the leakage of potassium from the interior of cells. Severe, life-threatening hyperkalemia can occur after

succinylcholine administration in patients with severe burns, trauma, nerve damage, neuromuscular disease, closed head injury, intraabdominal infections, and renal failure.⁷ Succinylcholine should also be avoided in patients in which increases in intraocular, intracranial, and intragastric pressures are undesirable. Other side effects of succinylcholine administration include myalgia and cardiac arrhythmias (e.g., sinus bradycardia, catecholamine-induced ventricular arrhythmias).⁷

Any agent than inhibits plasma cholinesterase (organophosphates, procaine) will prolong the duration of action of succinylcholine. Certain disease states such as liver disease, malnutrition, and chronic anemia can decrease the plasma cholinesterase level. Succinylcholine must be used cautiously, if at all, in these patients.⁴

The current goal in the research and development of newer neuromuscular blocking agents is to find a drug that can be offered as an alternative to succinylcholine. This drug would have both a rapid onset and duration of action and possess minimal unwanted side effects. Although the ideal replacement has yet to be discovered, drugs such as rocuronium and mivacurium have proved useful in certain clinical situations. Both are discussed in detail later in this chapter.

Nondepolarizing Agents

Atracurium besylate. Atracurium is an intermediate-acting nondepolarizing agent with an onset of action of 3 to 5 min and a duration of action of 20 to 35 min.⁸ It is metabolized primarily through Hofmann elimination and ester hydrolysis.⁹ For this reason atracurium is the muscle relaxant of choice in patients with hepatic or renal disease. The rate of spontaneous degradation through Hofmann elimination is pH and temperature dependent. Both acidemia and hypothermia will prolong atracurium-induced neuromuscular blockade. Administration of atracurium can cause histamine release at higher doses,

resulting in hypotension and tachycardia. Atracurium should be avoided in patients in which cardiovascular stability is desired. Administration of large doses slowly will attenuate these effects.¹⁰ Repeated doses or an infusion of atracurium produces a consistent degree of block and duration of action because of its noncumulative effects, making it an attractive choice for a constant-rate infusion for long-term paralysis.^{11,12} A metabolite of atracurium, laudanosine, can cause central nervous system (CNS) stimulation and cardiovascular depression, but this problem is rarely seen when clinical doses are used.¹²

Cisatracurium besylate. Cistracurium is the purified form of one of the 10 stereoisomers of atracurium. Because of this, the neuromuscular-blocking profile of cisatracurium is similar to that of atracurium. However, it is less likely to lead to histamine release. When administered to cats at up to 60 times the effective dose in 95% of cases (ED_{95}), plasma histamine levels were unchanged.¹³ In human patients Hofmann elimination accounts for 77% and renal clearance accounts for 16% of total body clearance.¹⁴ A study in anesthetized dogs reported the onset of action as 3.8 minutes and duration of action as 27.2 minutes.¹⁵

Vecuronium bromide. Vecuronium is an intermediate-acting nondepolarizing agent with an onset of action of 2 minutes and duration of action of 25 minutes.⁸ The lack of cardiovascular or histamine-releasing effects, even at higher doses, is an advantage.¹² Vecuronium is the muscle relaxant of choice for patients when hemodynamic stability is needed. Recovery from vecuronium-induced muscle relaxation depends on hepatic elimination. Animals with hepatic disease may exhibit a prolonged duration of action. Vecuronium is noncumulative and is well suited for repeated doses or constant-rate infusions.¹²

Pancuronium bromide. Pancuronium is a long-acting nondepolarizing agent with an onset of action of 2 to 3 minutes and duration of action of 30 to 45 minutes.⁸ It lacks histaminereleasing effects but does possess vagolytic and sympathomimetic effects, which can result in tachycardia, increased arterial blood pressure, and catecholamine-induced ventricular arrhythmias.¹⁶ Pancuronium is mainly eliminated by the kidney, with the remainder undergoing hepatic metabolism; therefore is should be used with caution in patients with renal or hepatic disease.¹⁷ Repeated doses or infusions of pancuronium are cumulative and can produce a delayed recovery.¹⁸

Mivacurium chloride. Mivacurium was recently developed as an alternative to succinylcholine for intubation in human patients. Its onset of action is 1 to 2 minute, with a duration of action of 15 to 20 minutes.¹⁹ Because its metabolism is by way of plasma cholinesterase, prolonged recoveries are possible in patients with hepatic disease, renal disease, or organophosphate toxicity.²⁰ Mivacurium can cause histamine release, is noncumulative, and can be used for infusion administration.¹⁹ In human patients the onset and depth of blockade has a high interpatient variability. Preliminary work in dogs suggested that the dose should be reduced below doses used in human patients.²¹ In a later study, it was shown that one third of the human dose given to dogs resulted in a duration of action five times longer than that with human patients.²² The species differences may be explained, in part, by the fact that normal plasma cholinesterase levels in dogs vary from 19% to 76% of human patients.²³ Also, the canine pseudocholinesterase enzyme may exhibit different affinity for the three primary isomers of mivacurium.²³ Mivacurium has not been available in the United States since 2006. It is listed on the Food and Drug Administration's Discontinued Drug Product List.

Rocuronium bromide. Like mivacurium, rocuronium was developed as an alternative to succinylcholine for intubation in human patients because of its rapid onset of action. In halothane-anesthetized dogs, rocuronium had an onset and duration of action of 1.1 ± 0.49 and 13.7 ± 0.49 minutes, respectively.²⁴ Rocuronium lacks significant cardiovascular and histamine-releasing effects.²⁵ It is metabolized primarily by the liver, with a small fraction eliminated by the kidney.²⁶ In small animal anesthesia, rocuronium may be chosen if a rapid onset of action without significant hemodynamic effects is desired.

Doxacurium chloride. Doxacurium is the most potent nondepolarizing agent available for use at this time.¹⁹ It is a longacting muscle relaxant with a slow onset of action and long duration of action in human patients. Doxacurium has minimal cardiovascular or histamine-releasing effects.²⁷ Because metabolism is through renal elimination, a prolonged or more variable duration of action is seen in patients with renal disease.²⁸ Doxacurium is not commonly used in veterinary medicine. Becaue of its long duration of action, doxacurium may not be suitable for routine clinical use in small animal patients, but it may be an attractive choice for researchers when longterm relaxation with minimal hemodynamic effects is desired.

Drug Interactions

Many medications that are given to veterinary patients during the perioperative period can alter the pharmacodynamics and pharmacokinetics of nondepolarizing agents, leading to an increased or decreased effect. Table 25-2 lists the medications and their effects on the muscle relaxant.

Monitoring Neuromuscular Blockade

Whenever a muscle relaxant is administered, the neuromuscular junction should be monitored to allow the proper dose of relaxant and antagonist to be determined accurately. Also, the degree of residual blockade during the recovery period, if any, can be detected and treated appropriately. Evoked responses are used to evaluate neuromuscular blockade. This involves stimulating a peripheral motor nerve in order to evaluate the resultant motor response. Several hand-held peripheral nerve stimulators are available (Figure 25-2).

Sites of Stimulation

Sites for stimulation of peripheral motor nerves in dogs and cats include the peroneal and ulnar nerves; the more accessible is chosen (Figure 25-3).

Electrical Stimulus Characteristics

There are standard methods of stimulating peripheral motor nerves because the physical characteristics of electrical stimuli influence the motor response they evoke. The output from the

Table 25-2Effect of Medication on Nondepolarizing Neuromuscular Blockade			
Drug	Effects on Depth/ Duration	Comments	
Antibiotics Aminoglycosides Lincomycin Clindamycin Tetracycline Polymixins	Increased	Calcium may reverse effect	
Anticholinesterases	Decreased

From Silverman DG, Mirakhur RK: Effects of other agents on nondepolarizing relaxants. In Silverman DG, editor: *Neuromuscular block in perioperative and intensive care*, Philadelphia, 1994, JB Lippincott.

peripheral nerve stimulator should be a square wave stimulus having duration of 0.2 to 0.3 milliseconds. Ideally, the output current is adjustable and should be sufficient to produce a supramaximal impulse.

After the two electrodes are placed over the nerve to be stimulated, the stimulus is adjusted to deliver a supramaximal current, slightly greater than that required to elicit a maximum motor response. This ensures that all neurons in the bundle are depolarized, which will cause the muscle fibers to contract in an all-or-none fashion. Any subsequent changes in the motor response are from effects at the neuromuscular junction.

Patterns of Stimulation

Peripheral nerve stimulators should provide single-twitch, tetanus of 50 Hz, and train-of-four stimulus patterns. Newer stimulators may also have the capability to deliver a double-burst pattern (Figure 25-4).

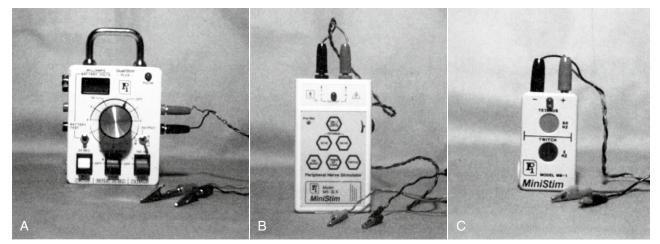

Figure 25-2 A-C, Several hand-held peripheral nerve stimulators available to monitor neuromuscular blockade in small animals.

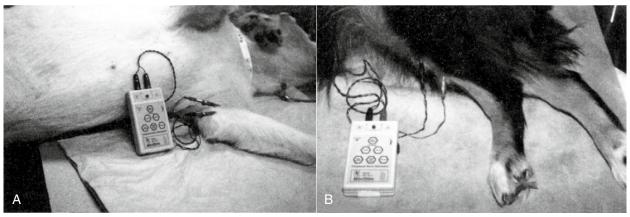

Figure 25-3 Sites for peripheral nerve stimulation in the dog. A, Ulnar nerve; B, superficial peroneal nerve.

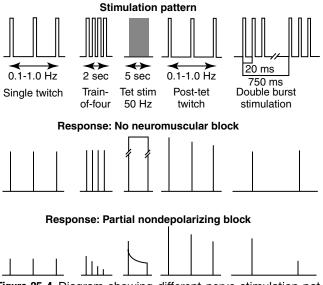

Figure 25-4 Diagram showing different nerve stimulation patterns for monitoring neuromuscular blockade. *Stim,* stimulation; *tet,* tetanic. (Courtesy Cullen LK: Muscle relaxants and neuromuscular block. In Thurman JC, Tranquilli WJ, Benson GJ, editors: *Lumb and Jones' veterinary anesthesia,* ed 3, Baltimore, 1996, Williams & Wilkins.) *Single-twitch method.* The single-twitch method is used to evaluate the degree of relaxation by dividing the elicited response by the control response. The control response is taken before the administration of the relaxant. The frequency should not be greater than 0.15 Hz (1 twitch/7-10 seconds). This is due to the prejunctional effects of the relaxant, which greatly decreases the amount of ACh release.²⁹ The resultant motor response will be less than the baseline values, making accurate determination of the degree of relaxant difficult. The disadvantages of using the single-twitch method are that a baseline response is necessary before administration of the muscle relaxant and that it is insensitive for the detection of residual blockade.³⁰

Train-of-four method. The train-of-four method consists of four supramaximal impulses delivered at a frequency of 2 Hz (2 twitches/second). The degree of blockade is evaluated by comparing the ratio of the fourth twitch to the first twitch (T_4/T_1 ratio). The train-of-four serves as its own control; therefore no baseline values before muscle relaxant administration are necessary. The train-of-four stimulus can be delivered intermittently or at regular intervals 10 to 20 seconds apart. In the absence of muscle relaxants, the T_4/T_1 ratio is approximately 1. Following the administration of a nondepolarizing muscle relaxant, the fourth, third, second, and first twitches disappear (fade) in that order as the block becomes more profound. The degree of fade, strength of the remaining twitches, and length of time that the twitches are absent depends on the dose of relaxant given. A T_4/T_1 ratio of 0.7 or higher correlates with clinical signs of adequate recovery from neuromuscular blockade.³¹

During phase 1 block with succinylcholine, there is a flat T_4 response (no fade). Repeated or prolonged infusions of succinylcholine changes the character of the block to phase 2, where fade during a train-of-four stimulus is seen.³²

Tetanic stimulation. Serial supramaximal stimulation at high frequency, 50 Hz, for 5 seconds causes sustained muscle contraction.³² After administration of a nondepolarizing muscle relaxant, fade is seen as the muscle is unable to maintain the strength generated by the tetanic stimulus.¹⁸ Although it is a sensitive indicator of residual paralysis during the recovery period, this method is painful and will elicit a physiologic response (tachycardia, hypertension, movement) in the lightly anesthetized animal.¹²

Double-burst stimulation. Double-burst stimulation consists of the delivery of two minitetanic (50 Hz) bursts. Each burst consists of three impulses and is 750 milliseconds apart.³³ The ratio of the second burst compared with the first burst (D_2/D_1) correlates highly to the T_4/T_1 ratio and is preferable to trainof-four monitoring to some individuals because fade is more readily seen.^{34,35} Another advantage is that D_1 is still detected at slightly deeper levels of block than is T_1 .³⁶

Quantifying Evoked Responses

During routine clinical use of muscle relaxants in veterinary patients, visual observation of the evoked response is used to detect the degree of block present. This method is unreliable, especially in detecting residual blockade.³⁷ With experience in using muscle relaxants in small animals, visual means are adequate in detecting clinical recovery, but more accurate methods are needed in research settings. The two methods most commonly used to accurately assess the motor response after peripheral nerve stimulation are mechanomyography (MMG) and electromyography (EMG). A third method, accelerography, has also been used in veterinary research patients but to a much lesser extent.

Mechanomyography. MMG measures the evoked contractile response of the stimulated muscle by force translation. This method is the most commonly used and has been well described in the cat, dog, and horse.^{24,38,39} Simply put, the paw or hoof of the front or rear limb is immobilized, the stimulating electrodes (surface or needle) placed over the nerve supplying the muscle to be studied, and a force transducer attached to the paw or hoof perpendicular to the twitch angle. A resting tension of 100 to 300 grams is applied to provide maximum tension development. After supramaximal single-twitch, train-of-four, tetanic, or double-burst stimulation, the evoked response is recorded on a strip chart. Although this method is extremely accurate, use of MMG in the clinical setting is limited because the limb must be immobilized, and no movement can occur throughout the duration of recording period because it will affect resting tension and twitch angle.³⁷

Electromyography. EMG involves the measurement of the compound action potential of the muscle fibers during a supramaximal stimulus of a peripheral motor nerve. Two stimulating electrodes are placed over the peripheral nerve. The active recording electrode is placed over the innervation zone of the muscle to be studied, usually midway between the origin and insertion. The reference electrode is placed over the insertion of the muscle. A ground electrode is positioned between the stimulating and recording electrodes to decrease stimulation artifact. Its advantages over MMG is that it requires no limb immobilization, no resting tension, and greater flexibility in the muscles monitored. Disadvantages are that proper skin preparation and electrode placement is crucial to obtain valid results.³⁷ Although used on human patients, this method has not been described for veterinary patients. This author has used EMG (Relaxograph, Datex) successfully on dogs and horses. In the dog the ulnar nerve is stimulated with recording electrodes placed over the abductor digiti quinti. In the horse the superficial peroneal nerve is stimulated with recording electrodes placed over the lateral digital extensor. Skin preparation involves shaving the hair with a single-edged razor, rubbing the skin vigorously with isopropyl alcohol, and allowing the skin to dry completely before surface electrode placement.

Mechanomyography Versus electromyography. Although MMG remains the gold standard for quantifying evoked responses in veterinary patients in the research setting, EMG may become an attractive choice for use in the clinical patients once the methodology is validated. In human patients differences exist between the two methods. Compared with MMG, the EMG method tends to show a lesser degree of relaxation with nondepolarizing agents and overestimates the degree of relaxation with depolarizing agents.^{40,41} Future studies in veterinary patients will help in the development of different criteria for onset and reversal on neuromuscular blockade based on the type of monitoring used.

Accelerography. Accelerography is based on Newton's second law: Force equals mass times acceleration. In other words, acceleration is directly proportional to the force if the mass is constant. During electrical stimulation of a peripheral nerve, a piezoelectric sensor assesses the acceleration during an isotonic contraction of the innervated muscle. A study in human patients comparing accelerography with EMG concluded that the wide variations in individual patients and the differences in clinical duration and recovery index do not allow the two monitoring techniques to be used interchangeably.⁴² Compared with MMG, published studies in human patients present inconsistent results. In one study accelerography showed good correlation and was considered a simple and reliable monitoring tool.⁴³ In two other studies, the limits of agreement were unacceptably wide.44,45 A study in dogs comparing the neuromuscular effect of vecuronium during either propofol or sevoflurane anesthesia used accelerography to quantify neuromuscular function.⁴⁶ The fibular nerve was stimulated with the acceleration transducer fixed over the cranial tibial muscle.

Accelerography appeared to be an acceptable technique for quantifying neuromuscular blockade in anesthetized dogs. More studies are needed, both in dogs and other species, to determine if it can be used easily and reliably in clinical veterinary patients.

REVERSAL OF NEUROMUSCULAR BLOCKADE

Recovery from succinylcholine (phase 1 block) and mivacurium-induced neuromuscular blockade is usually rapid and spontaneous owing to rapid hydrolysis by plasma cholinesterases. Delayed recovery will be seen in patients with decreased plasma cholinesterase levels.

Residual neuromuscular blockade from nondepolarizing agents and phase 2 block from succinylcholine may be reversed at the conclusion of surgery to prevent potentially serious complications in the recovery period. Complications include muscle weakness and inadequate ventilation, which can lead to life-threatening hypoxia or respiratory acidosis.

Before reversal of blockade, it is desirable to have 3 to 4 twitches of the train-of-four visible. This is achieved by close monitoring of neuromuscular function throughout surgery and not redosing the patient close to the time of anticipated reversal.

The anticholinesterase drugs used clinically include neostigmine, pyridostigmine, and edrophonium. Doses are listed in Table 25-3. They reverse neuromuscular blockade by inhibiting the enzyme acetylcholinesterase, which is responsible for the hydrolysis of ACh. The effect is an accumulation of ACh at muscarinic and nicotinic receptor sites. Because nondepolarizing agents and ACh compete for the same receptor binding sites, anything that increases the concentration of ACh tips the balance of competition in favor of ACh and restores neuromuscular transmission. Reversal of neuromuscular blockade requires only the nicotinic cholinergic effects of anticholinesterase drugs; therefore the muscarinic effects are attenuated or prevented by concurrent administration of an anticholinergic such as atropine or glycopyrrolate.

Sugammadex is the first selective relaxant binding agent (SRBA). It is a novel agent used to reverse neuromuscular blockade produced by rocuronium and, to a lesser extent, other steroidal muscle relaxants (rocuronium > vecuronium > pancuronium). Sugammadex is a modified gamma cyclodextrin that binds and encapsulates the rocuronium molecule.

Table 25-3	Doses of Neuromuscular Reversal Agents for Dogs and Cats	
Drug	Dose (mg/kg IV)

Edrophonium [†]	0.5	
Pyridostigmine [†]	0.2	

*Muir WW, Hubbell JAE,: *Handbook of veterinary anesthesia*, ed 4, St Louis, 2007, Mosby.

[†]Dose used at Veterinary Teaching Hospital, Texas A&M University.

Once bound within the lipophilic core of sugammadex, it is rendered unavailable to bind to the ACh receptor.⁴⁷ A significant advantage of sugammadex is the ability to reverse neuromuscular blockade without the use of anticholinesterase drugs. In addition, because there is no need to co-administer antimuscarinic drugs with sugammadex, its use is associated with greater cardiovascular and autonomic stability. Sugammadex is approved in the European Union but is not currently approved for use in the United States.

Monitoring neuromuscular function and support of ventilation must be continued until complete reversal has been accomplished. An adequate plane of anesthesia must be maintained while monitoring the degree of block with a peripheral nerve stimulator because this can cause the patient some discomfort, especially if tetanic stimulation is used. A T_4/T_1 ratio of 0.7 or greater correlates well to clinical recovery. Once reversal is complete and the use of the nerve stimulator is discontinued, the animal is allowed to recover from anesthesia. Although recurarization is uncommon after reversal, spontaneous respiratory efforts, sufficient to maintain adequate ventilation, should be present and monitored closely during the recovery period.

SKELETAL MUSCLE RELAXANTS (SPASMOLYTICS)

Although neuromuscular blocking agents are effective for skeletal muscle spasticity, these agents are too nonselective to be an appropriate choice for this purpose. Several other drugs are available and commonly used to reduce muscle tone without abolishing voluntary skeletal muscle contraction. Some of these drugs may also possess sedative effects, which may be beneficial to animals that are experiencing both anxiety and pain.

Physiology

Skeletal muscle spasticity may be due to an increase in tonic stretch reflexes originating from the CNS, with involvement of descending pathways, and results in hyperexcitability of motor neurons in the spinal cord. Several diseases involving increased muscle tone caused by defective neuronal control of muscle activity have been described in Scottish Terriers (Scotty cramp), Dalmatians, and Norwich Terriers.48,49 These dogs are normal at rest and on initiation of exercise, but episodic muscle rigidity or cramping are seen during heavy exercise or excitement. Familial reflex myoclonus has been described in Labrador Retrievers. Symptoms appear in young puppies and are characterized by paroxysmal muscle spasms and progressive muscle stiffness. Either a defect in the major inhibitory neurotransmitter glycine or altered genetic regulation of the spinal cord glycine receptor is thought to be the basis for this condition.⁵⁰ Intervertebral disk disease in dogs may cause painful spasms of the neck and shoulder (cervical disk) or back (thoracolumber disk) muscles. In certain clinical cases, skeletal muscle relaxants are used as part of a conservative management protocol for animals with intervertebral disk disease.

Pharmacology

Skeletal muscle relaxants act in the CNS or directly on skeletal muscle to reduce muscle tone and relieve spasticity without abolishing voluntary motor control. Centrally acting muscle relaxants block interneuronal pathways in the spinal cord and in the midbrain reticular activating system. These drugs have little effect on the diaphragm and respiratory muscles at therapeutic doses. Dantrolene, a hydantoin derivative, is a peripherally acting muscle relaxants that acts by decreasing the amount of calcium released from the sarcoplasmic reticulum.

Individual Agents

Centrally acting skeletal muscle relaxants used in small animal veterinary medicine include guaifenesin, methocarbamol, and the benzodiazepines. The most common side effect seen with these drugs is CNS depression, which is manifested as sedation and lethargy. Ataxia and muscle weakness are also possible. Additive depression can occur when these drugs are given concurrently with other CNS depressant agents. Anticholinesterase agents given with either guaifenesin or methocarbamol may result in severe muscle weakness. Dantrolene is the only clinically used peripherally acting skeletal muscle relaxant.

Guaifenesin

Although more commonly used in large animals, guaifenesin is used in small animal veterinary patients to induce muscle relaxation as an adjunct to general anesthesia. The dose in dogs is 33 to 88 mg/kg adminstered intravenously. Guaifenesin has also been used in the treatment of strychnine intoxication in dogs.

Methocarbamol

Methocarbamol is labeled for adjunctive therapy of acute inflammatory and traumatic conditions of skeletal muscle and the reduction of muscle spasms in dogs and cats. The dose is 44 mg/kg intravenously or 61 to 132 mg/kg orally, initially divided every 8 to 12 hours. For muscle relaxation as a part of conservative management of intervertebral disk disease in dogs, methocarbamol is given at a dose of 15 to 20 mg/kg orally three times a day. To control the severe effects of strychnine and tetanus, the dose in dogs and cats is 55 to 220 mg/kg intravenously (not to exceed 330 mg/kg daily). Half of the dose is given rapidly, whereupon the clinician waits until the patient begins to relax and then continues administering the drug to effect.

Diazepam

Diazepam is the primary benzodiazepine used for the purpose of muscle relaxation. Although its clinical indications include seizure control, appetite stimulation, and sedation, only its use as a muscle relaxant will be discussed here. Diazepam may be effective in reducing skeletal muscle spasticity in dogs with episodic muscle cramping such as Scotty cramp or in certain myopathic syndromes. The dose range is 0.5 to 2 mg/kg intravenously or orally three times daily. Diazepam is also used to treat intraurethral obstruction secondary to acquired lower urinary tract disease in male cats. It is believed that muscle spasms of the urethra, along with inflammation of the urethral tissue, make removal of the obstructing plug more difficult. Additionally, these factors may create a "functional" obstruction of the urinary tract even after the obstructing plug has been removed. Diazepam has been recommended for treatment of external urethral sphincter hypertonus at a dose of 2 to 10 mg/kg (total) orally every 8 hours. Because the urethral musculature contains a predominance of smooth muscle, it may be necessary to combine skeletal muscle relaxants (which affect only the external urethral sphincter) with smooth muscle relaxants, such as prazosin.

Dantrolene

The clinical indications for dantrolene include functional urethral obstruction resulting from increased urethral tone and treatment of malignant hyperthermia. For treatment of functional urethral obstruction, dantrolene is administered at a dose of 1 to 5 mg/kg orally every 8 hours (dogs) or 0.5 to 2 mg/kg every 8 hours (cats). Dantrolene has been shown to decrease urethral pressure in the postprostatic/penile urethral segment but has no effect on intraurethral pressures in the prostatic or preprostatic urethral segment.⁵¹ Concurrent use of smooth muscle relaxants may be of benefit in relieving urethral obstruction. For treatment of malignant hyperthermia, the dose of dantrolene is reported in dogs at 0.29 and 0.69 mg/kg intravenously.52,53 Dantrolene has moderate to poor oral bioavailability and is highly bound to albumin. Dantrolene undergoes hepatic metabolism with metabolites excreted in the urine. Adverse effects include hepatotoxicity, sedation, muscle weakness, and gastrointestinal effects.

NEUROTRANSMITTERS AND THEIR ROLE IN ABNORMAL BEHAVIORS

Little is known about the cellular mechanisms of abnormal behavior in humans or animals. The most likely neurotransmitters (NTs) associated with abnormal behaviors might be identified based on the NTs targeted by drugs used to modify the behaviors. NTs identified for their role or potential role in abnormal behaviors include the biogenic amines serotonin and histamine (H₁ subtype), the monoamine dopamine, the catecholamine norepinephrine, acetylcholine, gamma-aminobutyric acid (GABA), and the excitatory amino acids such as glutamate.¹⁻³ Several of these neurotransmitters are discussed in Chapter 27.

Behavior also can be affected by other chemicals, including circulating hormones, opioids, and neurokinins.

The NT most commonly associated with abnormal behaviors is serotonin.⁴ Accordingly, the more effective drugs for modification of behavior are those (e.g., fluoxetine, clomipramine) that tend to be selective for serotonin. Serotonin is synthesized in the brain from tryptophan. Serotonin receptors differ in anatomic location and behavioral roles, with the majority of 5-hydroxytryptamine (5-HT) receptors being located in the gastrointestinal tract. Receptors in the central nervous system (CNS) are located in the raphe nucleus, the basal ganglia, and the limbic area. At least nine 5-HT receptor subtypes have been identified, four of which appear to be particularly important to behavior or mood.³ The 5-HT₁ receptors, located primarily in the brain, are predominantly inhibitory (toward adenylyl cyclase) both presynaptically (autoreceptors; 1A and 1D) and postsynaptically (1A, 1D, 2A, 2C, and 3 and 4). Regulation of serotonin action is complex, involving both presynaptic and postsynaptic mechanisms³ with postsynaptic receptors regulating serotonin release from the presynaptic nerve endings. Serotonin may exert tonic inhibition on the dopaminergic system; drug-mediated increase may result in

extrapyramidal effects.⁴ Badino and coworkers⁵ compared serotonergic and adrenergic receptor density in dogs neurologically normal except for aggressive behavior (n = 8) and normal, nonaggressive dogs (n = 8). The concentration of high affinity (serotonin) 5-HT receptors was increased in the thalamus, and low affinity 5-HT receptors were increased throughout the regions of the CNS studied (frontal cortex, thalamus, hypothalamus, hippocampus) in aggressive dogs compared with nonaggressive dogs. Riva and coworkers⁶ demonstrated that plasma levels of serotonin and dopamine were higher in anxious dogs (n = 22) compared with control dogs (n = 13).

KEY POINT 26-1 Drugs that are among the most effective and safest for behavior modification are those that tend to be most selective for serotonin.

In addition to serotonin, dopamine is also increased in dogs with anxiety.⁶ Dopamine is synthesized in neurons from L-DOPA in presynaptic vesicles. Synthesis begins with oxidation of the dietary amino acid tyrosine, followed by decarboxylation to L-DOPA.³ Those neurons in which dopamine is found lack the enzyme that converts dopamine to norepinephrine. Dopamine is removed by monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT). Dopamine receptors are distributed throughout the brain, although less so than norepinephrine receptors. Dopamine appears to be largely located in the midbrain, hypothalamus, and limbic system (the part of the brain thought to control emotions).³ Dopamine receptors (at least five subtypes) are found in portions of the extrapyramidal system responsible for coordinated movement.^{1,2} At least four dopamine receptors are affected by mood disorders and stereotypics; increased dopamine appears to stimulate these abnormal behaviors.^{1,2} Because dopamine generally suppresses acetylcholine activity, blockade of dopamine receptors generally results in an increase in acetylcholine release.⁴

Norepinephrine is the end product of dopamine oxidation. Its inactivation occurs primarily by active transport or reuptake into presynaptic vesicles. The NT is then deaminated by mitochondrial monoamine oxidases or catechol-o-methyltransferase in the presynaptic nerve terminal. Norepinephrine is located predominantly in the gray matter of the pons and in the medulla; projections in the locus ceruleus into the limbic cortex regulate emotions. Norepinephrine interacts postsynaptically with α_1 receptors (G protein–mediated activation of phospholipase C and inositol triphosphate formation) and β receptors (activation of adenylyl cyclase) and presynaptically with α_2 receptors (G proteins).The behavioral effects of norepinephrine appear to affect arousal, functional reward systems, and mood. The latter effect may reflect a decrease in depression and an increase in mania.

GABA is a major inhibitory NT, being active at 30% of synapses in the human CNS, and particularly in the cortex and thalamus. Its precursor glutamate is widely distributed throughout the brain. As with norepinephrine, dopamine, and serotonin, GABA has a presynaptic transporter. Two primary receptor types, GABA_A and GABA_B, appear to cause postsynaptic inhibition by facilitating chloride ion influx into the neuron. Several drugs, including the benzodiazepines and barbiturates (e.g., phenobarbital), interact with the GABA_A receptor in an agonistic fashion, causing neuronal inhibition.¹ The physiologic and behavioral effects of GABA and its receptors have not yet been totally characterized (see Chapter 27).³

Several abnormal human behaviors have been associated with changes in excitatory NTs, including aggressive, impulsive, and schizophrenic disorders. Among the more important excitatory NTs is glutamate. Glutamate is preformed and stored in synaptic vesicles released by calcium-mediated endocytosis. Barbiturates and progesterone modulate behaviors, in part by inhibiting calcium uptake and thus release of glutamate at the NT.^{1,2}

Acetylcholine, the most widely distributed NT in the brain,³ is preformed from choline and acetyl coenzyme A and stored at the terminal end of the synapse in vesicles. Calcium stimulates its release by exocytosis into the synaptic cleft, where it is rapidly metabolized by acetylcholinesterase. Acetylcholine generally is an excitatory NT, interacting with nicotinic and muscarinic receptors. At least five muscarinic receptors are located in the CNS. Receptors (M₁) are also found in the gastrointestinal and cardiovascular systems, accounting for some of the adverse effects associated with several behavior-modifying drugs.¹

NTs tend to be formed and degraded locally. Both formation and inhibition offer pharmacologic targets. A number of drugs result in an increase in the presence of NTs in the synaptic cleft by inhibiting either the metabolism (e.g., dopamine) or the reuptake (e.g., serotonin, norepinephrine) of the NT after release (Figure 26-1).

DRUGS USED TO MODIFY BEHAVIORS

Drugs that modify behavior are classified initially on the basis of their (human) therapeutic use, followed by their chemistry and neurochemical activity.⁴ Included are the antipsychotic drugs (predominantly antidopaminergic in action), anxioselective drugs such as the azapirones (primarily antiserotonergic in action), drugs used to treat affective or mood disorders (antidepressants, lithium, and selected anticonvulsant drugs), and drugs used to treat anxiety and anxiety-related disorders (anxiolytics or minor tranquilizers, benzodiazepines). Other drugs include antihistamines, beta blockers, progestins, anticonvulsants, and opioid antagonists. Most of the drugs used to modify behaviors are used for treatment of other disorders, and as such may be discussed elsewhere in this volume. Only drugs that have veterinary application are discussed here. Table 26-1 provides dosing information about the use of these drugs.

KEY POINT 26-2 Drugs that modify the central nervous system should not be withdrawn suddenly. Extra precaution is indicated for drugs with short half-lives.

In general, the disposition of behavior-modifying drugs is complex, with characteristics that tend to be different among species. Oral absorption, first-pass metabolism, significant binding to serum proteins, profoundly large volumes of distribution, and metabolism to enantiomers and active metabolites (the latter potentially contributing to more activity than the parent compound) all contribute to these drugs' lack of predictable behavior when dosing regimens are extrapolated among species. Hepatic metabolism increases the risk of both hepatotoxicity and drug interactions. The former, although rarely reported in humans, appears to be increasing and warrants additional attention as the use of these drugs increases in animals. Many behavior-modifying drugs are inhibitors of cytochrome P450 (CYP). Drug interactions at the level of CYP are well known in human medicine and should be anticipated in animals, particularly if drugs are used in combination. However, differences in CYP distribution and activity preclude predictable extrapolation of reported drug interactions among the species. The potentially toxic nature of these drugs places the animal patient further at risk because many dosing regimens are extrapolated from humans. Exceptions include clomipramine, fluoxetine and selegiline, each of which has been approved for use in dogs. The disposition of several drugs also has been reported in cats.

Antipsychotic Drugs

Psychotic disorders in humans involve a severe disturbance of brain function characterized by thought and speech disruption and hallucinations or delusions.³ Although psychotic disorders do not appear to occur in veterinary medicine, drugs developed for their management in humans have proved efficacious for a number of veterinary applications. Antipsychotic drugs (also called *neuroleptics* or *major tranquilizers*) are largely structurally dissimilar from one another, but the commonality among them is dopamine, and particularly D₂ receptors, as a target. Drugs include the phenothiazines, the thioxanthenes (structurally related to the phenothiazines), heterocyclic dibenzepines, the butyrophenones, and diphenylbutylpiperidines (Figure 26-2).⁷

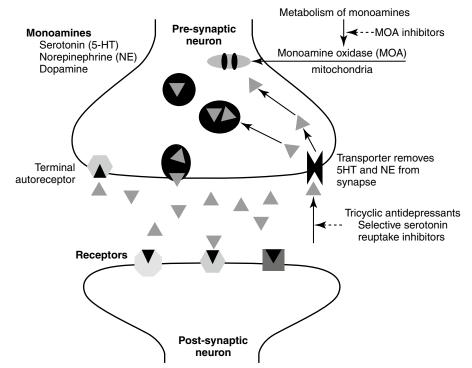

Figure 26-1 Mechanism of action of selected behavior-modifying drugs. Neurotransmitters responsible for behavior are released from the presynaptic neuron into the synaptic cleft and interact with postsynaptic receptors. Following exocytosis, inactivation of the transmitter occurs primarily by reuptake into the presynaptic neuron, the site of action of most behavior-modifying drugs. Activation also may involve metabolic degradation, as in the case of the monoamines (MOA).

Structure–Activity Relationships

Antipsychotic drugs are categorized by structure and by potency. Low-potency drugs (chlorpromazine, acepromazine, promazine) are characterized by greater sedation and cardiac and anticholinergic side effects compared with their highpotency counterparts. High-potency drugs (e.g., haloperidol, fluphenazine, trifluoperazine, prochlorperazine, and thiothixene) are administered at lower doses and are associated with less sedation and fewer anticholinergic and cardiac side effects. They do, however, have a greater incidence of extrapyramidal side effects.

The largest structural class of antipsychotics is the phenothiazines or tricyclic antipsychotics, which should not be confused with the tricyclic antidepressant drugs (discussed later). The tricyclic antipsychotic drugs are represented by phenothiazine, a three-ring structure containing a sulfur and nitro group in the ring connecting two benzene rings. Substitutions on one of the benzene rings yield different drugs (e.g., chlorpromazine, promazine), which differ in efficacy (see Figure 26-2). The pharmacology also is affected by substitutions of nitro groups such that potency (but not efficacy) is reduced by an aliphatic side chain (e.g., chlorpromazine, thorazine, acepromazine, and trifluopromazine).⁷ The length of the side chain also determines antihistaminergic properties, with twocarbon side chains such as that occurring in promethazine being more antihistaminergic. Drugs with higher potency have a piperazine side chain, as can be found on fluphenazine and rifluoperazone. Esterification with long-chain fatty acids results in long-acting (due to slow hydrolysis and absorption)

drugs (e.g., fluphenazine enanthate or decanoate).⁷ The use of these latter drugs in small animal veterinary medicine has yet to be established. The butyrophenone neuroleptics include haloperidol (the prototype) and droperidol. The latter is very short acting and highly sedative; thus its use is limited to anesthetic regimens.⁷

Pharmacologic Effects

The pharmacologic effects of antipsychotic drugs generally are similar among humans and animals.⁷ Phenothiazines are also categorized as tranquilizers. As tranquilizers, the phenothiazines are calming in nature, causing a decrease in spontaneous activity that generally decreases response to external stimuli.¹ The predominant antipsychotic action of the phenothiazines is *neuroleptic*, a term derived from the effect of the drugs on human psychiatric patients and intended to contrast with signs typical of CNS depression.⁷ The neuroleptic effects are attributed, although not conclusively so, to the antidopaminergic effects at D₂ receptors.⁷

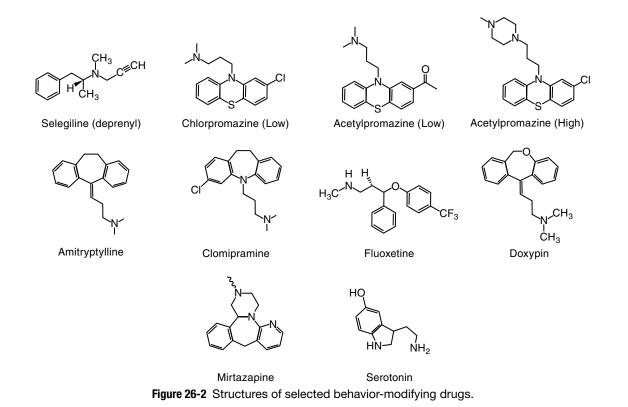

Some of the neuroleptics (e.g., the phenothiazines) have high affinity for and thus also antagonize D_1 dopamine receptors, although pharmacologic effects at these receptors appear to be minimal. Phenothiazines also block D_3 and D_4 (which are D_2 -like) receptors. Selected "atypical" antipsychotic drugs (e.g., clozapine) have a low affinity for D_2 receptors and are not characterized by extrapyramidal effects. They are, however, characterized by α_2 -adrenergic antagonism. Some of the antipsychotic drugs also have affinity for serotonergic (5-HT₂) receptors (e.g., clonazepam). Cholinergic and histaminergic

Drug	Drug Class	Indication	Dose	Route	Interval (hr)
Acepromezine	Phenothiazine, low potency		1-2 mg/kg	РО	8
1			0.05-0.1 mg/kg	IV, IM	8
Alprazolam	Benzodiazepine	Anxiolytic	0.125-0.25 mg/cat	РО	8-24

		Behavioral disorders, lick granulomas	2.2-5 mg/kg	РО	12-24
		Behavioral disorders, adjuvant	25-50 mg/cat	PO	12

PO, By mouth; *IV*, intravenous; *IM*, intramuscular; *D*, dog; *C*, cat; *SC*, subcutaneous.

 (H_1) receptors also are targeted by some of the drugs, resulting in unique pharmacologic effects among the neuroleptics. Variable interactions with different receptor types lead to unpredictable effects on the autonomic system. Among the neuroleptics, chlorpromazine has significant α -adrenergic antagonistic actions. In general, the antimuscarinic actions of neuroleptics are weak.

Neuroleptic effects include suppression of spontaneous movements or complex behaviors but minimal effects on spinal reflexes and unconditioned nociceptive avoidance behaviors. Interest in the environment is minimized (ataraxia), as are manifestations of emotion. Patients are easily aroused; ataxia or incoordination should not be evident at appropriate doses.⁷ Aggressive or impulsive behavior should gradually diminish. As a result, conditioned avoidance (but not unconditioned escape or avoidance) behavior and exploratory behavior are minimized. Feeding and emesis also are inhibited. At high doses, cataleptic immobility is evident (particularly in cats³), resulting in increased muscle tone (and the ability to place animals in an abnormal posture) and ptosis. Akathisia, an increase in restless activity, is an undesirable side effect that occurs in humans but apparently not in animals. Akathisia occurs as an adaptive response to increased phenothiazines in extrapyramidal tissues.7

The effects of phenothiazines occur throughout the CNS. Cortical effects are responsible for many of the neuroleptic actions. Antagonism of D_2 receptors is largely responsible for the various extrapyramidal effects of the drugs. Many of these sites appear to be spared from the adaptive changes of tolerance.⁷ Neuroleptics have been associated with an increased incidence of seizures.⁸ Selected drugs lower seizure threshold

as well as induce discharges typical of epileptic seizures. Aliphatic, low-potency phenothiazines are particularly characterized by this effect.⁷ Although the effect is more likely to occur in patients who are epileptic or who are predisposed to seizures, the effect is also a dose-dependent characteristic of some drugs. These drugs are contraindicated in human epileptic patients or patients undergoing withdrawal from central depressants.⁷ The relevance of this precaution to dogs is not clear. Both Tobias and coworkers9 and McConnell and coworkers¹⁰ retrospectively studied the frequency of seizures in epileptic dogs treated with low doses of acepromazine and found no increased risk (see also Chapter 27). Indeed, acepromazine was associated with decreased seizure activity in some of the patients that did not respond to other therapies. However, because the author experienced induction of seizures in a non-epileptic patient (lead poisoning) immediately after intravenous administration of acepromazine, caution is warranted when using phenothiazine derivatives in epileptic patients. Increasing doses slowly and accompanying with anticonvulsant therapy are indicated if the drugs must be used by epileptic patients.

The neuroleptic drugs have a number of effects in the limbic system. Although D_2 antagonism occurs in the limbic system, because D_3 receptor stimulation may be responsible for many of the behaviors targeted by neuroleptics, attempts are being made to identify D_3 -selective drugs for treatment of psychoses.⁷ Neuroleptics stimulate prolactin secretion in human beings. Indeed, the potency of neuroleptic action and ability to cause prolactin secretion are well correlated for most drugs. Pageat and coworkers¹¹ demonstrated that prolactemia correlates with response to selected behavior-modifying drugs. Tolerance is not likely to develop to this side effect. In humans prolactin secretion caused by neuroleptics also is responsible for breast engorgement and galactorrhea. Releases of growth hormone and corticotropin-releasing hormone occur in response to stress; neuroleptics (especially chlor-promazine) also interfere with the release of growth hormone, although apparently not sufficiently for treatment of acromegaly. Impaired release of serotonin may result in weight gain (particularly with low-potency drugs), and impaired glucose tolerance and insulin release may be impaired in "prediabetic" patients (especially with chlorpromazine).⁷

In the brainstem the neuroleptics have little effect, even in cases of acute overdosing. Life-threatening coma is rare. In contrast, most neuroleptics protect against nausea and emesis at the chemoreceptor trigger zone in the medulla. These effects occur at low doses. Potent piperazines and butyrophenones are also often effective against nausea stimulated by the vestibular system.⁷

Phenothiazines characterized by lower potency have a predominant sedative effect that is more apparent initially but tends to decline as tolerance develops. The phenothiazines are characterized by anxiolytic effects, but more specific anxiolytic drugs are available. In addition, the risk of either autonomic (e.g., low-potency drugs) or extrapyramidal (e.g., highly potent drugs) effects increases the likelihood of causing anxiety.⁷

The neuroleptic drugs impart physiologic (especially cardiovascular) effects through peripheral actions. The effects are complex because the neuroleptics interact with a number of receptor types that have cardiovascular effects. Hypotension induced by phenothiazines—low potency in particular reflects direct effects on the blood vessels, indirect actions in the CNS and autonomic receptors, and a direct negative inotropic effect on the heart. Chlorpromazine also has antiarrhythmic effects on the heart, similar to quinidine.

Disposition

The antipsychotics are characterized by variable bioavailability, high lipophilicity, high protein binding, and accumulation in a number of tissues. Elimination occurs primarily through hepatic metabolism. In humans the elimination half-life is long, ranging from 20 to 40 hours. Biologic effects persist for more than 24 hours, allowing once-daily therapy in humans.⁷ Metabolites can be detected in urine for several months.

Side Effects and Toxicity

The antipsychotic drugs tend to be very safe; lethal ingestion is rare in human patients. Side effects tend to reflect the pharmacologic actions of the drugs, including effects of the CNS and cardiovascular, endocrine, and autonomic systems.⁷ In human patients other effects include dry mouth, blurry vision, and constipation. Urinary retention may occur in male patients with prostatitis. At high doses antipsychotics may cause catalepsy, characterized by immobility, increased muscle tone, and abnormal postures.⁴ Extrapyramidal neurologic side effects reflecting inhibitionof dopamine occur in humans but have not been reported in animals. However, involuntary motor movements associated with extrapyramidal effects may be confused with seizures. The risk of seizures may be increased, but risk factors are not known (discussed previously). Some animals exhibit signs of hyperactivity after treatment with acepromazine.³ In addition, at least one report cites increased agitation and irritability after treatment of aggression with acepromazine.12 Jaundice has occurred in humans after taking chlorpromazine and may resolve despite continued treatment. Blood dyscrasias, including leukopenia, eosinophilia, and leukocytosis, occur but are less common with low-potency phenothiazines. Skin reactions tend to be common in people, again more commonly with low-potency phenothiazines. Small doses of acepromazine (0.1 mg/kg, given subcutaneously 30 minutes before testing) appear to have no effect on intravenous glucose tolerance testing in dogs.¹³ Acepromazine sedation (0.03 mg/kg given intramuscularly 30 minutes before measurement) markedly increased peak latencies but minimally affected peak amplitude of middle-latency auditoryevoked potential in dogs (n = 12).^{7,14}

Drug Interactions

Chlorpromazine is used in combination anesthetic regimens because of its ability to potentiate central depressants. Effects of analgesics and sedatives also can be enhanced. Interactions with antihypertensive drugs can be unpredictable and are more likely to be adverse with low-potency products.⁷ Selected phenothiazines can antagonize the positive inotropic effects of digoxin.

Clinical Indications

In general, the use of phenothiazines for treatment of aggressive behavioral abnormalities is inappropriate because both normal and abnormal behaviors are blunted. Acepromazine is particularly problematic. Restraint of aggressive dogs with the drug renders dogs more likely to be reactive to noises and more easily startled.¹ In addition, because the degree and duration of tranquilization vary, reactions in dogs are unpredictable. Phenothiazines are not selective as antianxiety drugs but can reduce responsiveness in general, and thus they are useful in some cases of episodic anxiety.³ Thioridazine has been used in one case of aberrant motor behavior.¹⁵ Newer atypical antipsychotics (e.g., risperidone) may prove useful for treatment of selected abnormal behaviors (e.g., environmental-specific anxieties, impulsive explosive disorders).⁴

Antidepressant Drugs

Much of the information regarding the use of these moodmodifying drugs in animals has been extrapolated from human use. These drugs are characterized by clinical pharmacology and mechanisms of action that are likely to differ markedly among animals. Yet limited scientific information is available to guide their use in animals. Among the human mood-modifying drugs that are approved for their use for treatment of behavioral disorders in either dogs or cats are the tricyclic antidepressants (TCAs) (clomipramine), the MAO inhibitors (selegiline), and selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine). Affective (behavior) disorders targeted by antidepressants in humans range from depression to manic-depressive disorders. In animals the list of targeted disorders is much greater and may be publically perceived to include any type of behavior deemed unacceptable by pet owners.

For a better understanding of the pharmacologic actions (intended and undesirable) of these drugs, it is necessary to appreciate the extent to which NTs targeted by these drugs are active in the brain. Among the most commonly targeted NTs is the biogenic amine system, with norepinephrine, 5-HT (serotonin), and dopamine serving as primary targets. Acetylcholine and histamine are common, although generally secondary, targets. In addition, α -adrenergic receptors may be stimulated by some of these drugs. The pharmacologic and side effects of these drugs vary with the NT targeted. Drugs that are more specific in their actions tend to be safer. Inability to predict the effect of antidepressant drugs on behavior reflects in part the inability to predict effects at the synapse as well as a lack of knowledge regarding the impact of neurotransmission on behavior. In general, blockade of dopamine transport appears to be stimulatory rather than antidepressant whereas inhibition of either serotonin or epinephrine reuptake appears to produce an antidepressant effect.

Tricyclic Antidepressants

Structure–Activity Relationships

The TCAs are among the most frequently prescribed drugs in human behavior medicine. Their name reflects their chemical structure (see Figure 26-2). The TCAs were identified as a group of potentially useful drugs for the modification of behavior in the 1940s after the generation of a number of drugs with antihistaminergic, sedative, analgesic, and antiparkinsonian effects. Imipramine was selected on the basis of its hypnotic and sedative effects. Imipramine differs from phenothiazine only by the replacement of sulfur with an ethylene bridge, yielding a seven-member ring. This compound proved ineffective in quieting agitated psychotic patients but very effective for selected mood disorders.⁷

The search for chemically related compounds yielded a number of additional drugs. Clomipramine, amitriptyline, and doxepin are all derivatives of imipramine.⁷ Each contains a tertiary amine at one of the substitution sites on the sevenmember ring. Desipramine, a major metabolite of imipramine, and nortriptyline, the *N*-demethylated metabolite of amitriptyline, are secondary amine tricyclics. Protriptyline and trimipramine are other TCAs with few veterinary applications.³ Differences in the effects of NT reuptake vary with the different amine structures.⁷

Mechanism of Action

The mechanism of action of the TCAs (and MAO inhibitors and SSRIs) is blockade of the mechanisms of physiologic inactivation (see Figure 26-1). For the TCAs the mechanism is inhibition of reuptake at presynaptic biogenic amine NT receptors in the brain. As reuptake is inhibited, the concentration of NTs increases, prolonging their actions (CNS stimulation). Differences in NTs affected reflect, in part, the chemical structures.⁷ Imipramine and its derivatives with a tertiary amine side chain block norepinephrine reuptake but have little effect on dopamine reuptake.

The secondary amine derivatives of imipramine are potent and highly selective inhibitors of norepinephrine reuptake; however, they are characterized by fewer autonomic and anticholinergic effects. Tertiary amines that are metabolized in the patient to secondary amines will have effects on norepinephrine reuptake. Clomipramine has marked effects on serotonin reuptake and minimal effects on other NTs or receptors, although a poorly understood dopaminergic effect has been described. Its active metabolite appears to inhibit norepinephrine uptake as well.¹⁶ Doxepin is characterized by greater antihistaminergic actions (thus explaining its frequent recommendation for chronic pruritus). Although amitriptyline is the most commonly prescribed drug for animals, clomipramine has recently been approved for treatment of separation anxiety in dogs.

The effect of clomipramine (3 mg/kg once daily orally for 6 weeks) on the concentration of monoamines (5HIAA [5-hydroxyindoleacetic acid], HVI [homovanillic acid] and MHPG [methoxy4-hydroxyphenylglycol]) in the cerebrospinal fluid was compared with that of placebo using a randomized crossover design in otherwise behaviorally normal dogs (n = 6) with obsessive–compulsive disorders (OCDs).¹⁶ The concentration of monoamines did not significantly differ (power of the study now known), leading the authors to conclude that clomipramine did not affect monoamine turnover in the brains of behaviorally normal dogs, further confirming the need for studies in affected dogs.

Pharmacologic Effects

Adaptation to pharmacologic effects. The effects of TCAs at presynaptic and postsynaptic receptors and autoregulation result in complex responses that are not well understood. Although inhibition of reuptake occurs very rapidly, peak effects still take several weeks. This prolonged time to maximal effect reflects in part disposition (e.g., time to steady-state for the parent compound and active metabolites; see later discussion of clinical pharmacology) but also appears to reflect adaptation in the CNS to changes in NT concentrations at the synapse. Administration of a TCA results in an immediate decrease in the synthesis and release of norepinephrine or serotonin (depending on the major target of the TCA) in selected areas of the brain. The effects appear to be mediated presynaptically through autoreceptors (α_2 or serotonin, respectively). Turnover, however, gradually normalizes within 1 to 3 weeks. Autoreceptors appear to be downregulated and become desensitized to the presence of the TCA.7 The number and sensitivity of postsynaptic adrenergic receptors do not appear to be affected by continued use of a TCA.

Adaptive responses appear to influence the pharmacologic properties of TCAs at adrenergic receptor sites. The TCAs have a moderate affinity for α_1 -receptors and only limited affinity for α_2 -receptors and β -receptors. Changes in serotonin receptors after repeated treatment with TCAs are complex. Although the impact is not clear, the general effect appears to be increased sensitivity to serotonin. This may be an important component to the outcome of prolonged treatment.⁷ The TCAs also appear to influence the effect of other NTs and their receptors, including GABA (unknown significance), and dopamine (D_2 ; desensitization of autoreceptors resulting in mood elevation). Other factors to consider regarding adaptation to TCA effects include changes in adenosine monophosphate–dependent protein kinases and potential changes at the level of gene expression.⁷

In addition to tolerance (to sedative and autonomic effects), physical dependence on the TCA can develop. Physical dependence after acute withdrawal is manifested in human patients as malaise, chills, coryza (head cold), and muscle aches.⁷ Slow discontinuation of the drug is recommended.

Autonomic nervous system. The predominant effect of TCAs on the autonomic nervous system appears to reflect inhibition of norepinephrine transport into adrenergic nerve terminals and antagonism of muscarinic cholinergic and α_1 -adrenergic responses to the NTs. Blurred vision, dry mouth, constipation, and urinary retention at therapeutic doses (documented in humans) appear to reflect anticholinergic effects.⁷

Cardiovascular system. Cardiovascular effects of TCAs occur at therapeutic doses and can become life threatening with overdose. Postural hypotension occurs in humans (unlikely in dogs or cats) as a result of α -adrenergic blockade. Mild sinus tachycardia results from inhibition of norepinephrine uptake and muscarinic (M₁) blockade.⁷ Conduction time is prolonged, especially at concentrations above 200 ng/mL. The TCA can also directly suppress the myocardium.⁷ The myocardial depressant effects are greater in the presence of underlying cardiac disease.

Clinical Pharmacology

The disposition of the TCA favors adverse reactions in that the characteristics of disposition are those that tend to vary greatly among animals, and extrapolation between species is complicated. Unfortunately, the disposition has not been scientifically studied in animals except for clomipramine, and information for other drugs or species is extrapolated from human or canine data. The TCAs are very lipophilic. As such, they are well absorbed after oral administration. They can, however, undergo marked first-pass metabolism. Typical drug concentrations achieved in humans at recommended doses are 100 to 250 ng/mL for amitriptyline, 150 to 500 ng/mL for clomipramine, and 200 to 300 ng/mL for imipramine.⁷ High doses can cause anticholinergic effects on the gastrointestinal tract, slowing absorption or making it erratic. Absorption in humans can result in peak concentrations as rapidly as 2 hours or as long as 12 hours after administration.⁷ The drugs are very highly protein bound, but unbound drug is characterized by a very large volume of distribution (10 to 15 L/kg in human patients), contributing to a long elimination half-life of the parent drug or its metabolites. Drug may bind avidly to selected tissues.

Drugs are eliminated by hepatic (oxidative) metabolism with the main reaction being N-demethylation to the active metabolite, desmethylclomipramine (DCMP). This reaction is catalyzed by CYP3A4, CYP2C19, CYP2C9, and CYP1A2. The parent and metabolite are hydroxylated by CYP2D6 and then glucuronidated.^{17,18} Metabolism is variable among human and canine patients, accounting for plasma concentrations that differ by tenfold to thirtyfold. Species and gender differences in metabolism or pharmacokinetics have been demonstrated for clompramine.^{17,18} Metabolism of TCA yields active and inactive metabolites. It is not clear what percentage of the antidepressant activity of the TCA is associated with the metabolites. Metabolites generally have an elimination half-life that is twice or more that of the parent compound.⁷ Thus accumulation of the metabolites can result in a marked proportion of the pharmacologic effect of TCAs.

Clomipramine is approved for use in dogs for treatment of separation anxiety. After multiple oral administration in dogs, both clomipramine and its principal active metabolite, desmethylclomipramine, accumulate in a dose-dependent manner at doses ranging from 1 to 4 mg/kg.¹⁹ Food does not appear to alter the rate or the extent of oral absorption,²⁰ with bioavailability of clomipramine being 20% and of the metabolite 140%. The ratio of metabolite to parent in dogs approximates 0.6, varying across time.²¹ After a single dose of 3 mg/ kg in normal dogs (n = 6), clomipramine C_{max} was quite variable for both clomipramine (16 to 310 ng/mL at 0.75 to 3.1 hr) and desmethylclomipramine (21 to 134 ng/mL at 1.4 to 8.8 hr).²² After multiple dosing, (28 d) clomipramine C_{max} again was markedly variable at 43 to 222 ng/mL (at 3 to 8 hr), compared with 21 to 134 ng/mL at 1.4 to 8.8 hr, for desmethylclomipramine. Hewson and coworkers²¹ reported trough concentrations of clomipramine ranging from 2 to 17 ng/mL and desmethylclomipramine ranging from 2 to 15 ng/mL following 26 days of dosing at 3 mg/kg; neither compound was detectable in three of six dogs at trough times (24 hr). Protein binding of both the parent compound and its metabolite are greater than 96%. Hepatic clearance of clomipramine in dogs is flow-limited; changes in hepatic blood flow, but not hepatic mass (i.e., CYP activity), should be expected to alter clomipramine elimination. However, rapid clearance is balanced by a very large volume of distribution. Despite this large volume, clomipramine elimination half-life is shorter and markedly variable in dogs ranging from 1.2 to 16 hours after a single oral dose in dogs (n = 6) compared to 20 in humans. After multiple (28 days) dosing, both variability and duration of half-life decreased to 1.5 to 9 hours.²¹ An average half-life of 5 to 6 hours was reported for dogs in a subsequent study.¹⁹ Half-life of the desmethyl clomipramine in dogs also is short (2 to 3.8 hours, compared to 36 hours in humans),^{19,21} with total concentration of the metabolite being less than that of the parent compound. Steady-state concentrations are reached by 4 days or less, resulting in response within 1 to 2 weeks. Cats metabolize (based on in vitro hepatic microsomal studies) clomipramine more slowly than do dog or rats, with male cats being less efficient metabolizers.¹⁷ The pharmacokinetics of clomipramine and its major metabolite desmethylclomipramine have been described in cats (n = 6) using a randomized crossover singledose oral (0.5 mg/kg) and intravenous (0.25 mg/kg) administration study).²³ After oral administration, C_{max} (µg/mL) was 0.87 ng/mL at 6.2 hours. After intravenous administration, volume of distribution and clearance were 0.393 L/kg and 0.833 mL * min/kg, respectively, resulting in an elimination half-life of 12.3 hours. Area under the curve (AUC) of clomipramine and desmethylclomipramine after oral administration were 948 and 613 ng * min/mL, respectively. Oral bioavailability of clomipramine and its active metabolite approximated 30%. Variability among cats was marked. On the basis of these data, Lainesse and coworkers¹⁸ found no correlation between either clomipramine or desmethylclomipramine concentrations and sleep scores. However, gender differences in metabolism may have contributed to the lack of correlation.

KEY POINT 26-3 For a number of the behavior-modifying drugs, slow elimination and formation of active metabolites complicate the design of dosing regimens.

Of the TCAs, only amitriptyline appears to have been studied after transdermal delivery in cats. Plasma drug concentrations were not detectable in cats (n = 6) receiving a single 5-mg transdermal (pluronic lecithin organo [PLO]) gel dose. This compared with a mean peak concentration of 61 ± 6.2 ng/mL after oral administration of 5 mg.²⁴ The author has demonstrated, using a randomized crossover, dummy-placebo controlled design, that although amitryptylline administered as a transdermal gel achieved detectable concentrations in 5/6 cats receiving 2 mg/kg twice daily for 3 weeks, bioavailability was very poor. After 3 weeks of dosing, serum drug concentrations were 46 to 101 ng/mL after gel administration compared to 1336 to 5230 ng/mL after oral administration at the same dose. The disappearance half-life in the cats receiving the oral drug (based on peak and trough dosing) was markedly variable among cats, ranging from 20 to approximately 85 hrs after 3 weeks. Two of the cats receiving the gel developed marked aural erythema and scaling. Despite the very high concentrations, 4/5 cats tolerated the oral administration well; the one cat with concentrations of 5230 ng/mL was depressed, with resolution occurring once the drug was discontinued. Interestingly, disappearance half-life of amitryptyilline was only 20 hrs in this cat, suggesting that oral bioavailabilitymay have been contributing to the high serum concentrations.

Side effects. Up to 5% of human patients receiving a TCA react adversely. Sedation is common with the TCAs.³ The most common reactions reflect antimuscarinic effect or overdosing. Cardiac toxicity (reflecting a quinidine-like membrane-stabilizing effect) is a less frequently reported but serious effect, but not apparently with clomipramine administration in dogs. The effect may be lethal at 15 mg/kg.⁴ Tachycardia may also reflect anticholinergic effects and must be differentiated from true cardiotoxicity. Other side effects include dry mouth, gastric distress, constipation, dizziness, tachycardia, or other arrhythmias, blurred vision, and urinary retention (particularly problematic in the presence of prostatic hypertrophy).⁷ Weakness and fatigue reflect CNS effects. Cardiac toxicity is more likely in patients who start therapy with cardiac disease. In healthy patients the most likely cardiac response is hypotension as a result of α-adrenergic blockade.

An undesirable side effect of antidepressant drugs in humans is referred to as the "switch process." Patients undergo a transition from depression to hypomanic or manic excitement.⁷ This effect has not been reported in animals. Confusion and delirium are behavior aberrations that occur commonly in human patients, with the incidence of 10% in all patients, increasing to more than 30% in elderly patients over age 50 years.⁷ Miscellaneous toxic effects in human patients include leukopenia, jaundice, and skin rashes. Weight gain occurs, particularly with those drugs that are selective for serotonin reuptake. Isolated reports that address the side effects of TCAs in dogs are uncommon. Goldberger and Rapoport²⁵ reported side effects in 5 of 13 dogs receiving clomipramine for lick granuloma. Clinical signs included lethargy, anorexia, diarrhea, and growling.

Acute poisoning with TCAs is common in human patients (accidental or intentional) and appears to be a significant potential problem in animals.²⁶ Symptoms in humans vary and are complex. Excitement and restlessness may be accompanied by myoclonus or tonic–clonic seizures. Coma may rapidly develop, associated with depressed expiration, hypoxia, hypothermia, and hypotension.⁷ Anticholinergic effects include mydriasis, dry mucosa, absent bowel sounds, urinary retention, and cardiac arrhythmias, including tachycardia. Clinical signs reported after accidental ingestion in animals²⁶ include hyperexcitement and vomiting as early manifestations, followed by ataxia, lethargy, and muscular tremors. Bradycardia and other cardiac arrhythmias occur later. These later signs occurred shortly before death in experimental animal models of TCA toxicosis.²⁶

Treatment for TCA toxicosis is supportive, including respiratory (intubation) and cardiovascular support. Gastric lavage with activated charcoal can be used early. Emetics probably should be avoided because of the risk of aspiration pneumonia in seizuring animals (some antiemetics may further predispose the animal to seizures). Short-acting barbiturates (or similar drugs) without pre-administration of atropine are preferred for anesthetic control during gastric lavage. Cathartics (sorbitol or sodium sulfate-Glauber's salt) can be of benefit. Magnesium sulfate should not be used because impaired gastrointestinal motility can facilitate absorption of magnesium. Resolution of coma may require several days; the threat of cardiac arrhythmias likewise persists for several days. Pharmacologic interventions for cardiac arrhythmias have not been well established. Alkalinization (sodium bicarbonate sufficient to maintain blood pH above 7.5: 2 to 3 mEq/ kg, administered intravenously over 15 to 30 minutes) may prevent death by increasing protein binding and increasing cardiac automaticity (as a result of potassium shifts).²⁶ Traditional cardiac drugs, including antiarrhythmics and digoxin, are contraindicated in human patients. However, phenytoin may provide safe antiarrhythmic effects and in human patients is useful for treatment of seizures.7 Relevance to dogs or cats is not clear: phenytoin has a short half-life in dogs and is associated with adverse events when administered IV (see Chapter 27). Diazepam is indicated for acute management of seizures. β-adrenergic receptor antagonists and lidocaine

may be useful.⁷ The risk of tonic–clonic seizures is increased in human patients, particularly at high doses.

Clomipramine generally is associated with less sedation than with the other TCAs.²⁷ Systemic phospholipidosis (excessive accumulation of phospholipids in tissues) occurs with chronic administration of cationic, amphophilic drugs, including the TCAs, and fluoxetine.

Indications

The TCAs have been recommended among animal behaviorists for most abnormal behaviors manifested in dogs or cats. These include, but are not limited to, behaviors associated with fear and aggression,^{27,28} stereotypics, OCDs or self-mutilation disorders, and excessive barking. The use of clomipramine is discussed later with specific disorders. However, using an open trial, Seksel and Lindeman²⁹ reported the efficacy and tolerance of clomipramine (1 to 2 mg/kg every 12 hours for the initial dose, increased up to 4 mg/kg twice daily) in a variety of behavioral disorders in dogs (n = 24). Included in the study were OCD (n = 9), separation anxiety (n = 14), and noise phobia (n = 4). Treatment included behavior modification and continued for at least 1 month after resolution of clinical signs. Resolution to marked improvement of clinical signs was reported in 67% of the dogs, whereas 21% reported slight to moderate improvement versus no change in 12.5% (3 of 24) animals. Clomipramine discontinuation (without return of the abnormal behavior) was described as successful in five of the nine animals in which it was attempted.

KEY POINT 26-4 The tricyclic antidepressants have been recommended among animal behaviorists for most abnormal behaviors manifested in dogs or cats. These include, but are not limited to, behaviors associated with fear and aggression, stereotypes, obsessive–compulsive or self-mutilation disorders, and excessive barking.

Contraindications

The TCAs are not recommended for animals with a metabolic disease. Specific contraindications include a history of cardiac or hepatic disease, seizures, glaucoma, hyperthyroidism, and thyroid hormone supplementation.^{27,28}

Drug Interactions

The TCAs can interact with a number of other drugs. Competition for protein-binding sites with other highly proteinbound drugs can result in increased drug concentrations; however, this may be balanced by increased hepatic clearance. Drugs that affect drug-metabolizing enzymes, through either inhibition or induction, also affect the clearance of TCAs. The sequelae of the impact are difficult to predict because active metabolites similarly are affected. In general, however, drugs that inhibit metabolism are likely to result in greater drug accumulation and increased risk of toxicity. TCAs and other antidepressants also can compete with other compounds for metabolism. The drugs themselves may affect metabolism of other drugs. Clomipramine inhibits the metabolism of other drugs; but a more relevant interaction may be the impact of other drugs on the metabolism of clomipramine (e.g., cimetidine).⁷ The antidepressants potentiate the effects of sedative drugs. The TCAs should not be used in combination with other drugs that modify CNS NTs. Included are MAO inhibitors and amitraz.^{27,28} In human patients a potentially lethal interaction has been reported when a TCA, particularly one that inhibits serotonin uptake, is combined with an MAO.⁷ The term *serotonin syndrome* has been applied to this interaction, which is characterized by restlessness, muscle twitches, hyperreflexia, shivering, and tremors.³⁰ Drugs or herbal products whose combination might result in the serotonin syndrome are indicated in Table 26-2.

Clinical Use

Most drugs take 2 to 3 weeks for clinical efficacy to be realized. The exception might be amitriptyline, which may cause a response in 3 to 5 days; however, maximum response may take longer, particularly in cats, for which the half-life may be long.²⁷ Dogs can respond to clomipramine in 1 to 2 weeks. In an approval study, clomipramine (Clomicalm) treatment

	Drugs or Supplements Whose Combined Use Increases the Risk of Serotonin Syndrome			
Drug Class	Interacting Drug Class	Example Drugs		
Monamine oxidase inhibitors	Tricyclic antidepressants	Amitriptyline		
		Imipramine		
		Clomipramine		
	Miscellaneous	Isocarboxazid		
		Phenelzine		
Serotonin uptake inhibitors	SSRI	Fluoxetine		
		Fluvoxamine		
		Paroxetine		
		Sertraline		
		Citalopram		
	Serotonin and norepin-	Trazazone		
	ephrine uptake inhibitors			
Bupriopion		Venlaflaxine		
Opioids		Fentanyl		
		Mepiridine

with behavior modification improved separation anxiety in dogs compared with behavior modification alone (according to package insert). King and coworkers^{31,32} (manufacturer sponsored studies) studied the efficacy of clomipramine for treatment of separation anxiety in dogs. Using a parallel, randomized, double-blinded design, researchers gave dogs with "hyper attachment" behavior (n = 97) either a low dose (0.5 to 1 mg/kg twice daily; n = 25), a standard dose (1 to <2 mg/kg twice daily; n = 28), or no dose of clomipramine (n = 32) along with behavior therapy for 12 weeks. At each of three assessment periods, treatment dogs responded better, and overall, to therapies three times more rapidly than nontreatment dogs in all behaviors (destructive or inappropriate elimination) with the exception of vocalization. Among the treatment dogs was an epileptic; this dog had no seizure episodes during the treatment period. Differences in the frequency of side effects among treatment groups were vomiting and gastritis, which occurred in 13/25 and 8/28 dogs in the low and standard group, respectively, compared with three in the placebo group, and lethargy or sleepiness in four of the standard group compared with two in the other two groups. Interestingly, one healthy dog collapsed with hyperthermia (111°F) and disseminated intravascular coagulopathy. No other underlying illness was reported; the dog survived the episode, but clomipramine was discontinued. In their follow-up questionnaire-based study,³² 12 dogs continued to receive clomipramine long term (13 to 16 months or more), with 10 of these dogs improving further. No increases in adverse events were identified. Behavior changes were also studied in dogs for which the drug was either discontinued (n = 48) or had not been administered within 4 months of the questionnaire (n = 16). However, the data are confounded by the use of other behavior-modifying drugs. Behaviors worsened in the first 2 weeks after therapy was discontinued in three of ten dogs receiving low-dose clomipramine; however, no dogs in the standard-dose group exhibited clinical signs potentially consistent with withdrawal. For treatment groups, after 2 weeks behavior worsened in 13% to 15% of dogs compared with 23% of dogs receiving placebo. Six of nine dogs for which clinical signs worsened had not responded totally to therapy during the trial, whereas three of nine had been considered successes. The time to worsening was longest for the standard dose group. On the basis of response to clomipramine, the authors raised the possibility that treatment accompanied by behavioral therapy might allow permanent control.

Clomipramine has been studied for acute management of anxiety in dogs. Frank and coworkers³³ prospectively studied transport-induced stress in Beagles treated with clomipramine (2 mg/kg twice daily for 7 days). Compared with placebo, treatment only tended to reduce clinical signs of panting or drooling; however, cortisol concentrations increased less in treated versus untreated controls after three 1-hour trips.

Therapeutic drug monitoring may facilitate the safe and effective use of the drugs. In human patients plasma concentrations that range between 100 and 250 ng/mL are most likely to cause satisfactory antidepressant effects; toxicity can be expected at concentrations above 500 ng/mL, with fatal consequences likely as concentrations approach 1000 ng/mL.⁷ Variability among human patients (and presumably among animals) supports the use of monitoring to guide therapy. Monitoring to avoid toxicity is, however, complicated by the recognition that serum concentrations by themselves are not reliable predictors of toxic responses. Because of the risk of withdrawal associated with physical dependence, discontinuation of TCAs should occur over a week or longer if therapy has been prolonged.⁷

Selective Serotonin Reuptake Inhibitors Structure–Activity Relationships and Mechanism of Action

The SSRIs enhance CNS serotonin by blocking presynaptic neuronal uptake (see Figure 26-1). They may also increase postsynaptic receptor sensitivity.3 Among the drugs currently approved for use in humans are fluoxetine, paroxetine, sertraline, and fluvoxamine. Of these, sertraline appears more potent (see the discussion of monitoring).⁷ Potency of fluoxetine for 5-HT receptors is similar to that of amitriptyline, but much less than that of amitryptyline for adrenergic, histaminic, muscarinic, opiate, or dopaminergic receptors. Consequently, fluoxetine is considered selective for serotonin. Because of their selectivity for serotonin uptake, the diverse effects that characterize TCAs are generally absent with SSRIs. Fluoxetine is prepared as a 50:50 racemic mixture; enantiomers are equally potent for 5-HT receptors although it is not clear if this is true for all species. However, for the metabolite (also racemic), the S metabolite isomer is fourteenfold more potent than the R isomer for 5-HT receptors.34

The lag time described for maximal efficacy of fluoxetine may reflect, in part, its impact on serotonin reuptake: Initially, increased serotonin in the somatodendritic area leads to $5-HT_{(1A)}$ downregulation or desensitization. Aznavour and coworkers³⁵ described response of 5-HT_(1A) receptors in the brains of cats to acute and chronic administration of fluoxetine. Described as the primary target of SSRI, these receptors are autoreceptors that inhibit the firing and release of serotonin by the neurons they regulate. They are activated in response to increased serotonin concentrations in the synapse associated with SSRI treatment. Their ability to inhibit 5-HT neuronal firing and release, however, is muted by desensitization associated with acute SSRI (or other agonist) therapy. Although initially transient, in 2 to 3 weeks this desensitization allows a return to baseline firing and release and is paramount for successful therapy with SSRI. The acute desensitization probably reflects internalization of the autoreceptors. In cats therapy with 5 mg/kg fluoxetine intravenously resulted in a marked decrease in 5HT_(1A) binding in the nucleus raphe dorsalis but not other regions of the brain. However, with chronic administration (5 mg/kg subcutaneously per day for 3 weeks), binding was not altered in any region of the brain, indicating that 5-HT₁ autoreceptors are fully desensitized and 5-HT neuronal firing returns to baseline, at least in healthy cats.

KEY POINT 26-5 A lag time should be expected for the maximum effect of selective serotonin inhibitors, particularly for drugs (and their active metabolites) characterized by long elimination half-lives.

Clinical Pharmacology

As with the TCAs, the clinical pharmacology of the SSRIs is complicated. Plasma concentrations thought to be effective for human patients range from 100 to 300 ng/mL for fluoxetine (and its active metabolites). Effective concentrations for paroxetine and sertraline are 30 to 100 and 25 to 50 ng/mL, respectively.⁷ Fluoxetine disposition is characterized by high protein binding, metabolism to an active compound, long elimination half-life of both parent and metabolite, a delayed onset of action, and drug interactions.⁷ For both the dog and the cat, because the active metabolite norfluoxetine represents a substantial, if not dominant, portion of the AUC (exposure), response to therapy cannot be evaluated at least until both fluoxetine and its metabolite reach steady state (approximately 10 to 14 days).

Fluoxetine is available as a chewable tablet approved for use in dogs. A number of efficacy studies were implemented during the approval process. Pasloske³⁴ reviewed fluoxetine disposition in dogs and cat in abstract form. In Beagles, after administration of a single 1 mg/kg dose, oral bioavailability averaged 72%, yielding a C_{max} for fluoxetine of 49 ng/mL at 1.8 hours, and for norfluoxetine 79 ng/mL. As in humans, the volume of distribution for fluoxetine is large in dogs, averaging 39 L/kg, reflecting accumulation that approximates a 100-fold increase compared with plasma in some tissues. Despite the very large volume of distribution of fluoxetine, elimination half-life averaged between 6 and 10 hours in Beagles. Norfluoxetine is the major metabolite formed from hepatic metabolism, accounting for more than 56% of the total peak area in dogs. The volume of distribution of norfluoxetine is one third of that for fluoxetine, at 10.7 L/kg, yet the elimination half-life of 48 to 57 hours for the metabolite is much longer than that of fluoxetine. The shorter half-life of fluoxetine compared with that of its metabolite reflects, in part, fluoxetine clearance, which, at 6 mL/kg/min, is threefold higher that that for norfluoxetine at 2 mL/kg/min.³⁴ The AUC for the S-isomer of fluoxetine (14 times more potent than R) was threefold higher than that for the R-isomer.

The disposition of fluoxetine also has been reported in cats receiving 1 mg/kg. Oral bioavailability approximates 100%; C_{max} is 83 ng/mL (at approximately 2 hours), compared with 25 ng/mL (at 40 hours) for norfluoxetine. The elimination half-life (0.5 mg/kg intravenously) of fluoxetine in cats is 34 to 47 hours, which is much longer than that in dogs. The volume of distribution in cats is smaller (by 50%) than that in dogs (18 L/kg), whereas clearance is similar (6.4 L/kg). The metabolite has a much larger volume of distribution compared with the parent in cats (32.6 L/kg), resulting in a longer elimination half-life (51 to 55 hours) for the metabolite (although clearance is similar to the parent at 7.4 mL/kg/min).

Whereas gradual withdrawal may not be necessary for fluoxetine because of its long half-life (including the metabolite), the same is not true for paroxetine, sertraline, or fluvoxamine. Several weeks of decreasing dosing should follow chronic dosing.

Fluoxetine has been studied after administration of a single dose as a PLO transdermal gel in cats (n = 12) at either 5 or 10 mg/kg, compared with 1 mg/kg orally.³⁶ For oral administration C_{max} of 94.8 ± 34 ng/mL was achieved at 8.5 ± 2.9 hours, with AUC being 5.4 \pm 2.4 μ g*hr/mL. This compares to a C_{max} of 23 ± 20.2 at 51 ± 28 hours for 5 mg/kg transdermal (AUC = 2.9 \pm 1.8) and 33 \pm 9.1 (C_{max}) at 87 \pm 34 hours (AUC of 5.4 \pm 0.5 μg*hr/mL) at 10 mg/kg. Although this study demonstrated systemic absorption of fluoxetine that approximated oral administration after transdermal administration (at 10 times the oral dose), single doses may not have been sufficient to generate therapeutic concentrations. Further, the variability in drug concentrations achieved was substantial, suggesting that absorption may not be predictable among animals. Because both the parent compound and metabolite have a long halflife in the cat, accumulation to effective concentrations may increase the potential efficacy after transdermal administration. Monitoring of the parent compound to document drug absorption after transdermal delivery should be considered. Although cats in this aforementioned study tolerated a single 10 mg/kg transdermal dose well, a second study of multiple dosing was terminated because of substantial dermal irritation after several days of therapy.7,36

Drug Interactions

Fluoxetine may inhibit its own metabolism through inhibition (both parent and metabolite) of CYPIID6-mediated demethylation.³⁴ The SSRIs also can inhibit the metabolism of other drugs; the order of potency of inhibition is paroxetine>norfluoxetine>fluoxetine=sertraline. Because of the risk of drug interactions, SSRIs should not be used in combination with other antidepressants (see earlier discussion of serotonin syndrome and drug interactions of TCAs and MAO inhibitors).⁷ Fluvoxamine minimally affects drug metabolism.

Side Effects

As a class, the SSRIs are generally considered safer than TCA in humans. Exceptions may occur for clomipramine in dogs. Unlike the TCAs, SSRIs have minimal effects on the cardiovascular system.⁷ Their safety for patients with underlying cardiac disease has not, however, been established. Sedation is not a common side effect and is least likely with fluoxetine.³ In humans gastrointestinal side effects are the most common, occurring in as many as 25% of patients receiving the drug.³ Their incidence is minimized by starting with a low dose and gradually increasing the dose until efficacy is evident.

Toxicity of fluoxetine has been studied in both dogs and cats.^{34,37} Steinberg and coworkers³⁷ found no adverse cardiovascular effects of fluoxetine in anesthetized dogs, concluding that it was thus safer than tricyclic antidepressants. Beagles survived up to 100 mg/kg when fluoxetine was administered as a single dose, although emesis, mydriasis, tremors, and anorexia occurred. In contrast, with multiple dosing dogs could not tolerate 10 to 20 mg/kg orally per day for 6 months.³⁴ Intolerance was manifested as tremors, anorexia, slow or incomplete pupillary response, mydriasis, aggressive behavior, nystagmus, emesis, hypoactivity, and ataxia. Aggressive behavior and anorexia also were evident. All of the physical signs of toxicity were reversible within 2 months of drug discontinuation. Tremors, slow or incomplete pupillary response, and occasional anorexia may be present at 1 mg/kg. Histologically, phospholipidosis occurred in the lung, liver, adrenals, lymph nodes, spleen, and peripheral leukocytes at 20 mg/kg and occasionally in the lung and leukocytes at 1 mg/ kg. Cats receiving a single dose of 50 mg/kg also developed emesis, mydriasis, tremors, and anorexia. Oral administration to cats of 1 and 3 mg/kg once daily was well tolerated, although sporadic anorexia and vomiting occurred occasionally at 3 mg/kg. At 5 mg/kg daily, toxicity appeared at approximately 60 days and was manifested as body tremors, hypoactivity, convulsions, low food consumption, and dehydration. In contrast to dogs, for which cardiovascular depression did not occur, heart rates decreased in a non-dose-dependent manner in cats. Infiltration of alveolar macrophages, consistent with phospholipidosis, occurred at 3 and 5 mg/kg daily. At 5 mg/ kg, centrilobular hepatocellular degeneration and decreased T-lymphocytes were detected.

Side effects also have been reported in animals after clinical use. In 4 of 14 dogs receiving fluoxetine for treatment of lick granuloma,³⁸ side effects included lethargy, anorexia, and hyperactivity. Another study³⁹ reported the same side effects as well as polydipsia, diarrhea, and increased or decreased appetite. At least 50% of animals appeared to develop some type of side effect, although side effects were described as mild. Side effects reported by owners in a study of fluoxetine for treatment of canine dominance-related aggression included fatigue, lethargy, and decreased appetite.⁴⁰

A very early study⁴¹ demonstrated that fluoxetine potentiates morphine hyperthermia in cats. Although SSRIs are considered stimulatory in the sense that serotonin increases and might thus be considered proconvulsant, Jobe and Browning⁴² argued that they may, in fact, be anticonvulsant and that deficiencies in norepinephrine and serotonin contribute to proconvulsant tendencies.

Citalopram is the most recent SSRI to be approved for use in the United States. However, its approval was delayed after a study in which 50% of dogs receiving 8 mg/kg as part of a preapproval toxicity study (for humans) died as a result of cardiac side effects at 17 to 31 weeks of therapy. Therefore the drug probably should not be used in dogs. Diarrhea is a side effect reported for both paroxetine and sertraline. Paroxetine may be more likely than fluoxetine to cause anticholinergic side effects.⁴ Initiating therapy with a low dose that is increased after the first week of therapy may prevent this side effect. Paroxetine also is associated with an idiosyncratic, dose-dependent increase in arousal, awakening, and rapid eye movement suppression in dogs.⁴

Clinical Indications and Use

Clinical use also is addressed with specific indications. Probably no behavior-modifying drug has received more attention in the veterinary and lay literature than fluoxetine.^{43,44}

Despite the plethora of opinions or testimonials regarding the efficacy of this drug for treatment of animal behavioral disorders, few scientific studies existed until its approval in dogs. Efficacy for treatment of lick granulomas is supported by a double-blind crossover study.³⁸ One third of the animals studied did not repeat the abnormal behavior when fluoxetine was discontinued. Fluoxetine also has been studied in an open (nonblinded) study of dogs with a variety of behavioral problems.³⁹ Approximately 65% of dogs with lick granuloma, 100% of animals with separation anxiety, and 85% of animals with tail mutilation disorders responded to fluoxetine. Unfortunately, data were not controlled for other treatments, making interpretation of the success of fluoxetine in this study difficult. The Freedom of Information Act file delineates several clinical trials of field studies that support its use. In a European study, doses of 1 to 4 mg/kg for 2 to 4 weeks were associated with improvement in 80% of dogs (n = 47) with separation anxiety. The most frequent adverse reactions were anorexia, weight loss, constipation, mydriasis and muscle tremors; clinical signs were considered unacceptable at 3 mg/kg. A field trial found improvement compared with control (n = 112) in dogs (n = 117) with separation anxiety treated for 56 days with fluoxetine therapy (1 to 2 mg/kg). All dogs received behavior modification. One dog in the control and three in the treatment groups developed seizures. Seizures developed 10 days after the end of therapy in one dog (this dog eventually died as a result of seizures), 45 days into therapy and 24 days into therapy. Simpson and coworkers⁴⁵ and Landsberg and coworkers⁴⁶ reported on the efficacy of fluoxetine for treatment of separation anxiety based on manufacturersponsored studies. A multicenter placebo-controlled, parallel double-blinded study was implemented in dogs (n = 208) with separation anxiety using fluoxetine (1-2 mg/kg) as a chewable tablet; treatment occurred for 6 weeks. At each week, dogs in the treatment group had improved compared with those receiving placebo; improvement occurred even in those dogs not receiving behavior modification. Destructive behavior and inappropriate urination were reduced. Seizures occurred in one dog in each group.

Fluoxetine also has been used successfully to treat psychogenic alopecia in a cat,⁴⁷ dominance aggression in dogs,⁴⁰ and inappropriate urination in cats.⁴⁸ As with TCAs, monitoring to guide therapy with SSRI is complicated. Effective concentrations have not been established in animals and must be extrapolated from human studies. The relationship between plasma drug concentrations and therapeutic efficacy has not been well established³ and is complicated by the presence of the active metabolite, which cannot be predicted by the parent compound. Paroxetine and fluvoxamine have no active metabolites (in human patients). One advantage of paroxetine over fluoxetine in veterinary medicine is convenience in dosing with the availability of multiple tablet sizes and scored tablets.

Atypical Antidepressants

Trazodone is a mixed serotonergic agonist-antagonist used to treat sleep disorders and major depression in humans. It is characterized by a wide therapeutic range (typical drug concentrations in humans after administration of the recommended dose are 800 to 1600 ng/mL.⁷ The likelihood of drug interactions appears to be limited, despite the fact that it is an inhibitor of CYP2D6 metabolism. It has been used in dogs to treat mild thunderstorm phobias either as sole therapy or in combination with a TCA or SSRI. It does not appear to be effective, even at high doses (10 mg/kg), for treatment of severe thunderstorm phobias in dogs. Side effects reported in dogs include vomiting, diarrhea, and sedation. Initiating therapy at a low dose with a gradual increase may minimize this side effect.

Monoamine Oxidase Inhibitors

Structure–Activity Relationships

The recognition that the antitubercular drug isoniazid tended to elevate the mood of patients receiving the drug for treatment of tuberculosis led to further discovery of drugs that inhibit MAO. The first drugs used were structurally related to hydrazine and were associated with marked hepatotoxicity. An attempt was made to synthesize CNS-stimulant compounds unrelated to hydrazine but similar to amphetamine. Ultimately, selegiline was a result of this later effort.⁷

The MAO inhibitors potentially affect a variety of monoamines by inhibiting mitochondrial MAO and the subsequent degradation of monoamines, most notably dopamine (see Figure 26-1). Most of the clinically relevant drugs are nonselective toward two major enzyme groups⁷ that are characterized by different substrate specificities. MAO-A prefers serotonin and is inhibited by clorgyline, an MAO-A-selective inhibitor, whereas MAO-B prefers phenylethylamine and is inhibited by selegiline (deprenyl). Selegiline is the only currently used MAO inhibitor characterized by selectivity. The drug targets MAO-B and is relatively selective for dopamine. It is approved for use in dogs for treatment of pituitary-dependent hyperadrenocorticism (purported to be a dopamine deficiency) and cognitive dysfunctions. Binding to the MAO is irreversible, and recovery from effects requires synthesis of new enzyme. In human patients this appears to require 1 to 2 weeks. Metabolism occurs more slowly in geriatric patients.7

Pharmacologic Effects

The potential antiepileptic effects of selegilinle^{49,50} are briefly addressed in Chapter 27. The behavioral effects of the MAO inhibitors occur on systems affected by sympathomimetic amines and serotonin. Although as a class the MAO inhibitors inhibit a number of enzyme systems other than MAO, generalizations to the class do not necessarily apply to selegiline. Selegiline potentiates dopamine in selected neurons and has been approved to treat Parkinson's disease in humans and cognitive dysfunctions in animals, conditions assumed to be associated with dopamine deficiency. Selegiline also scavenges oxygen radicals and reduces neuronal damage caused by reactive products of oxidative metabolism of dopamine or other compounds.⁷ A delay in the therapeutic effect of up to 2 or more weeks characterizes the use of selegiline. Reasons for the delay are not known.⁷

Clinical Pharmacology

The MAO inhibitors are readily absorbed after oral administration. Maximal inhibition occurs within 5 to 10 days. Despite a long biologic activity, efficacy appears to decrease in human patients if the drugs are administered at an interval longer than 24 hours.⁷ Selegiline is metabolized to L-amphetamine and L-methamphetamine in dogs and, along with an increase in CNS phenylethylamine, may contribute to clinical and side effects of selegiline.

Side Effects and Drug Interactions

Selective MAO inhibitors appear to be safe. Severe and potentially fatal interactions have, however, been described when MAO inhibitors were combined with other antidepressants. Particularly problematic is the combination of MAO inhibitors with drugs that inhibit the reuptake of serotonin (see earlier discussion of serotonin syndrome with TCAs). Amitraz also is an MAO inhibitor and should not be used concurrently with selegiline. Other drugs with which MAO inhibitors may interact include meperidine and precursors of biogenic amines. Selective MAOs such as selegiline are not necessarily safer than the older or nonselective inhibitors when combined with other drugs. Hypertensive crisis, a serious side effect that occurs when aged cheeses containing tyramine (a bacterial monoamine by-product) are ingested in the presence of nonselective MAO inhibitors, does not occur with selective MAO inhibitors such as selegiline.

KEY POINT 26-6 Although safe as sole agents, a number of drugs will interact with monoamine oxidase inhibitors, increasing the risk of toxicity.

Anxiolytics

Pharmacology

The primary anxiolytics used in veterinary medicine are the benzodiazepines (see Chapter 27 for more extensive discussion), including diazepam, its metabolite oxazepam, clorazepate (metabolized in the stomach to N-desmethyldiazepam, a major metabolite of diazepam), lorazepam, alprazolam, and clonazepam. Differences in the drugs largely reflect pharmacokinetic characteristics, although alprazolam is classified as a high potency drug. The assumed mechanism of action of these drugs is gabaminergic through interaction with the GABA_A receptor. The anxiolytic effects are separate from the general CNS depressant effects caused by these drugs. Their central effects are somewhat dose dependent. Sedative effects occur at low doses; as a result, excitement is tempered. Antianxiety effects are evident at moderate doses, being beneficial to social interactions. At high doses hypnotic effects become evident. Sedation becomes profound at high doses, ataxia is evident and sleep is facilitated.¹ Decreased skeletal muscle activityparticularly of value in animals experiencing seizures-is central in nature and is independent of sedative effects. Cats appear to be more prone than dogs to muscle relaxation.¹ Benzodiazepines may distribute differently in cats, with extensive binding of diazepam and its major metabolite, desmethyldiazepam, in the brain.⁵¹

The disposition and tolerance to and withdrawal of most of the benzodiazepines are discussed in Chapter 27. The effects of the benzodiazepines reflect in part metabolism to active, inactive, and potentially toxic metabolites. If efficacy reflects formation of an active metabolite (e.g., desmethyldiazepam), accumulation may be necessary before maximum effects are seen. Accumulation will be more likely with twice-daily dosing. The elimination half-life of many benzodiazepines in general is short. Efficacy can be prolonged by metabolism to active metabolites (in humans). Shorter-acting compounds include clorazepate and midazolam. Intermediate half-life drugs such as oxazepam, lorazepam, chlordiazepoxide, and alprazolam have no active metabolites. Longer-acting benzodiazepines include diazepam and clonazepam. Alternatively, clorazepate is available as a sustained-release product that can be administered less frequently.

Tolerance develops to the anticonvulsant and sedative effects of many benzodiazepines (see Chapter 27). Tolerance appears less likely to develop to the anxiolytic effects of these drugs.³ In contrast, withdrawal can accompany rapid discontinuation of the drug. Thus doses should be tapered gradually (e.g., 25% per week) as the drug is discontinued.^{1,3}

The cat has served as a sleep model for studies investigating the effect of therapeutic agents on sleep cycles in humans. Accordingly, a fair amount of dated literature is available regarding the use of benzodiazepines in cats. Although routes (e.g., intraperitoneal, which avoids first-pass metabolism) and doses are not always relevant to therapeutic use in cats, some information might be gleaned from the studies. For example, whereas flurazepam (1.25 to 2 mg/kg intraperitoneally) depresses reticular formation activity for 72 hours or more,⁵² tolerance develops even after one dose, and dependence (resulting in withdrawal signs) was maximal in 7 days.⁵³ Because of the diverse impact of benzodiazepines on CNS activity (including efficacy, tolerance, and withdrawal) and the variability that characterizes their disposition (e.g., variable first-pass metabolism, variability in the activity and half-life of metabolites), the use of this class of drugs, perhaps more so than others, should be based on scientific studies that establish not only pharmacokinetics but also acute and chronic pharmacodynamic responses.

Side Effects

In addition to changes in behavior, the benzodiazepines have been associated with a number of side effects in human patients. Reaction may be to the parent drug or a metabolite. Long-term use in human patients has been associated with neutropenia and liver disease. Acute fulminating hepatotoxicity has been reported in cats receiving diazepam orally.⁵⁴ Clinical signs include anorexia, vomiting, lethargy, hypothermia, and jaundice. The adversity appears to be dose dependent (and thus may be idiosyncratic), occurring in most animals within 5 to 11 days after therapy is begun. Mortality rates are high (8 of 11 cats in one report) despite intensive therapy. Histology revealed severe acute to subacute lobular to massive hepatic necroses, suppurative cholangitis, and biliary hyperplasia. Baseline hepatic function data might be collected

from cats before therapy is begun and again 3 to 5 days after therapy is begun in order to minimize the damage induced by diazepam administered to cats at risk. Any evidence of illness (or evidence of prolonged elimination) should lead to discontinuation of the drug. Clorazepate used in combination with phenobarbital in dogs for control of seizures has, in the author's experience, also been associated with liver disease. Tolerance will generally develop toward ataxia and sedation, which may accompany initial therapy. Paradoxical hyperactivity may require transitioning to another class of anxiolytics.⁴ Drug withdrawal should be gradually tapered for any benzodiazepine administered for more than 1 week, particularly for high-potency drugs such as alprazolam. The duration of withdrawal should be in proportion to the duration of therapy. Care should be taken not to miss doses, particularly with highpotency drugs such as alprazolam; twice-daily administration may be necessary to avoid clinical signs of withdrawal.

The Animal Poison Control Center of the American Society for the Prevention of Cruelty to Animals has reported alprazolam toxicity in dogs. Clinical signs developed within 30 minutes of ingestion and included ataxia/disorientation, depression, hyperactivity, vomiting, weakness, tremors, vocalization, tachycardia, tachypnea, hypothermia, diarrhea, and increased salivation. In addition to supportive treatment, flumazenil was suggested to counter severe CNS depression.⁵⁵

Clinical Indications

The benzodiazepines are less desirable as behavior-modifying drugs because of their nonspecific nature.¹ Thus a notable disadvantage of the long-term use of benzodiazepines is their tendency to interfere with the ability to learn in animals undergoing behavior modification as part of their treatment program.^{4,56} Animals may forget previous learned behaviors. An exception can be made for chlordiazepoxide, which appears to facilitate operant conditioning in nervous dogs (e.g., Pointer).³ Paradoxical reactions may occur in some animals, including rage, hyperexcitability, and anxiety. In addition, the risk that pet owners may use the animal's drug should lead to close scrutiny of the animal's drug needs and use.

KEY POINT 26-7 The short half-life and nonspecific nature of benzodiazepines decrease their efficacy as behavior modifiers.

Benzodiazepines are indicated for the treatment of anxiety. Alprazolam and clonazepam may be associated with fewer side effects and might be preferred¹; however, fewer reports exist regarding their use in animals. The benzodiazepines are contraindicated in aggressive patients.¹ Simpson and Simpson³ noted that the contraindication may depend on the cause of aggression. If aggression is a manifestation of an underlying fear or anxiety, then the benzodiazepines may reduce aggression. If, however, anxiety or fear is masking aggression, the benzodiazepine may increase aggression. Other indications for benzodiazepines include treatment of inappropriate elimination,¹ noise phobias, and selected anxieties such as visits to the veterinarian.^{1,3} Oxazepam and lorazepam are not metabolized to active metabolites; as such, their use might be preferred in patients with liver disease.

Anxioselective Drugs: Azapirones (Buspirone)

Structure–Activity Relationships

Buspirone also is referred to as a nonspecific anxiolytic. Members of this group were specifically developed for atypical depressions, nonspecific generalized anxiety disorders, and selected OCDs. Buspirone is the first nonsedating antianxiety drug to be marketed.³ Its effects appear to reflect blockade of 5-HT₁ receptors at both presynaptic and postsynaptic sites. Presynaptic inhibition increases serotonergic activity when serotonin is low, whereas postsynaptic control reduces serotonin when it is high.³ Buspirone will cause downregulation of 5-HT receptors. In addition, it will act as a dopamine agonist throughout the brain.³ Maximum efficacy may require several weeks.⁴

Side Effects

In contrast to benzodiazepine anxiolytic drugs, buspirone has no sedative, muscle relaxant, or anticonvulsant actions. It does not impair motor performance.³ Side effects to buspirone manifested in cats include increased aggressiveness (toward other household cats), increased affection toward owners, mild sedation, and agitation.⁵⁶ Vomiting and tachycardia also have been reported.⁵⁶ In contrast to the anxiolytic drugs and TCAs, buspirone is associated with a low abuse potential. Withdrawal symptoms after discontinuation of the drug apparently do not occur.¹ Because it is not metabolized by CYP enzymes, drug interactions are less likely compared with other behaviormodifying drugs.

Clinical Indications

Buspirone has been used to treat canine aggression, canine and feline stereotypic behaviors, self-mutilation, OCDs, thunderstorm phobias, and feline spraying.¹ Buspirone apparently has been particularly useful for treatment of anxiety associated with social situations such as aggression or marking behaviors.¹ One week of therapy may be sufficient to evaluate the drug. Buspirone might be used in combination with other drugs that target reuptake of serotonin, particularly if intraneuronal serotonin is depleted.⁴

Transdermal delivery of buspirone does not appear to be a reasonable method of administration in cats. Drug concentrations were not detectable in circulation in cats (n = 6) receiving a single dose of 2.5 mg transdermally as a PLO gel. This compared with a mean peak concentration of 3.5 + 5.5 ng/mL after oral administration of 2.5 mg.²⁴ Although a therapeutic range has not been established, typical drug concentrations after administration of a recommended dose in humans approximate 75 to 100 ng/mL.⁷

Miscellaneous (Nonspecific) Drugs Used To Modify Behavior

Progestins

Progestin interaction with GABA receptors is 10 to 50 times more potent than that of barbiturates.¹ This may account for the nonspecific calming effects of the drugs observed in veterinary medicine. The advent of newer behavior-modifying drugs (e.g., TCAs, SSRIs) and the incidence of side effects largely limit the use of progestins to animals that have failed other medications and are faced with euthanasia.

Several side effects have been well documented in animals receiving progestins for long periods. Among the more notable side effects, because of their magnitude or life-threatening nature, are gynecomastia, mammary gland neoplasia, diabetes mellitus, aplastic anemia, and pyometra.^{27,28} Animals should be monitored frequently for evidence of adversities.

Progestins are most wisely reserved for adjuvant shortterm therapy until the second drug takes effect (i.e., 4 to 6 weeks), and only the oral form is recommended. The progestins also are an alternative for animals in whom euthanasia is being considered; in such cases, a high dose (4 mg/kg orally every 24 hours) has been recommended in order to stimulate a rapid response.²⁷

Anticonvulsants

A number of anticonvulsant drugs have been used to treat behavioral abnormalities. The most notable used for animals include the barbiturate phenobarbital (and its congener primidone) and phenytoin, a hydantoin derivative. Their use has been somewhat efficacious for treatment of overactive or aggressive behaviors (which actually may have been an expression of psychomotor epilepsy).¹ Efficacy is, however, generally dependent on administration of sedative (and, with long-term use, potentially toxic) effects. More notably, their use has largely been replaced by the TCAs or SSRIs. The side effects of these drugs (discussed in Chapter 27) limit their long-term use, although monitoring (as with anticonvulsant therapy) may help prevent toxicity.

Phenytoin has been useful for the treatment of explosive aggression in human patients. Phenobarbital may prove useful for controlling excessive feline vocalization during car travel¹ or canine aggression.⁵⁷ Carbamazepine (an iminodibenzyl derivative of imipramine) also has been used to treat explosive aggression in humans. Valproic acid may be useful for treatment of aggression.⁵⁷

Opioid Agonists and Antagonists

The drugs are discussed more in depth for pain control (see Chapter 28). The antagonists in particular have proved useful in the treatment of selective OCDs in humans. Efficacy also has been reported to treat selected self-mutilation disorders in dogs (e.g., acral lick dermatitis or lick granuloma).^{1,3,57} Pure antagonists, including naloxone and naltrexone, the latter an orally bioavailable product, and mixed agonists-antagonists such as pentazocine appear effective. These drugs block mu and kappa receptors. The assumed mechanism of action is blockade of self-reward mediated by endogenous opioid release that may accompany self-destructive behavior. Using a double-blind crossover study, a single dose of naloxone (1 mg/ kg subcutaneously) decreased excessive grooming behavior in cats (n = 12) for 2.5 to 24 weeks (median 12 weeks). Likewise, a single dose of haloperidol (2 mg/kg intravenously) decreased grooming behavior, with effects lasting 16 weeks in 6 of 10 cats. The authors postulated that efficacy of naloxone might be limited only to recently developed stereotypic behaviors, whereas haloperidol might be effective for more chronic behaviors.⁵⁸ Hydrocodone (for destructive behaviors) and naloxone and haloperidone (for OCDs) have shown some efficacy for treatment of behavioral disorders. Dextromethorphan, a non-narcotic opioid, also is an N-meth-D-aspartate receptor antagonist (see Chapter 28) and has shown some efficacy for OCDs. Dodman and coworkers⁵⁹ prospectively compared the effect of dextromethorphan (2 mg/kg orally twice daily) with placebo for treatment of chewing or excessive grooming in dogs (n = 14) with chronic allergic dermatitis. A randomized double-blinded crossover design was used for each 2-week phase of the study. The percentage of time that abnormal behaviors and pruritus were observed was less in dogs in the treatment group.

Antihistamines

The mildly sedative (e.g., with hydroyzine) or hypnotic (e.g., with diphenhydramine) effects caused by H_1 receptor blockade can be of benefit for some behavioral disorders. These drugs are discussed in greater depth as antiinflammatories (see Chapter 29) and antiemetics at the vestibular apparatus (see Chapter 19). Indications as behavior-modifying drugs might include the treatment of chronic pruritus, late-night activity, car travel, and selected transient behaviors accompanied by pacing and vocalization.¹

β-Blockers

 β -adrenergic blockers (e.g., propranolol, pindolol) have been used in human medicine for the treatment of aggressive outbursts associated with self-mutilation or injury problems, intermittent explosive behaviors, conduct disorders, dementia, and schizophrenia.¹ The use of these drugs for similar disorders in animals has not, however, been very successful.¹ Nonselective β -blockers also have been used to treat anxiety in human beings. One animal behaviorist reports success with propranolol or pindolol (the latter also affecting serotonin receptors) for the treatment of fear aggression in dogs.⁵⁷

Stimulants

Stimulants include dextroamphetamine, methylphenidate (Ritalin), and pemoline, a drug whose actions are similar to those of methylphenidate. Stimulants are characterized by paradoxical effects in that they cause excitement in the normal patient but a calming effect in the hyperactive patient. Their indication for human patients is for the treatment of attention deficits. Conditions of hyperactivity are rare in veterinary medicine. Proper diagnosis is imperative to successful therapy with stimulants.

They act to increase sympathomimetic stimulation. Side effects include increased heart and respiratory rate and anorexia. Tremors and hyperthermia may occur. The drugs are contraindicated for patients with cardiovascular disease, glaucoma, and hyperthyroidism. The drugs should not be used in combination with other behavior-modifying drugs.¹ Methylphenidate toxicosis was described in a 10-year-old cat

treated with a 5-mg tablet. Plasma concentrations of 83 ng/mL (5 to 16 times the therapeutic range recommended in humans) were associated with restlessness, vocalizing, and circling. Treatment was environmental (external stimuli minimized); clinical signs resolved within 25 hours of ingestion.⁶⁰

Others

Pheromones are increasingly becoming popular adjuvants for the treatment of behavioral and other disorders. Their use has been reviewed.⁶¹ Pheromones used to modify behavior include Dog Appeasing Pheromone (DAP). A number of clinical trials have been performed with DAP, most showing some degree of improvement, regardless of the behavior studied. However, study design, including appropriateness of sample size, control, blinding, and randomization procedures, should be carefully critiqued as the validity of the conclusions and their application to clinical practice is considered. Taylor and Mills⁶² studied the effect of DAP (assumed to be maternal appeasing pheromone) in newly adopted puppies. Based on the number of nights puppies cried, DAP reduced the time compared with placebo, but only in gun dog breeds. Incorporation of DAP into a collar was studied as a means to reduce travel-related problems in dogs (n = 62).⁶³ The study was neither controlled nor blinded. Response was based on assessment of 21 behavioral signs assessed every 3 weeks; dogs were subjected to car rides at least twice weekly for 9 weeks. Significant improvement occurred in nine of the signs, with reduction in fear intensity the most consistent. DAP was also studied for its ability to decrease aggressive behavior associated with veterinary examination (n = 15 dogs), but no significant effect was found regarding aggression. Dogs, however, were more relaxed compared with those in the placebo group.⁶⁴ Todd and coworkers⁶⁵studied the effect on barking of DAP administered to shelter dogs treated for 7 consecutive days (n = 37 treated, 13 control). Mean barking amplitude and frequency were reduced. Responses toward strangers (e.g., sniffing frequency) also were reduced. DAP has been compared with clomipramine to treat separation anxiety⁶⁶ and noise phobias^{67,68} (see later discussions), and feline facial pheromone (FFP) has been studied for inappropriate urination (see later discussions).69

Herbals

Several herbal products have been recommended in humans for treatment of behavioral problems. Hypercium and St. John's wort have been studied in controlled trials in humans, with variable activity. Hypercium contains at least 10 active agents, with hypericin and hyperforin identified as inhibitors of amine transport. Sceletium contains mesembrine, which may be clinically active. The mechanism is not clear but appears to be different than that of traditional SSRI s on the basis of neuronal discharge in cats.⁷⁰ S-Adenyosyl methionine has demonstrated mood elevation in humans, and ginkgo biloba extract has demonstrated some effects with mild dementia.⁷ The risk of interactions between herbal products and drugs should not be ignored. The combination of herbal ingredients that target serotonin with one another or with drugs that share a similar pharmacologic effect may contribute to manifestations indicative of the serotonin syndrome.

KEY POINT 26-8 Care should be taken when combining drugs or supplements that target serotonin.

Other Considerations

Drug Combinations

For patients that are refractory to drug therapy, behavioral modification therapy, or environmental changes, combination drug therapy might be considered. Drugs should be selected on the basis of their having mechanisms that will complement one another. However, care must be taken to ensure that combined drugs do not result in adverse drug reactions as a result of drug interactions, particularly at the level of mechanism of action or drug metabolism. Particularly problematic will be the combinations of drugs and herbal agents that affect serotonin. Among the drugs most likely to be safe when combined with other modifying drugs are the benzodiazepines. Examples of combinations that may be reasonable include⁴ neuroleptic phenothiazines with drugs that target serotonin for treatment of OCDs; buspirone with SSRIs or TCAs, and combined use of beta blockers.

Newer Drugs and Therapies

Treatment of human behavioral disorders continues to be a major focus of research and development. Newer agents are likely to focus on the noradrenergic or serotonergic pathways, with selectivity for either receptor or system to be expected. The plethora of serotonin receptor subtypes should lead to drugs with increasing selectivity (i.e., 5-HT_{1A}, $_{2A}$, $_{2C}$, or 3). Example drugs selectively targeting neuronal transport of norepinephrine include levoprotiline, and a tomoxetine. Drugs classified as mixed serotonin-norepinephrine transport antagonists such are venlafaxine coupled with serotonergic drugs (thus enhancing serotonergic properties beyond SSRIs or TCAs) has led to studies of duloxetine and milnacipran, the latter an analog of buspirone. Complex atypical antidepressants include the α -2 adrenergic receptors antagonists such as mianserin and mirtazapine. MAO inhibition continues to be a focus of development, although the risk of drug interactions remains high. Other drugs of interest for potential development include drugs that target GABA-A receptors, cerebral peptides (opioids, neurokinin K), and neuroactive steroids.⁷

Mirtazapine is a piperazino–azepine antidepressant that is structurally similar to serotonin (see Figure 26-2). It is characterized by blockade of 5-HT_2 and 5-HT_3 receptors and histamine (subtype 1) receptors. Sympathetic (norepinephrine) and serotonergic (5-HT_1) actions reflect antagonism of alpha₂ autoreceptors (similar to yohimbime) and heteroreceptors (receptors that alter release of mediators other than their ligand). In humans adverse events to mirtazapine tend to be limited in part because of its target selectivity. Its actions at 5-HT_1 receptors have been referred to as *indirect agonist*. Its antiserotonergic effects contribute to its efficacy as an antiemetic, with effects similar to ondansetron. Regarding its behavioral modification, a meta-analysis comparing

mirtazapine and amitryptyline treatment for behavioral disorders in humans demonstrated equal efficacy. Mirtazapine has not yet been studied in animals. In humans disposition is complex, warranting scientific studies to support its use in dogs and cats. Oral bioavailability in humans is approximately 50%, largely owing to first-pass metabolism. In addition to plasma protein binding (approximately 85%), 40% of the drug is bound to erythrocytes. Hepatic metabolism is extensive, by way of CYP2D6 and CYP3A4.71 Approximately 50% of the AUC of active drug reflects the demethylmirtazapine metabolite (CYP3A4). However, the potency of the metabolite is only 10% to 20% of the parent compound; as such, the active metabolite contributes to only 5% to 10% of bioactivity. Elimination half-life is both gender and age dependent, ranging from 14 to 32 hours in men and 30 to 40 hours in women. Time to steady state (in humans) is 4 days. The elimination half-life is increased 33% to 40% in the presence of either hepatic or severe (but not mild) renal disease. Not surprisingly, mirtazapine is involved in a number of pharmacokinetic drug interactions, involving selected behavior-modifying drugs, as a result of pharmacokinetic (e.g., cimetidine, risperidone, fluoxetine, and amitryptyline) and pharmacodynamic (behavior-modifying drugs, diazepam) effects. In humans behavior-modifying response does not correlate with plasma drug concentrations; mean concentrations associated with response range from 5.7 to about 111 at the lowest (0.21 mg/kg) and highest (0.64 mg/ kg) effective doses, respectively. However, despite its complex disposition, mirtazapine is characterized by a wide therapeutic margin such that increased dosing is not associated with serious toxicity.⁷¹Anecdotally, mirtazapine has been used to stimulate appetite in dogs and cats.

TREATMENT OF SPECIFIC BEHAVIORAL DISORDERS

Care must be taken to distinguish behavior that is perceived to be abnormal by the pet owner and normal behavior. Pharmacologic management of abnormal behavior should be approached as an adjunct, and specifically as a facilitator, to normalizing behavior rather than as a cure. The treatment of disorders of veterinary behavior has been the topic of a 2008 Veterinary Clinics of North America conference.⁷² A number of nondrug techniques have been recommended by many animal behaviorists.^{3,73-77} Abnormal behaviors that require drug therapy should be simultaneously managed with behavior-modification training. For example, decreasing arousal and fear can facilitate learning a new behavior.^{27,28} The evidence supporting use of behavior-modifying drugs is increasing, but welldesigned clinical trials are still limited. Before a study involving pharmacologic control is accepted as guidance for management of behavioral disorders in animals, the study design must be closely scrutinized for evidence of randomization; placebo control; blinding procedures that minimize bias; equal handling of treatment groups; and perhaps most commonly overlooked, a sufficient number of animals to detect a significant difference. Outcome measures most appropriately support the study hypothesis or purpose. The inability of a study to prove a significant treatment effect should not be interpreted as no treatment groups or that the treatment groups are the same.

KEY POINT 26-9 Pharmacologic management of abnormal behavior should be approached as an adjunct, and specifically as a facilitator, to normalizing behavior rather than as a cure.

In addition to the lack of well-designed clinical trials, many of the drugs used to modify behavior can cause serious side effects, and the clinical pharmacology of the drugs increases the likelihood of adversity because of unpredictability of plasma or tissue drug concentrations. Many of the side effects may not be readily observed by the pet owner, further increasing the risk of side effects. Finally, slow response to therapy may lead to unsupervised manipulation of dosing regimens by the pet owner, again predisposing the animal to adverse reactions. Owners should be well counseled regarding the risks and benefits of behavior-modifying drugs, including potential changes in behavior that may be less desirable than the behavior targeted by the drug. Although many drugs recommended for use in dogs and cats are approved for human, but not veterinary, use, behavior-modifying drugs stand out as having potential risks of adversity.²⁶ Obtaining informed owner consent may be prudent before implementing therapy with these drugs. Caution should be taken to prevent substance abuse by pet owners.

Monitoring serum drug concentrations may be of benefit for selected drugs. Monitoring must, however, be performed in conjunction with clinical response, including both efficacy and safety. Antidepressants should be used cautiously or not at all for patients suffering from metabolic illnesses. Adequate time must be allowed before a drug or a dosing regimen is considered to fail. At least two drug elimination half-lives plus the time described to maximum efficacy for the particular drug should elapse. In general, combinations of behavior-modifying drugs should be avoided. One drug should be withdrawn, often slowly, before another is begun. A drug-free time of two drug elimination half-lives is recommended in humans before a new drug is begun. Generally, 10 to 20 days should elapse until a drug-free period has been sufficiently long for a shortacting drug and up to 6 to 8 weeks for longer-acting drugs.¹

The following description of drug therapy for selected behaviors is not intended to be a "cookbook" approach to managing abnormal behavior in dogs and cats. Rather, clinicians should familiarize themselves with the assumed behavior and its proper nondrug behavioral modification management. Clinicians should be thoroughly familiar with the drug to be used. Because indications are less clear with these drugs, an emphasis should be placed on side effects, drug interactions, and contraindications. Consultation with a veterinary behaviorist is strongly recommended before implementing any drug therapy.

COGNITIVE DYSFUNCTION

The use of deprenyl to treat cognitive dysfunction in animals is supported by the efforts of Ruehl.⁷⁸ Reported in abstract, using a randomized, placebo-controlled design, dogs (n = 199)

with cognitive dysfunction received either placebo or 0.2 mg/ kg or 1 mg/kg daily of selegiline HCl (Anipryl). Response in the higher-dose group (1 mg/kg) significantly improved compared with the placebo group; response in the lower-dose group was not reported.

Among the postulated causes of cognitive dysfunction is age-related neuropathy. Among the leading causes of neuropathy is the progressive and accumulated changes in the neuron induced by reactive oxygen species generated through normal mitochondrial aerobic respiration. Damage reflects not only direct effects caused by the radicals but also mutations in DNA and formation of aldehydes and secondary toxins.79 Accumulative damage coupled with limited regenerative capacity results in changes associated with age. A direct relationship between age and loss of oxidative scavenging ability supports the free radical theory of aging. As such, attenuation or reversal of the process might be achieved through treatment with compounds that facilitate maintenance of or an increase in radical scavenging ability. For example, Ikdea-Douglas and coworkers⁷⁹ demonstrated that 90 days of dietary antioxidant supplementation was associated with improved performance on landmark-discrimination tasks in aged (9 to 13 years) Beagles (n = 30). Improvements in behavior could be associated with concentrations of antioxidant supplementation, although the role of inflammation control could not be ruled out. Vitamin E (all-rac- α -tocopherol) was supplemented as a lipid-soluble antioxidant at low (83 ppm) to high (799 ppm) concentrations. Other supplements included vitamin C (an aqueous antioxidant), and L-carnitine and dl-α-lipolic acid as mitochondrial cofactors. Osella and coworkers⁸⁰ reported the efficacy of a neuroprotective nutraceutical (Senilife) that contains phosphatidylserine, ginkgo biloba extract, d-a-tocopherol, and pyridoxine in dogs (n = 8) with cognitive dysfunction. However, no placebo group was treated. The authors reported that animals were markedly improved, although none underwent complete remission. The use of other nutraceuticals for treatment of age-related diseases has been reviewed by others.⁸¹ Finally, efficacy of deprenyl may reflect, in part, its neuroprotectant ability through scavenging of oxygen radicals.

Canine Behaviors

Dominance-Related Aggression

Aggression appears to be related to noradrenergic, dopaminergic, and serotonergic receptors; of these, the serotonergic appear most important. Consequently, drugs that are selective for serotonin receptors may be more effective for aggression. Among the TCAs, clomipramine might be preferred. One group⁸² found no effect of amitriptyline for treatment of aggressive behaviors using both a prospective and retrospective approach. Prospectively, amitriptyline was compared with placebo using randomized, double-blind, placebo-controlled crossover design in 12 dogs; retrospectively, no treatment effect for amitriptyline was found in 27 dogs. The authors concluded, on the basis of both studies, that amitriptyline did not improve aggressive behaviors. However, their conclusion is likely to be limited by the power of the study. Variability in the underlying causes of aggression may have further

limited interpretation. Hewson and coworkers²² also reported no effect for clomipramine on dominance aggression in dogs (n = 29). Their study was well controlled and blinded, but again, the ability to detect a significant difference was not reported.

Fluoxetine, paroxetine, and sertraline are selective for serotonin uptake; among these, fluoxetine has been used in dogs for dominance aggression.⁸³ Fluoxetine (1 mg/kg orally every 24 hours) significantly decreased owner-directed aggression in eight of nine dogs in a single-blind crossover study; although "placebo controlled," placebo was administered only 1 of the 5 weeks of treatment. Behavioral modification was not included with drug therapy.⁸³

Administration of tryptophan, a serotonin precursor, has been associated with reduced aggression. Other drugs that may reduce aggression include propranolol (episodic aggression in people), carbamazepine, lithium, and phenobarbital.⁸⁴ Long-term adverse effects outweigh the potential behaviormodifying effect of progestin administration for aggression. Anxiolytic drugs may reduce dominance-related aggression if aggression is a manifestation of fear or anxiety.^{3,12} Aggression may worsen in some patients treated with benzodiazepine derivatives, however, especially if normal inhibitory mechanisms are suppressed.³ In human patients anticonvulsants have been useful for treatment of "explosive" aggression. Phenytoin and carbamazepine both have been used. In animals carbamazepine is preferred for profound aggression that has not responded to other therapy.¹ Monitoring may facilitate successful therapy; concentrations known to be effective for control of seizures in human patients (6 to 10 µg/mL) may be effective for control of aggression in animals.¹

Stereotypic Motor Behaviors, Obsessive Disorders, and Self-Mutilating Disorders

Luescher⁸⁵ has reviewed treatment of compulsive disorders in dogs and cats. Stereotypics are repetitive behaviors without an obvious goal and thus appear pointless and mindless to the observer.⁵⁷ They are usually derived from normal behaviors and may be a component of displacement behavior (reflecting an inability to perform more than one strongly motivated behavior) or a compulsive disorder. They are generally associated with chronic conflict, confinement, and sensory deprivation. OCDs are poorly defined in veterinary medicine. In humans OCDs are ritualistic and sufficiently invasive either cognitively or physically to interfere with normal function.^{1,86} They may reflect a chronic state of conflict anxiety, leading to displacement. Abnormal behaviors in animals that might be considered OCDs include stereotypic, ritualistic circling, spinning, pacing, howling, flank sucking, and fly biting; selected ingestive behaviors; polydipsia; and self-mutilation or grooming behaviors, including acral lick granuloma.^{1,2,86,87} In humans the disorders may reflect aberrant serotonin metabolism and possibly increased dopamine. Therefore treatment has focused on serotonergic metabolism. A similar approach seems to work for dogs with OCDs. A series of cases of obsessive-compulsive behaviors in dogs provides evidence of the potential efficacy of clomipramine but not amitriptyline.^{1,86} Other reports support the use of clomipramine for treatment of OCDs.^{25,89} One single-blind crossover study of lick granuloma found clomipramine but not desipramine to reduce licking by 50% in half of patients studied.²⁵ Another clinical report noted the efficacy of clomipramine, but not diazepam, naloxone, or phenobarbital, in a single dog affected with self-trauma.⁸⁸

Well-designed controlled clinical trials supporting drug therapy for OCDs or stereotypics are increasing. One welldesigned study (randomized, placebo-controlled, doubleblinded, balanced crossover) in dogs (n = 51) with canine compulsive disorder (including spinning and acral lick dermatitis) were fourfold more likely to improve (although not be cured) after 4 weeks of treatment with clomipramine.²² A retrospective study in dogs (n = 103) and cats (n = 23) with OCDs found first that compliance with behavior modification was high; second, that the combination of behavior modification and medication was associated with a marked decrease (>50%) in intensity and frequency of OCDs in most animals; and third, that clomipramine was significantly more efficacious than amitriptyline.⁸⁹

Fluoxetine has been reported as useful for treatment of OCDs or self-mutilation, including acral lick granuloma^{38,39,90} and tail mutilation.³⁹ Wynchank and Berk⁹⁰ studied the efficacy of fluoxetine (20 mg) using a randomized, doubleblinded, placebo-controlled study in dogs (n = 63); dogs were treated for 6 weeks. Both owners and veterinarians reported improvement. Clomipramine also has been studied. In an open clinical trial, clomipramine (2 mg/kg orally once daily) was associated with marked healing of acral lick granuloma in 8 of 10 dogs within 3 weeks. Dogs were studied for 6 months, with response maintained in three dogs at least 3 months after therapy was discontinued.⁹¹

The phenothiazine derivative thioridazine was reported as useful in one case of aberrant motor behavior.¹⁵

Opioid antagonists also have been reported to be effective for stereotypic behaviors in dogs manifested as self-mutilation acral lick dermatitis. Release of endogenous opioids may serve as a reward system after mutilation. Breaking the reward cycle with antagonists may resolve the behavior.^{57,87} Both naltrexone and nalmefene, pure opioid antagonists, were found to be useful. In one study self-mutilation activity significantly decreased in seven of eleven dogs and was partially effective in three more.92 On the basis of accompanying pharmacokinetic studies, concentrations of 20 to 50 ng/mL of nalmefene were considered therapeutic. The short half-life of the drug (2 to 3 hours in dogs) may necessitate frequent dosing. Using a double-blind crossover study, a single dose of naloxone (1 mg/ kg subcutaneously) decreased excessive grooming behavior in cats (n = 12) for 2.5 to 24 weeks (median 12 weeks). Likewise, a single dose of haloperidol (2 mg/kg intravenously) decreased grooming behavior, with effects lasting 16 weeks in six of ten cats. The authors postulated that efficacy of naloxone might be limited only to recently developed stereotypic behaviors, whereas haloperidol might be effective for more chronic behaviors.⁵⁸ Dextromethorphan inhibits the uptake of serotonin (see Table 26-2)93 The successful use of dextromethorphan (2 mg/kg every 12 hours orally for 2 weeks) for treatment of self-licking, self-chewing, and self-biting associated with pruritus has been described in a series of dogs.⁵⁹ Pruritus scores also decreased in the dogs. Animals (n = 14) were studied using a placebo-controlled, randomized, double-blind crossover study. Dextromethorphan was administered as the pure drug substrate, with filler administered in a gelatin capsule. Two dogs were withdrawn because of side effects (lethargy and diarrhea, respectively).

Multiple-Animal Households

Abnormal behaviors sometimes accompanying the addition of a new pet to the household that already has one or more pets (generally dogs) include excessive barking, territorial defense, predatory aggression (exhibited in dogs allowed to roam unsupervised), or intraspecies aggression (aggression toward other dogs either within or outside the household). Drugs that modify anxiety or fearfulness should be considered as adjuvant therapy. Included are the TCAs amitriptyline²⁷ and clomipramine (fear or anxiety), the SSRIs fluoxetine and paroxetine, the azapirone buspirone (antianxiety), and progestins. Of these drugs, fluoxetine and clomipramine may be most preferred. Amitriptyline and buspirone in particular have been cited for a potential increase in aggressive tendencies²⁷ with interdog aggression. Care should be taken to adhere to previously stated concerns regarding progestin therapy.

Excessive Barking

Occasionally, excessive barking reflects an OCD. Most cases are conducive to behavioral modification. Surgical treatment (vocal cordectomy) is a less desirable alternative treatment. The use of behavior-modifying drugs should be reserved for cases in which fear, separation anxiety, or other compulsive component can be identified in association with the behavior.²⁸ Drugs should be administered for a short period (2 to 4 months) and in conjunction with behavior modification. Once the desirable behavior is achieved and maintained for 4 to 6 weeks, medication can be tapered gradually until it is discontinued. Occasional cases may require lifelong medication in conjunction with behavioral modification. Drugs recommended by animal behaviorists include clomipramine, amitriptyline, buspirone, and fluoxetine.²⁸ Thioridazine was reported useful in one case of excessive barking accompanied by tail biting.¹⁵

Destructive Behavior

Destructive behavior can be dangerous to the animal (e.g., when foreign or toxic material is ingested) and economically undesirable to the pet owner. Causes of the behavior may vary with age. The underlying cause of the behavior may reflect exploration and play; attention-seeking behavior; or expression of territory, fear, or separation anxiety. Cognitive dysfunction in geriatric animals also may be manifested as destructive behavior.⁹⁴ Although behavioral modification is an important component of therapy, drug therapy may be urgent for animals in which the behavior is potentially harmful and for animals whose owners are intolerant of the behavior. Treatment of specific causes of destructive behavior is addressed with those disorders.

Tranquilizers such as the phenothiazine derivatives (acepromazine) may seem appropriate for destructive behavior and occasionally might prove useful. However, sedative effects may cause the animal to sleep rather than interact with family members.94 Likewise, use of anxiolytics (e.g., clorazepate, diazepam) can cause sedation. Although rapid acting, the anxiolytics must be administered frequently. In addition, they may interfere with the learning ability of the animal undergoing behavior modification.94 The efficacy of buspirone is generally poor. In addition, it is costly and characterized by a slow onset of action. Because it is safe, however, its use may be warranted in some cases.⁹⁴ For animals whose destructive behavior reflects separation anxiety, a TCA (amitriptyline, clomipramine) or SSRI (fluoxetine) is indicated. As with buspirone, a long onset of action time and relatively high cost should be anticipated.

Anxieties and Noise Phobias

Sherman and Mills⁹⁵ reviewed anxieties and noise phobias. A common complaint of owners is that their dogs exhibit disruptive behavior when left alone.⁷⁴ Behaviors include urination, defecation, barking, howling, chewing, and digging. An Internet survey of owners of dogs with noise phobias indicated a high level of frustration regarding attempts to control the behavior pharmacologically. Of the 69 respondents, 38% attempted some type of therapy, including behavioral therapy, training, prescribed medications, herbal remedies, or some combination of these treatments. Of these, only five reported improvement.⁹⁶ Riva and coworkers⁶ demonstrated that plasma serotonin and dopamine were increased in dogs (n = 22) with anxiety disorders compared with control animals; norepinephrine, L-DOPA, and selected other NTs did not differ.

Clomipramine has been approved for use in dogs for treatment of separation anxiety. Its use was reported in 1997 in abstract form⁹⁷ based on a placebo-controlled clinical trial in dogs (n = 77). In addition to placebo, dogs were administered a low (0.5 to less than 1 mg/kg twice daily; n = 24) or a high (1 to 2 mg/kg) dose of clomipramine every 12 hours. Response was based on changes in four behaviors (vocalization, destruction, defecation, or urination) monitored at 4, 8, and 12 weeks. Significant improvement was detected in the high-dose group at 8 and 12 weeks; side effects were limited to more frequent vomiting, which was nonetheless described as infrequent and mild. In contrast, Podberscek and Serpell⁹⁸ reported the lack of efficacy of clomipramine for treatment of separation anxiety in dogs (n = 49) following a placebo-controlled, double-blinded clinical trial. However, outcome measures in this study were based on owner-response questionnaires. The power of the study to detect a significant difference was not provided. Gaultier and coworkers⁶⁶ compared DAP (n = 30) to clomipramine (n = 27) for treatment of separation anxiety. The DAP was administered in paraffin oil by way of a reservoir electrical diffuser, which was placed in a room where the dog spent most of its time. The study design was a multicenter, randomized, positive-controlled, parallel clinical trial. Clomipramine (n = 27) was administered as a positive control at 1 to 2 mg/kg orally twice a day; the study was designed to

confirm noninferiority rather than lack of differences between the two treatment groups. A placebo diffuser was placed in the home of positive control dogs. Animals were treated for 28 days. Efficacy outcomes did not differ between the groups; however, the lack of a negative control (because of ethical considerations) and the significant placebo effect that has been demonstrated by other studies⁹⁸ should lead to cautious interpretation. In contrast to efficacy, undesirable effects were greater in the clomipramine group (gastrointestinal: vomiting, appetite changes).

Melatonin is produced from serotonin in the pineal gland; its use as an adjuvant anticonvulsant is addressed in Chapter 27. Its use as an adjuvant for treatment of thunderstorm phobias is anecdotally promoted, although no scientific studies have been reported. A homeopathic treatment has been studied⁹⁹ for treatment of noise phobias in dogs (n = 15). Dogs were studied prospectively using a randomized, placebo-controlled (n = 15) design. All treated dogs and 14 of 15 placebotreated dogs responded, resulting in no significant differences between the groups; this study exemplifies the importance of placebo-controlled studies.

Separation anxiety appears to respond well to fluoxetine; one open study reported a 100% response rate.³⁹ Benzodiazepines also may be effective for treatment of anxiety. Examples include chlordiazepoxide or diazepam.¹⁰⁰ An advantage of the latter group is rapid response.

Fear behaviors in dogs are also common.⁷⁵ Fear is commonly manifested toward loud noises such as thunderstorms and firecrackers, sudden movements, unfamiliar people, or novel environment. Before the advent of specific anxiolytic or antidepressant medications, tranquilizers such as phenothiazines or anticonvulsants such as phenobarbital were recommended for pharmacologic management of fear behaviors in dogs.⁷⁵ The efficacy of phenothiazine tranquilizers, however, reflects reduction of general responsiveness and is only likely for episodic anxieties.³ Benzodiazepines (including diazepam, clorazepate, and other derivatives) have stood the test of time for treatment of noise phobias.^{57,75} They have been used to treat thunderstorm or other noise phobias. They must, however, be administered before the inciting event. For thunderstorm phobias oral administration should occur at or before the first atmospheric sign,¹ such as changes in atmospheric pressure, wind, or ambient light conditions. Clorazepate (sustainedrelease form) may be preferred to diazepam, which requires more frequent administration. Alprazolam, characterized by a longer half-life, may also prove more beneficial.¹

The combination of benzodiazepines with clomipramine has been anecdotally supported and subsequently studied.¹⁰¹ Using an unblinded, uncontrolled design, dogs (n = 40; 32 completed the study) with storm phobias were treated with clomipramine (2 mg/kg orally every 12 hours for 3 months, then decreased to 1 mg/kg for 2 weeks and 0.5 mg/kg for 2 weeks) combined with alprazolam (0.02 mg/kg orally, as needed 1 hour before anticipated storms and every 4 hours as needed). Dogs also received counter conditioning. Improvement occurred in 94% of patients and was maintained at least 4 months after study completion. Although storm phobia was reported (by

caregiver) to resolve in only two dogs, behaviors associated with the phobia (panting, pacing, trembling, remaining near the caregiver, hiding, excessive salivation, destructiveness, excessive vocalization, self-trauma, and inappropriate elimination) decreased significantly during treatment. Improvement was greater during true storms (rain, thunder, and lightning) than during rain only. Response to auditory simulation did not change. The authors concluded that the combination of clomipramine, alprazolam, and behavior modification effectively decreased but did not cure the phobia.¹⁰¹

Dodman and Shuster⁵⁷ reported that phobias can be palliatively treated but not eradicated with buspirone. Onset of action may, however, take up to 4 weeks.

Nonapproved mediations have been suggested for treatment of noise phobias. Two examples include DAP and melatonin. The pheromone is marketed as spray (VPL) and might prudently be used in combination with other therapies. It has been studied using either retrospective⁶⁸ or an open noncontrolled clinical trial of 30 dogs.⁶⁷ Owners rated changes in responses of 14 behavioral signs, with ratings improving in 9 of the 14. The use of melatonin for other behavior disorders and seizures has been variably addressed elsewhere, and noise phobias join other putative, albeit unproven, uses. Melatonin should not be combined with other drugs that increase synaptic serotonin.

Sexual Behaviors

Abnormal sexual behaviors are unusual. Both too "much" and too "little" behavior will benefit from a full reproductive workup, including serum sex steroidal hormone measurements. Behaviors that reflect "too much" generally are those targeted for behavioral modification, which might include drug therapy. Sexual behaviors that might be considered abnormal in uncastrated male dogs include house soiling and possessive or dominance aggression. Care must be taken to distinguish soiling from marking. Castration is the preferred treatment. Abnormal behaviors of castrated dogs include mounting, which may be accompanied by aggression, destructiveness, house soiling, and barking.^{76,77} Previous discussions regarding these behaviors apply when the behavior is a manifestation of sexual behavior.

Psychogenic Dermatoses

Psychogenic dermatoses generally consist of both a dermatologic and a behavioral component. Discriminating between the two components is difficult but vital to successful therapy. Some psychogenic dermatosis will respond only to behavioral management, others only to dermatologic management, and some will require both behavioral and dermatologic therapy.⁸⁷ Dermatoses requiring medical management are discussed in greater depth in Chapter 22.

Clinical manifestations of psychogenic dermatoses include pruritus, acral lick dermatitis, OCDs (e.g., trichotillomania), and self-mutilation manifestations (see previous discussion of OCDs). Causes of psychogenic dermatoses are complex and may include boredom; endogenous opioid release (previously discussed); attention-seeking behavior; and, less commonly, separation anxiety.⁸⁷ A number of drugs have been recommended for treatment of psychogenic dermatoses.⁸⁷ These include antihistamines such as hydroxyzine or chlorpheniramine; TCAs, in particular clomipramine and doxepin, followed by amitriptyline¹⁰²; and opioid antagonists (especially for acral lick dermatitis) such as naltrexone. Doxepin stands out among the TCAs for its antihistaminergic effects.

Hyperactivity

Hyperactivity must be distinguished from overactivity. The former is a medical condition. Hyperactivity or hyperkinesia is a very rare behavior in dogs and cats. It has been reported in association with aggression in dogs.⁵⁷ Low doses of stimulant drugs, such as dextroamphetamine, may be useful. Dextroamphetamine can be used to provocatively diagnose the syndrome (2.5 to 5 mg orally in a medium-size dog). The patient should be calmed, and heart rate and respiratory rate should decrease.⁵⁷ Dextroamphetamine can be used to manage hyperactive dogs. The addition of β -blockers has proved useful for human patients, but this use has not been documented in animals.⁵⁷

Narcolepsy

Narcolepsy is an incurable neurologic disease manifested as a disturbance in the normal sleep cycle. It is an inherited (autosomal recessive) disorder in several breeds. Treatment includes methylphenidate or a TCA. Protriptyline is a nonsedative TCA that has been used successfully in human narcoleptic patients. The drug has been used successfully in one dog in which narcolepsy manifested as hyperinsomnia.¹⁰³

Feline Behaviors

Inappropriate Elimination

Inappropriate elimination (urinary or defecation) was the most commonly identified risk factor for relinquishment of pet cats to an animal shelter in one study.¹⁰⁴ Treatment of inappropriate elimination is highly individualized. Inappropriate elimination may reflect a marking behavior (generally identified by the location of urine on vertical surfaces). Abnormal or excessive marking behavior may reflect an increase in territorialism or anxiety.⁵⁶ Inappropriate elimination also is an abnormal behavior that frequently has a medical rather than a behavioral cause. Care must be taken to distinguish between the two causes so that correct medical care can be provided when indicated.56 For abnormal behaviors, careful history taking should help identify the cause of the abnormal behavior. Care should be taken to discriminate an aversion to the litter box from a desire to eliminate elsewhere; the former might easily be managed by simply moving the litter box.⁵⁶ For all behavioral causes, environmental and behavioral modification should precede any type of pharmacologic management. Surgical castration is recommended in males. If inappropriate urination reflects a social behavior or anxiety, the use of a behavior-modifying drug may be indicated.⁵⁶

Buspirone, diazepam, TCA, and progestins have been recommended for treatment of inappropriate elimination in cats. Male and female cats appear equally likely to respond. Buspirone is safe but costly. In an open clinical trial, marking decreased by at least 75% in approximately 55% of cats (n = 62); however, relapse occurred in 50% of the responders.¹⁰⁵ Cats that do respond generally do so within 1 week.⁵⁶ Cats that are the sole cat in a household appear to be less likely to respond to buspirone (compared with diazepam) than are cats from multiple-cat households.¹⁰⁶ Cats may, however, become more aggressive (or "assertive") when treated with buspirone.¹ Relapse of inappropriate urination appears less likely when the cat is treated with buspirone (approximately 50%) than with diazepam (approximately 75% to 91% relapse).^{12,105,107}

Diazepam can be effective for treatment of inappropriate elimination in cats (55% to 75% success rates in two studies). As with buspirone, males and females appear to respond equally well, although spayed females are less likely to respond, whereas castrated males are more likely to respond.^{1,56} However, a potential disadvantage of the benzodiazepines and, most notably, oral diazepam is acute hepatic failure.⁵⁴ In the report of 12 cases, acute hepatic disease occurred despite use of the drug according to recommended dosing regimens. Drugs within the class of benzodiazepines that are less likely to undergo oxidative metabolism (e.g., oxazepam) may be less likely to induce hepatic failure, although their efficacy for treating abnormal elimination has not been validated.^{1,56} Cats treated with diazepam are likely to stagger for the first several days of therapy,¹ with spontaneous resolution occurring afterward. Chlordiazepoxide and clorazepate also have been useful for suppressing inappropriate elimination in cats,¹ although drug concentrations may be less predictable than in diazepam.

Among the TCAs, use of amitriptyline is reported most commonly, although evidence is anecdotal rather than scientific.56 The incidence of adverse reactions may preclude use of amitriptyline. Clomipramine seems reasonable instead of amitriptyline on the basis of a nonrandomized, single-blinded, placebo-controlled crossover study in cats (n = 26) expressing inappropriate elimination behavior. Placebo was administered 5 days before and 3 days after a 7-day treatment period with 5 mg of clomipramine administered orally once daily. Based on the number of urine marks, the inappropriate behavior resolved in 35% of the cats, and a 75 % reduction in the number of marks occurred in 80% of the cats.¹⁰⁸ The findings of Landsberg and Horwitz,⁷² reported in abstract form, were similar. Cats (n = 25) received 0.5 mg/kg daily in an open trial; 84% responded (at least a 75% reduction in marking behaviors), generally within 2 to 3 weeks.

Using a randomized, placebo-controlled multicenter clinical trial, King and coworkers¹⁰⁹ reported a response in neutered cats (n = 67) with clomipramine at either a low (0.125 to 0.25 mg/kg), medium (0.25 to 0.5 mg/kg), or high (0.5 to 1 mg/kg) dose when administered once daily for up to 12 weeks. Behavioral and environmental modifications were encouraged. Sedation was reported in 54% of the cats but was not sufficient to cause withdrawal from the study. This study supports the use of a low dose of clomipramine but also supports a gradual increase in dose in nonresponders if necessary.

Fluoxetine also has demonstrated efficacy for control of inappropriate urination. Using a randomized, placebo-controlled,

double-blinded design, the effect of fluoxetine (1 mg/kg orally once daily) on urine spraying was studied in neutered cats (n = 17).⁴⁸ Drug therapy was accompanied by environmental management. Within 1 week of therapy, all but one cat had responded, with the last responding by week 2. Differences between the placebo and treatment group increased as drug therapy continued, supporting a lag time between initiation of therapy and maximal response time noted for fluoxetine in humans. Weekly episodes of spraying reduced from 8.6 ± 2 to 1.7 \pm 0.6 compared with 5.5 \pm 1.8 episodes in placebo-treated cats. Cats were treated for 8 weeks and monitored for an additional 4 weeks after therapy. Marking behavior returned in six of nine drug-treated cats, with those cats marking most before drug therapy also marking most at the end of the 4-week posttherapy monitoring period. Appetite decreased in four of nine cats receiving therapy; vomiting and lethargy were reported rarely.

FFP has been studied for treatment of urine spraying in cats using a double-blinded placebo-controlled design (n = 22).⁶⁹ Comparisons were made within each group to baseline but not to one another. Spraying decreased compared with baseline in the treatment but not the placebo group.

The use of progestins (discussed in Chapter 19) to treat inappropriate urination should be reserved for animals that have failed all other alternatives. A single case report cited the successful use of alprazolam (2.5 mg orally every 12 hours) for treatment of soiling. Response occurred within 1 week of therapy, with mild sedation the only reported side effect. The behavior returned after the alprazolam dose was discontinued over the next 6 weeks.¹¹⁰

The use of fluorescein has been recommended to detect the soiling culprit in multicat households. The injectable product is sold as a 10% (10 g/dL; 100 mg/mL) solution, which can be administered orally in the evening (50 mg once daily with food or 30 mg once daily without food) for 4 to 5 days.

Social Behaviors and Aggression

Disorders of aggression are the second most common cause of abnormal behavior in cats.¹¹¹ Causes associated with aggression include dominance; fear; defensive, territorial, or play aggression toward another cat; or play and fear aggression toward the owner or another person. Intolerance of petting often is manifested as an aggressive behavior. For many types of aggression (an exception being fear aggression), neutering may decrease the undesirable behavior.¹¹¹ Behavioral modification techniques are the preferred method of treatment. Pharmacologic management is indicated for cats that do not respond to behavioral modification or in conjunction with behavioral modification. Little information is available, however, regarding treatment of aggression in cats. Benzodiazepines have been used with variable results. Chlordiazepoxide or diazepam has been recommended for frustration or social anxiety in cats.^{12,100,112} Diazepam may, however, increase predatory behavior in cats.³

Psychogenic Dermatoses

Feline psychogenic alopecia manifests as a traumatically induced regional alopecia. Underlying dermatologic causes include flea allergy, food allergy, and allergic inhalant dermatitis. Neurodermatitis also includes evidence of more damage (excoriations, crusting) and is more common in highstrung cats (e.g., Siamese, Burmese, Abyssinian). The lesions reflect overzealous grooming. Recommended treatments include TCAs (clomipramine and amitriptyline) or antihistamines.⁸⁷ Fluoxetine was successful in a report of a single cat⁴⁷ and clomipramine in another.¹¹³

Sexual Behaviors

Abnormal sexual behaviors in cats that may require management generally occur in toms and include urine spraying and mounting. Spraying by uncastrated cats is more appropriately treated by environmental management or according to previous discussions regarding inappropriate elimination; mounting that has not responded to behavioral modification techniques may respond to amitriptyline or another TCA.^{76,77}

Depression

Among the classic signs of depression in the cat is anorexia; early intervention is important. Benzodiazepines should be used as appetite stimulants as early as possible. For depression, clomipramine hydrochloride or fluoxetine has been recommended (either drug at 0.5 mg/kg orally once daily).¹¹⁴ Clomipramine is preferred if anorexia is intermittent and associated with endogenous or environmental stressors; fluoxetine is preferred for long-term management. Treatment may be required for 4 to 6 months and should be accompanied by behavior and environmental modification.

Successful control of seizures with anticonvulsant drugs reflects a balance in achieving seizure control and minimizing undesirable drug side effects. Variability in the disposition of anticonvulsants and interactions among them and other drugs are important confounders of successful therapy. This chapter reviews selected anticonvulsants, focusing on drugs most likely to control seizures in small animals However, drugs that have been used historically and selected drugs that are used in humans but for which information is available in dogs or cats are also discussed, in part to explain why they may be less than ideal choices. The proper use of anticonvulsants is discussed, with an emphasis on the differences in individual drug disposition, detection of these differences (e.g., therapeutic drug monitoring), and rational approaches to responding to these differences by dose modification. The primary topic of discussion is treatment of generalized, tonic-clonic seizures, the most common type afflicting small animals. Opinions regarding anticonvulsant therapy vary among clinicians. Treatment of behavioral disorders that might manifest as seizural type activity is discussed in Chapter 26. Some of the comments and recommendations offered in the discussions of selected drugs

reflect personal observations obtained in the direction of a therapeutic drug monitoring service or through clinical trials that focus on the use of anticonvulsants either alone or in combination with phenobarbital.

It is important to approach epilepsy as a clinical manifestation of an underlying disease. Thus therapy is more likely to be effective if the underlying disease is treated. Such causes should be identified and appropriately treated-if possible, before chronic anticonvulsant therapy is instituted. Neutering of affected animals (male and female) is strongly encouraged not only for ethical reasons (i.e., precluding perpetuation of contributing genes) but also to minimize the potential adverse effect of circulating sex hormones on neuronal membrane stability. Unfortunately, the underlying cause of epilepsy often cannot be identified (idiopathic epilepsy) or, if identified, cannot be corrected such that seizures are adequately controlled. In such instances, regardless of the cause of seizures, management is based on control with anticonvulsant drugs. Undesirable side effects are often the limiting factor in the use of anticonvulsant drugs, and not all seizures necessarily require treatment.

KEY POINT 27-1 Long-term therapy with anticonvulsant drugs increases the risk of adverse reactions and drug interactions in the epileptic patient.

Certainly immediate, short-term anticonvulsant therapy is indicated for status epilepticus (see later definition) or cluster seizures. Chronic therapy is generally indicated for seizures that last more than 3 minutes, cluster seizures (for which there is no delineable interictal period), or seizures that occur more frequently than once a month. Seizures that are not sufficiently controlled can lead to additional seizuring (kindling) or to the development of a second "mirror" focus of seizure activity. This might be manifested as a decreasing interictal period or a worsening of seizure activity (including duration).

PHYSIOLOGY AND SEIZURE PATHOPHYSIOLOGY

Anatomy

Neurons are either layered or clustered (forming nuclei) and classified according to function (sensory, motor, or interneuron), location, or the neurotransmitter synthesized and released by the neuron.¹ Neurons are outnumbered by several orders of magnitude by other cells, including macroglia, microglia, and cells of the vascular elements. Microglia are related to macrophage/monocyte lineage and are either resident or recruited during inflammation. The macroglia are the most abundant of the supportive cells and include, among other cells, astrocytes and oligodendroglia. The latter are the myelin-producing cells, whereas astrocytes provide metabolic support and remove extracellular neurotransmitters.

Barriers to Drug Distribution

The blood-brain barrier and blood-cerebrospinal fluid (CSF) barrier form a permeability boundary, rendering the brain a sanctuary by limiting penetration of macromolecules. They also act as selective barriers to inflow and outflow of small, charged molecules, including drugs, neurotransmitters, and their precursors or metabolites. The blood-brain barrier is absent in selected locations, thus allowing the brain to monitor chemicals. These areas include but are not limited to the area postrema, median eminence of hypothalamus, and the posterior pituitary and pineal glands. Cerebral ischemia and inflammation modify the integrity and function of the barriers. The blood-brain barrier comprises blood capillaries that differ in structure compared to other tissues in that they lack fenestrae and are joined by tight junctions similar to the epithelium of other tissues. Microvessels comprise about 95% of the total surface area of the barrier. Astrocyte foot processes encapsulate the capillaries, forming the tight junctions (Figure 27-1). Because pinocytosis also is absent, compounds can enter the brain only by passive diffusion, limiting penetration to small, lipid-soluble, non-ionized molecules. In addition to the physical barrier, function mechanisms exist to preclude central nervous system (CNS) penetration. These include degradative enzymes, which target not only chemicals but also many peptides, and high concentrations of efflux transporters. These include adenosine triphosphate (ATP)–binding cassette proteins such as P-glycoprotein (among the most abundant and most well characterized) and others, resulting in a combined broad substrate specificity that targets many drugs.² The substrate specificity of the P-glycoprotein transporter is large; its role in breed susceptibility to CNS adverse drug reactions is discussed in Chapters 2 and 3. Interactions involving P-glycoprotein (or other efflux transporters) are among the drug interactions described at the level of the blood–brain barrier.³ In the dog this protein is regulated by only one gene (ABCB1).⁴

The blood-CSF barrier prevents compounds moving from interstitial fluid into brain parenchyma.⁵ This barrier is located in the epithelium of the choroid plexus, limiting movement of compounds from the blood into the CSF. The choroid plexus consists of the highly vascularized pia mater and cells with microvilli on the CSF side. The plexus dips into pockets formed by folding of ependymal cells onto themselves, forming a double layer structure between the dura and pia (i.e., the arachnoid membrane). This double layer contains the subarachnoid space. Although the capillaries of the choroid plexus are fenestrated, the adjacent choroidal epithelial cells form tight junctions, precluding movement of most macromolecules. Like the blood-brain barrier, the blood-CSF barrier contains organic acid transporters that preclude penetration of many therapeutic agents.⁶ The role of efflux pumps and P-glycoprotein in particular is discussed later.

The formidable barrier presented to chemical penetration of the brain contributes to therapeutic failure when treating dysfunction of the CNS. A number of strategies have been described to enhance drug delivery to the brain.⁶ These include manipulation of the drugs such that they are chemically more likely to penetrate the barrier, administration of prodrugs, the combination of drugs with compounds that decrease drug efflux, the design of vectors or other carriers that are able to penetrate, and temporary disruption of the barriers themselves. The use of nanotechnology offers potentially viable options.⁷ Finally, alternative routes of delivery include intraventricular, intrathecal, olfactory, and direct interstitial routes. None thus far has proved consistently safe or relevant to all therapeutic agents.

Physiology of Neuronal Activation

Neuronal activity can be manipulated through molecular mechanisms at several levels: (1) ion channels, which mediate excitability; (2) neurotransmitters and their receptors; (3) auxiliary intramembranous or cytoplasmic transductive molecules that couple receptor signals to intracellular actions; and (4) neurotransmitter transporters that facilitate their conservation through reaccumulation into the terminal (plasma membrane proteins) and then synaptic vesicles (vesicular transporters) (Figure 27-2). The combined influence of these molecular entities regulate three major cations (Na⁺, K⁺ and Ca²⁺) and the major anion (Cl⁻). The cations are directly regulated through voltage-dependent Ca²⁺, N⁺, and K⁺ channels, allowing for rapid changes in ion permeability, thus facilitating the excitation–secretion coupling necessary for transmitter release. They also are influenced by ligand-gated ion

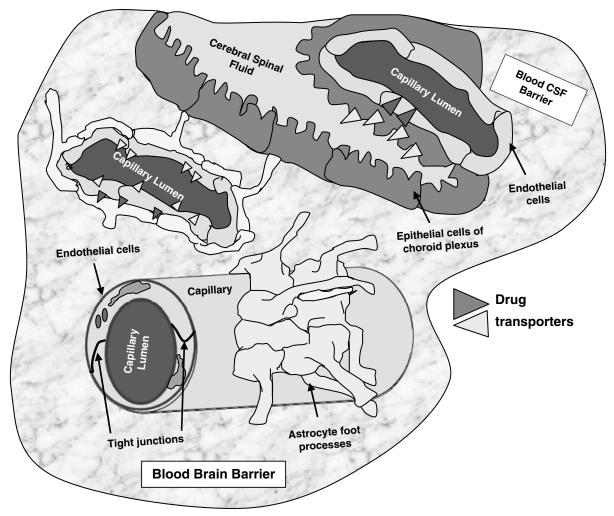

Figure 27-1 Diagrammatic representation of the blood brain *(left)* and blood–cerebrospinal fluid *(right)* barriers, structures that limit compound movement from blood into the interstitial fluids of brain parenchyma. The endothelium of the capillaries of the blood–brain barrier lack fenestrae, are joined by tight junctions, and are encapsulated by astrocyte foot processes. Only small, lipid-soluble, non-ionized molecules in the blood stream are likely to move through the endothelium into the brain. The blood–CSF barrier is formed from the epithelium of the choroid plexus, which forms tight junctions. The plexus dips into a double-celled structure made from folding of ependymals cells on themselves. (See text for other mechanisms by which drugs might be excluded from each of these sites.)

channels, which in turn are regulated by neurotransmitter binding. These include but are not limited to glutamate receptors and ionophore receptors for acetylcholine (nicotinic), GABA_A, and glycine.¹

Neurons generally release the same substance at each synpaptic terminal in which the neuron is involved. Neurotransmitters generally result in either excitation, reflecting an influx of positively charged ions, depolarizations, and reduced membrane resistance, or inhibition, resulting in hyperpolarization and decreased membrane resistance. Selected transmitters (e.g., monoamines and peptides) may enhance or suppress the classical neuronal response to the neurotransmitter. **Neurohormones** receive synaptic information from central neurons and respond by secreting transmitters into circulation. **Neuromodulators** originate from nonsynaptic sites but influence nerve cell excitability. Examples include CO₂; ammonia; circulating steroid hormones (neurosteroids); and locally released adenosine, eicosanoids, and nitric oxide. **Neuromediators** participate in the postsynaptic response and are exemplified by the secondary messengers cyclic AMP or GMP and inositol phosphates.

KEY POINT 27-2 Drugs that target the inhibitory neurotransmitter gamma-aminobutyric acid have traditionally been among the most effective anticonvulsant drugs.

Neurotransmitters

Amino acid neurotransmitters include the excitatory dicarboxylic amino acids glutamate and aspartate and the inhibitory monocarboxylic ω -amino acids glycine, **gamma-aminobutyric acid** (GABA), β -alanine, and taurine (Figure 27-3, Table 27-1). Because of their ubiquitous distribution in the brain and their rapid, reversible, and reduntant effects, amino acid

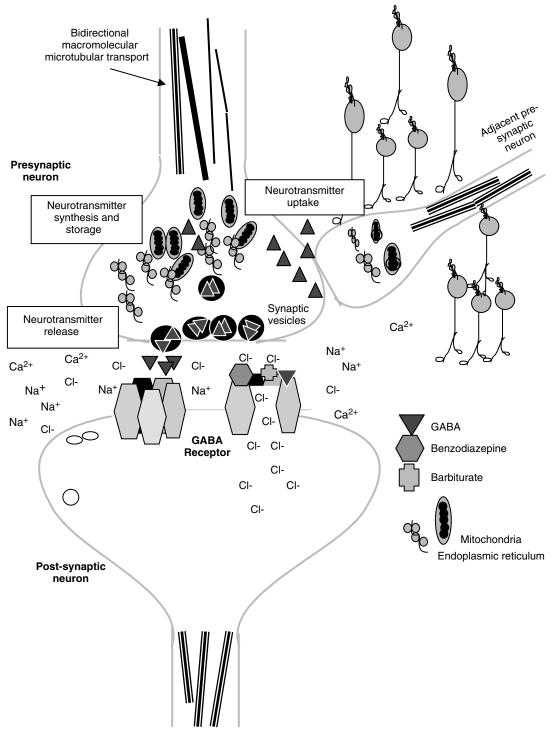

Figure 27-2 Potential therapeutic targets of anticonvulsant and behavior-modifying drugs include the presynaptic nerve terminal and the postsynaptic neuron. Presynaptically, microtubules allow for bidirectional transport of macromolecules to and from the neuronal cell body and distal processes; motors responsible for transport may be subject to drug action. Active uptake, synthesis, storage, and release of neurotransmitters may also be targeted. Postsynaptically, neurotransmitter-receptor interaction can be targeted. The receptor for gamma-aminobutyric acid (GABA) has binding sites for GABA, barbiturates, and benzodiazepines. Interaction between the drug and receptor causes a channel in the receptor to open to chloride flux. Increased chloride concentrations inside the cell increase electronegativity, thus hyperpolarizing the cell. Intracellular targets that express synaptic activity may also be targeted.

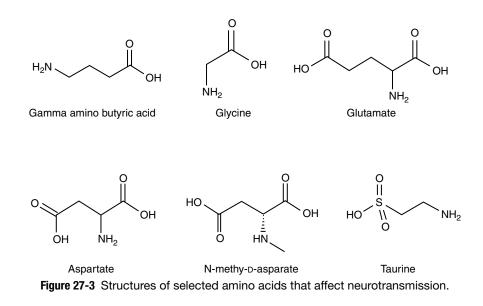

Table 27-1 Neurotransmitters Influential in the Treatment of Seizures

Neurotransmitter	Receptors	Target	Agonists	Antagonist	Transporter blocker	Comment
Acetylcholine	Nicotinic	Inotropic, fast excitatory, cationic channels				
	Alpha and beta isoforms	N/A				
	Muscarinic	GPCR modulatory				
Aspartate	GLU	Inotropic, fast, excitatory, cationic channels	Kainate, AMPA		None	
	KA					
	NMDA	Inotropic, slow, excitatory, Mg ²⁺ gated	NMDA	Phencyclidine		
	NMDA 1,2		Glutamine,			
	(A-D)		aspartate			
	mGLU	GPCR, second messengers	Multiple			
Dopamine	D ₁₋₅	GPCR (Gs: D ₁ , D ₅ ; Gi: D ₂₋₄)	Bromocriptine (D ₂)	Domperidone (D ₂)	Cocaine	
GABA	GABA _(A)	Inotropic; fast, inhibitory, Cl ⁻ channel	Barbiturates, Benzodiazepines	Picrotoxin, Penicillin, pentylenetetrazole		5 Isoforms
	GABA(B)	Presynaptic and postsynaptic receptor actions	Baclofen			
	GABA(C)	Inotropic; slow, sustained, inhibitor, Cl ⁻ channel				
Glutamate	AMPA	Inotropic; fast, excitatory, cationic channel (as with aspartate GLU)				
Glycine	Alpha and beta	Inotropic; fast, inhibitory, Cl ⁻ channels		Strychnine		
Histamine	H ₃	Autoreceptor: inhibition of transmitter release				
Norepinephrine	Alpha (_{1A-D})	GPCR			Cocaine	
	Alpha (_{2A-C})	GPCR		Yohimbine		
Serotonin	5-HT _{1 (A-F)}	GPCR		Clomipramine, fluoxetine		
	5-HT ₂	GPCR				
	$5-HT_3$	Ligand gated				

N/A; Not applicable; GPCR, G protein–coupled receptor; GLU, glutamate; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; KA, kainic acid; NMDA, N-methyl-D-aspartate; Mg²⁺, magnesium; GABA, gamma-aminobutyric acid; 5-HT, 5-hydroxytryptamine.

neurotransmitters were precluded from initial inclusion as classical neurotransmitters. Glycine, glutamate, and GABA are now considered central neurotransmitters. GABA is enzymatically formed from glutamic acid by glutamic acid decarboxylase. The effects of GABA are experimentally identified in response to picrotoxin and bicuculline. These include inhibitory actions at the level of the local interneuron and potentially presynaptic inhibition in the spinal cord. Convulsant compounds that appear to act through GABA receptors include the selective antagonists penicillin and pentylenetetrazole. Nontherapeutic agents have also been identified that mimic GABA, inhibit its active reuptake, or alter its turnover. Three types of GABA receptors have been identified: A, B, and C, with type A being the most common. It is a ligand-gated, chloride channel ionotropic receptor and is the site of action of many drugs, including benzodiazepines, barbiturates, anesthetic steroids, and volatile anesthetics. The B type GABA receptor is a G protein-coupled receptor (GPCR) that interacts with Gi to inhibit adenylyl cyclase, activate K⁺ channels, and reduce Ca²⁺ conductance. The B type receptors act presynaptically as autoreceptors, inhibiting GABA release. Type C GABA receptors are less common, but GABA is much more potent for this receptor. The type C receptor is distinguished by its lack of interaction with several compounds that interact with type A GABA receptors, including baclofen, benzodiazepines, and barbiturates.

Amino Acids

Glycine receptors are located primarily in the brainstem and spinal cord, where they are inhibitory in nature.

Glutamate and aspartate occur in very high concentrations and are powerful excitatory signals throughout the brain. Glutamate receptors are either ligand-gated ionotropic receptor channels or G protein coupled. Ligand-gated ion channels include N-methyl-D-aspartate (NMDA) and non-NMDA receptors (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA] and kainic acid [KA]).^{1,8,9} The NMDA receptors, derivatives of aspartic acid, are pH sensitive, and response to endogenous signals, including zinc ions, selected neurosteroids, arachidonic acid metabolites, redox regions, and selected polyamines. Although NDMA receptors are involved in normal synaptic transmission, they appear to be more closely involved with induction of synaptic plasticity. This includes long-term potentiation, which reflects an increase in the magnitude of the postsynaptic response to presynaptic stimulation of a specific strength. The activation of NMDA receptors requires simultaneous firing of at least two neurons, including binding of glutamate released from the synapse and simultaneous postsynaptic depolarization from different neurons. High concentrations of glutamate can cause neuronal death. The mechanism partially, but not solely, reflects excessive activation of NMDA or AMPA/KA receptors and calcium influx. For example, ischemia or hypoglycemia may be associated with massive glutamate release; when coupled with impaired cellular reuptake, cell death may occur. Depletion of Na⁺ and K⁺ and increased extracellular Zn2⁺ may play a role in activation of necrotic or apoptotic cascades.¹ The role of these receptors in pain is discussed in Chapter 28.

Monoamines

Acetylcholine is an excitatory neurotransmitter for Renshaw interneurons and other CNS cells. Actions reflect interactions between nicotinic and muscarinic receptors.

Several catecholamines act as neurotransmitters in the CNS. **Dopamine** comprises more than 50% of CNS catecholamine and is found in high concentrations is selected areas. Its effect depends on the subreceptor targeted, with five thus far identified in the brain (see Table 27-1). **Epinephrine** is present only in limited areas, and its role has not yet been identified. However, **norepinephrine** is found throughout the brain but in very large concentrations in the hypothalamus, certain zones in the limbic system, and other regions. All three receptor types (alpha 1, alpha 2, and beta) and subtypes are located in the brain. The nonclassical electrophysiologic synaptic effects of norepinephrine vary with the state but are considered "enabling." Although excitatory in nature, the effects of norepinephrine (and serotonin) can be anticonvulsant, rather than proconvulsant.¹⁰

Biogenic Amines

Serotonin is one of two biogenic amines active in the CNS. Thus far 14 receptor (5-hydroxytryptamine [5-HT]) types or subtypes are found in CNS nuclei that are located in or adjacent to the midline regions of the pons and upper brainstem. Up to five different 5-HT₁ receptor subtypes inhibit adenylyl cyclase or regulate K⁺ and Ca²⁺ channels. 5-HT₂ receptor subtypes (three) are linked to G proteins and phospholipase C. 5-HT_{2C} may modulate CSF production. 5-HT₃ receptors are located in the area postrema and solitary tract nucleus, where they cause emesis and antinociception. Members of the 5-HT₄ through 5-HT₇ receptor types have not yet been studied in the CNS.

Histamine is the second biogenic amine that serves as a neurotransmitter. Four subtypes have been described in the CNS, all acting through G proteins. Most neurons that synthesize histamine are located in the ventral posterior hypothalamus and extend throughout the entire CNS through ascending and descending tracts.¹

Synaptic Vesicle Protein

The importance of the synaptic vesicle protein 2 (SV2) emerged as part of the research into the mechanism of action of levetiracetam. Levetiracetam, but not other anticonvulsants, binds to synaptic vesicle (SV) protein through the brain in a steroselective, concentration-dependent manner.¹¹ However, ethosuximide, pentobarbital, and pentylenetetrazole compete with levetiracetam for binding. The distribution of the protein does not follow any pattern consistent with classical receptors, and the protein is located in synaptic vesicled (SVs). Three isoforms exist (A, B, C), with SV2A the most widely distributed. Knockout mice without SV2A die within 3 weeks as a result of spontaneous seizures. The role of SV2A is not clear, but it may modulate exocytosis that precedes neurotransmitter release; disruption of activity appears to result in calcium accumulation and increased neurotransmitter release.11

The Action Potential

The normal resting membrane potential (RMP) of the neuronal cell is 70 mV. The electrical difference across the cell membrane is maintained by a Na⁺, K⁺-ATPase pump. Depolarization and the generation of an action potential occur when the RMP becomes sufficiently positive to reach threshold. As with other membranes, the RMP of a neuron is determined by the concentration of negative and positive ions across the membrane. Important ions include Na⁺, K⁺, Ca²⁺, and Cl⁻. The concentration reflects ion fluxes and thus permeability of the cell membrane to the ions. Fluxes resulting in an increase in positive ions inside the cell relative to the outside hypopolarize the RMP, bringing it closer to threshold and subsequent depolarization. The tendency of a neuron to depolarize reflects, in part, the sum total effect of neurotransmitters (NTs) that interact with the cell membrane. Inhibitory NTs such as GABA render the RMP more negative and less susceptible to depolarization (see Figure 27-2).12 The principal postsynaptic receptor for GABA is the GABA_A receptor; activation increases inflow of Cl- ions into the cell, hyperpolarizing the neuron. Glycine and serine are also inhibitory neurotransmitters. Excitatory neurotransmitters, such as acetylcholine and glutamate, elevate the RMP to a more positive status, rendering it more susceptible to reaching the threshold necessary for depolarization.¹²

Pathology

Conventional evidence indicates that neurons are terminally differentiated cells and do not respond to proliferate stimuli. The presence of neuronal stem cells may, however, offer an avenue of treatment for degenerative conditions or damage. In the absence of proliferation, neurons have developed adaptive functional and structural responses to injury.¹

Several animal models have been used to study either seizures or epilepsy. Models intended to study epilepsy ideally include both seizure activity as well as chronic epileptiform behavior (i.e., spontaneous seizures).¹³ The attributes of animal models are generally based on their relevance to human epilepsy in regard to electrophysiologic activity, etiology, pathologies, signalment, associated behavioral changes, and response to anticonvulsant drugs. That multiple models have been developed for study reflects the more than 100 human seizure or epileptic disorders. Chemical convulsants that cause seizures after systemic or direct administration include KA (a glutamate analog), pilocarpine, NMDA, and GABA antagonists, Pentylenetetrazole is among the most commonly used chemicals; repeated injections mimic electrical kindling. Injections of high doses consistently and predictably cause tonicclonic seizures, allowing its use as a screen for new drugs. Lower doses induce absencelike seizures. Kindling models are considered epileptic models and involve periodic stimulation of low-intensity signals in the amygdala, resulting in tonicclonic seizures. The animal remains sensitive to electrical stimulation, with the number of stimuli necessary to induce seizures quantifiable. Genetic models have been either developed or genetically designed;¹³ for example, deletion of the gene encoding tyrosine kinase prevents the genesis of epilepsy in the kindling model administration of chemoconvulsants.¹

Seizures are the clinical results of rapid, excessive neuronal discharge in the brain. Seizures are classified as primary (i.e., genetic) or acquired, and as generalized or focal. Generalized seizures are much more common in small animals; the incidence is greater in dogs than in cats. With seizure onset of a generalized character, convulsive electroencephalographic activity begins simultaneously in all brain regions.¹⁴ Epilepsy is a disorder of the brain characterized by an enduring predisposition to generate seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one epileptic seizure.¹⁰

KEY POINT 27-3 Epilepsy is a clinical manifestation of an underlying disorder and is not likely to be cured unless the cause is corrected.

Seizures in epileptic subjects often are attributed to a cortical origin. However, the brainstem, particularly the pontine reticular formation, also can manifest self-sustained seizure discharge and may be important in the generation and expression of generalized tonic convulsions.15 Depression of reticular core activity is an essential characteristic of antiepileptic drugs, suggesting that the reticular formation is involved in the spread and generalization of clinical seizures.¹⁶ In the dog the most common form of epilepsy is generalized tonic-clonic or grand mal seizures.17 Epilepsy or seizure disorders of the CNS in the dog may be caused by an acquired organic lesion such as brain tumor, head trauma, toxicosis, electrolyte imbalance, hypoglycemia, renal failure, or hepatic disease (acquired or secondary epilepsy) or may be genetic or inherited ("true," idiopathic, or primary epilepsy). An autosomal gene associated with a sex-linked suppressor on the X chromosome may explain the higher incidence of seizures in male dogs. Interestingly, in human medicine the role of autoantibodies is emerging as a potential underlying cause of neurotoxicity and associated epileptic seizures.¹⁸

Status epilepticus (SE) refers to failure of the patient to recover to a normal alert state between repeated tonic–clonic attacks or episodes that last at least 30 minutes.¹⁹ Convulsive or tonic–clonic SE is a medical emergency in which convulsive seizures must be terminated by treatment with anticonvulsant agents. In humans epileptic seizures must not be allowed to persist more than 60 minutes if severe, permanent neurologic injury or death is to be avoided.¹⁹ The longer an epileptic seizure persists, the greater the incidence of mortality and morbidity. Hyperthermia caused by continuous muscle contraction may become life threatening during continued seizure activity. Brain damage resulting from hypoxia or the sequelae of hyperthermia is more likely if more than 30 minutes of uninterrupted seizures occur.

KEY POINT 27-4 Permanent neurologic damage may occur if seizures persist longer than 60 minutes.

During seizures individual neurons depolarize and fire action potentials at high frequencies. Increased excitability reflects increased extracellular potassium and decreased extracellular calcium. Once initiated, the seizure discharge may synchronize with other neurons and propagate or spread

Table **27-2**

to surrounding areas in the brain. Seizures can be initiated by four general mechanisms:

- Altered neuronal membrane function. Permeability changes may occur as a result of hypoxia, inflammation, trauma, or other disease. Changes may reflect altered voltage-gated ion channels (calcium, sodium, or potassium) or ion exchangers (e.g., sodium/hydrogen/potassium).
- Altered receptor number, sensitivity, or function. Examples include nicotinic cholinergic or glutamate receptors. As an example, glutamate receptors initiate seizures experimentally with antagonism of NMDA receptors blocking the excitatory effects and AMPA/kainate.^{3,20,21}
- 3. Altered neurotransmitter physiology, including changes in concentration, transporter, or function. Potential contributors include either decreased inhibitory neurotransmitters, such as GABA, the most potent inhibitory neurotransmitter in the CNS, or increased excitatory neurotransmitters, such as glutamate. The role of gabaminergic mechanisms in seizure activity has been well established in animal models, based on seizure activity caused by GABA agonists or drugs that impair GABA synthesis (e.g., glutamic acid decarboxylase) and eradication of seizure activity in response to GABA antagonists (as reviewed by Ellenberger and coworkers).²² Altered neurotransmitters have been described in epileptic dogs, including increased glutamate concentrations and decreased GABA concentrations.²³ More recently, Ellenberger and coworkers²² reported lower CSF concentrations of both GABA and glutamate in epileptic Labrador Retrievers (n = 35; 14 treated with phenobarbital \leq 3 weeks) compared with other epileptic dogs (n = 94; 42 treated with phenobarbital <2 weeks) or non-epileptic controls (Beagles). Lower aspartate concentrations also were detected in all epileptic dogs compared with control dogs.
- 4. Changes in extracellular potassium and calcium concentrations might also contribute to seizure activity.^{12,24}

PRINCIPLES OF ANTICONVULSANT THERAPY

Anticonvulsants block seizure initiation and propagation by blocking either abnormal events in a single neuron or the synchronization of related neurons. Thus a goal of therapy is reduction in the firing frequency. A common mechanism by which this goal might be achieved is prevention of sodium channel recovery from inactivation (i.e., prolongation of the refractory period) (Table 27-2). It is during this period that membranes are nonresponsive to other signals. Example drugs that target this mechanism include carbamazepine, phenytoin, valproic acid, toparimate, and zonisamide.²⁵ Another common mechanism is increased interaction between agonists and GABA_A, which facilitates hyperpolarization. Drugs that act as agonists at the GABA(A) receptor include the barbiturates, and the benzodiazepines. At high concentrations these drugs also may also inhibit high-frequency firing. Other drugs include tiagabine, which targets the GABA transporter, GAT-1, decreasing neuronal and glial uptake of GABA and levetiracetam, which targets SV proteins. In general, drugs that

target more than one mechanism tend to be most effective. Alternatively, combination therapy with drugs that target different mechanisms of neuronal function may be effective in seizures that do not respond to single-drug therapy.

KEY POINT 27-5 Mechanisms of action should be complementary when combining anticonvulsant drugs.

Anticonvulsant drugs target seizures; antiepileptic drugs target epilepsy. For the remainder of this chapter, the terms may be used interchangeably, in part because most antiepileptic drugs are also anticonvulsant drugs. Because successful anticonvulsant therapy may depend on the maintenance of plasma drug

concentrations within the therapeutic range, understanding the disposition of each anticonvulsant is paramount to therapeutic success.^{26,27} Epilepsy is controlled, not cured, with historical rates of success in only 60% to 70% of the cases, although control might be improved to at least 85% if monitoring supports therapy (see later discussion).²⁸ Generally, but not always, treatment for epilepsy involves drug administration for the rest of the animal's life.²⁹ The most common anticonvulsant drugs that have been used in veterinary medicine are phenobarbital, diazepam, and potassium bromide (Figure 27-4). A number of newer (human) drugs are increasingly being used, including zonisamide, levetiracetam, several benzodiazepines (clorazepate, clonazepam), gabapentin, and (less frequently) felbamate. Older drugs whose historical use has declined include primidone, phenytoin, and valproic acid. Drugs commonly used in humans that are minimally used in dogs or cats include ethosuximide, lamotrigine, and topiramate. Scientific support of efficacy for each of these drugs in dogs or cats generally is limited; differences compared with humans should be anticipated, not only because of differences in the underlying pathophysiology of disease but also in the disposition of the drugs among species and pharmacodynamic response. Even if pharmacokinetic information is available, generally the data were generated in a small sample size of healthy, drug-free animals. Pharmacokinetic differences in anticonvulsant drugs among and within breeds and species can be profound, with drug disposition often affecting the efficacy of the drug. Studies in Beagles or other pure breeds may not reflect the canine population as a whole. Antiepileptic drugs are generally administered chronically. As such an understanding of the determinants of drug disposition (Chapter 1) is paramount to

understanding their most effective use, particularly as it pertains to drug toxicity and avoidance of drug fluctuations during a dosing interval that might contribute to either therapeutic failure. The more important points are as follows.

PHARMACOKINETIC CONSIDERATIONS

Absorption determines the magnitude of, but also the time to, peak anticonvulsant effect. Most anticonvulsants are administered either orally or intravenously, although alternative routes such as nasal and rectal administration are proving increasingly useful for emergency administration (Table 27-3). Most of the anticonvulsants used as antiepileptic drugs are well absorbed after oral administration, with the notable exception of phenytoin. Because food may slow the absorption of anticonvulsant drugs, peak plasma drug concentrations may occur as late as 4 to 6 hours after administration. This generally is not a problem with chronic dosing for drugs that accumulate, but it may affect the time of peak sample collection. Fasting before sample collection might be prudent. Rectal administration has offered a clinically effective alternative for administration for several anticonvulsant drugs. The colonic absorption of anticonvulsant drugs can be predicted to some degree by hydrophilicity. For example, whereas gabapentin is poorly bioavailable compared with phenytoin, maximum plasma concentration of phenytoin after colonic administration equals that after oral administration.30 A potentially emerging problem - suggested by the author's therapeutic drug monitoring service - are differences in oral bioavailability of human generic products prescribed for animals. The therapeutic equivalence (including bioavailability)

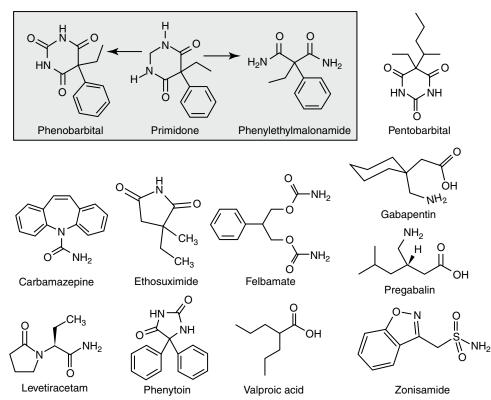

Figure 27-4 Structures of selected clinically useful anticonvulsant drugs. Note the similarities in structures of primidone and its active metabolite, phenobarbital.

Table 27-3 Dose	es of Drugs Used To Treat Disorders of the Peripheral or Central Nervous System									
Drug	Indication	Dose	Route	Interval (hr)						
Bethanechol	Urinary bladder atony, dysautonomia	2.5-25 mg/dog	РО	8						
Bromide, potassium or sodium	Anticonvulsant	Loading dose: 90-150 mg/kg	PO (with food)	5 days for a total of 450-600 mg/kg						
		Maintenance: 30-90 mg/kg	PO (with food)	24; monitor						
Carbamazepine	Anticonvulsant	15-20 mg/dog	РО	12						
-		2-3 mg/kg (D)	РО	8-12						
Chlorpromazine hydrochloride	Muscle relaxation during tetanus	0.5 mg/kg (D)	IM, IV	12						
	Amphetamine poisoning	10-18 mg/kg	IV	Once						
Clonazepam	Adjunctive anticonvulsant	0.5-1.5 mg/kg (D)	РО	8-12						
	Status epilepticus	1-10 mg/dog	РО	6-24						
		50-200 μg/kg (D)	IV	To effect						
Clorazepate dipotassium	Behavioral disorders, anxiolytic drug	1-2 mg/kg (C)	РО	8-12						
	Anticonvulsant	0.5-2 mg/kg (D)	РО	8-12						
Diazepam	Behavioral disorders, psychogenic alopecia	1-2 mg/cat	РО	12						
	Behavioral disorders, separation anxiety	0.5-2.2 mg/kg (D)	РО	As needed						
	Restraint	0.2-0.6 mg/kg (D)	IV	To effect						
		0.25 mg	РО	8						
Diazepam	Sedation	0.5-2.2 mg/kg	РО	As needed						
	Anticonvulsant	0.15-0.70 mg/kg (C)	PO	8						
		2-5 mg/cat	PO	8						
	Anticonvulsant (acute)	1-4 mg/kg (D)	PO	6-8						
	Anticonvulsant	2-5 mg/kg	IV, PO	8						
	Status epilepticus, certain toxicoses	1-2 mg/kg 0.5-5 mg/kg	Per rectum IV	As needed As needed. Start with a lower dose and increase in increments of 5-20 mg.						
	Strychnine-induced seizures	2-5 mg/kg	IV	As needed						
	Acquired tremors	0.25 mg/kg (D)	PO	6-8						
	Scotty cramps	0.5-2 mg/kg(D)	IV, PO	To effect or every 8						
	Preanesthetic	0.1-0.2 mg/kg(D)	IV (slowly)	to enece of every o						
		0.22-0.44 mg/kg. Maximum of 5 mg	IM, IV	To effect						
		0.5 mg/kg	IV	To effect						
	Irritable colon syndrome	0.15 mg/kg (D)	РО	8						
	Reflex dyssynergia (urethral obstruction)	2.5-5 mg/cat	РО	6-8						
		1.25-2.5 mg/cat	РО	8-12						
		0.5 mg/kg	IV	To effect						
	Appetite stimulant	0.05-0.4 mg/kg (C)	IM, IV, PO	24 or 48						
		1 mg/cat	PO	24						
	Functional urethral obstruction	2-10 mg	РО	8						
Ethosuximide	Seizures	Loading dose: 40 mg/kg Maintenance dose: 20	PO PO	Once						
Felbamate	Anticonvulsant	mg/kg 15-65 mg/kg (D). Maximum of 200 mg (small) and 400 mg (large)	РО	8-12 as needed						
	Hepatic encephalopathy	0.01-0.02 mg	IV	As needed						
Flumazenil		0								
		3 mg/kg	РО	24						
Flumazenil Gabapentin	Analgesic adjuvant, cancer pain Analgesic, neuropathic pain	3 mg/kg 10-30 mg/kg (D)	PO PO	24 8						

Drug	Indication	Dose	Route	Interval (hr)
Glyceryl monoacetate	Sodium fluoroacetate toxicosis	0.55 mg/kg. Maximum of 2-4 mg/kg	IM	Hourly until maximum dose reached
Levetiracetam	Anticonvulsant	20 mg/kg	РО	8; monitor
Lorazepam	Status epilepticus	0.2 mg/kg (D)	IV, intranasal	As needed
Methocarbamol	Controlling effects of strychnine and tetanus	55-220 mg/kg. Maximum of 330 mg/kg/day	IV	Give first half of dose rapidly until relaxation occurs then continue.
		Initial: 44-66 mg/kg (D)	PO PO	8-12
Mathada a data da a		Followed by: 20-66 mg/kg	IV	8-12
Methylprednisolone sodium succinate	Spinal trauma	Loading dose: 30 mg/kg (D)		Once
		Followed by: 5.4 mg/kg Or followed by: 15 mg/kg	IV CRI IV, SC	24-48 Once in 2, then every 6 × 2 days. Taper dose over 5-7 days.
4-Methylpyrazole 5%	Ethylene glycol toxicosis	Loading dose: 20 mg/kg (D)	IV	Once
		Followed by: 5 mg/kg (D)	IV	12×2 treatments
		Then: 5 mg/kg (D)	IV	Once (at 36 hours after initial injection)
Pentobarbital	Status epilepticus	5-15 mg/kg	IV	To effect
	Sedation	2-4 mg/kg	IV, PO	6 or to effect
	Anesthesia	10-30 mg/kg (D)	IV	Administer first half as a bolus, then to effect
		25 mg/kg (C)	IV	Administer first half as a bolus, then to effect
Phenobarbital	Status epileptic	Loading: 3-30 mg/kg (D)	IM, IV, PO	Increase by 3 mg/kg increments to effect
		3-6 mg/kg Each 3 mg/kg increases plasma drug concentrations by approximately 5 μg/mL	IM, IV, PO IV, IM, PO	12-24; monitor
	Maintenance antiseizure therapy	2-4 mg/kg	IV, PO	12; monitor
	Irritable colon syndrome	2.2 mg/kg (D)	PO	12
	Sedation	1-2 mg/kg (D)	PO	8-12
		1 mg/kg (C)	PO	12
Phenytoin	Tumor-induced hypoglycemia	6 mg/kg (D)	PO	8-12
	Anticonvulsant	20-40 mg/kg (D)	РО	8
		2-3 mg/kg (C)	PO	24
Physostigmine	Ivermectin toxicity	0.06 mg/kg	IV (slowly)	30-90 min, as needed
	Muscarinic mushroom intoxication	0.5-3 mg/dog	IM	30-90 min, as needed
Physostigmine 0.5%	Dysautonomia	Apply 0.3 cm (0.125 inches)/ cat	Topical	8
Picrotoxin (use is controversial)	Ivermectin toxicity	1 mg/min	IV (over 8 min)	Once
Pilocarpine 1% ophthalmic solution	Dysautonomia	1 drop	Both eyes	6
Potassium permanganate (1:2,000)	Strychnine toxicosis	5 mL/kg	PO (gastric lavage)	As needed
Pregabalin	Chronic pain, anticonvulsant	4 mg/kg (D)	РО	8
Primidone	Anticonvulsant	Loading dose: 55 mg/kg (D)	РО	Once. Efficacy of primidone reflects metabolism to phenobarbital; monitor.
		Maintenance dose: 10-15 mg/ kg (D)	РО	8 to 12

Table 27-3 Doses of Drugs Used To Treat Disorders of the Peripheral or Central Nervous

Drug	Indication	Dose	Route	Interval (hr)

that characterizes human generic products may not translate to therapeutic equivalence when that product is used in animals. Pharmacies may change a generic product intermittently as product prices change. Dispensing pharmacists may not understand the potential risk of differences in bioavailability between animals and humans. The prudent client should query pharmacists regarding changes in products, and the discerning clinician might encourage monitoring with new prescriptions, particularly in patients at risk for life-threatening seizures.

Rectal availability of diazepam has been well demonstrated. Intranasal administration has also been demonstrated as an effective route for selected drugs, particularly benzodiazepines. However, the physical volume that can be administered intranasally may limit practical application.

KEY POINT 27-6 Bioequivalence required of human drugs may not translate to bioequivalence in animals.

Distribution into the CNS is important for all anticonvulsant drugs, although at steady state, each generally distributes sufficiently into the CNS. Indeed, most anticonvulsant drugs are sufficiently lipid soluble that they are distributed to a volume that exceeds total body water (i.e., more than 0.6 L/kg). In contrast to chronic use, for acute situations rate and amount of drug movement into the CNS may not be sufficient for the rapid response necessary to resolve life-threatening seizures. Drug binding to serum proteins may limit the amount and rate of drug moving into the CNS. However, diazepam is the most lipid-soluble anticonvulsant and very rapidly distributes in the CNS despite its 90% protein binding (see Figure 27-4). Phenobarbital is less lipid soluble and is 50% protein-bound, and therapeutic effects may take as long as 15 minutes to be achieved. Löscher and Frey³¹ described the relative half-times to penetration of anticonvulsant drugs into the CSF of dogs. For diazepam its active metabolites desmethyldiazepam and oxazepam, clonazepam, and ethosuximide, the distribution half-time was 3 to 7 minutes, compared with 12 to 18 minutes for valproic acid, phenytoin, phenobarbital, and carbamazepine. In contrast, distribution half-time for primidone, its metabolite phenylethylmalonamide, and the active metabolite of carbamazepine

(i.e., carbamazepine-10, 11-epoxide) was 40 to 50 minutes. Lipophilicity, rather than extent of protein binding or degree of ionization, was the major determinant of the rate of distribution.

The role of P-glycoprotein and other ABC transporters in CNS drug distribution is well recognized, being present at both the blood-brain and blood-CSF barriers. The efflux pumps, often accompanied by drug-metabolizing enzymes, contribute to the poor CNS drug penetrability. However, Mealey and coworkers³² suggest that the impact of P-glycoprotein is very limited at the blood-CSF barrier compared with the bloodbrain barrier in dogs, based on similar penetration of a radiolabeled P-glycoprotein substrate into the CSF, but not brain, of normal (wild-type) dogs compared with ABCB1 knockout dogs. The role that efflux pumps contribute toward epilepsy, particularly refractory, is emerging.² Increased concentrations of Ppg are associated with seizures and refractory in human patients. In animal models of refractory epilepsy, efflux pump inhibitors have been associated with an increase in drug response. Yet several studies have demonstrated that the anticonvulsant drugs often are not substrates for Ppg. Using a canine osteosarcoma cell line, West and Mealey⁴ demonstrated that diazepam, gabapentin, lamotrigine, levetiracetam, and phenobarbital were weak substrates, whereas carbamazepine, felbamate, phenytoin, topiramate, and zonisamide were not substrates. However, other factors may affect the state of P-glycoprotein. For example, glutamate induces P-glycoprotein expression, which may contribute to a pre-epilpetic condition. Pekcec and coworkers³³ demonstrated upregulation of P-glycoprotein in dogs after an episode of SE. Furthermore, a number of other transporters may exist in the brain that might also affect anticonvulsant drugs.

Lipid solubility, which characterizes many anticonvulsants, necessitates hepatic metabolism if the drugs are to be eliminated. Metabolism of anticonvulsant drugs can have a profound effect on therapeutic success. The effect in part depends on the sequelae of phase I metabolism on the particular drug (i.e., inactivation, activation, or generation of toxic compounds). The rate of metabolism of anticonvulsants is variable: Phenobarbital is slowly metabolized, characterized by a long half-life, whereas diazepam is metabolized rapidly and is characterized by a short half-life (Table 27-4). The rate of metabolism

may vary markedly among species: Phenytoin is metabolized slowly in humans but is characterized by a half-life of less than 2 hours in dogs. Phase I metabolism often yields an active compound; anticonvulsant efficacy of the metabolite may be equal, greater, or less than that of to the parent drug. Primidone must be metabolized to its active metabolite, phenobarbital before it is effective in dogs. Clorazepate, a benzodiazepine, is a prodrug derivative of a diazepam metabolite that is converted in the stomach to its active form (Figure 27-5). Although diazepam is rapidly metabolized, its duration of pharmacologic effect is prolonged because most of its metabolites have some degree of anticonvulsant effect. The half-life of the metabolites may also be longer than those of the parent compounds.

Hepatic metabolism affects both efficacy and safety, in part because of its influence on fluctuation of drug concentrations during the dosing interval. Although it is clearance (regardless of hepatic or renal) that physiologically affects drug concentrations throughout the dosing interval, half-life is the practical pharmacokinetic measure of its impact (Box 27-1; see also Chapter 1). Neither antiepileptic efficacy nor safety of an anticonvulsant drug should be evaluated until at least 87% of steady-state concentrations has been reached, plus one seizure interval (such that the brain is challenged; see Table 27-1). Every time a dosing regimen is changed, a new steady-state equilibrium should be reached before final reevaluation. The time that must elapse before steady-state concentrations and maximum therapeutic response can occur may be unacceptably long for patients suffering from severe, life-threatening seizures or from unacceptable adverse effects to the initial antiepileptic drug. For such patients a loading dose might be administered such that therapeutic antiepileptic drug concentrations are achieved rapidly. The amount of the loading dose necessary to achieve steady-state concentrations (not equilibrium) increases proportionately with the half-life of the drug to be loaded: The loading dose is a sum of all the daily doses that would have been administered before steady state occurs, less any drug that will be eliminated from the body during that time period. The major disadvantage of a loading dose is the sudden effect of therapeutic concentrations in the CNS; no time is allowed for adaptation, and adverse effects (sedation, ataxia) are more likely than with gradual increases in drug concentrations. The maintenance antiepileptic drug dose that follows the loading dose is designed to maintain concentrations achieved by the loading dose. Both loading and maintenance doses are based on population disposition parameters; monitoring should be used to ensure that dosing regimens achieve targets

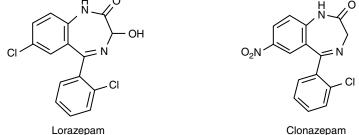

Figure 27-5 Phase I metabolism of diazepam yields metabolites of active, although less potent, metabolites. Clorazepate is metabolized in the stomach. Desmethyl diazepam, nordiazepam.

Box **27-1**

Impact of Dosing Interval and Half-Life

The shorter the half-life of the drug compared with the dosing interval, the more drug concentrations will fluctuate during a dosing interval; the longer the elimination half-life is compared to the dosing interval, the less fluctuation and the more accumulation across time. For example, if the half-life of phenobarbital approximates 72 hours in dogs, 50% of the first dose remains in the body by the sixth dose if the drug is given twice daily. Consequently, phenobarbital accumulates across time and will continue to do so until a steady-state concentration is reached. With a 72-hour half-life, only a small amount of each dose is eliminated during a 12-hour dosing interval-that is, before the next dose is administered. Accordingly, peak and trough concentrations will vary little during a 12-hour dosing interval, as long as the half-life does not dramatically shorten (i.e., due to induction). As steadystate equilibrium is reached (three to five drug half-lives), accumulated phenobarbital concentrations will be much greater than concentrations were after the first dose. The magnitude of accumulation (i.e., maximum drug concentration after the first dose compared with steady-state concentrations) increases as the difference between the dosing interval and half-life increases. Doses for such drugs are designed such that therapeutic concentrations are achieved at steady state. From a clinical standpoint, response to therapy should not be evaluated until steady state is reached; however, by one half-life, concentrations should be at 50% of maximum, which may be enough to affect seizure activity. For such drugs each daily dose contributes little to the total amount of drug in the animal, and therefore adding a single extra dose in a seizuring (or pre-ictal) patient will generally not affect drug concentrations. Rather, a "mini" loading dose generally must be given to rapidly increase drug concentrations sufficient to control seizures. On the other hand, should the patient miss a single dose (and for some drugs, multiple doses), the patient may be "protected" by the slow decline in drug concentrations reflecting the long half-life. In contrast, for drugs with a short half-life compared with the dosing interval, most of each dose is eliminated between doses. Fluctuation between peak and trough concentrations during a dosing interval can be dramatic and dangerous. For example, for a drug with a 12-hour half-life, concentrations will fluctuate 50% during a 12-hour dosing interval and 75% with a 24-hour dosing interval. For such drugs accumulation either does not occur or is minimal. Likewise, steady-state equilibrium does not really apply. Because each dose essentially achieves the maximum (and minimum) concentrations, response to therapy can be assessed rapidly. Likewise, should the patient need rapid control, an additional dose may be helpful because the total amount of drug in the body is generally provided with each dose. However, should a dose be missed for such drugs, a rapid decline in drug concentrations can precipitate seizures, including status epilepticus.

for the patient. Generally, antiepileptic drug monitoring is indicated immediately after the loading dose is completed (e.g., the next day). Patients should be monitored again one half-life later to ensure that the maintenance dose is able to maintain concentrations achieved with the loading dose. If the maintenance dose does not maintain what is achieved with the loading dose, the majority of the change as new steady state is reached with the new dose will occur during the first half-life of the drug. **KEY POINT 27-7** The impact of drug half-life on therapeutic efficacy may be profound. Attention to detail becomes more important for drugs with a short half-life.

SAFETY

The safety of anticonvulsant drugs is profoundly affected by metabolism, not only by virtue of short elimination half-lives (for some drugs) but also because of toxicity. Phase I metabolites, by their nature, are reactive. Although intended to progress to phase II metabolism (with subsequent detoxification, particularly by glutathione), some reactive metabolites can interact with and damage surrounding tissues; concentration in the liver can lead to predictable (type A or type I, also referred to as "intrinsic") hepatotoxicity. Thus the risk of hepatotoxicity is likely to be increased with dose and frequency of administration. However, idiosyncratic toxicity (i.e., neither dose nor duration dependent) may also be the sequelae of a metabolite. Although dogs receiving chronic anticonvulsant therapy often develop abnormalities in serum biochemistries and hepatic function tests,34-36 only about 15% of dogs receiving longterm anticonvulsant therapy have been estimated to be at risk to develop serious hepatotoxicity. This risk is, however, greatly increased if drug concentrations approach the maximum therapeutic range. Primidone is probably most commonly associated with hepatotoxicity in dogs, followed by phenobarbital and then phenytoin in combination therapy.³⁴⁻³⁶ One of the many reasons that phenytoin is no longer used as an anticonvulsant in dogs is hepatotoxicity. The risk of hepatotoxicity is discussed with each individual anticonvulsant. Toxicity may be enhanced by concurrent administration of drugs (e.g., phenobarbital) that induce drug-metabolizing enzymes and therefore increase the formation of potentially toxic (particularly phenytoin) intermediates.

Selected anticonvulsants (including phenytoin, phenobarbital, and zonisamide) can affect thyroid hormones; testing before initiation of anticonvulsant therapy might be prudent. Mechanisms include displacement from binding proteins (e.g., phenytoin), increased peripheral metabolism (e.g., phenobarbital), or decreased synthesis (e.g., zonisamide). These effects are discussed with the individual drug. Several anticonvulsants have been associated with changes in serum lipids (e.g., phenobarbital, carbamazepine, valproic acid) in both dogs³⁷ and humans.³⁸

DRUG INTERACTIONS

Most drug interactions involving antiepileptic drugs occur at the level of hepatic drug-metabolizing enzymes. Hepatic metabolism increases the risk of drug interactions; use of any drug metabolized by the liver should be lead to a focus on potential drug interactions. For some anticonvulsants (especially phenobarbital), drug interactions and sequelae have been well described; both induction and inhibition of drugmetabolizing enzymes have been reported. Phenobarbital is the most potent hepatic drug-metabolizing enzyme inducer known and will increase the rate and extend of hepatic metabolism of many drugs, including phenobarbital. Combinations of anticonvulsants can lead to unpredictable effects on drug metabolism. Antiepileptic drugs metabolized by the liver likewise can be affected by other drugs that alter drug-metabolizing enzyme. Cimetidine, ketoconazole, and chloramphenicol are drugs that decrease drug metabolism and have the potential to profoundly increase concentrations of the anticonvulsant. Drug interactions may also involve P-glycoprotein or other efflux transporters.² The impact of these interactions is an emerging area of research for antiepileptic drugs.

KEY POINT 27-8 The clinician should anticipate that the risk of drug interactions and hepatotoxicity is directly proportional to the proportion of the antiepileptic drug metabolized by the liver.

Drug interactions also can occur for drugs renally excreted, as is exemplified by bromide and drugs that affect urine chloride. Drug–diet interactions also have been described for bromide.

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring can be a critically impotant tool in the successful control of the difficult epileptic patient. However, not all anticonvulsant drugs can be nor need be monitored (see Chapter 5). For example, a therapeutic range must be established for the drug (and, if established in humans, be relevant for dogs or cats), and response must correlate with plasma drug concentrations. An easy, cost-effective assay that requires minimal sample handling must be available. Among the anticonvulsants to be discussed, automated assays are available for several anticonvulsants whereas more tedious and thus costly assays (e.g., high performance liquid chromoatography) must be implemented for others. Regardless of the methodology, clinician should confirm that the laboratory has validated any procedure used to quantitate drug in the target species and implements an external quality-assurance program.

In human medicine, the use of therapeutic drug monitoring for newer anticonvulsants (which tend to be safer) is not as well established compared with that for older drugs, in part because of the lack of generally accepted target ranges (Table 27-5). However, Bialer and coworkers²⁷ demonstrated a concentration–response relationship for antiepileptic drugs in humans, justifying monitoring. Controlled clinical trials establishing concentration–response relationships are needed in both human and animals to establish therapeutic ranges. Currently, the range in serum concentration associated with efficacy is large for some drugs and overlaps with toxicity in some patients.³⁹ Nevertheless, therapeutic drug monitoring

(+)Bromide (K+) 119 Bromide (Na+) 103 D= Dog remains a recognized tool for individualization of drug therapy. The author suggests a "start-up", "follow-up", "check-up," and "what's-up" approach to monitoring (Box 27-2). Clearly, monitoring should be implemented to avoid toxic concentrations and to establish the minimum effective range for the epileptic patient This latter reason is particularly relevant for previously controlled patients suffering from breakthrough seizures (previously well controlled): a decrease in drug concentrations compared with baseline should lead to a focus on owner compliance, drug interactions, changes in disposition, and so forth, whereas seizures despite no change in concentrations might be interpreted as worsening of underlying disease and the potential need to control seizures more aggressively. therapy not be considered failed until trough concentrations are in the higher

Box 27-2

Therapeutic Drug Monitoring and Antiepileptic Drugs

When to monitor:

Start-up: To establish base-line concentrations, and ideally the minimum effective concentration for the patient. This is particularly important in the patient that subsequently has break-through seizures or a sudden change in clinical signs suggestive of side effects or adverse events. Start up monitoring should be designed to establish a minmum effective dose such that the patient is not exposed to higher than necessary concentrations. Start-up is also indicated to establish when a uncontrolled patient has exceeded the maximum therapeutic range and further increases in therapy are not likely to contribute significantly to seizure control. At that point (and ideally only at that point) is combination therapy implemented. Start-up monitoring also should be implemented within a day of a loading dose.

Follow-up: Every time a new dosing regimen is implemented the patient should be remonitored at steady-state (this might be withheld until response is realized). A new dosing regimen is defined by any change in dose or interval, or the appearance of a patient factor that might change drug disposition. This includes transitioning from a loading dose to a maintenance dose or adjusting a maintenance dose. Monitoring also should be implemented if a change is anticipated in the patient that might alter drug half-life and thus drug concentrations. Examples include the addition (or discontinuation) of one or more drugs (antiepileptic drugs or nonantiepileptic drugs that can influence the disposition of the antiepileptic drug), a change in the diet (e.g., for bromide), or a change in patient health such that disposition might change as disease progresses or responds to therapy. Determining the most appropriate time point for monitoring will be complicated in patients in which drug halflife has changed and is no longer predicted by sample population statistics. For such patients more frequent monitoring is suggested.

Check-up: Monitoring proactively is particularly important for patients at risk for therapeutic failure. Monitoring is also important as patients age, are placed on diets, etc. The interval of routine monitoring should be individually determined, ranging from 3 months in patients with proven history of variability in drug concentrations to yearly as part of the annual physical examination.

What's-up? Monitoring should be implemented if a previously controlled patient begins to experience seizures or clinical signs emerge suggested of side adverse events. Availability of baseline greatly facilitates interpretation. Monitoring helps identify factors which might cause drug concentrations to change (e.g., drug interactions, change in diet, poor owner compliance). Monitoring should also be implemented to help clarify the role of disease in clinical signs.

Loading dose: If a loading dose is used, drug concentrations should be monitored after a loading dose, one drug elimination half-life later and, to establish a new steady state, three to five drug half-lives later. The sample collected at one drug elimination half-life should be equivalent to the loading dose sample; if not, the mainte-

nance dose must be adjusted accordingly. The collection of a sample one half-life after a loading dose is minimally useful unless a postload sample has been collected; because the patient is not yet at steady state with the maintenance dose, plasma drug concentrations are still in a state of flux. *No loading dose:* If a loading dose is not administered, and the drug is characterized by a long half-life (i.e., several weeks to months until steady state is reached), a sample can be collected at one half-life to allow proactive evaluation of the appropriateness of a chosen dosing regimen: doubling the concentration measured at one half-life predicts baseline steady-state concentrations. If the predicted concentrations are not on target, the maintenance dose can be adjusted. Otherwise, for most drugs, monitoring can begin with a baseline sample collected at three to five drug half-lives.

Number of samples: The need for peak, trough, or both samples depends on the half-life of the drug. If the half-life in the patient is substantially longer than the dosing interval (we recommend greater than 2 to 3 times), peak and trough concentrations will be very similar, and a single trough sample collected just before a dose is sufficient (e.g., bromide, and for the majority of patients, phenobarbital; zonisamide). The trough sample is preferred: not only does it reveal the lowest concentration to which the patient is exposed during a dosing interval, it also is not impact by absorption and distribution and thus is most likely to be consistent for across-time comparisons. For drugs that might fluctuate markedly during a dosing interval (e.g., levetiracetam, gabapentin, pregabalin, and zonisamide in some pateints), both a peak and trough sample should be taken to determine patient half-life. If the half-live is revealed to be long, then subsequent single trough samples are indicated.

Other considerations: Animals should be fasted before samples are collected, particularly for drugs that do not accumulate (i.e., those that are characterized by a short half-life). Special handling preparations generally are unusual, although each laboratory should be called to confirm special handling procedures. Serum separator tubes are contraindicated because the silicon separator can bind anticonvulsant drugs and falsely decrease serum drug concentrations. If used, serum should be immediately harvested after centrifugation.¹⁴⁹

Interpretation of therapeutic drug monitoring results can be facilitated by a clinical pharmacologist. Monitoring should be used to identify the therapeutic range for the individual patient. Therapeutic failure should not be considered if a patient is having seizures simply because the therapeutic range has been achieved, nor should a drug be discontinued or the dose increased if a patient is not having seizures despite subtherapeutic concentrations. For a patient that is not sufficiently controlled, doses can be gradually increased until the maximum range has been reached and the risk of adverse affects becomes too great. Many patients require and can tolerate concentrations of less toxic drugs (e.g., bromide) that are well above the maximum. end of the therapeutic range. Serum separator tubes should not be used for collection of samples intended for therapeutic drug monitoring.

KEY POINT 27-9 Among the most important reasons for monitoring antiepileptic drugs is to establish a baseline for comparison in the event of breakthrough seizures.

ANTICONVULSANT DRUGS

Phenobarbital

Mechanism of Action

Phenobarbital sodium (see Figure 27-4) specifically depresses the motor centers of the cerebral cortex, thus enhancing anticonvulsant properties. Electroshock experiments with cats and other species established phenobarbital as one of the most potent anticonvulsants available. It has the widest spectrum of activity in different convulsive seizure patterns. Many AED have been synthesized as structural variants of phenobarbital. For example, primidone is a close congener of phenobarbital.

Phenobarbital is the most effective anticonvulsant to delay progressive intensification of seizure activity that may accompany epilepsy. Phenobarbital both increases the seizure threshold required for seizure discharge and decreases the spread of discharge to surrounding neurons; its primary mechanism is enhancement of responsiveness to the inhibitory postsynaptic effects of GABA. Interaction of GABA opens a chloride channel, resulting in higher intracellular concentrations of chloride and hyperpolarization of the RMP (see Figure 27-3). Phenobarbital also, however, inhibits glutamate activity and probably calcium fluxes across the neuronal membrane. A study that compared CSF concentrations of GABA and glutamate in epileptic Labrador Retrievers versus non-Labrador Retrievers and in non-epileptic Beagles also compared concentrations in those epileptic dogs treated with phenobarbital and those not treated.²² Within the non-Labrador Retriever phenobarbitaltreated group, GABA, glutamate, and aspartate CSF concentrations were lower compared with those of their untreated counterparts. This difference was not detected in the Labrador Retrievers treated versus untreated groups; however, only 14 Labrador Retrievers were receiving phenobarbital, which may have limited the power to detect a significant difference.

Phenobarbital might be considered a broad-spectrum anticonvulsant. Despite introduction of new antiepileptic drugs, phenobarbital has generally been the anticonvulsant of choice for the cat and dog.¹⁷ It is effective in all types of epileptic seizures observed in cats and dogs.

Disposition

As a weak acid (pK_a 7.3), phenobarbital is well absorbed after oral administration, although peak plasma concentrations may not be reached for 4 to 6 hours after administration. The absorption half-life in dogs is 1.27 ± 0.21 hours.⁴⁰ With an elimination half-life of 0.26 ± 0.18 , about 6.4 hours may be required for near complete absorption of phenobarbital from the gastrointestinal tract. Absorption is 88% to 95% complete.⁴¹ Phenobarbital is 45% bound to serum protein in dogs.⁴² The volume of distribution of phenobarbital in dogs is 0.7 ± 0.15 L/kg and 0.7 ± 0.4 in cats.⁴³ Approximately 16 days (8 to 15.5 days) of multiple dosing is necessary to attain steady-state serum concentrations in the normal (uninduced) animal; however, induction may cause this period to be shorter after a change in the dosing regimen of an animal already receiving phenobarbital. Maintenance doses of 5.5 mg/kg daily (in one to three equal doses) administered orally are required to reach an average serum concentration of 20 µg/mL, according to one study.⁴⁴

KEY POINT 27-10 The efficacy of phenobarbital must be balanced with the risk of liver disease, which increases as drug concentrations increase.

Through microsomal enzyme action, phenobarbital is metabolized by oxidative hydroxylation to form hydroxyphenobarbital. This metabolite has a weak anticonvulsant activity that does not contribute significantly to the action of phenobarbital. Hydroxyphenobarbital is rapidly eliminated from blood by conjugation with glucuronide and excretion in urine of the dog. Up to 25% of the parent drug is eliminated renally in dogs. Individual variability in the rate of phenobarbital elimination is marked owing to differences in hepatic metabolism. Half-life varies not only between and within species but also in the same animal, in part because of induction (discussed later).

Breed differences may exist in phenobarbital clearance. Frey and Löscher⁴² reported a half-life of phenobarbital at 64 ± 15 hours in largely mongrel dogs, but 32 ± 4.8 in Beagles; clearance was 7.0 \pm 1.3 and 13 \pm 1.7 mL/kg/min, respectively. Alkalinization of urine (pH >7.5) accelerates excretion of unaltered phenobarbital by reducing back-diffusion (tubular reabsorption) through drug ionization.⁴⁵ Fukunaga and coworkers⁴⁶ demonstrated that a twice-daily fed diet containing either 0.6 gof potassium citrate (pH 7.8 to 8.2) or 0.2 g of ammonium chloride (pH approximating 5.9 to 6.5) increased urine clearance of a single dose of phenobarbital compared with a water vehicle (pH 6.8 to 7.5) in Beagles (n = 5; female). However, the effect did not significantly (statistically nor clinically)impact peak plasma drug concentrations (µg/mL: 3.25, 2.96, and 2.97 µg/mL for water placebo, ammonium chloride, or potassium citrate, respectively) or area under the curve. Yet, half-life was affected (52, 59.6, and 51.1 hours, respectively), and as such peak concentrations might be slightly affected if the drug is dosed to steady state.

Phenobarbital is a potent inducer of hepatic drug-metabolizing enzymes and is capable of increasing the rate of clearance of other drugs metabolized by the liver as well as increasing its own rate of metabolism.⁴⁷ In the dog phenobarbital (2 mg/kg) administered orally 3 times a day for 5 days results in an elimination half-life between 37 and 75 hours, with a mean elimination half-life of 53 ± 15 hours.⁴⁴ After a single 5-mg/kg intravenous dose, clearance is 5.6 to 6.6 mL/kg per hour, and elimination half-life is 92.6 ± 23.7 hours in dogs⁴⁰ and 47 ± 3 hours after oral administration (5 mg/kg) in cats. The effects of multiple doses of phenobarbital were documented by Ravis and coworkers.⁴⁸ After 90 days of treatment (5.5 mg/kg), mean elimination half-life decreased from 88.7 \pm 19.6 hours to 47.5 \pm 10.7 hours in dogs. In cats 21 days of oral phenobarbital at 5 mg/kg resulted in a half-life of 43 \pm 3 hours.⁴³

Preparations

Phenobarbital is available as either an oral or an injectable preparation. Oral tablets contain 0.25, 0.50, or 1 grain (15, 30, and 65 mg, respectively) phenobarbital. An elixir is also available (4 mg/mL) for treatment of very small animals. The injectable form is intended for intravenous use but can be given intramuscularly and rectally. Under the 1970 Controlled Substances Act, phenobarbital is classified as a Schedule IV drug.

Clinical Use

Phenobarbital is reportedly effective in 60% to 80% of canine patients suffering from epilepsy if serum concentrations of the drug are maintained within the recommended therapeutic ranges of 20 to 45 µg/mL.49 This is consistent with the early work of Farnbach,⁵⁰ who reported that the concentrations of phenobarbital necessary to control seizures (control defined as interictal interval prolonged at least twice that of the pretreatment period). Concentrations considered effective (n = 22) ranged from extremes of 6.5 to 81.3 µg/mL, with others ranging from 14.2 to 46 µg/mL (mean 23 µg/mL); however, concentrations not associated with control (n=20) ranged from 4.7 to 42 μ g/mL. Efficacy might be higher if therapeutic failure is not considered until the maximum end of the range (i.e., 35 to 45 µg/mL) has been reached (Figure 27-6.). The author has reported 85% efficacy in eradication of seizures in spontaneous canine epilepsy with phenobarbital concentrations at $25.4 \pm 5.7 \,\mu\text{g/mL}$ with such an approach.²⁸ In this same study, phenobarbital was found to be superior to bromide for first choice control of seizures in dogs (see the discussion of bromide). Phenobarbital has been used successfully to treat hypersialosis.51

Patients should not considered refractory to phenobarbital therapy until plasma concentrations reach 35 to 40 µg/ mL unless unacceptable side effects persist at lower concentrations. However, because of the potential for phenobarbital-induced hepatotoxicity, the author often recommends adjuvant therapy once phenobarbital concentrations exceed 25 µg/mL in an uncontrolled dog. The dose necessary to achieve target concentrations may vary dramatically among dogs and in the same dog across time because of differences or changes in drug disposition. Changes are likely to reflect, in part, induction of drug-metabolizing enzymes; monitoring should occur 1 to 2 months after baseline is established to detect the possible impact of induction. Measurement of both a peak and trough sample can detect a short half-life; for patients in which phenobarbital half-life is 24 hours or less, the same or a slightly higher (e.g., 25% increase) total dose divided into 8-hour rather than 12-hour intervals may minimize fluctuation of plasma drug concentrations. Clearly, once-daily dosing should be avoided in the face of induction that decreases halflife to 36 hours or less. Phenobarbital elimination half-lives of 9 to 12 hours have been documented in the author's laboratory

in some dogs that have been receiving phenobarbital for several months.

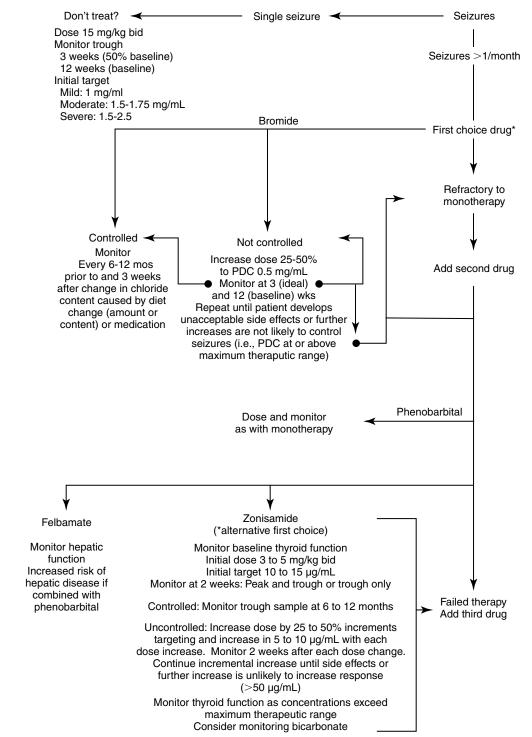

Phenobarbital can be administered intravenously for acute control of seizures, although a lag time (i.e., 20 to 30 minutes) may be observed before control of seizures. An intravenous loading dose of 12 mg/kg is designed to achieve therapeutic concentrations (20 μ g/mL) immediately; the dose can be decreased proportionately (on the basis of serum phenobarbital concentrations) if the patient is currently receiving phenobarbital. Alternatively, the calculated dose can be given in four to six equal hourly doses. Collection of a postload monitoring sample would be prudent once seizures are controlled; this sample can provide a target for maintenance therapy. A second sample 2 or 3 days later should be used to assess the oral maintenance dose. If used in combination with intravenous diazepam (for its more immediate effects) to prolong the control of seizures, the phenobarbital dose might be administered intramuscularly to avoid respiratory and cardiovascular depression. Once seizures are controlled with phenobarbital alone, monitoring should establish the target concentration for chronic therapy in the patient.

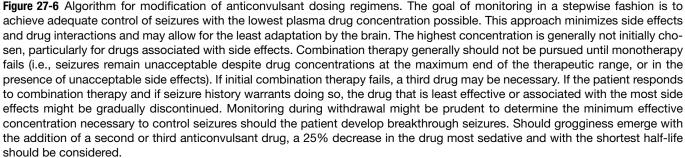

KEY POINT 27-11 The long half-life of phenobarbital precludes rapid response unless a mini "loading" dose is administered.

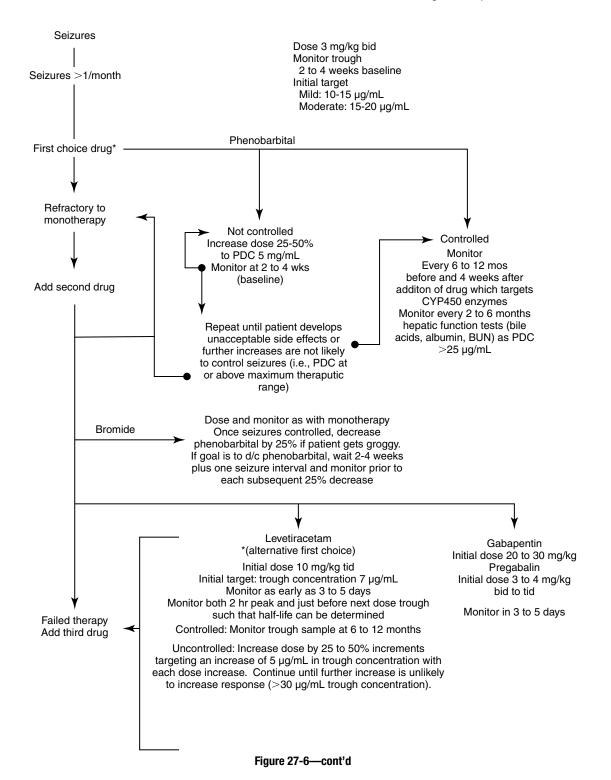

Limited information is available regarding the use of phenobarbital in cats. Phenobarbital administered at 6 mg/kg daily was useful in suppressing experimentally induced hippocampal generalized seizures in cats; drug concentrations ranged between 15 and 25 μ g/mL. After-discharge was totally suppressed in 33% of cats at 35 to 50 μ g/mL (12 mg/kg daily). However, phenobarbital was less effective for amygdaloid-kindled seizures.⁵²

Drug Interactions

Hepatic microsomal enzyme activity, especially mixedfunction oxidase (cytochrome P450 [CYP]) induction, is accelerated by phenobarbital.⁵³⁻⁵⁶ Enzyme induction by phenobarbital appears to be dose related.⁵⁷ Long-acting barbiturates are better inducers of microsomal enzyme activity than are short-acting compounds. For example, compared on a molar basis, phenobarbital has been described as the most potent enzyme stimulatory agent known,⁵⁸ whereas pentobarbital and thiopental sodium are less potent inducers of microsomal enzyme activity, in part because duration of therapy dose, and thus impact, is limited. Enzyme induction may take weeks to months and may occur with each dose increase. Induction has been documented in dogs⁵⁹⁻⁶² but apparently not in cats. Although it may occur occur in the latter species, saturation of drug met. Phenobarbital was associated with a twofold increase in CYP protein and increased clearance of the hepatic metabolism marker antipyrine in Beagles treated with 5 mg/kg orally every 12 hours for 35 days. Among the CYP isoenzymes characterized by an increase in activity were CYP1A, CYP2B, CYP2C, and CYP3A; in contrast, CYP2D did not appear to increase.63

Induction does not immediately resolve once a drug is discontinued: For example, once phenobarbital initiates induction, up to 7 months may be required for complete resolution in the dog. Fukunaga and coworkers⁶⁴ demonstrated that antipyrine clearance was increased in response to phenobarbital at 4 weeks but not 6 weeks in dogs receiving 5 mg/kg of phenobarbital twice daily. Clearance was increased by close to 60% during phenobarbital therapy. Interestingly, volume of distribution increased almost threefold, and half-life *increased*, as did mean residence time, despite the change in clearance. The investigators did not include a control group that did not receive phenobarbital, complicating interpretation. Clinically, as per the author's therapeutic drug monitoring laboratory, however, induction often decreases the elimination half-life and thus duration of therapeutic response to other drugs metabolized by those enzymes induced by phenobarbital (see Chapter 2). In the dog, experimental documentation includes digoxin and digitoxin^{44,65,66} and thiopental.⁶⁷ However, induction does not

appear to affect thiopentone (thiopental) dose requirements in the dog.⁶⁸ For drugs in which toxic metabolites are produced, the induced liver will produce more metabolites; therefore potentially hepatotoxic drugs should not be used with phenobarbital. *N*-Acetylcysteine should be used in cases of druginduced acute hepatopathy, regardless of the cause (exceptions might be made in the presence of hepatic encephalopathy). Longer term support might include s-adenosyl methionine (SAMe) or milk thistle as well as other therapies.

Phenobarbital therapy (2.5 mg/kg orally every 12 hours for 30 days) was associated with a decrease in the peak concentrations of benzodiazepines (diazepam/oxazepam) after single-dose administration of 2 mg/kg either intravenously (about 10%, from 5963 to 5565 ng/mL) or rectally (about 60% decrease, from 630 to 270 ng/mL). However, the target associated with seizure control (150 ng/mL) was achieved in five of six dogs within 8 minutes of rectal administration.⁶⁹

KEY POINT 27-12 Phenobarbital is among the most potent inducers of drug-metabolizing enzymes. Serum alkaline phosphatase also may be induced.

Side Effects

Behavior. Polyphagia, polydipsia, and polyuria are side effects that occur in animals receiving clinical dosages of phenobarbital. The polyuric effect is apparently due to an inhibitory action in the release of antidiuretic hormone. ⁷⁰ Identical sedative side effects are observed in the dog after treatment with phenobarbital or primidone (discussed later).¹⁷ Dogs appear fatigued and listless after receiving either drug; some are weak in the rear legs, and ataxia occurs. All of these effects may be long lasting and may persist in some cases for the duration of treatment; however, tolerance to these effects generally develops in most dogs 1 to 2 weeks after initiating the dosing regimens.

Bone marrow dyscrasias and others. Phenobarbital can cause what is an apparent allergic reaction manifested as a bone marrow dyscrasia in dogs. Pancytopenia or (more commonly) neutropenia is detected after a complete blood count in animals that presented with a variety of clinical signs. Bone marrow suppression generally resolves rapidly once phenobarbital is discontinued.⁷¹ Bone marrow necrosis also has been associated with phenobarbital. 72 Care should be taken to begin an alternative anticonvulsant drug (e.g., bromide) in animals that are at risk for worsening of seizures should phenobarbital be rapidly discontinued. It is likely that a metabolite is the cause of the dyscrasia; as such, an anticonvulsant minimally metabolized by the liver may be a wiser choice for drug replacement. Phenobarbital-induced coagulopathy has been reported in the cat.73 Superficial necrolytic dermatitis has been reported in dogs receiving phenobarbital.74

Thyroid. Phenobarbital can induce tissue (peripheral tissues and the liver) metabolism of thyroid hormones. Serum total thyroxine (T_4), total triiodothyronine (T_3), free T_4 , and thyroid-stimulating hormone (TSH) concentrations were compared in epileptic dogs (n = 78) with seizure disorders and treated with phenobarbital (n = 55), phenobarbital and

bromide (n = 15), and bromide (n = 8) and clinically normal dogs (n = 150). Whereas T_3 and TSH total did not differ among groups, total and free T4 were lower in phenobarbital and phenobarbital plus bromide compared with concentrations in clinically normal dogs. Bromide-treated dogs did not differ from clinically normal dogs. Serum total and free T₄ concentrations were lower than normal (i.e., in the range typical for dogs with hypothyroidism) in the dogs treated with phenobarbital.75 In a second study of experimental dogs (n = 12), Gieger and coworkers⁷⁶ demonstrated that phenobarbital at 4.4 to 6.6 mg/kg adminstered orally twice daily for 27 weeks resulted in significant decreases in serum T₄ and free T₄ and increased TSH. These changes persisted for up to 4 weeks after discontinuation of therapy.⁷⁶ Thyroid screens in apparently normal animals that yield results indicative of hypothyroidism do not necessarily indicate the need for treatment; indeed, overtreatment may result in undesirable CNS stimulation. On the other hand, if an animal presents with clinical signs consistent with hypothyroidism, replacement therapy may be indicated.

Osteomalacia. In humans long-term (more than 2 years) treatment of epileptic patients with selected anticonvulsants (phenobarbital and primidone but not phenytoin) has been associated with development of osteomalacia; subnormal serum calcium is seen in such patients. The mechanism is not clear, although accelerated conversion accelerated of vitamin D₃ to 25-hydroxycholecalciferol (25-OHD3) but not 25-OHD3 to 1,25-dihydroxycholecalciferol (1,25-(OH)2D3) is a documented effect of phenobarbital.⁷⁶

Hepatotoxicity. At high plasma drug concentrations (i.e., more than 30 to 40 µg/mL), phenobarbital appears to be hepatotoxic.77 Animals whose liver is induced and thus requires high doses of phenobarbital to maintain drug concentrations in the lower therapeutic range may also be more susceptible to toxicity because of increased formation of metabolites. Phenobarbital will also cause nonpathologic changes in hepatic clinical laboratory tests because of induction of enzymes. Serum alkaline phosphatase (SAP) and the transaminases are likely to increase with chronic therapy.34,36,77-79 These are not necessarily indicative of liver disease. However, Gaskill and coworkers^{79a} suggest that changes in SAP associated with phenobarbital are indicative of hepatopathy rather than hepatic disease. Changes associated with true hepatic pathology appear to be more likely with primidone (see later discussion). Moderate elevations in alanine transaminase and SAP, coupled with changes in hepatic function (e.g., serum bile acids, albumin, and serum [blood] urea nitrogen) are more indicative of hepatic pathology (i.e., liver disease). Hepatic function tests (e.g., serum bile acids) should be studied to monitor the development or progression of liver disease. Bilirubin has not been a sensitive indicator of liver disease induced by phenobarbital in the author's experience; indeed, it generally increases only with end-stage liver disease, if at all. Interestingly, decreased serum cholesterol levels have occurred relatively early. Liver enzymes should not be monitored until several days after a seizure to avoid the impact of hypoxia and other effects on hepatic leakage enzymes. Consistent increases in serum bile acids and decreased serum urea nitrogen and albumin concentrations are supportive of phenobarbital-induced hepatic disease and the need for rapid but cautious withdrawal of phenobarbital in concert with initiation of an alternative anticonvulsant. Toxicity can occur within several months but appears reversible if the drug is discontinued before fibrotic disease develops.⁷⁹ The incidence of serious liver toxicity might be reduced by avoiding combinations of drugs in which more than one is characterized by hepatic metabolism, using therapeutic drug monitoring to achieve adequate serum concentrations at the smallest dose possible, and evaluating clinical pathology changes every 4 to 6 months (or more frequently in animals at risk) while the patient is receiving therapy. Although liver disease associated with phenobarbital therapy has been occasionally noted at phenobarbital concentrations ranging from 12 to 25 µg/mL in patients being monitored in the author's laboratory, the direct cause and effect was not established.

KEY POINT 27-13 Hepatic function tests (serum albumin, urea nitrogen, and bile acids) should be the basis for diagnosis of phenobarbital hepatotoxicity.

Decreasing drug concentrations should also reduce the progression of chronic disease to cirrhotic disease, although what constitutes a safe target phenobarbital concentration in these patients has not been documented. Bromide therapy should be initiated for patients with liver disease (regardless of the cause) who must also receive anticonvulsant therapy. Despite its ability to cause hepatotoxicity, phenobarbital appears to be a safe and effective anticonvulsant if drug concentrations can be maintained well below the recommended maximum.

Hypertriglyceridemia. Phenobarbital is among several anticonvulsant drugs (others being carbamazepine and valproic acid) associated with serum lipid profiles in children.³⁸ Effects of phenobarbital are described as transient. Phenobarbital has been associated with hypertriglyceridemia in dogs.³⁷ Median fasting serum triglyceride (mmol/L) was 0.6 (range 0.9 to 1.6) for phenobarbital (n = 28) and 0.6 (range 1.2 to 3.6 mmol/L) for the combination of phenobarbital and bromide (n = 29); compared to non-epileptic control dogs at 0.4 (n = 57) (range 0.6 to 0.9) not receiving phenobarbital.³⁷ Of the 57 dogs studied, triglycerides were increased in 33% when compared with a reference range established in the non-epileptic dogs. Phenobarbital was higher and more variable in dogs receiving phenobarbital with bromide (109 \pm 47 μ mole/L) only compared with dogs receiving phenobarbital alone (83 \pm 21 μ mole/L). Body condition score was significantly related to increased triglycerides. Although no correlation was found between phenobarbital and triglyceride concentrations, a trend was identified between phenobarbital dose and triglycerides. However, the control group consisted of normal healthy animals rather than epileptics not receiving anticonvulsants, and an additional study is warranted to address the potential risk of higher triglycerides in epileptic dogs receiving phenobarbital compared to no phenobarbital.

Phenobarbital may be associated with pancreatitis. Although studies have focused on bromide, studies supporting this association have documented an increased risk in patients receiving both bromide and phenobarbital, as well as phenobarbital alone.^{80,81}

Treatment of Acute Phenobarbital Toxicosis

Treatment of acute phenobarbital toxicosis is generally supportive. Dogs apparently can tolerate marked acute overdosing (in the author's experience, concentrations approximately 150 μ g/mL) without persistent effects, once the drug has been discontinued. Sedation is the most detrimental effect. Artificial respiration with oxygen should be administered to prevent respiratory arrest induced. Although less effective than oxygen, doxapram or other analeptic drugs might stimulate the respiratory center. Alkalinization of the urine accelerates renal excretion of phenobarbital because of ion trapping in the urine, although this is not easily accomplished.⁴⁵ Activated charcoal effectively accelerates the body clearance of phenobarbital.82 When charcoal is administered in the human, the biological half-life of phenobarbital is decreased from 110 ± 8 to 45 ± 6 hours; it increases the total body clearance of phenobarbital from 4.4 ± 0.2 to 12.0 ± 1.6 mL/kg per hour.⁸² Assuming drug metabolizing enzymes are not saturated (threshold not known in the dog or cat), the time needed for phenobarbital concentrations to decline such that sedation is no longer present depends on the drug concentrations (i.e., the extent of overdose) and the elimination half-life of the drug in the patient. For example, at 150 µg/mL, approximately three halflives must elapse before concentrations drop below 35 µg/mL; for a 72-hour half-life, 9 days must elapse. Both the magnitude and half-life (assuming saturation has not occurred) of phenobarbital can be monitored in an overdose patient; a sample should be collected on presentation and again 24 hours later. Timing of sample collections must accompany the samples if a half-life is to be calculated. A follow-up sample 2 or 3 days later can confirm that the original half-life was correct (i.e., saturation has not occurred). In cases indicative of acute hepatopathy, N-acetylcysteine should be administered, as for acetaminophen toxicosis.

Primidone

Primidone is metabolized in the liver to phenylethylmalonic acid (PEMA) and phenobarbital (see Figure 27-4).83 Although all three compounds have anticonvulsant activities, phenobarbital is much more potent and has a longer half-life than primidone and PEMA (and thus accumulates). Thus phenobarbital contributes up to 85% of the anticonvulsant activity, and phenobarbital concentrations, not the parent drug, correlates with primidone efficacy.⁴⁹ Frey and Löscher⁴² studied both primidone and PEMA after intravenous and oral administration in dogs and Beagles (see Table 27-4). Primidone is characterized by a short half-life (6 to 12 hours) compared with phenobarbital, although concentrations decrease, presumably as a result of induction, after 14 days of therapy. Phenobarbital reached approximately 65 mmol/mL (11 µg/ml) compared with 50 mol/mL for PEMA, with primidone at 14 mol/mL. The rate of entry into the CNS ranged from 0.01 to 0.023/min for primidone and 0.11 to 0.022/min for PEMA. In 15 epileptic dogs,⁴⁹ primidone administered at a range of 10.6 to 20.3 mg/kg

every 8 hours yielded mean phenobarbital, PEMA, and primidone concentrations were (presumably at steady state) 31.9, 16.5, and 0.9 µg/mL, respectively. As such, phenobarbital should be monitored rather than primidone, using the phenobarbital therapeutic range. Further, all attributes and detractors previously discussed for phenobarbital generally apply to primidone. Primidone has been used in patients refractory to phenobarbital at the maximum therapeutic drug concentration (i.e., 40 µg/mL), but its efficacy in this scenario has not been proved.^{17,84,85} Efficacy may simply reflect improved conversion to phenobarbital (i.e., animals that are induced may metabolize the drug to greater concentrations of phenobarbital than generated from administration of phenobarbital alone). Farnbach^{50,86} reported that the concentration of phenobarbital associated with effective anticonvulsant therapy in dogs given primidone (n = 12) ranged from 4.8 to 70.7 μ g/mL (median 27; dose 15.2 to 81 mg/kg daily), compared with ineffective concentrations (n = 11), which ranged from 0.3 to 52.8 (dose 5.5 to 83.3 mg/kg). According to Farnbach,^{50,86} there is no advantage to using primidone rather than phenobarbital for control of epilepsy in most dogs.

The conversion ratio of primidone to phenobarbital is 3.8:1. A patient should receive approximately 65 mg (1 grain) of phenobarbital for each 250 mg of primidone. Because this rate does not reflect the potential effects of phenobarbital (i.e., primidone) induction, however, animals may convert primidone to phenobarbital at different rates. Baseline phenobarbital concentrations should be established before conversion. Conversion should probably be progressive (e.g., 25% change each month) in at-risk patients (i.e., those whose seizure history includes prolonged or cluster seizures). Cats do not metabolize primidone to phenobarbital as efficiently as dogs.⁸⁷ Phenobarbital, PEMA, and primidone concentrations (μ g/mL) were 4.1, 11.5, and 5.1, respectively, in cats (n = 11) receiving 20 mg/kg primidone orally twice daily for up to 90 days. The elimination half-life was 7 hours. Although primidone was considered safe, anticonvulsant concentrations were not therapeutic. Thus the safety of primidone at effective concentrations has not been established in cats, and its use is not recommended for the treatment of feline seizures.

Side Effects

All side effects noted for phenobarbital are caused by primidone. Primidone may induce nystagmus, nausea, drowsiness, and ataxia. According to Schwartz-Porsche et al.,¹⁷ polydipsia is more common in dogs treated with primidone. In humans it is recommended that therapeutic plasma concentrations of primidone and its metabolite phenobarbital not exceed 15 and 30 µg/mL, respectively. Megaloblastic anemia is one of the more serious adverse effects of primidone in humans. Pruritis characterized by alopecia, scaling, ulceration, pigmentation, and fissuring has been recorded in dogs.⁸⁶

KEY POINT 27-14 The use of primidone, a prodrug for phenobarbital, is discouraged because of the increased risk of liver disease. In the dog primidone induces progressive hepatic injury, as manifested by increases in liver enzyme values.⁸⁹ In a clinical study, signs of liver toxicity were reported in 14 of 20 dogs.¹⁷ Hepatic cirrhosis associated with primidone and phenobarbital after 7 years of use has been reported in a dog.⁹⁰ Primidone-induced dermatitis has been reported in a dog.⁸⁸

Drug Interactions

Drug interactions previously described for phenobarbital also occur with primidone. Primidone should not be used concurrently with chloramphenicol, which is a potent inhibitor of the microsomal enzyme system. Severe CNS depression and inappetence occur in the dog after concurrent use of these drugs.⁹¹

Pentobarbital Sodium

Pentobarbital sodium (pentobarbitone sodium; Nembutal Sodium), administered intravenously, is considered to be the most efficacious drug for abolishing refractory SE in the dog. Pentobarbital is a general anesthetic (not an anticonvulsant), but it is nonetheless an effective drug for control of nonresponsive seizures; extreme care is required not to overdose. An added advantage of pentobarbital is its ability to scavenge oxygen radicals and decrease cerebral oxygen consumption (see later discussion of increased intracranial pressure). The effective dose varies considerably from one animal to the next. Consequently, pentobarbital is carefully given to effect. Careful monitoring of the cardiovascular and respiratory systems is necessary. Prolonged treatment may be necessary for some patients; some human patients remain anesthetized for up to 9 days before seizures are controlled.

In humans tonic–clonic SE, which is refractory to phenobarbital, phenytoin, or diazepam, may respond to an intravenous infusion of pentobarbital given continuously for 3 days.⁹² It is then discontinued, and oral phenobarbital, along with other anticonvulsants, is advocated to control recurring epileptic episodes.

Pentobarbital intoxication has been reported after ingestion of drug-tainted tissue. One case report⁹³ described a bitch that became intoxicated after consuming a puppy that had been euthanized with pentobarbital. Other reports have involved zoo animals ingesting food derived from barbituratecontaminated horse meat.⁹⁴

Benzodiazepines: Diazepam, Clorazepate, Clonazepam, and Lorazepam

Mechanism of Action

Benzodiazepines enhance the inhibitory effects of GABA in both the brain and spinal cord (see Figure 27-2). Thus they not only decrease seizure spread but also block arousal and centrally depress spinal reflexes (see Chapter 26 for additional discussion). In dogs, tolerance to the anticonvulsant activity of diazepam develops rapidly, within 1 week, and as such, diazepam is not an effective anticonvulsant for chronic therapy in dogs. Intravenous diazepam is, however, the drug of choice for the treatment of SE in both dogs and cats, in part because of its mechanism bt also because it rapidly crosses the blood–brain barrier into the CSF.

Disposition

Diazepam is the prototype benzodiazepine used in small animals. The drug is well absorbed after oral administration but undergoes rapid and extensive hepatic metabolism. Although only 1% to 3% of diazepam is orally bioavailable, 74% to 100% of the drug and all active metabolites are available.⁴² Diazepam is generally administered intravenously but can also be administered intramuscularly, although absorption is not predictable using this route. In human pediatric and canine patients, diazepam has been administered rectally.^{95,96}

The metabolites of diazepam (nordiazepam [desmethyldiazepam] and oxazepam) are active (see Figure 27-4), although less so (25% to 33%) than the parent compound. 3-Hydroxydiazepam also is a metabolite, although its anticonvulsant activity is not known.⁹⁶ Although less potent than the parent compound, the half-lives of the metabolites are slightly longer than that of diazepam (3.6 hours for desmethyldiazepam and 5.2 hours for oxazepam, compared with 15 minutes for diazepam).94,96 After oral administration diazepam undergoes rapid first-pass metabolism, with diazepam representing only 1% to 3% of the total (parent and metabolite) area under the curve, compared with 7% to 21% after intravenous administration. Oral bioavailability of all compounds approximates 74% to 100%. After oral administration metabolite concentration surpasses that of the parent compound.⁹⁶ Using a crossover study in both mixed-breed dogs (n = 6) and Beagles (n = 4), intravenous (0.5 mg/kg) or rectal (2 mg/kg to mixed-breed dogs and 0.5 mg/kg to Beagles) administration, and high-performance liquid chromatography to detect either diazepam and its active metabolites, desmethyldiazepam (nordiazepam) and oxazepam, Papich and Alcorn⁹⁵ demonstrated that the sum total of metabolites will surpass the parent compound. Löscher and Frey⁹⁷ reported that the sum bioavailabililty (%) of parent compound and metabolites ranged from 74 to 100 (median 86). Although rectal bioavailaibity of diazepam was only 7.4 \pm 5.9% and 2.7 \pm 3.2 % for the high and low dose (or mixed breed and Beagles), respectively, bioavailability of diazepam and its two metabolites increased to 79.9 ± 20.7 and 66.0 ± 23.8 for the high dose and low dose, respectively. After intravenous administration, diazepam was characterized by an elimination half-life of approximately of 15 minutes, compared with approximately 2.5 hours disappearance half-life for desmethyldiazepam and 3.8 hours for oxazepam. Peak concentrations of both diazepam and desmethyldiazepam after intravenous administration (0.5 mg/kg) approximated 800 ng/mL; oxazepam peaked at approximately 350 ng/mL. However, whereas diazepam concentrations were below 100 ng/ mL within 45 minutes of administration, concentrations were above 300 ng/mL (adjusting for 30% potency of diazepam) for desmethyldiazepam at 8 hours and oxazepam at 1.5 hours. Rectal administration of 2 mg/kg diazepam yielded peak diazepam concentrations of only 75 ng/mL; this compared to peak desmethyldiazepam and oxazepam concentrations of approximately 1600 and 550 ng/mL, respectively. Both desmethyldiazepam and oxazepam concentrations remained above 300 ng/mL at study end (8 hours). As such, rectal administration of diazepam can be expected to yield effective anticonvulsant

activity, with concentrations remaining above the minimum recommended for about 8 hours for desmethyldiazepam.⁹⁵

KEY POINT 27-15 Benzodiazepams tend to be the most rapidly acting anticonvulsants and thus are indicated for acute seizure management.

Diazepam has also been studied in dogs (n=6) after intranasal administration (0.5 mg/kg) either as drops or a commercially available atomizer. Bioavailability approximated 40%. Of the two routes, the atomizer was well tolerated. ⁹⁸ Another study diazepam administered IN (0.5 mg/kg; drug measured as benzodiazepines) in dogs (n = 6, crossover design) reported mean peak plasma concentration of benzodiazepine was 448 \pm 41 ng/mL at 4.5 minutes, compared with 1316 \pm 216 at 3 minutes after intravenous administration. Intranasal bioavailability of benzodiazepine was 80 \pm 9%. Plasma drug concentrations exceeded the recommended anticonvulsant therapeutic concentration (300 ng/mL).⁹⁹

The generation of active metabolites complicates the utility of therapeutic monitoring for benzodiazepines as a guide to therapy because anticonvulsant activity is not necessarily correlated with concentration of the parent compound. For diazepam all metabolites and parent drugs should be measured. Methods based on polarized immunofluorescence appear to correlate with total activity relatively well but are likely to underestimate concentrations by 50% or more;^{94,95} the amount of underestimation does not appear to be predictable but probably reflects failure to detect oxazepam.

Benzodiazepines enter the CSF rapidly, with peak concentrations usually occurring within 15 minutes of intravenous administration. The more lipophilic drugs enter CSF most rapidly. CSF to plasma drug ratios generally are less than unity, although concentrations may stay higher in CSF compared to plasma, prolonging the duration nof effect.¹⁰⁰ Both diazepam and desmethyldiazepam rapidly pass into the CSF.^{96,101}

Diazepam and nordiazepam have been studied in cats after intravenous administration of 5, 10, and 20 mg/kg of diazepam and 5 and 10 mg/kg of nordiazepam. Elimination of both drugs was linear over the range of doses covered. Total body clearance of diazepam ($4.72 \pm 2.45 \text{ mL/min/kg}$) was sixfold greater than that of nordiazepam ($0.85 \pm 0.25 \text{ mL/min/kg}$). Approximately 50% of an administered dose of diazepam was biotransformed to nordiazepam in the cat.¹⁰²

Clorazepate is metabolized in the stomach to its active metabolite, nordiazepam (desmethyl diazepam), which is also a major, although less efficacious, metabolite of diazepam. After oral administration of 2 mg/kg, clorazepate reaches peak benzodiazepine concentration of 446 to 1542 ng/mL in dogs; mean residence time was 8.5 hours. After multiple administration, mean residence time was significantly longer (approximately 12 hours).¹⁰³ Scherkl and coworkers¹⁰¹ described the consequences of long-term use of clorazepate in dogs. After 2 hours of clorazepate infusion, only nordiazepam was detected in CSF. The elimination half-life of nordiazepam ranged from 7.2 to 12 hours and did not change with 6 weeks of oral therapy. Only nordiazepam and oxazepam were in plasma. Oral

doses of 2 mg/kg were associated with ataxia and difficulty standing; these signs resolved 3 to 4 days after treatment. Concentrations of 0.180 to 0.780 μ g/mL were associated with decreased seizure threshold. Tolerance was demonstrated in two of six dogs, with some, but not total, loss of anticonvulsant activity. Withdrawal also was demonstrated by manifestation of generalized tonic-clonic seizures in two of six dogs rapidly withdrawn from therapy; death occurred in one of the dogs. The remaining four dogs exhibited no signs of withdrawal.

KEY POINT 27-16 Dogs, but not cats, develop tolerance to diazepam and will become refractory to its anticonvulsant effects after approximately 2 weeks.

Clorazepate anecdotally is an alternative anticonvulsant in cats (3.75 to 7.5 mg/cat orally every 8 to 12 hours). However, because it is an active metabolite of diazepam in other species, its role in diazepam-induced hepatotoxicity cannot be ruled out and caution is probably indicated with its use in cats.

Lorazepam is a benzodiazepine derivative used as an anxiolytic in human medicine. It has been studied after intravenous and rectal administration in dogs,¹⁰⁴ although its role in the management of seizures has not been identified. After IV administration of 0.2 mg/kg IV, concentrations remained above 190 ng/mL for 20 min in two of three dogs, and above 30 ng/ mL for 90 min in all dogs. However, lorazepam was not detectable after rectal administration of 1 mg/kg, presumably due to high first pass metabolism. Lorazepam also has been studied after intranasal administration. Lorezpam is absorbed almost 3 times as rapidly after intranasal administration compared with oral administration, yielding a relative bioavailability that approximates 2.5 times that after oral administration.¹⁰⁵ Mariami reported in abstract form that the IN administration of 0.2 mg/kg in dogs yielded peak plasma lorazepam concentrations of 106 ng/mL compared with 165 ng/mL following intravenous administration. Concentrations of lorazepam achieved 30 ng/ mL (effective anticonvulsant target in humans) by 9 minutes after IN administration in six of six dogs and remained at or above the target for 60 minutes in three of six dogs. Midazolam also has been studied after IN administration with IN aadminsitration exceeding oral administration by 2.5 fold.¹⁰⁶

Clonazepam (Klonopin) is a benzodiazepine derivative and chemically is 5-(o-chlorophenyl)-1,3-dihydro-7-nitro-2H-1,4-benzodiazepine-2-one (see Figure 27-4). It is more potent than diazepam and is used only in the emergency treatment of SE in the dog.⁴² Clonazepam is given orally or intravenously (0.05-0.2 mg/kg; the intravenous preparation is not available in the United States). Accumulation occurs with continued administration. Tolerance develops within days to weeks after administration, however, as a result of hepatic enzyme induction. Consequently, clonazepam, like diazepam, is unsatisfactory for long-term control of epilepsy in dogs. However, it might be considered for long-term use in cats (0.016 mg/kg/ day; target concentration 70 ng/mL). The relationship between clonazepam and liver disease has not been addressed in cats. The disposition of clonazepam has been described in the dog (see Table 27-4).107,108

Preparations

Diazepam is available as both an intravenous and an oral preparation; clorazepate is available as an oral preparation and a sustained-release preparation.¹⁰⁹ It is classified as a Schedule IV drug under the 1970 Controlled Substances Act. Clonazepam is available as an intravenous preparation (not in the United States) and as oral tablets.

Safety

Sedation is the most common direct side effect of the benzodiazepines. Adverse effects (sedation, ataxia, increased appetite, and in some cases hyperactivity) are likely to occur if concentrations reach 500 ng/mL. An 8-hour rather than a 12-hour dosing interval may be indicated to avoid both toxic and side effects. Care must be taken not to discontinue benzodiazepines abruptly because of the potential for SE.¹¹⁰

Diazepam may cause hepatotoxicity in cats.¹¹¹ Reports have focused on cats receiving diazepam as an appetite stimulant rather than as an anticonvulsant. Manifestations include vomiting, depression, jaundice, lethargy, and acute death. Clinical laboratory tests associated with toxicity include increased serum alanine transaminase, aspartate transferase, and alkaline phosphatase activities and increased bilirubin. Toxicity does not appear to be associated with the dose or duration. Toxicity has not been experimentally induced, suggesting that the reaction is idiosyncratic (i.e., nonpredictable).

Physical dependency toward benzodiapenes has been described in dogs, with the risk and severity of signs of withdrawal dependent on dose and drug. Studies that demonstrate dependency often are based on precipitation of clinical signs after administration of a benzodiazepine antagonist; the severity of withdrawal also appears to be dependent on the dose of flumazenil. Both diazepam and lorazepam can be associated with withdrawal in dogs, although only high doses (60 and 1000 mg/kg per day, respectively, for diazaepam and lorazepam) have been studied. Clinical signs included, but were not limited to, tremor, "hot foot walking," rigidity, and decreased food intake. Lorazepam withdrawal appears to be much less intense but has a shorter latency to onset than the diazepam in manifestation of abstinence syndrome. For diazepam, withdrawal signs include bi-phasic clonic and tonic-clonic convulsions, appearing at 24 and 48 hours. Diazapam syndrome was lethal in two dogs studied experimentally. Administration of diazepam can reduce but not obliterate the major signs of the diazepam withdrawal. The syndrome was worsened by the administration of a benzodiazepine antagonist, although tonic-clonic seizures were not precipitated¹¹² A followup study described withdrawal after oral administration of increasing doses of diazepam administered every 8 hours for 5 to 6 weeks: 0.05625, 0.225, 0.5625, 4.5, 9, or 36 mg/kg daily every 8 hours. Abstinence was precipitated by administration of a benzodiazepine antagonist, flumazenil, at 0.66, 2, 6, 18, 36, and 72 mg/kg, but included a placebo. Withdrawal intensity increased proportionately with the dose of diazepam and the dose of flumazenil. The pattern of withdrawal signs varied with dogs receiving high doses of diazepam more sensitive to flumazenil than those receiving lower doses. Seizure activity occurred only in dogs receiving 9 and 36 mg/kg/day of diazepam. Withdrawal signs increased linearly with plasma and brain concentrations of diazepam, oxazepam, and nordiazepam but not with free concentrations of diazepam alone.¹¹³

Although desmethyldiazepam (nordiazepam) has been theorized to be the metabolite causing physical dependence in dogs receiving diazepam (in part because the area under the curve for nordiazepam is much greater than that for diazepam),¹¹⁴ follow-up studies using benzodiazepines whose area under the curve is not surpassed by nordiazepam suggest otherwise.^{115,116}

The ability of flumazenil to induce clinical signs of withdrawal, including clonic seizures, in dogs, is well described.¹¹⁴ Flumazenil precipitated withdrawal scores were higher in dogs receiving diazepam (and halazepam, which is converted to nordiazepam) compared with nordiazepam, although clonic seizures were greater in the diazepam- and nordiazepam-dependent dogs, compared with halazepam-dependent dogs. The magnitude of withdrawal does not appear to reflect a predominance of one parent compound or metabolite but rather a combined effect.¹¹⁵ Oral flunitrazepam at 7.6 mg/kg per day caused more severe clinical signs of precipitated withdrawal, compared with diazepam (at 6 to 9 mg/kg every 6 hours) administered in four equally divided doses. However, precipitated signs persisted longer with diazepam than flunitrazepam, leading investigators to conclude that diazepam and flunitrazepam were equivalent in their ability to produce induced signs of withdrawal. Difference in kinetics, including protein-binding, among drugs and metabolites, as well as receptor interactions are likely to play a role in differences in response. For example, the estimated free plasma concentration of flunitrazepam and its metabolites was equal to or greater than that of diazepam and its metabolites; further, affinity of flunitrazepam for the benzodiazepine receptor is greater than that of either diazepam, nordiazepam, or oxazepam.¹¹⁶ The disposition of flumazenil in dogs has been described after oral dosing. Rapid absorption is followed by rapid elimination with concentrations being essentially nondetectable in 4 hours.¹¹⁷ Interestingly, benzodiazepine withdrawal induced by flumazenil was described in one study to occur particularly as plasma concentrations markedly decreased.¹¹⁷

Drug Interactions

Clinically important drug interactions resulting from chronic diazepam therapy have not been reported. Despite reports to the contrary,¹¹⁸ interactions between clorazepate and phenobarbital appear to confound therapy. In our studies clorazepate consistently increases phenobarbital concentrations in patients that have been receiving long-term phenobarbital therapy if doses of clorazepate exceed 1 mg/kg every 8 to 12 hours. The increases are usually evident by the first month of therapy but may take longer. It may be necessary to decrease phenobarbital doses. Yet clorazepate concentrations tend to decrease across time despite no change in dose, presumably because of the inductive effects of phenobarbital. As clorazepate concentrations decrease, phenobarbital concentrations may also decrease, which may put an epileptic at risk, particularly if the dose of phenobarbital has been reduced.

Therapeutic Use

As in humans, efficacy, including rapidity of onset, coupled with lack of toxicity, leads to intravenous diazepam as the first drug of choice for control of SE in humans.45 Likewise, diazepam is the drug of choice for emergency treatment of SE in dogs and cats.⁴² However, because of its short half-life, diazepam is likely to have to be repeated once or twice during the first 2 hours of stabilization.⁴⁹ Not surprisingly, various methods of administration have been recommended in an attempt to maintain effective diazepam concentrations necessary to maintain efficacy. Intravenous doses vary, beginning at 5 to 20 mg or 0.5 to 1 mg/kg.42 The dose can be repeated in 1 to 2 minutes if necessary; giving the same dose intramuscularly may provide longer therapeutic concentrations. If a response has not occurred after the second dose of the drug, an intravenous infusion can be implemented (note that the infusion line should first be flushed with the diazepam solution to allow diazepam binding to the polyvinyl). Alternative anticonvulsants might be considered in animals failing to respond (discussed later). Patients that respond to the first or second dosages of diazepam are carefully monitored, and if SE returns within 2 to 4 hours after the initial treatment, the diazepam regimen is repeated. Intravenous diazepam may be replaced with other benzodiazepines, such as clonazepam (0.05 to 0.2 mg/kg), toward which tolerance develops more slowly. For cats an intravenous dose (5 to 10 mg) generally is given to effect. The dose may need to be repeated; up to 20 mg may be necessary. High doses should be injected slowly. Diazepam (0.5 mg/kg using 5 mg/mL solution) has been used successfully by rectal administration for home control of cluster seizures.¹¹⁹

For chronic therapy rapid metabolism coupled with rapid development of tolerance precludes long-term treatment with diazepam and several other benzodiazepines in dogs.²⁹ However, compared with diazepam, tolerance does not appear to develop as readily to the anticonvulsant effects of clorazepate in dogs. Clorazepate has been studied when added to phenobarbital in dogs still seizuring despite phenobarbital concentrations that exceeded 32 µg/ml (author, unpublished data). Seizures were eradicated in about 35% of animals and reduced 50% or more in another 15%. However, its use in combination with phenobarbital was complicated by drug interactions (including marked fluctuations in nordiazepam disappearance half-life), and an apparent increased risk of hepatotoxicity. Drug interactions between phenobarbital and clorazepate may necessitate dose modification in response to changes in drug concentrations. The short half-life (which might be documented with sequential peak and trough plasma drug concentration measurements) may increase the risk of seizures if drug concentrations decrease below effective concentrations in the patient. The therapeutic range of benzodiazepines (including metabolites) in dogs has been extrapolated from human studies and does not reflect combination therapy. For efficacy, trough concentrations should be maintained at least above 100 ng/mL, although monitoring should establish each patient's range. Dogs receiving phenobarbital are likely to become groggy when peak clorazepate concentrations exceed 300 to 500 ng/mL (varying with the patient).

For chronic control in cats, diazepam can be given orally in doses of 2 to 5 mg 2 or 3 times daily; diazepam may be increased or decreased in increments of 2 mg with or without phenobarbital. Whereas distribution of diazepam in the cat brain reflects blood flow, nordiazepam accumulates to high concentrations throughout all brain matter, which may be the reason for its efficacy with long-term use.¹²⁰

Bromide

Bromide is an old anticonvulsant that was used in the 1800s for control of seizures. However, it has enjoyed a resurgence in veterinary medicine, proving to be an effective add-on anticonvulsant for refractory (canine) seizures, as well as a sole anticonvulsant for some canine patients.

Mechanism of Action

Bromides mechanism of action is not completely understood.¹²¹ The original proposed mechanism—replacement of negatively charged chloride with bromide in the neuron—is unlikely because bromide is less negatively charged than chloride.¹²² In vitro, bromide enhances GABA-activated currents, leading the authors to conclude that bromide potentiates inhibitory postsynaptic potentials of GABA. Regardless of the mechanism, the anticonvulsant effects of bromide correlate with plasma concentration.¹²³

Disposition

The pharmacokinetics of bromide have been described using either the sodium or potassium salt. In a small study, the halflife in dogs was reported as 21 to 24 days after oral administration, suggesting steady-state concentrations being achieved only at 2.5 to 3 months.¹²⁴ Distribution is to extracellular fluid,¹²⁵ yet sufficient quantities penetrate the CNS. Bromide is eliminated slowly (presumably as a result of marked reabsorption) in the kidney. Bromide appears to compete with chloride for renal elimination, with elimination appearing to decrease proportionately to the amount of chloride in the diet.^{126,127}

KEY POINT 27-17 As a renally excreted compound, bromide is not likely to be involved in drug interactions. However, serum bromide concentrations will change proportionately and inversely with the amount of chloride consumed by the patient.

Bromide (20 mg/kg bromide; approximately 26 mg/kg sodium bromide) has been studied in Beagles as the sodium salt after intravenous (n = 4) and oral (n = 4) administration, but only at the daily maintenance dose (which is about $\frac{1}{15}$ to $\frac{1}{20}$ the loading dose).¹²⁸ Dogs received a diet containing 0.4% chloride on a dry-matter basis. Elimination half-life after intravenous administration was 39 ± 10 days and after oral administration, 46 ± 9 days; clearance (reported in ml/kg/day) was 9 ± 3.9, and apparent volume of distribution (Vd area) was 0.45 ± 0.07 L/kg. Oral bioavailability (calculated from mean area under the curve from intravenous and oral groups) was 46%. A study by the same investigators¹²⁷ in Beagles measured changes in bromide (sodium; 14 mg/kg orally)

disposition in response to dietary chloride content (0.2, 0.4, and 1.3%, dry-matter basis). Mean apparent elimination halflife decreased from 69 ± 22 days (0.2%) to 24 ± 7 days (1.3%). Predicted maximum drug concentrations were quite variable within treatment groups but were profoundly influenced by dietary chloride content, ranging from 1.95 ± 1.1 mg/mL at 0.2% chloride, 1.27 ± 0.36 mg/mL at 0.4% chloride, to a low of 0.3 ± 0.15 mg/mL at 1.3% dietary chloride.

A study of potassium bromide (20 mg/kg per day bromide or approximately 30 mg/kg potassium bromide), mixed as a 20 mg/mL solution in canned dog food, in Beagles (n = 6) receiving 0.55 to 0.72% dietary chloride reported a median bromide concentration at 115 days of 2.45 mg/mL (low of 1.8 and high of 2.7 mg/mL); the time to steady state was not provided, but concentrations were within 90% of steady-state concentrations by 60 days.¹²⁹ The median elimination half-life, estimated from time to reach steady state, was 15 days (low of 12, high of 20 days). Renal clearance (based on 24-hour urine collection) ranged from 6 to 12 .6 mL/kg per day (median 8.2). The median ratio of bromide in CSF to serum at day 9 was 0.63; this improved to 0.86 (0.82 to 0.99) by day 120. An increase in dose sufficient to generate serum bromide concentrations 3.4 mg/mL (median; does not provide but designed to target 4 mg/mL) resulted in an increase in the CSF: serum ratio to 0.86, suggesting a greater risk than anticipated of CNS side effects. Whereas neurologic side effects were not described at the dose of 60 mg/kg per day, caudal paresis and ataxia developed in two of six dogs. Electrodiagnostic changes were mild even at the high dose; within individual dogs, latency shifts were mild and either progressively increased over time or appeared with doses designed to target 4 mg/mL.

Bromide was studied (report in progress by the author) after rectal administration in normal hound dogs after a loading dose (600 mg/kg) of sterile potassium bromide solution (concentration 250 mg/mL) over 24 hours, either by 6 intrarectal boluses of 100 mg/kg, each every 4 hours, or constant-rate infusion (CRI) throughout the 24-hour period. The average peak serum bromide concentration after intrarectal loading was 0.91 mg/mL (range: 0.81 to 1.11 mg/mL), compared with 1.10 mg/mL after intravenous loading (range: 0.89 to 1.22 mg/mL). The average peak serum K⁺ concentration during potassium bromide loading was 5.80 mEq/L (range: 5.5 to 6.8 mEq/L) and 6.14 mEq/L (range: 5.6 to 7.7 mEq/L) for intrarectal and intravenous loading, respectively (normal range: 3.5 to 5.5 mEq/L). The mean half-life $(t_{1/2})$ of intrarectally administered bromide was 488.8 hours, or 20.4 days. A side effect of both intrarectal and intravenous potassium bromide loading was mild sedation, and of intrarectal loading was transient (24 to 48 hours) diarrhea. Bioavailability (F) of intrarectally administered bromide for the 24-hour loading period was calculated to be 107% for the five dogs. In two dogs overall bioavailability (F) of intrarectally administered bromide was calculated to be 57.7%. Results of this study indicate that potassium bromide is well absorbed rectally and that a 24-hour intrarectal loading protocol is safe to administer in normal dogs.

Bromide has been studied in cats after oral administration of the potassium salt at the lower end of the canine dose. After a dose of 30 mg/kg, maximum serum bromide concentration was 1.1 ± 0.2 mg/mL at 8 weeks. Mean disappearance half-life was 1.6 ± 0.2 weeks. Steady state was achieved at a mean of 5.3 ± 1.1 weeks.^{129a} However, the use of bromide in cats is discouraged due to safety reasons.^{129a}

KEY POINT 27-18 Bromide in cats may lead to signs consistent with bronchial asthma.

Preparations and Sources

Bromide is available as a potassium or sodium salt. Triple bromide salt preparations (Na, K, and NH_4) also may be available through some pharmacies. The accompanying cation does not appear to alter efficacy, although sodium bromide is more difficult to solubilize in water than is potassium bromide. In addition, because potassium weighs less than sodium, 1 g of sodium bromide contains more bromide (78% bromide, or 780 mg) than does 1 g of potassium bromide (67% bromide, or 670 mg). Thus the amount of sodium bromide used to make a solution should be less (211 mg/mL) than potassium bromide (250 mg/mL) to achieve equivalent amounts of bromide in the solution. At the time of publication, a commercial product of potassium bromide is being marketed as a chewable tablet and solution. The product contains B vitamins as well. This product has not been approved by the Food and Drug Administration. It is being marketed under the "generally recognized as safe" category reserved for food of food ingredients; however, this status does not apply to drugs It is important to recognize that the product has not undergone premarket evaluation by any regulatory agency for safety, efficacy, or quality and although its use is not necessarily discouraged, clinicians should be aware that this is a manufactured-compounded product.

Potassium bromide can be compounded by veterinarians or pharmacists on an individual-need basis. It can be purchased through chemical companies (request medicinal or ACS grade [Curtin Matheson]). Chemical companies have refused to sell bromide for medicinal purposes without an investigational new animal drug application (INADA). This application is no longer necessary, however, because the Food and Drug Administration (Division of Drug Compliance) will grant regulatory discretion.

Bromide can be compounded in a syrup or water solution or administered in a gelatin capsule. A number of compounding pharmacies now offer this service, although the compounded solution can be much more costly when compounded by a pharmacist compared with the cost of the ingredients. The solution can be compounded by the clinician with minimal equipment, particularly if monitoring is used to document maintenance of drug concentrations with compounded preparations. If purchased (1-kg bottle) from a chemical company, potassium bromide can be weighed and divided into 250-g (four equal) packets. A liter bottle of distilled water can be purchased from any grocery store. Before the bromide is mixed, a line should be drawn at the 1-L volume mark and approximately 50% of the water removed and set aside. One of the four 250-g packets of bromide is added to the bottle and the bottle shaken well to dissolve the bromide (this may require aggressive shaking and the addition of more water). Once the bromide is dissolved, the volume should be returned to 1 L with either water or a flavored syrup. The final solution will approximate 250 mg/mL. The solution should be stable for at least 6 months, and refrigeration should minimize microbial growth in the solution. Refrigerating the solution may cause the salt to crystallize; warming the solution should cause the drug to redissolve. Note that while this solution can be dispensed from a practice, it cannot legally be sold to others.

Side Effects

Adverse reactions to bromide tend to be dose dependent. They appear to be related to the anticonvulsant or other centrally acting effects of the drug and predominantly affect the CNS (e.g., ataxia, grogginess). This is supported by the recent retrospective report of Rossmeisl and Inzana,130 which described signs of "bromism" in epileptic dogs (n = 31). Clinical signs included ataxia and stupor, with one dog being comatose. Other clinical signs included bilateral mydriasis; head pressing was evident in two dogs. Mean bromide concentration at time of admission was 3.7 ± 0.3 mg/mL compared with the most recent monitoring result before admission $(1.9 \pm 0.3 \text{ mg/mL})$ and compared with a control group of epileptic dogs without bromism at 1.7 ± 0.1 mg/mL. Of the 31 dogs, 26 dogs also were receiving phenobarbital at a mean concentration of 31 \pm 12 µg/mL; control group phenobarbital was 26 \pm 1 µg/mL. Causes for the increase in bromide were attributed to reduction in renal function, dosing error, shifting from potassium to sodium bromide, and exposure to bromide in drinking water or alternative medications. Changes in diets, the most common reason for increased bromide in the author's therapeutic drug monitoring laboratory, was not addressed. Diuresis was implemented in affected dogs (n = 27); four of these dogs had breakthrough seizures. Furosemide therapy was initiated in five dogs; however, it is not clear what impact furosemide has on bromide clearance.

Up to 3 months may be required for accommodation to the sedative effects of bromide. This reflects in part the time necessary to reach steady-state concentrations. Gradual reduction of phenobarbital in 25% increments may resolve some of the side effects and may be preferred to saline diuresis in those patients for which nonthreatening clinical signs of bromism emerge. Alternatively, the bromide dose can be decreased by 25%, although 1 to 2 weeks may elapse before a response is seen. Sodium bromide administered as a loading dose sufficient to achieve steady-state concentrations has been reported to be well tolerated in dogs.¹³¹

Fluids containing sodium chloride can be used to treat acute bromide toxicity; monitoring should occur immediately after saline treatment to establish a new baseline. Note that diuresis may increase the risk of breakthrough seizures and SE. Diuresis should be reserved for animals with profound sedation for which a decrease in phenobarbital (if on combination therapy) or bromide will not provide a sufficiently rapid response. Pruritic skin lesions may occur, particularly in patients that had pruritic disorders before starting therapy. A short period of glucocorticoid therapy may control pruritis. Hyperactivity is an occasional side effect and may or may not be dose dependent. Like other anticonvulsants, bromide tends to increase the appetite of dogs. Vomition is not uncommon and appears to reflect the hypertonicity of the salt and direct gastric irritation. Solutions appear to be better tolerated than capsules, although this may vary. Dividing the daily dose into smaller, more frequent doses or feeding before or with medication may decrease gastrointestinal side effects. Sodium bromide may be more tolerated than other bromide salts.

Pancreatitis has been associated with the use of bromide when combined with phenobarbital. A retrospective report found 10% of dogs receiving a combination of potassium bromide and phenobarbital developed clinical signs consistent with pancreatitis, compared with 0.3% of dogs receiving phenobarbital alone.⁸⁰ Serum pancreatic lipase immunoreactivity was found to be increased in the serum of dogs receiving either bromide or phenobarbital, alone or in combination, indicating that the risk may occur with either drug.⁸¹

Although cats tolerated 8 weeks of oral potassium bromide dosing (experimentally) at 30 mg/kg, clinical patients do not appear to tolerate the drug as well. However, in a retrospective study, bromide (n = 4) or bromide and phenobarbital (n = 3) was associated with eradication of seizures in 7 of 15 cats (bromide dosage range, 1 to 1.6 mg/kg [0.45 to 0.73 mg/lb]); however, bromide administration was associated with adverse effects in 8 of 16 cats. Coughing developed in six of these cats, leading to euthanasia in one cat and discontinuation of bromide administration in two cats. Although somewhat effective in seizure control, the incidence of adverse effects may not warrant routine use of bromide for control of seizures in cats.

Because it is renally eliminated, bromide does not negatively interact with other anticonvulsants metabolized by the liver. However, dietary (or therapeutic) chloride will compete with bromide for renal excretion and can shorten bromide half-life, probably because the kidneys will selectively resorb chloride.¹²⁷ In addition, laboratory assays may not be able to distinguish among anions; for some, bromide may artificially increase serum chloride measurements.¹³²

Therapeutic Use

Bromide has been used to treat seizures in dogs for over 15 years. Initially, it was used as an adjunct to phenobarbital therapy, an indication that persists.^{133,134} However, it is increasingly being used as sole therapy.²⁸ Therapeutic ranges vary, with initial studies indicating 0.7 to 2 mg/mL.134 More recently, dogs (n = 122; from 1992-1996) with major motor epilepsy were studied retrospectively to determine the therapeutic range of bromide, either alone or in combination with phenobarbital or primidone. Bromide successfully controlled seizures (≥50% reduction in seizure frequency) in 72% of animals. Phenobarbital or primidone could be discontinued in 19% of animals receiving the combination. For dogs that continued to receive both drugs, 45% remained controlled with a phenobarbital dose below 20 µg/mL. The concentration of bromide necessary to control seizures when given as sole therapy was higher (1.9 mg/mL) than when combined with either barbiturate (1.6 mg/mL). The authors concluded that the range for bromide

depends on whether bromide will provide sole anticonvulstant support (0.8 to 2.4 mg/mL) or is combined with a barbiturate (0.88 to 3 mg/mL). If phenobarbital could not be discontinued, the range necessary for control was 9 to 36 µg/mL.135 A distinction in therapeutic ranges as sole or combination therapy of bromide may not be necessary. Concentrations may fall outside or within a range of 1 to 3 mg/mL (based on the gold chloride method of detection) as needed to control the patient's seizures, regardless of concomitant therapy. Because the side effects of bromide apparently are not associated with cellular toxicity (unlike phenobarbital), the therapeutic range can be surpassed in animals, if tolerated and if necessary to control seizures. Drug concentrations can be increased beyond this concentration if there is no evidence of toxicity. Some animals will present with side effects at concentrations in the lower end of the range, particularly if a loading dose is administered. Therefore it is generally wise to avoid a loading dose if seizure history and drug safety (e.g., phenobarbital) is supportive. Bromide generally should be given once or twice daily, depending on the animal's gastric tolerance of the drug. Twice-daily administration of bromide offers no benefit over once-daily administration, with the potential exception of decreased gastric irritation. Indeed, an animal can miss several days of dosing with minimal impact on serum drug concentrations. Missed doses in such instances should be given when convenient. On the other hand, if bromide is better tolerated when broken into much smaller, more frequent doses, no disadvantages are apparent with this approach, other than inconvenience to the owner.

KEY POINT 27-19 The long half-life causes the loading dose of bromide (450 mg/kg) to be substantially higher than the daily maintenance dose (30 mg/kg).

In humans bromide has been used to treat intractable seizures in pediatric patients.81,136,137 Bromide's initial introduction into veterinary medicine was as an add-on anticonvulsant, particularly combined with phenobarbital, for control of refractory seizures in dogs or in patients that have developed liver disease in association with phenobarbital therapy. Increasingly, however, bromide is proving efficacious as a first-choice antiepileptic drug for dogs. For example, bromide has been used as the sole drug for patients whose seizure history is limited to mild seizure episodes.¹³³ Because of its long half-life, bromide may be the drug of choice for dogs whose owners are noncompliant because the plasma drug concentrations are not easily manipulated. The author studied bromide as an add-on anticonvulsant in dogs with refractory epilepsy (n = 20) in which seizures continued despite phenobarbital concentations at 32 µg/ml or more. Bromide eradicated seizures in 60% of the patients and reduced seizure frequency by 50% or more in another 20%.

Two choices should be considered when starting bromide therapy: administration of a maintenance dose, which allows the body to gradually adapt to the presence of the drug, or administration of a loading dose. The maintenance dose approach is indicated when possible to minimize the advent of side effects. A targeted concentration should be selected (lower concentrations for milder seizures; higher concentrations may be necessary for severe seizures). In general, 30 mg/kg per day orally will achieve 1 mg/mL at steady state. For every 0.5 mg/mL increment above 1 mg/mL, another 15 mg/kg per day should be administered. To proactively monitor when using the maintenance dose approach to steady state, one sample should be collected at 3 weeks, or halfway to steady state. Doubling the measured concentrations provides an estimate of steady-state concentrations. However, because kinetics vary among animals, a steady-state sample should be collected to confirm baseline concentrations at 3 months.

The second option for beginning bromide therapy is implementation of loading dose. This approach is recommended in patients for which lack of seizure control can be life threatening (including the risk of euthanasia by a distraught owner), or in patients for whom serum phenobarbital concentrations must be rapidly decreased because of hepatotoxicity or bone marrow suppression. Both loading dose and maintenance dose must be established; the loading dose is designed to target steady-state concentrations, but the patient will not be at steady state until being on the same dose for 2 to 3 months. Thus as the loading dose is discontinued and the maintenance dose is begun, a new time to steady state begins. Drug concentrations may increase or decrease compared with the loading dose as steady-state concentrations are reached. Monitoring can ensure that the maintenance dose will maintain what the loading dose achieved. However, this requires a sample collected after loading (within 1 or 2 days) to document what loading achieved, and another sample one elimination half-life after the maintenance dose is started (about 3 weeks). This time is chosen because if concentrations are not maintained by the loading dose, the majority of change (50%) will occur in the first elimination half-life. If the two samples are not within about 10 to 15% of one another (i.e., postload and 3-week maintenance), the maintenance dose should be increased or decreased accordingly. Generally, an increase at the 3-week point is not problematic (and often is desirable), but a decrease is undesirable. If not curtailed by an increase in the maintenance dose, as steady state is reached, the decrease may be sufficient to lead to seizures 2 to 3 months after the loading dose successfully controlled seizures.

A loading dose should reflect all the doses that would have been given as steady state is reached, less drug eliminated by clearance. Thus the loading dose of bromide is substantially higher than the maintenance dose. To target the lower end of the therapeutic range (1 mg/mL), 450 mg/kg should be given as a loading dose. Thereafter, for every 0.5 mg/mL desired increase in bromide concentrations, the loading dose should be increased by approximately 225 mg/kg. Because animals may not tolerate the loading dose as a single oral dose, it generally is divided into 10 equal doses given twice daily for 5 days. However, note that the maintenance dose should be added to the loading dose if the targeted concentration is to be reached. For example, to target 1.5 mg/mL with a 5-day loading period, the patient should receive 675 mg/kg split over a 5-day period, plus a maintenance dose of 45 mg/kg/day. Thus for 6 days, the patient should receive approximately 135 mg/kg. On day 6 the maintenance dose of 45 mg/kg is begun and a postload sample

is collected (assume the loading dose achieved 1.3 mg/mL). A second sample is collected 3 weeks later. Allowing for some variability in analytic error, then the maintenance dose can be adjusted in proportion to the difference between the postload and 3 week sample. For example, if the postload was 1.3 mg/ ml, and a 3-week concentration is 0.8 mg/mL, the maintenance dose may need to be increased by about 25% to 30%). If a patient already is receiving bromide and an increase in concentrations is desired (e.g., 0.5 mg/mL), the maintenance dose can be increased 15 mg/kg/day. A third sample can be checked at 3 weeks to make sure drug concentrations are moving in the right direction. If a rapid response is desired in a patient already receiving bromide, a "mini" loading dose of 225 to 250 mg/kg total can be given along with an increase in maintenance dose.

The use of bromide as an add-on anticonvulsant to phenobarbital also is discussed later in this chapter. Monitoring in such patients is important if the goal of the additional bromide is to decrease or discontinue phenobarbital. If the goal is to replace phenobarbital, the bromide target should approximate the current phenobarbital concentration in the patient. For example, if the patient has phenobarbital concentrations of 20 µg/mL, (midtherapeutic range), then the bromide dosing regimen might approximate the midtherapeutic range (i.e., about 1.5 to 2 mg/mL). To prevent excessive grogginess, bromide should be initiated as a maintenance rather than loading dose. At least 3 weeks of dosing (i.e., halfway to steady state) should occur, ideally, to allow a halfway to steady-state sample that confirms the bromide dose is on target before phenobarbital is decreased. However, if the patient becomes unacceptably groggy at any point, assuming the seizure history is appropriate, phenobarbital rather than bromide should be decreased by 25% (not only is bromide safer, response will be more rapid for phenobarbital because its half-life is shorter). If all remains well as the new phenobarbital dose reaches steady state (about 2 weeks), assuming the patient has been challenged by a seizure (thus waiting at least one seizure interval is ideal), then an additional 25% decline in phenobarbital can be considered. Ideally, phenobarbital concentrations are measured at each step. This process can be repeated until phenobarbital is eradicated or the patient seizures again. A much more rapid approach will be necessary in animals that develop a lifethreatening adversity to phenobarbital (including bone marrow dyscrasias). In such cases a loading dose is indicated, with immediate (6- to 7-day) and 3-week postload samples being critical to ensure maintenance of bromide concentrations in the targeted range. If the loading dose option is taken, phenobarbital probably can be decreased by 25% to 50% as little as 2 to 3 days into the loading dose. Ideally, phenobarbital concentrations should not be decreased completely unless the patient has a bromide concentration of 1.5 mg/mL. For some patients phenobarbital can be completely discontinued once bromide is begun. For others, a combination may be necessary to control seizures. Unfortunately, for a small percentage of animals, seizures may continue even if both drugs are at the maximum end of the therapeutic range or side effects are untenable.

For life-threatening seizures that have not responded to phenobarbital, bromide also can be given rectally as a loading dose (see the discussion of disposition). Efficacy and safety of bromide versus phenobarbital has been compared in spontaneously epileptic dogs (n=46)²⁸ using a parallel, randomized double-blinded study design. Enrollment was based on seizure history, physical and neurologic examinations, and clinical pathology. Dogs were loaded over a 7-day period to achieve the minimum end of the therapeutic range of the assigned drug phenobarbital (3.5 mg/kg), or bromide (15 mg/kg) was administered every 12 hours. Data (clinical pathology and drug concentrations) were measured at baseline and at 30-day intervals for 6 months. All but three patients completed the study. Seizures initially worsened in three dogs on bromide but not in any phenobarbital-treated patient. Compared with baseline, mean seizure number, frequency, and severity were reduced at 6 months for both drugs; seizure duration was shorter for phenobarbital but not bromide. Seizure activity was eradicated in a greater percentage of phenobarbital-treated patients (85%) compared with bromide-treated patients (65%), and the seizure duration decreased more for those on phenobarbital than for those on bromide, but successful control (at least 50% reduction in seizure number with no unacceptable adverse drug reactions) tended (p = 0.06) to be better only for those in the phenobarbital group. For patients in which seizures were eradicated, mean phenobarbital concentration was 25.4 ± 5.4 (95% confidence interval of 23 to 28 µg/mL) (see Table 27-4) but ranged from 12 μ g/mL to 34 μ g/mL (dose was 4.1 ± 1.1 mg/kg). For bromide mean concentration associated with eradication of seizures was 1.8 \pm 0.5 mg/mL at a range of 0.9 to 3.3 mg/mL (dose of 31 ± 11 mg/kg). Both drugs caused abnormal behaviors. Weight increased by 10% in both groups. Changes in clinical pathology were limited to increased (but within normal) serum alkaline phosphatase and decreased (but within normal) serum albumin at 6 months for phenobarbital compared with baseline and compared with bromide at 6 months. Side effects at 1 month were greater for phenobarbital vs bromide and ataxia (55% vs 22%), polyuria (35% vs 13%), but greater for bromide vs phenobarbital for polyphagia (43% vs 30%), vomiting (57% vs 20%), and hyperactivity (43% vs 35%). At 6 months, most clinical signs had resolved to less than 15% of animals in either group with the exception of vomiting that continued in 21% of dogs in the bromide group (0% in the phenobarbital group). One dog failed phenobarbital therapy because of neutropenia; two dogs failed bromide due to vomiting. This study suggests that both phenobarbital and bromide are reasonable first choices for control of epilepsy in dogs, although phenobarbital may provide better control. Side effects can be expected to be greater in bromide following chronic dosing.

KEY POINT 27-20 If a loading dose is administered, monitoring should occur immediately and then again in 3 weeks. The two concentrations should match if the maintenance dose is correct.

Although bromide has been used in the cat successfully, adverse effects (consistent with bronchial asthma) are sufficiently common that an alternative anticonvulsant should be considered.^{129a} While administration of bromide (n = 4) or

bromide and phenobarbital (n = 3) was associated with eradication of seizures in 7 of 15 cats (serum bromide concentration range, 1.0 to 1.6 mg/mL); bromide coughing developed in 6 cats, leading to euthanasia in 1 cat and discontinuation of bromide administration in 2 cats.

Carbamazepine

Carbamazepine is approved for human use as an antiepileptic drug and currently is considered a primary drug for treatment of partial and tonic-clonic seizures. Further, it is a primary choice for treatment of trigeminal neuralgia; this and its efficacy for treatment of manic-depressive disorders may reflect its chemical similarity to tricyclic antidepressants.²⁵ Its mechanism appears to slow recovery of sodium channels, preventing repetitive firing. In humans pharmacokinetics are complex. Slow, erratic oral absorption may take as long as 8 hours and appears to be dose dependent. Carbamazepine is approximately 75% protein bound. Hepatic metabolism, principally by CYP3A4, includes production of an active metabolite, carbamazepine 10,11 epoxide, which may achieve up to 50% of the CNS concentrations of the parent compound. Other metabolites are mostly glucuronidated and excreted in the urine. Carbamazepine induces cytochrome P450 isoenzymes CYP2C and CYP3A. As such, carbamazepine is involved in a number of drug interactions, decreasing the concentrations of several drugs (e.g., valproate, lamotrigine, tiagabine, topiramate, and other nonanticonvulsants). It can in turn be influenced by inducers (phenobarbital, phenytoin, valproic acid) and inhibitors (e.g., erythromycin, cimetidine, fluoxetine) of drug-metabolizing enzymes. Adversities in humans include both acute toxicity (stupor and coma) and increased seizures. Other neurologic signs may emerge with long-term use, potentially reflecting neurotoxicity to which tolerance may develop. Bone marrow suppression and other evidence of hypersensitivity may occur. However, some cases of leukopenia or thrombocytopenia may be only transient, resolving after several weeks. Carbamazepine also reduces antidiuretic hormone but, paradoxically, may cause water retention, a potentially serious complication in patients with cardiac disease. A therapeutic range of 6 to 12 µg/mL (based on the parent compound) has been suggested, but the relationship between parent concentration and response is complex. Side effects have been reported at 9 µg/mL.

Description of the disposition of carbamazepine in dogs is limited, with one report comparing two oral pharmaceutical preparations (see Table 27-4).¹³⁸ Both the parent compound and active metabolite are characterized by a short half-life (3 hours), which will limit therapeutic use. Carbamazepine has been used intermittently in dogs. A case report¹³⁹ described successful long-term control of psychomotor seizures in one dog, although parent drug could not be detected in serum. The patient previously had been treated with a variety of anticonvulsants alone or in combination. However, the patient immediately responded to carbamazepine at 7 mg/kg twice daily. The dose was increased to 14 mg/kg. The drug was discontinued because the patient developed leukopenia. Although the leukopenia resolved, clinical signs returned. Therapy was reinstituted, clinical signs resolved, and leukopenia returned but resolved after 3 to 4 months of therapy. In his review Holland¹³⁹ notes that doses of carbamazepine in dogs have ranged from 4 to 40 mg/kg divided into 2 daily doses.

Oxcarbazepine is an antiepileptic drug that is a keto-analog of carbamazepine approved as a prodrug. Similar to carbamazepine in action, its induction of drug-metabolizing enzymes is less potent than that of carbamazepine, leading to its substitution with combination therapy.

Ethosuximide

Ethosuximide is a succinimide anticonvulsant used to treat absence seizures in humans. Its mechanism is reduced threshold of T-calcium channels in the thalamus. At therapeutic concentrations it is not effective against tonic hind limb extension of electroshock nor kindled seizures.²⁵ Side effects include CNS depression and gastrointestinal upset. Allergic skin reactions have been reported in humans. It has been studied in a limited number of dogs. A concentration of 50 to 70 µg/ mL was maintained by oral administration of 15 to 25 mg/kg thrice daily after a loading dose of 40 mg/kg; recommended therapeutic concentrations range from 40 to 100 µg/mL.^{42,140} The duration of dosing was not provided.

Felbamate

Felbamate was approved in the United States in the late 1990s for treatment of human epilepsy either as the sole drug or in combination with other anticonvulsants. Similar to meprobamate in chemistry, felbamate's mechanism of action appears to be inhibition of NMDA receptor-mediated calcium or sodium influx (inhibition of excitatory signals) as well as potentiation of GABA receptor-mediated chloride (negative) influx.¹⁴¹ Thus the drug should have a broad mechanism of anticonvulsant activity with an action that might be considered complementary to phenobarbital.

The drug was proved very safe and efficacious in the treatment of partial and generalized seizures in experimental animals^{142,143} and humans, particularly children.^{144,145} Initially studied as monotherapy treatment of partial seizures, the drug has since proved useful as monotherapy for other seizures, including generalized seizures.¹⁴⁵⁻¹⁴⁸ When added to phenobarbital in refractory canine epileptics in an unpublished clinical report by the author, it eradicated seizures in 35% and decrease seizure numbers by at least 50% or more in another 20%.¹⁴⁹

Felbamate is well absorbed after oral administration, although bioavailability in pediatric animals may be as little as 30% of that in adult dogs, necessitating a higher dose.¹⁵ The drug is eliminated by hepatic metabolism to metabolites that are largely inactive.¹⁵⁰ Initial preclinical toxicity studies in the dog revealed felbamate to be completely absorbed after oral administration of 1.6 to 1000 mg/kg. At each dose C_{max} was 12.6 to 168.4 µg/mL, respectively, in dogs with T_{max} occurring at 3 to 7 hours, respectively. Plasma elimination half-life was 4.1 to 4.5 hours at both doses. After multiple oral doses of 50 mg/kg, plasma concentrations did not appear to change, and much (at least 50%) of the drug (based on [14C] felbamate)

was eliminated in the urine (58% to 87.7%), with at least 7% eliminated in feces and the remainder in bile.¹⁵¹ Volume of distribution was 0.72 L/kg, and binding to plasma proteins was at most 36%. Plasma clearance was 108 mL*h/kg renal clearance of unchanged drug was between 20% and 35%, and hepatic clearance resulting from metabolism was between 65% and 80% of overall clearance.¹⁵¹

KEY POINT 27-21 The combination of phenobarbital with any other drug eliminated primarily by cytochrome P450 is likely to increase the risk of liver disease.

In adult dogs the half-life of felbamate is 4 to 8 hours (mean of 5.2 hours); the elimination half-life is shorter in pediatric (Beagle) dogs (mean of 2.5 hours) probably.^{151,152} Felbamate also was studied in adult and pediatric dogs at 60 mg/kg orally once a day for 10 days. Oral bioavailability was less in pediatric dogs compared with adults, apparently because of more rapid clearance. Bioavailability also decreased by day 10 compared with day 1. Safety has been experimentally documented at doses ranging from 15 mg/kg divided twice daily (the starting therapeutic dose) to 300 mg/kg. Oral bioavailability is markedly variable. The oral disposition of felbamate has been described in adult and pediatric male and female dogs after single (see Table 27-4) and multiple dosing. ¹⁵² Felbamate was characterized by a lower C_{max} (33 and 37 µg/mL for males and females, respectively) and area under the curve and shorter half-life $(2.87 \pm 0.52 \text{ [males]} \text{ and } 2.93 \pm 0.33 \text{ [females]} \text{ in pedi$ atric animals compared with adults (see Table 27-4). Clearance increased to 0.98 - 0.11 L/hr/kg), resulting in a decrease in half-life from 8.48 and 6.17 hours (males and females, respectively) to 6.1 and 5.1 hr (males and females, respectively) after multiple dosing (10 days).

Sedation, polyuria, polyphagia, and polydipsia, side effects typical of most anticonvulsants, do not appear to occur in dogs. Aplastic anemia caused by bone marrow suppression, however, developed in 1 of 10,000 patients (human) receiving felbamate,¹⁵³ leading to marked curtailment of the use of the drug in humans. Felbamate has not been sufficiently used in dogs to detect a similar side effect, although it is probably as likely to occur in dogs as in humans. Hepatotoxicy has been reported in dogs receiving both phenobarbital and felbamate and has occurred in 3 of 15 patient treated with combination therapy by the author in an unpublished clinical trial. However, the author has administered felbamate to dogs also receiving phenobarbital at doses as high as 300 mg/kg divided daily for over 6 months with no apparent initial adverse effects. In one of 15 dogs receiving this regimen, progressive liver disease that ultimately proved fatal developed 1.5 years into the combination therapy. Because felbamate is a drug metabolized by the liver, prudence suggests not combining it with phenobarbital, particularly in patients requiring high serum concentrations of phenobarbital to control seizures. In humans interactions have led to increases in phenobarbital by felbamate,¹⁵⁴ although this appears to be due to selective inhibition of a cytochrome P450 enzyme in only 25% of the population. Phenobarbital concentrations should be measured to detect any drug interaction that might lead to an increase in drug concentrations and a subsequent increased risk of liver disease. Greater risk may reflect decreased felbamate concentrations resulting from induction by phenobarbital.¹⁵⁴ Currently, there is no easy, cost-effective means for assaying felbamate, although selected laboratories may offer the service. Human therapeutic concentrations range from 20 to 100 μ g/mL, with trough concentrations ideally remaining in the range of 60 to 80 μ g/mL for best efficacy.¹⁵⁵

Gabapentin

Gabapentin is an anticonvulsant approved in 1994 for treatment of partial seizures with or without generalization in humans with epilepsy.¹⁵⁶⁻¹⁵⁸ It has been used in dogs (and anectodally in cats). It appears to act by a novel mechanism promoting the release of GABA, although the actual mechanism of release is not known. Although gabapentin is absorbed well after oral administration, its absorption appears to be dose dependent, relying on a saturable transport process. This process has been cited as the reason that antiepileptic drug effects last longer than anticipated on the basis of drug halflife, potentially allowing twice-daily administration. The short half-life of gabapentin (in humans) results in steady-state concentrations within 24 to 48 hours. In humans the drug is eliminated entirely by renal elimination, thus avoiding some of the risks of hepatotoxicity and drug interaction. Because the drug is relatively safe, therapeutic drug monitoring is not necessary; rather, the dose is increased as needed to control seizures. Mild dizziness, nausea, and vomiting have occurred in a small percentage of human patients.

Gabapentin studies with animals are limited.¹⁵⁹⁻¹⁶² Gabapentin has been studied in the dog after oral administration of 50 mg/kg. Oral bioavailability was 80%, and plasma protein binding was below 3%. Mean intravenous elimination half-life of 2.9 hours has been reported in dogs. Repeated administration did not alter gabapentin pharmacokinetics, nor did gabapentin induce hepatic drug-metabolizing enzymes. In the dog 34% of the dose was metabolized to the inactive N-methyl form. The principal route of excretion was the urine.^{161,162} A more recent study compared gabapentin (600 mg to Beagles) after oral administration of either an immediate or a slow-release product (see Table 27-4).¹⁶³ The sustained-release product did not disintegrate, but the release kinetics were not substantially different from those of the immediate-release product.

The addition of gabapentin (35 to 50 mg/kg divided every 8 to 12 hours) to either phenobarbital or bromide was studied in epileptic dogs (n = 17) using an open, uncontrolled design. The interictal period increased, but the number of seizures did not. However, seizures were eradicated in three dogs. Side effects that developed with the addition of gabapentin included sedation, which resolved within several days, and hind limb ataxia, which resolved with a reduction in the bromide dose.¹⁶⁴ One of the major disadvantages of this drug is its expense, although several generic preparations are now available. Gabapentin may not be effective for the control of epilepsy when used at doses extrapolated from human patients. Clinical trials are indicated to establish the most appropriate dosing regimen for

dogs or cats. Gabapentin is among the drugs for which SE may occur during withdrawal.¹⁶⁵

KEY POINT 27-22 The advantage of either gabapentin or pregabalin as adjuvant antiepileptic drugs is renal excretion and thus reduced risk of drug interactions or hepatotoxicity.

Pregabalin

Pregabalin is the S enantiomer of 3-(aminoethyl)-5-methylhexanoic acid, an analog of GABA. It is also structurally related to the amino acid leucine and gabapentin (Figure 26-4). Pregabalin has been developed for the treatment of neuropathic pain and as adjunctive therapy in the treatment of partial seizures. However, according to manufacturergenerated approval research, its mechanism of action is not clear.¹⁶⁶ It does not appear to involve gabaminergic transmission, does not alter binding or responses at GABA-A or GABA-B receptors, and is not a substrate or blocker of GABA transporter GABA transaminase. It decreases central neuronal excitability by binding to an auxiliary subunit (alpha₂-delta protein) of a voltage-gated neuronal calcium channel on neurons. It also reduces the release of multiple neurotransmitters (in vitro concentration of 1.6 ng/mL), glutamate, norepinephrine, substance P, and calcitonin gene-related peptide. It serves as a substrate of L-amino acid transporter in neuronal cell membranes, which facilitates pregabalin transport into the cell. In animal models pregabalin controls seizures induced by a variety of methods, including threshold clonic seizures from pentylenetetrazol, and behavioral and electrographic seizures in hippocampal-kindled rats.

Pregabalin appears to be well absorbed after oral administration, minimally bound to plasma proteins, and distributed well to tissues, including the brain. In dogs it is characterized by a volume of distribution of 0.6 L/kg. In most species (e.g., rodents, primates) studied, pregabalin is eliminated principally unchanged in the urine. However, in dogs, while \geq 80% of a dose is excreted in the urine, approximately 45% of the dose excreted as the N-methyl metabolite. However, pregablin does not appear to affect cytochrome P450 drug-metabolizing enzymes. The disposition of pregabalin has been described in apparently healthy Labrador Retriever–Greyhound cross dogs (four female, two male) after a single oral dose of 4.mg/ kg (Table 27-4). The duration that plasma drug concentrations were above the presumed minimum effective concentration of 2.8 µg/mL ranged from 7 to 14.5 hours.¹⁶⁷

Dewey and coworkers described the use of pregabalin as an adjunct to anticonvulsant therapy in the control of epilepsy in 11 dogs using an uncontrolled clinical trial.¹⁶⁸ Animals had not responded sufficiently to either phenobarbital or bromide, or a combination of the two. Insufficient control was defined as two or more seizures per month despite concentration in the recommended therapeutic range of the appropriate drug. For phenobarbital concentrations ranged from 20 to 40 μ g/mL and for bromide 0.2 to 2.81 mg/mL. Dogs whose bromide concentrations were subtherapeutic were receiving phenobarbital in the therapeutic range. Dogs were treated with 3 to 4 mg/kg pregabalin every 8 hours, yielding mean pregabalin concentrations of 6.4+ μ g/mL. Therapy resulted in a reduction of seizures by at least 50% (range of 23% to 83%) in seven of nine dogs that completed the study. However, 10 of the 11 dogs developed adverse effects, including ataxia. Increases in liver enzymes were present during the study, but it is not clear if these increases were related to phenobarbital or pregabalin. Although the study provides support for the possible use of pregabalin as an add-on anticonvulsant, a controlled clinical trial is indicated in dogs to assess both efficacy and safety.

Levetiracetam

Levetiracetam is a single (S)-enantiomer acetamide-derivative antiepileptic drug. Its mechanism of action is novel and does not appear to involve any known neurotransmitter, ion channel protein, or receptor. Rather, it appears to interact with synaptic vesicles (SVA), and appears to impede conduction of impulses across the synapse. Levetiracetam was most useful experimentally in blocking seizures caused by pilocarpine and KA and in the kindling model of rats, both models for complex partial seizures with secondary generalization. Food does not impair the extent, but does impair the rate, of oral absorption. In humans close to 70% of the drug is renally excreted; hepatic metabolism of the remainder reflects acetamide hydrolysis, which is not CYP 450 dependent. Levetiracetam is metabolized by plasma B-esterases, which will continue once blood is drawn. As such, serum rather than plasma or whole blood is the desired test tissue of choice.¹⁶⁹ The elimination half-life in humans is approximately 7 hours. Drug interactions appear to be minimal; competition for renal tubular secretory proteins may occur.

KEY POINT 27-23 The novel mechanism of action of levetiracetam and its wide therapeutic margin are balanced by its very short half-life.

The disposition of levetiracetam has been described in mongrel dogs (n=6).170,171 Intravenous administration of 20 mg/kg yielded a maximum concentration of approximately 44 μ g/mL, volume of distribution of 0.45 \pm 0.13 L/kg, clearance of 1.5 mL/min/kg, elimination half-life of 3.6 ± 0.8 hours and mean residence time of 5 ± 1 hours. In a different study¹⁷² (male and female dogs), oral administration of 54 mg/kg yielded a C_{max} of 50 to 65 µg/mL (mean of 53 and 55 µg/mL in male and female dogs, respectively), and an elimination half-life of 2 to 3 hours. Dewey and coworkers¹⁷³ reported the disposition of levetiracetam in dogs (n = 6) after a single dose (60 mg/kg over 2 min) administered intravenously. The extrapolated peak plasma drug concentration (Co) was 254 \pm 81 mg/mL, steady-state volume of distribution of 0.48 L/kg, and clearance of 1.4 mL*min/kg. The elimination half-life was 4 ± 0.82 hours, and mean residence time was 6 ± 0.9 hours. The dose was well tolerated. Patterson and coworkers¹⁷⁴ studied levetiracetam after intravenous, intramuscular, and oral (19.5 to 2.6 mg/kg) administration in hound dogs (n = 6). Peak drug concentrations were 37 ± 5 , 30.3 ± 3 , and $30 \pm 4 \mu g/$ mL after intravenous (Co:extrapolated peak plasma concentration), intramuscular, and oral administration, respectively. The volume of distribution (beta) was 0.55 L/kg, and clearance was 55 mL/min (not standardized to kg). Elimination half-life was 3 ± 0.3 hours. Bioavailability after intramuscular and oral administration were 113+13% and 100+7%, respectively. No pain was detected with intentional perivascular injection.

In dogs 1200 mg/kg administered intravenously or 2000 mg/kg administered orally was not lethal but was associated with salivation, vomiting, tachycardia, and restlessness; 1200 mg/kg per day for 13 and 52 weeks resulted in transient restlessness and tremor and centrally mediated salivation and vomiting.. Long-term administration (\geq 6 months) in some species was associated with enzyme induction (centrilobular hypertrophy) at 50 mg/kg per day. Liver weight increased, although histopathologic changes did not appear in the liver.

The disposition of levetiracetam has been described in cats (n=10) receiving 20 mg/kg either intravenously or orally as a single dose.¹⁷⁵ Cats tolerated dosing well, with no significant adverse effects noted. However, transient mild to moderate hypersalivation occurred with oral dosing. Median peak concentration after intravenous dosing was 37.52 µg/mL (range 28.05 to 51.86 µg/ mL), with a median half-life of 2.86 hours (range 2.07 to 4.08 hours) and mean residence time of 4.57 hours (range 3.09 to 6). Clearance was 2 mL/kg/min (range 1.5 to 3.4 mL/kg/min) and steady-state volume of distribution was 0.52 L/kg (range 0.33 to 0.64 L/kg). After oral dosing therapeutic plasma concentrations were achieved in 7 of 10 cats within 10 minutes and remained within the therapeutic range for at least 9 hours. Median peak concentration (C_{max}) was 25.54 µg/mL (range 13.22 to 37.11 μ g/mL), T_{max} was 1.67 hours (range 0.33 to 4 hours), T_{1/2} was 2.95 hours (range 1.86 to 4.63 hours), and mean residence time was 5.65 hours (range 4.23 to 7.86). Mean oral bioavailabililty was 100%. When levetiracetam is monitored, because of its very short half-life (according to the author's measurements, as short as 1 hour in dogs and cats), the therapeutic range should be applied to trough rather than peak concentrations. Ideally, both a peak and trough should be measured at least once a year in the patient to determine drug half-life.

Response to levetiracetam of dogs (n=14) with refractory epilepsy was described prospectively.¹⁷⁶ Refractoriness was based on monitoring; eligibility required that drug concentrations be in the upper quartile of the recommended range (mean $32 \pm 4.6 \,\mu\text{g/mL}$). Levetiracetam was administered at 10 mg/kg orally every 8 hours; the dose was increased to 20 mg/ kg thrice daily if seizures did not decline by at least 50%. At 2 months 8 of 10 dogs responded, with seizure number reduced by 73% and number of days or months reduced by 67%. At 6 months 6 of 11 dogs remained classified as responders. However, with long-term follow-up, only three animals remained responders, suggesting that efficacy of levetiracetam declined. Drug concentrations were not measured; as such, the cause of therapeutic failure (i.e., tolerance or worsening disease) was not distinguished from declining drug concentrations.¹⁷⁶

The use of levetiracetam in cats has been reported.^{175,177} Four cats with seizure disorders that were poorly controlled with phenobarbital alone were treated with oral levetiracetam as an add-on drug at a dose regimen of 20 mg/kg body weight, every 8 hours. Levetiracetam serum concentrations were within the reported therapeutic range for people (5 to 30 to 45 μ g/mL) for all samples in all cats. The overall average serum levetiracetam level for all cats was 16.5 μ g/mL (range: 6.9 to 24.3 μ g/mL). The median serum disappearance half-life (t ½) of (based on peak and trough samples) was 5.3 hours. Seizure frequency was reduced by an average of 30.5% in three cats and increased by 33.3% in one cat. The results of this pilot study suggest that levetiracetam is a safe drug for cats that may provide some therapeutic benefit when used as an add-on to phenobarbital.

KEY POINT 27-24 Trough (rather than peak) concentrations of levetiracetam should target the recommended therapeutic range.

Phenytoin Sodium

Phenytoin sodium, previously named *diphenylhydantoin*, depresses motor areas of the cortex (antiepileptic action) without depressing sensory areas. It is approved by the Food and Drug Administration for control of epileptiform convulsions in dogs.

Phenytoin is a hydantoin derivative (see Figure 27-4);⁴⁵ others of lesser importance are mephenytoin and ethotoin. Hydantoins are five-member ring structures, whereas barbiturates are six-member structures. A major point of difference between the hydantoins and barbiturates is the absence of a C=O group. Phenytoin is not a general anticonvulsant, as is phenobarbital, and is not used for emergency treatment of poisoning by convulsant drugs or tetanic seizures. Oral preparations are available in suspension, capsule, and tablet forms. Phenytoin (50 mg/mL) is also available for human use in a special solvent for intravenous administration. Intravenous injection of the drug causes a marked drop in arterial pressure and is not advised in the dog.¹⁷⁸

Phenytoin is no longer used to control seizures in the dog because of its lack of efficacy,¹⁷⁹ which may be related to decreased bioavailability and rapid clearance. Phenytoin is much less effective in the dog than either phenobarbital or primidone in the control of epileptic seizures.⁵⁰ The half-life of phenytoin is too short in the dog to permit maintenance of adequate drug concentrations in plasma and the CNS.¹⁷ When administered alone, phenytoin cannot be considered a satisfactory drug for treatment of epilepsy in the dog.^{29,180} Because of drug interactions and enhanced hepatotoxicity, a combination of phenytoin with phenobarbital is not a viable alternative.

KEY POINT 27-25 Phenytoin is not a preferred drug for treatment of epilepsy because of its short half-life, variability, poor oral bioavailability, and potential for toxicity.

In the cat phenytoin is relatively toxic and generally undesirable as an anticonvulsant.⁷⁰ The efficacy and safety of phenytoin in cats have not been determined.²⁹

Pharmacologic Activity

Phenytoin produces a stabilizing effect on synaptic junctions that ordinarily allow nerve impulses to be readily transmitted at lower thresholds. Consequently, the level of synaptic excitability that permits impulses to be transmitted easily is reduced or stabilized or both. This effect appears to be associated with active extrusion of Na⁺ from neurons and decreased posttetanic potentiation or spread of nerve impulses to adjacent neurons. Phenytoin may reduce calcium movement across cell membranes. Further, phenytoin may inhibit activation of protein phosphorylation by the calcium–calmodulin complex.¹⁸¹ Phosphorylation and norepinephrine release in neurons requires calmodulin. Reduction in spread of the "burst" activity associated with epilepsy prevents genesis of the cortical seizure. Phenytoin stabilizes hyperexcitable neurons without causing general depression of the CNS.⁴⁵

Disposition

Absorption of phenytoin is erratic after intramuscular administration. This may be related to crystallization of the drug at the injection site because of alteration in pH by tissues.⁴⁵ Administration of phenytoin by the intramuscular route is not advised because considerable necrosis and sloughing at the injection site occur.¹⁷⁸ Absorption of the drug from the gastrointestinal tract of the dog is rapid but erratic and incomplete.¹⁷⁹ Bioavailability of phenytoin from the tablet formulation averages 36% in the dog.¹⁸⁰ Poor oral absorption and differences in product bioavailability contribute to the difficulty in achieving effective serum levels of phenytoin. The generic preparations of phenytoin should not be used.¹⁸² Dosing at 30 mg/kg thrice daily for 3 days resulted in concentrations of less than 8.5 µg/ mL.¹⁷⁹ Dosing at 10 mg/kg thrice daily for 5 to 8 days yielded concentrations less than 2.5 µg/mL.

At therapeutic concentrations (10 to 20 µg/mL), phenytoin is highly bound (75% to 85%) to plasma proteins in animals and humans.¹⁸³ The high degree of phenytoin binding predisposes this acidic drug to interaction with other drugs by a displacing effect at protein (albumin) binding sites, although the relevance of this in the presence of increased clearance is not known. In uremic patients decreased plasma protein binding is associated with accelerated renal clearance or elimination of the drug. Phenytoin readily crosses the placenta.¹⁸⁴ High concentrations of phenytoin are attained in the maternal liver and maternal and fetal hearts. The brain (ostensibly the primary target organ) contains nearly the lowest concentration of the drug.

Phenytoin is metabolized via CYP2C9 and to a lesser degree CYP2C19¹⁸⁵ into metahydroxyphenytoin or parahydroxyphenytoin, which are conjugated with glucuronic acid. In humans approximately 60% to 75% of the daily dose of phenytoin is excreted in the glucuronide form;⁴⁵ the dog also converts a high percentage of phenytoin into this form. In addition, diphenylhydantoic acid, a minor metabolite in some laboratory animals, and dihydrodiol are formed in dogs. Interestingly, high concentrations of diphenylhydantoic acid are found in cat urine. The dihydrodiol metabolite is probably involved in formation of catechol metabolites; these are also formed in most animals.¹⁸⁶ Epoxide metabolites are also speculated to be formed in humans. Because phenytoin is not very soluble in water, little of the unmetabolized drug is excreted in urine.

In the dog, despite relatively large single daily oral doses (50 mg/kg), the plasma concentration of the drug is low, perhaps reflecting the short half-life of 6 to 7.8 hours¹⁸⁷ compared with 4 to 6 hours after an intramuscular injection (50 mg/kg) as well. The shorter half-life of the second study probably reflects induction after multiple dosing;¹⁸⁸ the half-life of phenytoin in the dog dramatically decreases after 7 to 9 days of treatment.^{179,180.} A 2.5-hour half-life was predicted for phenytoin after 14 days of therapy compared with 3.3 hours with single dosing. Other studies have confirmed a short half-life for phenytoin in the dog: After a single intravenous dose (15 mg/kg), a value of 4.5 hours was obtained by Sanders and coworkers,¹⁸⁹ and a half-life of 3.65 hours was determined by Pedersoli and coworkers¹⁹⁰ after an intravenous bolus of 11 mg/kg. The clearance of phenytoin has been described as dose dependent in dogs.¹⁷⁹ More recently, using a parallel design, the disposition of phenytoin was described in Beagles (n=5) after 5 days of intravenuos administration of 12 mg/kg (see Table 27-5).¹⁹¹

After oral administration (10 mg/kg) in the cat, plasma half-life of phenytoin was 24 to 108 hours,^{188,192} contributing to the prolonged effect of phenytoin observed in the cat more than in other species. This may reflect decreased glucuronide conjugation.

Clinical Use

In humans clinical therapeutic effects and intoxication are related to the blood concentration of phenytoin. A reduction in the number of seizures occurs when phenytoin blood concentrations exceed 10 µg/mL. Recommended therapeutic doses of phenytoin administered orally every 8 hours for control of seizure disorders in the dog indicate considerable variation: 6.6 to 11 mg/kg,¹⁷⁸ 11 mg/kg,⁴⁹ and 35 mg/kg.¹⁷⁹ However, oral administration of phenytoin (4.4 and 11 mg/ kg) every 8 hours fails to reach serum concentrations of 10 μ g/mL in the dog. Indeed, serum phenytoin after either single or repeated oral doses of 10 mg/kg does not exceed a concentration of 2 µg/mL.¹⁷⁹ To achieve a serum concentration of approximately 10 µg/mL phenytoin, it appears that an oral dose of at least 35 mg/kg given thrice daily is necessary for the adult dog.49,179 According to Pedersoli and coworkers,190 an oral dosage schedule of 20 mg/kg every 8 hours of the phenytoin microcrystalline suspension should be sufficient to reach a serum concentration of 10 µg/mL or higher. This dose, however, will maintain a plasma therapeutic level for only the first 2 or 3 days of treatment.¹⁸⁰ Farnbach⁵⁰ found that only 3 of 77 epileptic dogs receiving phenytoin were controlled; concentrations in all dogs ranged from 0.2 to 13 μ g/mL, with a median of 2.3 µg/mL, despite doses ranging from 3 to 129 mg/kg per day (generally divided into twice-daily doses).

Drug Interactions

The combined use of phenytoin and phenobarbital or primidone may lead to increased formation of epoxide metabolites in animals. This could possibly result in cholestatic hepatic injury similar to that reported in three dogs.³⁶ The effect may also reflect induction by phenytoin. Phenytoin must be considered a potent inducer of the hepatic microsomal enzyme system in the dog.¹⁸⁰ Between 7 and 9 days after administration of phenytoin, its half-life may be reduced from 5.5 to 1.3 hours. In contrast, the half-life after oral administration in humans averages 22 hours, with a range of 7 to 42 hours. This contrasts to humans, in which phenytoin has a moderate inducing ability in the human. The differences between the two species may help explain the efficacy of phenytoin for control of epileptic seizures in humans compared to dogs. Further, although the combined use of phenytoin and phenobarbital is considered optimal therapy in humans,55 use of both drugs is controversial because both induce hepatic microsomal enzyme activity. This combined induction complicates successful therapy because therapeutic concentrations are difficult to achieve and the increased production of potentially toxic metabolites.¹⁷⁸ Metabolism of a number of chemicals or drugs is enhanced by phenytoin. These include digitoxin, dexamethasone, and cortisol.¹⁹³ In humans the half-life of theophylline decreases by 50% with an increase in clearance of twofold.¹⁹⁴

Phenytoin metabolism in humans is inhibited by other drugs prolonging their effect. Examples include dicumarol, chloramphenicol, phenylbutazone, and the phenothiazines. In vitro inhibition has been demonstrated by diazepam and propoxyphene hydrochloride. In the dog the serum half-life of intravenous phenytoin increased from 3 to 15 hours when administered with chloramphenicol, and signs of phenytoin toxicosis reversed within 24 hours after cessation of chloramphenicol treatment.¹⁹⁵ Phenylbutazone is also known to increase plasma concentration as a result of inhibition.⁴⁵ Despite predominant renal elimination, vigabatrin, a drug similar to gabapentin, deceased phenytoin clearance by 31% and increased phenytoin half-life by 45% in Beagles.¹⁹¹ In contrast, gabapentin had no effect.

Serum phenytoin concentration declines in the presence of folic acid therapy, presumably because the hydroxylase enzyme that metabolizes phenytoin is folate dependent. Phenytoin may prolong the prothrombin time.¹⁹⁶ Blood coagulation defects similar to that induced by vitamin K deficiency can occur in neonates exposed to phenytoin in utero. The coagulation defect can be reversed by treatment with vitamin K.

Blood Concentrations and Associated Toxicity

In humans mild signs of intoxication such as nystagmus develop with blood levels of 20 μ g/mL; patients with levels over 40 μ g/mL have marked nystagmus and are uncoordinated and lethargic. Blood levels in the dog would probably have to increase a comparable 100% to 400% as in humans before serious signs of intoxication develop.

Hepatitis, jaundice, and death after clinical use of phenytoin have been reported in one dog that initially received primidone (500 mg daily).¹⁹⁷ Toxic hepatopathy and intrahepatic cholestasis associated with phenytoin administration in combination with phenobarbital or primidone (or both) have been reported in three dogs.^{36,89} Two distinct forms of hepatotoxicity have been ascribed to reflect the sequelae of anticonvulsant phenytoin in dogs.³⁶ The first (type B reaction) is characterized by clinical signs after extended treatment at lower than recommended doses and may result from

an (unpredictable) idiosyncratic reaction. Indications are that histologic changes with this form will progress from chronic hepatitis to cirrhosis. The second form is more frequently characterized by intrahepatic cholestasis and is associated with a poor prognosis. This form of liver disease has been associated with high doses of phenytoin in combination with primidone or phenobarbital and may represent an intrinsic hepatotoxicity. Induction of enzymes is likely to increase formation of toxic metabolites, which may contribute to hepatotoxicity. Hepatotoxicity resulting from phenytoin is more likely if the drug is used in combination therapy with either primidone or phenobarbital. Toxicity may be related to generation of toxic metabolites. Two forms of toxicity appear to occur with phenytoin therapy: a dose-independent chronic hepatitis that may progress to cirrhosis and that appears to be reversible after discontinuation of the drug early in the disease and a dose-dependent intrahepatic cholestasis that is accompanied by a poor prognosis.

Other Side Effects

The CNS side effects of phenytoin in the dog are moderate in part because of its action but also because it is rapidly metabolized.⁴⁹ Transient incoordination and oversedation may occasionally occur after administration of phenytoin. A moderate degree of polyphagia, polydipsia, and polyuria may be seen in animals medicated with this drug. Sialosis, weight loss, and vomiting have been reported after the use of phenytoin in the cat. Inhibition of release of antidiuretic hormone accounts for the polyuria that develops after administration of phenytoin. Insulin secretion also is inhibited.⁴⁵

Displacement of T_4 by highly protein-bound drugs (e.g., phenytoin) from T_4 -binding globulin increases T_4 concentrations, induction of hepatic drug-metabolizing enzymes results in increased clearance of both T_4 and T_3 , and increased conversion of T_4 to T_3 by peripheral tissues further decreases T_4 . The latter mechanism has been postulated as the reason that T_3 concentrations may remain normal despite increased T_3 clearance¹⁹⁸ in patients receiving phenytoin. Clinical signs of hypothyroidism may not be apparent in such cases. Note, however, that both serum T_4 and free T_4 may be decreased in some patients receiving anticonvulsants.

Fosphenytoin is a phosphate ester prodrug of phenytoin, with the latter being released after dephosphorylation by tissue (liver, red blood cells, and others) phosphatases.¹⁹⁹ Enzymatic conversion half-life is about 3 minutes in dogs, with equimolar concentrations of phenytoin emerging with fosphenytoin. Similar antiarrhythmic (antiseizure was not reported) effects occurred for fosphenytoin and phenytoin in dogs. Side effects are similar to phenytoin, although local irritation was less with intramuscular administration of fosphenytoin compared with phenytoin. No information could be found regarding use of fosphenytoin in dogs.

Topiramate

Topiramate is a monosaccharide D-fructose anticonvulsant derivative developed in the 1980s.²⁰⁰ Its mechanism of action is not entirely understood but includes enhanced gabaminergic

actions at the GABA-A receptor. Sodium channel blockade may also be involved (package insert). Its effects are similar to those of diazepam but are not blocked by flumazenil, suggesting actions through a novel, non-benzodiazepine (BDZ)–sensitive binding site on the GABA-A receptor. It may also inhibit the kainite/AMPA (but not NMDA) glutamate receptor. Topiramate appears to increase the seizure threshold and prevent seizure spread. In selected studies potency is similar to phenytoin and phenobarbital. However, while useful in kindled and ischemia-induced epilepsy, it has variable efficacy for prevention of pentylenetetrazole (a GABA-A receptor antagonist) or picrotoxin-induced seizures. In humans it has been predictably effective in controlling partial and secondary seizures but not absence seizures.

In humans topiramate is eliminated primarily through the kidneys as the parent compound, although up to eight metabolites have been identified.

Topiramate inhibits isoenzymes of carbonic anhydrase; this mechanism appears to be more relevant to side effects than control of seizures. Binding to the enzyme results in a large proportion of the drug being located in erythrocytes at low concentrations. Its oral disposition has been reported in male and female Beagles; intravenous data are available for one dog (see Table 27-4).²⁰¹ Based on comparison of the area under the curve after 10 mg/kg intravenously and orally, oral bioavailability appears to be about 35% for tabular form but is increased twofold when administered as a solution. Dogs treated with up to 400 mg/kg experienced no lethal side effects, although acute toxicity associated with ataxia, decreased motor activity, tremors, and clonic convulsions occurred. Dosing for 3 and 12 months was not associated with overt indicators of toxicity in dogs. However, increased liver weights (indicative of induction), increased serum gastrin levels and gastric mucosal hyperplasia, and renal and urinary epithelial hypertrophy have been associated with long-term use in other species. Topiramate is available as a sprinkle formulation. Its use apparently has not been reported in dogs or cats.

Valproic Acid

Valproic acid is a vehicle used for other drugs that was serendipitously found to have anticonvulsant properties. It is a simple branched-chain carboxylic acid (see Figure 27-4). Valproic acid is effective against a variety of seizures, including absence seizures. Its mechanism of action appears to be similar to that of phenytoin in that it prolongs recovery of voltage-activated Na⁺ channels from inactivation. It may also affect Ca²⁺ fluxes but does not appear to impair GABA. The drug is rapidly absorbed, highly protein bound, and in humans has a half-life of 10 to 15 hours. The half-life can, however, be shortened in the presence of other (inducing) anticonvulsant drugs.

The difficulty in using this drug in dogs probably reflects an inability to achieve therapeutic concentrations. Valproic acid is metabolized in the liver; metabolites can be as potent as the parent compound in controlling seizures, although only one of them enters the CNS to any appreciable extent. Valproic acid can alter liver enzymes (up to 40% of human); increases can be associated with toxicity. Hepatotoxicity is likely to be increased when used in combination with other drugs. It also causes gastrointestinal upset and, like other anticonvulsants, CNS side effects (e.g., sedation, ataxia). Valproic acid has not proved very useful for controlling seizures in dogs. It might be considered in combination with phenobarbital, although drug interactions may complicate therapy.

The disposition of valproic acid has been reported for dogs by several authors (reviewed by Frey and Löscher)⁴² (see Table 27-4). Peak serum concentration after oral absorption is markedly variable and appears to be greater with solution $(30 \text{ to } 60 \text{ } \mu\text{g/mL} \text{ at } 20 \text{ } \text{mg/kg})$ compared with tablets (30 to 75 mg/kg)µg/mL at 40 mg/kg). However, bioavailability is not as divergent, reaching 89 ± 8.2 for solution compared with 78 ± 17 for tablets.42 Löscher202 demonstrated that therapeutic drug concentrations could be maintained in part because of decreased protein binding in dogs compared with humans. Half-life of valproic acid did not change over 14 days of treatment at 168 to 180 mg/kg (divided into three equal doses). Löscher attributed some antiepileptic efficacy of valproate to its metabolites, which appear to accumulate in dogs (n = 3). In a study of multiple oral dosing (60 mg/kg thrice daily for 14 days), mean plasma concentrations of valproic acid, 2-en- valproic acid, 3-hydroxy-valproic acid, 3 keto-valproic acid, and "total equivalents" of valproic acid were 20, 3.1, less than 0.4, and 3.7 (23 equivalents) on day 1 of dosing, compared with 8, 16, 0.7, and 9.1 (18 equivalents) at day 14.

The use of valproic acid for treatment in idiopathic epileptic dogs (27 female and 40 male), 29 of which were considered refractory to anticonvulsant drugs was described by Nafe and coworkers.²⁰³ The addition of valproic acid (25 to 40 mg/kg per day) resulted in improvement in six of eleven dogs already receiving phenytoin or phenobarbital and one of six dogs receiving primidone (dog was tapered off of primidone). Valproic acid (25 to 105 mg/kg per day) alone markedly improved seizures in 7 of 16 dogs, and the combination of valproic acid and phenobarbital resulted in marked improvement in 14 of 24 dogs. One dog developed noninflammatory alopecia.

Zonisamide

Developed in Japan, zonisamide, 3-sulfamoylmethyl-1,2 benzisoxazole, is a synthetic sulfonamide-based anticonvulsant approved for use in the United States in 1998 for treatment of seizures related to human epilepsy.²⁰⁴ The efficacy of zonisamide for treatment of human epilepsy is similar to phenobarbital and superior to other classic drugs, including valproic acid and phenytoin. Its mechanism is not clear, but it appears to inhibit neuronal voltage-dependent sodium and T-type calcium channels.^{205,206} It also modulates the dopaminergic system and accelerates the release of GABA from the hippocampus.^{207,208} An additional potential advantage of zonisamide is free radical scavenging, which protects against the destructive nature of radicals, especially in neuronal membranes.²⁰⁹ Finally, zonisamide blocks the propagation of seizures from cortex to subcortical areas of the brain. Its antiepileptic efficacy has been described as similar to that of phenytoin or valproic acid, thus minimally affecting normal neuronal activity. These multiple mechanisms of action may

translate to improved efficacy compared with other anticonvulsant drugs.

The clinical pharmacology of zonisamide has been investigated in humans with similar characteristics in dogs.²¹⁰⁻²¹² Disposition is complicated. Oral absorption tends to be rapid, complete, and minimally impaired by food. After 12 hours of dosing, zonisamide concentrations in the brain are twofold that in plasma. The extent of protein binding is not sufficient to limit the rapid movement into the brain. Binding of zonisamide to erythrocytes (red blood cells) and plasma proteins contributes to complex kinetics. Erythrocyte concentrations in whole blood tend to be twice as high as plasma and serum in humans and are characterized by binding that is both saturable and nonsaturable;²¹³ the saturable portion may reflect binding to carbonic anhydrase in epileptic patients. Accumulation of drug in red blood cells is reversible, and the complex relationship between zonisamide and red blood cells may make therapeutic drug monitoring of plasma or serum advantageous. Metabolism of zonisamide involves both phase I and phase II hepatic metabolism, with cytochrome P450 3A4 being the major isozyme and a glucuronidated compound the major metabolite.²¹⁴ Enzymes CYP3A4, CYP3A5, and CYP2C19 contribute to metabolism in humans.²¹⁵ Renal elimination and recovery of zonisamide indicate parent drug recovery of 35%. Using radiolabeled (carbon) zonisamide administered to dogs, 83% of the drug was excreted in 72-hour urine as the either the parent compound or metabolites. The remaining proportion was recovered in feces.²¹⁰ The terminal half-life of zonisamide in the dog after a single oral dose (20 mg/kg) administration differed depending on the tissue studied, with the shortest being 15 hours for plasma and the longest 42 hours for red blood cells.²¹⁰ The longer elimination half-life allows a convenient dosing interval while minimizing dramatic fluctuations in zonisamide concentrations that might cause recurrence of seizures. Recommended therapeutic concentrations for zonisamide initially were 10 to 70 µg/mL, with 16.5 to 49.6 µg/mL also suggested when dosed twice daily.²¹⁶ The author recommends the more commonly accepted 10 to 40 µg/mL; however, monitoring should be based on patient need. Nonlinear pharmacokinetics have been reported in some human patients, particularly with chronic dosing, resulting in disproportionate, and thus unexpected, increases in drug concentrations compared with changes in dose. In dogs undergoing toxicity studies, plasma concentrations never reached steady state over the course of 13 weeks of dosing at 75 mg/kg, compared with proportional steady-state concentrations by week 13 at 10 to 30 mg/ kg.212

KEY POINT 27-26 Its unique mechanism of action, reasonable half-life, and wide therapeutic margin render zonisamide an increasingly useful drug for control of epilepsy in dogs and cats.

Clinical pharmacokinetics of zonisamide have been described in normal dogs (n = 8), four male and four female, ranging from 3 to 4 years of age, using a randomized cross-over design after single intravenous and oral administration,

6.85 and 10.25 mg/kg, respectively.²¹⁷ Zonisamide concentrations differed among blood compartments after single dosing, with oral maximum concentration (C_{max}) being greatest in red blood cells (28.73µg/mL) and least (14.36 µg/mL) in plasma. Clearance of zonisamide was 57.55 mL/hr/kg from plasma and 5.06 mL/hr/kg from red blood cells. However, zonisamide concentrations did not differ among blood compartments at the end of multiple dosing, suggesting any blood component can be monitored. The fraction of unbound drug was $60.48 \pm$ 13.4%. Elimination half-life in plasma was 16.4 hours in serum and 57.4 hours in red blood cells. Volume of distribution also differed, being greater (1 L/kg) in plasma and least in (0.4 L/kg) red blood cells. Bioavailability was 126.8% for red blood cells and 189.6% for plasma. After multiple dosing (10.17 mg/kg) twice daily for 8 weeks, the accumulation ratio of zonisamide was 3.5 (plasma) and 4.3 (red blood cells). The resulting mean C_{max} at steady state was 56 ± 12 µg/mL, suggesting a beginning dose of 2 to 3 mg/kg twice daily to target the low end of the therapeutic range. The half-life at 8 weeks was 23 ± 6 hours. Plasma drug concentrations varied by 17.2% between 12-hour dosing intervals, which suggests that a 12-hour dosing interval is appropriate. Differences in clinical pathology data occurred at the end of the 8-week study period, although all results remained within normal limits. Serum alkaline phosphatase and calcium increased above baseline, whereas total serum protein and albumin both decreased below baseline.

Zonisamide pharmacokinetics have been described in cats (n = 5) after a single dose of 10 mg/kg (see Table 27-4).²¹⁸ Safety and adverse reactions were studied during chronic (9 weeks) dosing at 20 mg/kg once daily. Zonisamide was not well tolerated at this dose; 50% of cats exhibited vomiting, diarrhea, and anorexia. Mean peak and trough concentration with chronic dosing in all cats were 46 and 59 µg/mL, respectively, with concentration at 42, 59, and 79 in cats with adversities. Zonisamide appears to be minimally involved in drug interactions typicalof highly protein-bound drugs.²¹⁰ However, it is involved with interactions involving CYP enzymes. Nakasa and coworkers²¹⁵ demonstrated that clearance was decreased 31%, 23%, and 17% by ketoconazole, cyclosporine A, and miconazole, respectively; fluconazole inhibited clearance to a lesser degree, but itraconazole appeared to have no effect.

Oral bioavailability of human generic preparations should not be assumed to act similarly in dogs and cats. Accordingly, clinicians and owners both should request that dispensing pharmacists inform the owner or veterinarian if the dispensing pharmacy has changed to a different generic preparation since the last prescription.

Zonisamide does not appear to affect its own metabolism nor the metabolism of other drugs in animals or humans. Phenobarbital will shorten zonisamide half-life. The impact of 35 days of dosing phenobarbital on the disposition of zonisamide was studied in dogs. Unfortunately, all data were pictorially represented, limiting assessment of changes in disposition.²¹⁹ After 35 days of phenobarbital administration, concentrations appeared to decrease to about 2.75 µg/mL, returning to 3.5 only after approximately 12 weeks after phenobarbital was discontinued. The decrease in half-life appeared to be about 3 hours, or approximately 30%. Phenobarbital shortened the half-life of zonisamide from 27 to 36 hours in humans, resulting in lower plasma drug concentrations.²²⁰ The impact of phenobarbital does not appear to be profound, but monitoring is warranted, and collection of both a peak and a trough sample might be warranted in patients receiving phenobarbital with zonisamide. The effect does not appear to warrant starting the drug at higher doses in patients on phenobarbital unless monitoring has confirmed the need.

Dogs appear to tolerate zonisamide well; concentrations in samples submitted for monitoring at the author's laboratory indicate concentrations that exceed 60, 80, and in some dogs, 100 μ g/ml well. Dose increases for zonisamide in dogs may cause disproportionate increases in plasma drug concentrations based on data in the author's laboratory. It is possible this may reflect saturation of acetylation enzymes in the dogs.

As a sulfonamide, zonisamide inhibits thyroid synthesis of thyroid hormones. Anticonvulsants (phenytoin) may also have a direct negative effect on TSH response to thyrotropinreleasing hormone. Drug-induced changes in T₄-binding globulins have also been documented in human patients taking anticonvulsants. Boothe and Perkins²¹⁷ demonstrated that zonisamide dosed for 8 weeks was associated with a decrease in total T₄ below normal limits. Free T₄ and TSH were also decreased from pretreatment concentrations, although both were within normal limits. Zonisamide concentrations were higher than the recommended therapeutic range. Thyroxin and TSH concentrations might facilitate diagnosis of hypothyroidism in animals receiving zonisamide.¹⁹⁸ Note that thyroid supplementation suppresses response to TSH, and testing should not be performed until supplementation has been discontinued for 4 to 6 weeks. As with carbonic anhydrase inhibitors, zonisamide has been linked to metabolic acidosis in humans. The FDA recommends that bicarbonate be measured before and intermittently during therapy. Renal calculi have formed in a very small number of human patients receiving zonisamide for long periods. Because it does not contain an aryl-amine, allergic responses associated with sulfonamide antimicrobials may not occur in dogs.

Clinical reports of zonisamide use in animals are limited. In one report zonisamide was effective in reduction of seizures in patients with epilepsy that had not sufficiently responded to one or more anticonvulsants (including phenobarbital and/ or bromide) in 7 of 12 dogs at doses designed to achieve 10 to 40 μ g/mL. Dose reduction or discontinuation of concurrent anticonvulsant was possible in 8 of 12 dogs. Mean concentrations approximated 20 μ g/mL; mean dose was 9 mg/kg every 12 hours.²²¹ A second open clinical trial studied zonisamide for treatment of refractory seizures in dogs (n = 13).²²² Mean reduction in seizure was 70%, with three dogs relapsing. Drug concentrations were not measured.

KEY POINT 27-27 At high concentrations, zonisamide will inhibit thyroid gland synthesis. Therapy should be initiated at a low dose and concentrations increased as needed to control seizures.

ACUTE MANAGEMENT OF SEIZURES

Status Epilepticus

The leading cause of SE in humans is inappropriate low concentrations, with noncompliance with prescribed medications among the most common reasons. Accordingly, the application of the principles of pharmacology to anticonvulsant therapy should facilitate effective control and the avoidance of SE. A number of proepileptic drugs are also cited as causes for SE (discussed later).²²³

Early therapeutic intervention is more important than drug choice; in humans intervention within the first 30 minutes was associated with an 80% response to first-choice drugs, whereas 60% of patients in SE for more than 2 hours did not respond to first-line therapy. Physiologic responses of concern include fever, cardiac arrhythmias, changes in systemic (initially hypertension and later hypotension) and pulmonary blood pressures, and altered blood chemistries.²²³

In humans²²³ the traditional definition of SE as continuous or repetitive seizures lasting 20 minutes or more has been challenged; therapy for SE is recommended for two or more generalized convulsions without full recovery of consciousness between seizures, or continuous convulsive activity lasting more than 10 minutes. However, recommendations have been reduced to 5 minutes because few seizures last this long.

Benzodiazepines tend to be more effective early but not later, whereas NMDA receptor antagonists (e.g., ketamine) tend to be effective later but not early. In humans, drugs of choice vary with the duration of SE. The suggested approach is 6 to 10 minutes: intravenous lorazepam, followed by diazepam or midazolam (intranasally, or intramuscularly); 10 to 20 minutes: fospheyntoin for 10 to 60 min followed by midazolam by CRI or phenobarbital IV if no response,propofol by CRI or valproate if no response, and finally, the addition or alternative of pentobarbital or midazolam if no response. For seizures greater than 60 minutes in duration, pentobarbital is indicated. Despite ketamine's potential efficacy as an anticonvulsant drug, antagonism of NMDA may result in severe neurotoxicity, and its use in SE should be reserved until scientific data support its efficacy.

In dogs or cats, treatment for more than one seizure per hour is a medical emergency.⁴⁹ The use of drugs for acute management of seizures is addressed in detail with individual drugs. In general, however, acute therapy of seizures (e.g., SE) is preferentially implemented with diazepam (intravenous bolus to effect). Diazepam has a short half-life, and it may be necessary to repeat the dose once or twice during the first 2 hours to stabilize the dog.49 To terminate the seizures, various methods of administration have been recommended. Diazepam is recommended in an intravenous dose of 5 to 20 mg. Frey and Löscher⁴² recommended an intravenous dose of 0.5 to 1 mg/kg. Control by diazepam can be prolonged by continued administration as a CRI (2 to 5 mg/hr of 5% dextrose; the infusion line should first be flushed with the diazepam solution to allow diazepam binding to the polyvinyl), or coadministration of phenobarbital (2 to 6 mg/kg intramuscularly to avoid respiratory or cardiac depression). Clonazepam

(0.05 to 0.2 mg/kg intravenously) may provide antiepileptic efficacy that lasts longer (but is not necessarily any more efficacious) than that of diazepam. Unfortunately, an intravenous preparation is not available in the United States. Alternatively, phenobarbital can be administered as the first choice (intravenous bolus to effect, as a loading dose). Note that for each 3 mg/kg of phenobarbital given intravenously, serum concentration increases approximately 5 μ g/mL. For a patient not receiving phenobarbital at the time that therapy is begun, up to 18-mg/kg total dose (given in 3- to 6-mg/kg increments at 15- to 30-minute intervals) may be necessary to achieve the midtherapeutic range (30 µg/mL). Drug distribution of phenobarbital into the CNS may take 15 to 30 minutes. Failure to control seizures may indicate the need for pentobarbital. As such, the risk of cardiovascular or respiratory depression is great. An advantage to the use of pentobarbital, however, is its protective effects on the brain during periods of hypoxia induced by the seizure.

KEY POINT 27-28 Although diazepam is very effective, its short duration of action may require alternative drugs or methods of administration.

Alternative routes of anticonvulsant therapy might be considered for clients attempting to control life-threatening seizures without immediate access to veterinary medical assistance. Phenobarbital (5 mg/kg), diazepam, and bromide are partially to completely bioavailable after rectal administration.^{94,95} The risk of potassium overload can be minimized by administration of the loading dose over a 12- to 24-hour period in 5- to 15-mL increments.

A small number (20) of human patients with refractory epilepsy were treated with either propofol (14) or midazolam (6) in a retrospective study. For each drug seizures were eradicated in about 65% of patients. However, overall mortality, although not statistically significant, was higher with propofol (57%) compared with midazolam (17%).²²⁴

General gas anesthesia generally is not recommended in the patient with SE because of the risk of hepatotoxicity induced by the anesthetic that may occur with prolonged therapy. If the clinician decides that general gas anesthesia is necessary, anesthetics that are minimally hepatotoxic are preferable. Discontinuation of therapy should be undertaken cautiously to minimize the risk of seizures. Propofol and etomidate are two chemical restraining agents that, are characterized by anticonvulsant effects, although these drugs are expensive. Of the two, etomidate (a human drug only) may be characterized by CNS-protective effects. These drugs can be administered as intravenous infusions to effect (see later discussion regarding brain trauma).

Diazepam can be used in the cat to control acute epileptic disorders regardless of etiology Generally, an intravenous dose (5 to 10 mg) is given to effect. A dose as high as 20 mg may be necessary; if high dosages are used, they must be injected slowly. The procedure commonly followed is to administer 2 to 10 mg intravenously and then wait 10 minutes. If seizures persist, phenobarbital sodium can be administered (5 to 60 mg). Caution must be taken not to oversedate or depress the

animal when these drugs are administered in close succession. Should the animal manifest refractoriness to diazepam and phenobarbital, as in SE, pentobarbital anesthesia is then carefully administered to effect.

SE may require management of cerebral edema (see later discussion of brain trauma and injury).

CHRONIC CONTROL OF SEIZURES

Use of selected antiepileptic drugs to control seizures has been discussed with regard to individual drugs. What constitutes successful anticonvulsant therapy will vary among clinicians and may be defined by client satisfaction. Eradication of seizures may be an unachievable goal; decreased frequency, severity, or duration of the seizure episode may be considered a success for many animals. Indeed, close counseling of clients and reorientation to what constitutes successful control may be important techniques to successfully treating an epileptic dog. Chronic control of epilepsy is likely to be a balancing act for many patients: controlling seizures without putting the patient's health at excessive risk. Because patients are likely to need drug therapy for the rest of their lives, establishing a minimum effective dose for any anticonvulsant drug is prudent. Monitoring is important to prevent toxic concentrations, or to confirm ineffectiveness at high concentrations, even for newer, safer drugs. Monitoring should be used to determine the minimum effective dose for each patient. In the case of breakthrough seizures, monitoring can help the clinician determine whether the seizures reflect a decrease in drug concentrations (which should lead the clinician to confirm owner compliance, addressing potential drug or diet interactions, and so forth) or a change in the underlying pathophysiology (leading to further diagnostics and potential treatment).

KEY POINT 27-29 Ideally, long-term control of therapy should begin with a single drug, with combination therapy initiated only after the first drug fails. Failure should be assumed only as drug concentrations approach the maximum end of the therapeutic range.

If manipulation of a dosing regimen is the focus of successful control, a chosen therapeutic regimen should not be abandoned until steady-state plasma drug concentrations have been reached. Thus an animal should not be considered refractory to a drug simply because it is receiving more than the recommended dose or its serum concentrations are within the therapeutic range. A drug should not be abandoned until serum concentrations in the maximum therapeutic range (and, in some circumstances, exceeding it if the drug is sufficiently safe) have been documented or unacceptable adverse side effects occur. Regardless of the anticonvulsant used, therapy should never be stopped suddenly, and drug concentrations should not be allowed to drop precipitously during a dosing interval. SE may occur. Cautious exceptions might be made for drugs with a very long half-life (e.g., bromide) that naturally gradually decline (as long as chloride content in the animal has not increased).

The thyroid and liver status of patients should be determined before initiation of therapy. Anticonvulsant-induced liver disease should be distinguished from hepatic induction for several anticonvulsant drugs; unnecessary discontinuation of a drug that is controlling seizures might thus be avoided. Moderate elevations in the serum transaminases and SAP activity and abnormalities (more than 50 mmol/L) in fasting bile acids and serum albumin are indicative of hepatic pathology. The incidence of serious liver toxicity can be reduced by avoiding combination therapy with more than one drug metabolized by the liver; using therapeutic drug monitoring²²⁵ (see Chapter 5) to achieve adequate serum concentrations at the smallest dose possible; and evaluating hepatic function every 6 months or more, depending on the magnitude of phenobarbital serum concentrations. The higher the plasma drug concentration, the more important hepatic monitoring becomes. Seizure-induced hypoxia can result in liver damage; thus evaluation of the liver should not occur in association with a seizure episode. Hepatotoxicity induced by anticonvulsants is often reversible if the drug dose is sufficiently decreased before cirrhotic changes occur.

Phenobarbital has remained the first-choice anticonvulsant for chronic control of seizures in both dogs and cats because of its efficacy and, as long as drug concentrations do not approach the maximum therapeutic concentration, safety. However, increasingly evidence is emerging that other anticonvulsants may be effective. Therapeutic drug monitoring should be used to ensure that adequate serum drug concentrations have been achieved before the patient is considered refractory. As concentrations of phenobarbital approach the maximum end of the therapeutic range, an alternative regimen should be considered. The addition of a second anticonvulsant is the most likely next step.

Combination Therapy

Use of combination therapy appears to be popular in veterinary medicine, on the basis of therapeutic drug monitoring information in the author's laboratory. Although combination therapy is a reasonable approach for control of seizures in patients that fail to reasonably respond to first-choice anticonvulsants (e.g., plasma drug concentrations approach or enter the high end of the therapeutic range, or unacceptable side effects emerge), many of these patients are on two or more drugs, each of which is in the subtherapeutic to lowtherapeutic range. The American Epilepsy Society notes that most human patients can be controlled with single-drug therapy and that higher concentrations of a single drug are preferred to lower concentrations of multiple drugs. Single-drug therapy should be considered prudent for several reasons. The most obvious is avoidance of side effects (the combined side effects of a drug might, like efficacy, be worse than either drug by itself), fewer drug interactions, better owner compliance, and reduced cost (because multiple drugs require more than one prescription and additional monitoring). Other reasons to limit combination therapy to patients with proven need are likely to be less obvious. However, no drug therapy is likely to be innocuous. Drugs that affect the CNS may be problematic because of the sophisticated mechanisms that exist to minimize the effects of CNS drugs. These include efflux proteins, receptor downregulation, and desensitization. In the author's opinion, because the CNS does not *want* drugs in the CNS, an attempt should be made to respect the body's attempt to limit exposure of the brain to drugs. Accordingly, the author recommends that single-drug therapy be targeted and combination therapy be instituted only in patients that have failed initial therapy.

Bromide increasingly is recommended as a first-choice antiepileptic drug. Although Boothe and Dewey²⁸ demonstrated that it is not as efficacious as phenobarbital for control of seizures in dogs, its lack of drug interactions and improved safety compared with phenobarbital warrant consideration as first choice, particularly in older dogs for which the risk of drug interactions and liver disease might be decreased.

Bromide also has been recommended as the first combination drug of choice for dogs should phenobarbital therapy fail. However, as newer predominantly renally excreted drugs become available in generic preparations, their use should be considered so as to avoid the gastrointestinal side effects of bromide. Bromide increasingly is being used as the sole anticonvulsant, although a severe seizure history may warrant using a more accepted and predictable first-choice drug (e.g., phenobarbital).

Controlling refractory seizures with any anticonvulsant drug might be facilitated using a stair-step approach. Using bromide as an example, increase concentrations in 0.5-mg/ mL increments. If the patient develops seizures at one concentration, the concentration is increased to the next level. This is continued until the patient is acceptably controlled or sedation becomes untenable. In the latter case, decreasing phenobarbital concentrations by 25% may help resolve grogginess. If the goal of bromide therapy is to wean the patient off an anticonvulsant (using phenobarbital as an example), concentrations should be confirmed before implementing a stairstep decrease. For example, bromide concentrations ideally are at least 1.5 mg/mL before phenobarbital is decreased by 25%. Every time the dose of an anticonvulsant is changed, at least 3 drug half-lives, plus one seizure interval (to assure the patient is challenged by a seizure at the new concentration), must lapse before the impact of the dose change can be fully assessed. For phenobarbital, at least 2 to 4 weeks should lapse before a second decrease is implemented. Ideally, the anticonvulsant is monitored at each decrease in dosage so that a target has been identified, should seizures return. Deciding what concentration to target with the second anticonvulsant can be difficult. If the goal is to simply add a second anticonvulsant, targeting in the lower therapeutic range of the new drug is reasonable. If the goal is to reduce the first anticonvulsant, the target of the second drug might be a little higher. If the goal is to eradicate the original anticonvulsant, at the very least, the second drug concentration should be at the same level of the therapeutic range (if not higher) than the first. For example, if a patient's phenobarbital dose is 25 µg/mL (midtherapeutic range), bromide should be at least 2 mg/mL before a decrease is considered. Some animals will require higher concentrations: for example, for bromide, higher than 2.5 mg/mL before phenobarbital can be lowered to less than 20 μ g/mL (the standard goal). It may not be possible to decrease the first anticonvulsant in some patients, despite the addition of a second drug at concentrations that are in the high therapeutic range. On the other hand, some patients can be completely weaned off the first anticonvulsant (e.g., phenobarbital).

Diazepam has been the second drug of choice for chronic control of seizures in cats. However, its use may be limited by the concern for hepatic disease. In the author's monitoring laboratory, either zonisamide or levetiracetam appear to be well tolerated and effective, with gabapentin a third viable alternative.

Discontinuing Therapy

Whether anticonvulsant therapy facilitates remission of spontaneous seizures is not clear, although a tendency for contemporary anticonvulsant therapy to be associated with epileptic cure has been described in humans.²²⁶ In human medicine, antiepileptic drugs can be withdrawn in 60% of patients that remain seizure free for 2 to 4 years. A similar statistic is not available in veterinary medicine. The likelihood of success can be somewhat correlated with the underlying cause or type of seizure, with the best chance occurring in the nonjuvenile patient with idiopathic generalized epilepsy. Such patients should have a normal neurologic exam, and the absence of a structural brain lesions. The author recommends that therapy might be discontinued in those patients whose drug concentrations are substantially below the recommended therapeutic range. Should the decision be made to discontinue therapy, concentrations might first be monitored (to provide a target to which concentrations can be returned if the patient has a seizure) and then the antiepileptic drug be slowly discontinued over several months (e.g., 25% each month). Note that with each decrease, the response should be assessed after the drug has reached steady state plus one seizure interval (i.e., ensure, to the extent possible, that the patient is challenged by a seizure before the next decrease is implemented).

Alternative Therapies

Melatonin is described as having demonstrated anticonvulsant activity in many animal models.²²⁵ A study in gerbils demonstrated greater survival in animals treated with melatonin (25 µg subcutaneously daily). Anticonvulsant activity of melatonin may reflect antioxidant activity and subsequent free radical scavenging.²²⁸ In an open, uncontrolled study in epileptic children refractory to standard therapy, melatonin (3 mg at bedtime), seizure activity decreased and sleep improved in five of six patients.²²⁸

Deprenyl was associated with reduction in experimentally induced seizures in a rat kindling seizure model after multiple intraperitoneal dosing.²²⁹ L-Deprenyl (and to a lesser degree, D-deprenyl) was effective in controlling electroshockinduced seizures in mice when administered at 1 to 40 mg/ kg intraperitoneally, with the highest reduction (44%) occurring at the highest dose. Although less potent, D-deprenyl also reduced seizures but was toxic at doses higher than 10 mg/kg. Pentylenetetrazol nduced clonic and myoclonic, but not tonic, seizures. Seizures also were decreased by L-deprenyl at 5 mg/kg intraperitoneally (but not subcutaneously); 10 mg/kg did not provide further control. The spectrum of anticonvulsant activity was described as comparable to that of phenobarbital (and levetiracetam), including breadth of seizure type controlled. A proposed mechanism is inhibition of norepinephrine and dopamine metabolism. Other proposed mechanisms include modulation of NMDA receptor activity and stimulation of melatonin synthesis in the pineal gland. In his review, Löscher²²⁹ notes that tricyclic antidepressants provide some anticonvulsant effects through inhibition of norepinephrine uptake.

The role of phenothiazines, and acepromazine in particular, in epileptic dogs is controversial. Although phenothiazines are connected with seizures in humans,²³⁰ the contraindication for phenothiazines, and specifically acepromazine, in epileptic animals is less clear. The author has personally induced seizures in a dog suffering from lead poisoning that developed acute respiratory distress syndrome. Treatment with acepromazine was immediately followed by severe seizures. However, Tobias and coworkers²³¹ retrospectively studied the use of acepromazine in epileptic dogs (n = 47; 15 with idiopathic epilepsy) with seizures that received acepromazine for diagnostic testing, anesthetic premedication, to facilitate postoperative recovery, or to decrease excitatory behavior; acepromazine was given with the intent of reducing seizures in 11 of the dogs. Acepromazine also was administered to 11 of the 47 dogs in order to decrease seizure activity, with either seizures stopping for 1.5 to 8 hours (n = 8) or not recurring (n = 2). Chlorpromazine has been used (2 to 4 mg/kg orally every 8 to 12 hours) to treat SE, with 9 of 10 dogs responding (as reviewed by Tobias and coworkers).²³¹ McConnell and coworkers²³² also retrospectively studied the medical records of 31 dogs experiencing no seizures (n = 3) or a history of acute or chronic seizures, including SE (n = 3) or cluster seizures (n = 22). Fifteen of 22 dogs with a history of seizures were receiving AED medication. Dogs were treated with a median of 2 but up to 5 doses of acepromazine during hospitalization; the intravenous dose ranged from 0.008 to 0.057 mg/kg. Seizures (n = 23) occurred in 11 of 31 dogs during hospitalization; 15 before and 8 (n = 4 dogs) after treatment with acepromazine. The dose of acepromazine in dogs that experienced seizures after administration ranged from 0.019 to 0.036 mg/kg, with seizures occurring at 18 minutes to 10 hours after administration. It is the author's opinion that these retrospective studies support the potential use of acepromazine in epileptic dogs as adjuvant therapy-and potentially as anticonvulsant therapy, but only after welldesigned placebo or other controlled randomized clinical trials in epileptic patients have determined the impact in epileptic dogs or cats.

DRUGS CONTRAINDICATED FOR EPILEPTIC PATIENTS

A number of medications are associated with decreased seizure threshold and an increased risk of SE in humans (Table 27-6). Several anticonvulsant drugs may be proepileptic at suprapharmacologic doses (e.g., phenytoin).²²³ The impact of phenothiazines was discussed with alternative drugs. Drugs inducing seizures in selected patients include fluorinated quinolones, lidocaine, and possibly metoclopramide. Seizures induced by lidocaine should be treated with a benzodiazepine (e.g., diazepam).²³³ Morphine sulfate and related compounds as well as CNS stimulants such as the methylxanthines and behavior-modifying drugs should be avoided. Chloramphenicol also activates the CNS and should not be used in dogs known to have epileptiform seizures. Glucocorticoids may also decrease seizure threshold, although they stabilize neuronal membranes. Long-term effects on the neuronal membrane, however, may reflect downregulation of glucocorticoid receptors and thus loss of the stabilizing effect. Long-term use of glucocorticoids might be minimized for epileptic patients. Behavior-modifying drugs are CNS stimulants and, accordingly, might be associated with an increased risk of seizures. Cocaine acts on monoamine transporters to block the reuptake of dopamine, norepinephrine and serotonin from synapses following their release. Activity at dopamine, adrenergic and serotonin receptors will increase, although the major effects of cocaine are thought to be reflect actions on dopaminergic systems. Cocaine will also increase motor activity by increasing dopamine in the striatum, and at high doses can cause psychosis. Finally, cocaine also acts as a sympathomimetic, increasing

Table 27-6Potentially Proconvulsant Drugs10,223

activity of the sympathetic nervous system, due to its action on norepinephrine transport.

Drugs associated with seizures in nonhuman animal models have included but are not limited to the tricyclic antidepressants, bupropion, and doxepin. However, increased concentration of serotonin or norepinephrine by transport inhibitors are likely to be associated with anticonvulsant rather than proconvulsant effects in epileptic patients, despite the fact that overdose may be associated with seizures.¹⁰ Finally, drugs for which CNS derangements or seizures are a listed side effect generally should be avoided in epileptic animals.

TREATMENT OF OTHER NEUROLOGIC CONDITIONS

Brain Trauma or Injury

Pathophysiology of Brain Injury

After head trauma, secondary injury occurs in both contused and adjacent tissues.²³⁴ A cascade of events begins with massive depolarization and ion fluxes that initiate increased energy expenditure by the sodium/potassium adenosine triphosphatase (ATPase) pump, the main regulator of cell volume and electrochemical gradient. Systemic hypotension and disrupted cerebral blood flow exacerbate ATP depletion. Brain tissue is extremely sensitive to decreased oxygenation. Glutamate, an excitatory neurotransmitter that allows calcium influx into the neuron, appears to play an important role in the early stages of secondary brain injury caused by head trauma. Normal intracellular concentrations are approximately 1500-fold greater than extracellular concentrations. Well-developed energyrequiring mechanisms exist to maintain very low extracellular glutamate concentrations; this system becomes overwhelmed as a result of the combined effects of efflux of intracellular glutamate and decreased energy. As a result, calcium influx causes uncontrolled release of intracellular calcium and subsequent cytotoxic events, including uncoupling of oxidative phosphorylation necessary for ATP. Enzyme systems activated included protein kinase C, the phospholipases (and thus arachidonic acid cascades and platelet-activating factor), and nitric oxide synthase. Oxygen radicals are released, leading to irreversible cell injury and death.234

Blood flow to the CNS is well autoregulated through a combination of metabolic, vascular pressure, and oxygen-related mechanisms. Cerebral vasculature and intracranial pressure (ICP) must, however, be functioning normally. Metabolic demands of the brain appear to affect regional blood flow through the effects of pH and adenosine on vascular tone. Increased metabolic activity decreases vascular tone, causing vasodilation. Arterial Pco₂ has global control of the brain such that increases result in increased cerebral blood flow (and increased ICP), whereas decreases cause decreased cerebral flow. The potential exists for these reflex responses to exceed (in the case of increase) or to be insufficient (in the case of decrease) for the metabolic needs. Response to PCO₂ is regional, complicating the use of hyperventilation as a treatment for increased ICP.²³⁴ Local nitric oxide synthesis plays a role in regional blood flow and can contribute to secondary brain injury.

The cerebral ischemic response is global and depends on an intact vasomotor center. It occurs relatively late in response to poor perfusion. Increased ICP decreases cerebral perfusion. Increased PCO_2 causes the vasomotor center to increase heart rate and intense systemic vasoconstriction in an attempt to support cerebral blood flow. Clinically, the increase in systemic blood pressure may cause a decrease in heart rate, an indicator that increased ICP is limiting cerebral blood flow. The lack of the ischemic response does not, however, indicate that ICP increase is not severe; rather, it may reflect vasomotor damage.

Causes of Severe Brain Injury

Primary brain injury occurs as a result of direct brain trauma.²³⁴⁻²³⁶ Secondary brain injury reflects damage to the brain as a result of increased metabolic demands, inadequate cerebral blood flow, or both. Epilepsy causes the former by increasing metabolic demands (oxygen and glucose). Hyperthermia increases ICP (several millimeters of increase for each degree of increase in body temperature) by increasing metabolic demands. Head trauma tends to cause the latter by increasing ICP. Systemic hypotension also can cause secondary brain injury. Because the patient with severe head injury is less tolerant of derangements in metabolism, both hyperglycemia and hypoglycemia can contribute to secondary damage. Hypoglycemia contributes to decreased ATP production, whereas hyperglycemia can lead to anaerobic glycolysis and cellular acidosis in cells with impaired mitochondrial function.

Cerebral Edema

Cerebral edema can be categorized into a number of forms, each of which can occur after head trauma.²³⁷ Vasogenic edema reflects increased permeability of the blood-brain barrier and may be exemplified by focal cerebral contusion and hemorrhage. Water, sodium, and protein increase in the interstitial space. In addition to trauma, causes of vasogenic edema include loss of the tight endothelial junctions (as might occur during infusion of hyperosmotic solutions), tumors, hyperthermia, and epileptic seizures. Mediators associated with vasogenic edema include bradykinin, serotonin, histamine, and the eicosanoids (especially leukotrienes), as well as free oxygen radicals. Drugs that increase cerebral blood flow will increase the rate of cerebral edema. White matter has more compliance, and most of the edema accumulates there.

Cytotoxic edema occurs intracellularly when membrane sodium/potassium ATPase pump mechanisms fail because of a lack of energy. Energy loss can reflect decreased cerebral blood flow (i.e., ischemia). Potassium accumulation occurs in the extracellular space. Calcium influx initiates a cascade of events that are lethal to astrocytes. The remaining types of edema might be considered a variation of either vasogenic or cytotoxic edema. Hydrostatic edema reflects accumulation of protein-free fluid in the interstitial tissues. Hydrostatic edema probably results from an abrupt increase in the hydrostatic pressure gradient between the intravascular and extravascular spaces. Osmotic brain edema occurs as serum osmolality (generally caused by hyponatremia) declines below a critical threshold. The use of 5% dextrose can contribute to osmotic brain edema. Interstitial edema is exemplified by high-pressure hydrocephalus associated with increased hydrostatic pressure in the ventricular CSF. Water infiltrates into the periventricular tissues. This type of edema occurs rarely after CNS trauma.

At the cellular level, traumatic brain injury is associated with loss of the axonal cytoskeleton and subsequent irreversible of axonal division with 12 hours. This damage is associated with very high concentrations of glutamate.²³⁸ Traumatic depolarization, characterized by a massive influx of ions at the moment of injury, may reflect excitatory neurotransmitters and is among the most important mechanisms of cellular injury leading to cerebral edema and increased ICP. Cerebral edema and axonal swelling are sequelae; these may respond to interventions intended to block oxidative or nitrosative stresses.²³⁸ The blood-brain barrier also is disrupted with severe injuries, perhaps in response to vascular endothelial growth factor and subsequent release of nitric oxide. Secondary neuronal damages reflect the neuroinflammatory response, resulting in production of reactive oxygen species and inflammatory cytokines. Cyclophilin (targeted by cyclosporine) appears to be among the mediators contributing to postinjury inflammation.238

Treatment of traumatic brain injury focuses on control of brain edema and ICP. This includes reversal of the underlying cause, medical management, and surgical decompression.

Increased Intracranial Pressure

The control of increased ICP is paramount in the treatment of head trauma. In humans approximately 40% of those losing consciousness after a traumatic episode will develop intracranial hypertension, and mortality will parallel increases in ICP. Indeed, ICP is a strong predictor of outcome, and monitoring ICP in human medicine has become a safe and effective tool for monitoring both the need for and efficacy of treatment.

Early and aggressive treatment has been shown to improve outcome.^{235,236} The pressure at which ICP is maintained is not clear, but humans maintained at 15 mm Hg (normal being 20 mm Hg) had an improved outcome compared with those managed at 25 mm Hg. This may reflect the fact that herniation after lesions in some areas can occur despite ICP being normal (20 mm Hg). Recommendations in human medicine are to treat ICP when increased above 20 mm Hg for more than 15 minutes. Hypotension (systolic blood pressure <90 mm Hg) and hypoxia (Pao₂ <60 mm Hg) also commonly occur in patients with head trauma and can contribute to increased ICP. Of the two, however, hypotension is more devastating and is predictive of a poorer outcome of severe head injury. Thus hypotension should be prevented and immediately treated when present.

KEY POINT 27-30 Treatment of increased cranial pressure should be early and aggressive.

Surgical removal of brain volume is the easiest method (in humans) of lowering ICP. Removal of CSF is another method.²³⁹ Medical management is facilitated by discriminating the cause

of ICP. Omeprazole may be useful for long-term management of increased CSF production. Although the mechanism is not clear, in an experimental rabbit model, 0.2 mg/kg reduced production by 35%.^{239a}

Medical Management

Because little information is known regarding the direct treatment of damaged neuronal tissue, treatment focuses on maintaining as normal an environment as possible to support neuronal regeneration. Supportive management focuses on maintaining normal physiologic homeostasis. Blood pressure, arterial oxygenation (pulse oximetry and arterial blood gases), body temperature, and fluid and electrolyte balance should be maintained. Electrocardiographic monitoring also is indicated. Hypotension in particular must be avoided in the patient with increased ICP; the hyperdynamic state (physiologic responses compensating for hypovolemia) will complicate control of ICP. Hyperglycemia can increase metabolism and should be avoided and aggressively managed in the patient with head trauma. Fluids containing dextrose should be avoided in such patients.

Adjuvant Nonpharmacologic Management

Elevation of the head 30 degrees above heart level appears to be beneficial in decreasing ICP.^{235,236,240} Hypercapnia must be avoided in patients with head trauma; this includes hypercapnia that may be iatrogenically induced during procedures intended to support the respiratory system. Hyperventilation to maintain a Paco₂ of 27 to 30 mm Hg can decrease cerebral blood flow and help lower ICP. It is, however, dependent on intact autoregulation. Hyperventilation can decrease the metabolic activities of the brain and induce or potentiate cerebral ischemia. Its effectiveness in diminishing cerebral blood volume decreases with time (at 72 to 96 hours), and a rebound effect with restoration to normocapnia may potentially increase ICP.

Hypocarbia is easy to induce. Its use in the management of increased ICP might be reserved for the initial stages. Later use should be accompanied by strict monitoring of ICP, especially as hyperventilation is discontinued. Profound hyperventilation should be avoided. Hypothermia currently is being investigated for use in the prevention of CNS ischemia associated with severe head injuries.²³⁹ It has been used experimentally in dogs. Mild degrees of hypothermia (between 31° and 35°C) are recommended to prevent cardiovascular instability.²⁴⁰

Diuretics

Osmotic diuretics are commonly used to treat intracranial hypertension.^{235,236,239,241} Both mannitol and urea have been used, although mannitol has largely replaced urea. Mannitol is a 6-carbon sugar, similar in structure to glucose, but it is not able to cross the normal blood–brain barrier.²³⁹ Thus it remains in the extracellular and intravascular spaces of the brain, where it will cause an osmotic draw toward the extravascular tissues, and intracranial fluid will move into the vascular space. The effect of mannitol on increased ICP are severalfold. Reversal of the blood–brain osmotic gradient

decreases extracellular fluid volume in both the normal and damaged brain. This effect is delayed for 15 to 30 minutes but can continue for up to 6 hours. Blood viscosity is lowered, causing reflex vasoconstriction and lowered ICP. This effect, however, requires that mannitol be administered as a bolus, not slowly.^{235,236,239}

Doses of 0.25 mg/kg appear to be as effective as larger doses (1 mg/kg) in lowering ICP. Repeated administration of mannitol can induce hyperosmolar states, rendering it ineffective and subjecting the patient to the risk of renal failure. Additionally, continuous administration of mannitol can lead to increased penetration of the blood–brain barrier in the injured brain, resulting in a rebound ICP increase. For these reasons, serum osmolality should not be allowed to increase above 320 mOsm/L. Additionally, this effect is more likely if mannitol is give as a CRI rather than as a rapid bolus.²³⁹

A Cochrane Review has addressed the efficacy of mannitol for treatment of acute brain injury in humans.²⁴² Four clinical trials were eligible for review. Among these, mannitol (1 g/kg generally over 5 minutes) was compared with standard care, with pentobarbital (10 mg/kg intravenous bolus followed by CRI of 0.5 to 3 mg/kg such that ICP remained less than 20 torr), with hypertonic saline (2.5 mL/kg of a 7.5% solution over 20 minutes) and with placebo (5 mL/kg 0.9% saline), with treatment occurring before hospitalization. Treatment consisted of 5 mL/kg of a 20% (1 g/kg) mannitol solution; placebo groups were given saline. The review concluded that no evidence existed to support prehospitalization treatment, evidence showed that mannitol might be preferred to pentobarbital but hypertonic saline might be preferred to mannitol. The overall conclusion of the review is that reliable evidence on which recommendations might be made for the use of mannitol in patients with traumatic brain injury was lacking. The review further concluded that randomized clinical trials were clearly indicated.

Benefits of nonosmotic diuretics in the treatment of increased ICP are less clear. Furosemide is not as effective as mannitol, but it may prolong its effects.²³⁷ It may interact synergistically with mannitol to decrease ICP.^{235,236} However, it also may exacerbate the dehydrating effects of mannitol and complicate the maintenance of normovolemia.

KEY POINT 27-31 Clear evidence supporting the efficacy of mannitol for treatment of intracranial pressure is lacking.

Neuroprotection

Jain²³⁸ reviewed neuroprotection associated with traumatic brain injury. Drugs that may be relevant include immunomodulators and antiinflammatory compounds. The observation that cyclophilin (an inducer of micochondrial permeability) concentrations increase and appear to contribute to secondary neurodegeneration after traumatic brain injury provides a basis for use of cyclosporine.²³⁸ Cyclosporine is available or being developed in a neuroprotective formula for military personnel subjected to brain injury or gas poisoning. Erythropoietin has demonstrated several potential mechanisms of neuroprotection. This includes inhibition of apoptosis, reduction of cerebral edema, and possibly reduction of glutamate concentrations. A variety of neurotrophic factors are under investigation.²³⁸ Phase II or III clinical trials examining the effect of darbepoietin or human recombinant erythropoietin are currently under way. Other pharmacologic approaches have included NMDA or AMPA-receptor antagonists; a phase II clinical trial examining the effects of ketamine is under way in children. Several antiepileptic drugs also have demonstrated oxygen radical scavenging or other neuroprotectant effects.

KEY POINT 27-32 Among the drugs to be considered for neuroprotection are cyclosporine and methylprednisolone.

Glucocorticoids

Naturally occurring neurosteroids allosterically modulate the GABA_(A) receptors, protecting against NMDA overactivation and ischemia associated with injury. Endogenous examples include progesterone and its metabolite, alloprenanolone. Interestingly, progesterone appears to facilitate repair of the blood-brain barrier, as well as decreasing edema and muting the inflammatory response.²³⁸ A phase II clinical trial involving progesterone is apparently under way in human medicine.²³⁸ In contrast to endogenous neurosteroids, the role of glucocorticoids in traumatic brain injury is less clear. Kamano²⁴³ reviewed the earlier evidence supporting their use, and particularly megadose of methylprednisolone in human patients with severe brain injury. Although such dosing may be appropriate for acute spinal cord injury, the same is not true for acute head injury.

The use of steroids to treat increased ICP is generally ineffective, with the possible exception of increases associated with tumors.²³⁹ The potential beneficial effects support consideration of their use in patients with increased ICP. Damaged vascular permeability might be restored in areas of damage, rendering them particularly useful for vasogenic edema (e.g., such as that caused by tumors). Decreased CSF production has been documented in dogs.^{239,244} Oxygen-mediated free radical lipid peroxidation can be reduced by glucocorticoids, particularly methylprednisolone.²⁴⁵Despite these potential therapeutic benefit of glucocorticoids for patients with head trauma.²³⁹ Jain²³⁸ notes that a phase III corticoisteroid clinical trial in humans failed to show efficacy. However, a phase II clinical trial (in humans) involving prednisone showed some efficacy.

The use of glucocorticoids may increase the risk of a poor outcome in patients with traumatic brain injury.^{235,236} Their effects on metabolism (increasing peripheral glucose and cerebral glutamate) and immunosuppression contribute to their potential detrimental effects. Among the glucocorticoids, methylprednisolone appears to have the greatest radical-scavenging ability and, should glucocorticoids be used in CNS trauma, would be preferred to others. If there is to be a positive benefit, it will be realized only with early administration. Steroids that have no glucocorticoid activity, such as the lazaroids, provide oxygen radical–scavenging effects without many of the detrimental effects of glucocorticoids. These products are not yet commercially available.

Barbiturates

Although their use is very labor intensive (and thus reserved for critical care environments), barbiturates (pentobarbital, human dose 10 mg/kg over 30 minutes, followed by 1 to 1.5 mg/kg per hour) have been shown to be beneficial for human patients with severe head injury who have not responded to other therapies. Thus barbiturates may be indicated for patients with sustained, refractory intracranial hypertension. Barbiturates decrease cerebral metabolism, alter vascular tone, and inhibit lipid peroxidation mediated by free radicals.²³⁹ Lowered metabolism decreases the cerebral ischemia threshold, allowing lower cerebral oxygenation and thus cerebral blood flow (without ischemic damage).²³⁹ Barbiturates also may decrease intracellular calcium.²⁴⁰ Although they appear to rapidly lower ICP, barbiturates place the patient in a coma and thus can cause complications resulting from hypotension, hypothermia, and hypercapnia.

In human medicine the use of barbiturates is accomplished in conjunction with intubation and ventilation, fluid administration, and monitoring of arterial blood pressure (pulmonary artery catheter) and temperature. In human patients support of the pulmonary system is rigorous to prevent pneumonia or atelectasis. Electroencephalographic monitoring accompanies barbiturate therapy in order to document a dose sufficient for burst suppression. Serum barbiturate concentrations are measured (ideally maintained between 30 and 50 mg per day). The efficacy of the barbiturates in lowering ICP are less likely in patients with cardiovascular complications (e.g., hypotension). Once ICP control has been satisfactory for 24 to 48 hours, the drug can be gradually tapered (e.g., 50% per day) to prevent uncontrolled rebound hypertension. Mannitol may be helpful during this period to control ICP. Prophylactic control with barbiturates appears to offer no therapeutic advantage.239

Fluid Therapy

Crystalloids, colloids, and blood may be indicated for treatment of brain trauma or injury. Physiologic crystalloids containing saline or saline and glucose, with or without the addition of potassium, generally can be administered as necessary to prevent hypovelemic shock. Whereas glucose is essential as an energy substrate, under anaerobic conditions it can be converted to lactate, contributing to neurotoxic acidosis.²⁴¹ Albumin and other colloids are indicated for acute volume expansion, although subsequent metabolism to smaller molecules can contribute to disruption of ion balance. Blood remains the best resuscitative fluid in patients that are hypovolemic and hypotensive.²⁴¹ Infusion of plasma protein (50 to 100 mL) after mannitol administration also has been recommended to prevent hypovolemia.²³⁵ Colloidal products such as hetastarch or Oxyglobin may be similarly effective.

Anticonvulsants

Prophylactic use of anticonvulsants has been recommended for patients with head trauma to minimize the risk of posttraumatic seizure disorders. Seizures increase ICP and may be masked by unconsciousness. Indeed, electroencephalography is recommended for patients with unexplained autonomic dysfunction or increased ICP to detect possible SE. Seizures are more likely when treating for intracranial hypertension. Because the risk of seizures is high, neurologists frequently recommend anticonvulsant therapy for their human patients.

Analgesics, Sedatives, Paralytics, and General Anesthetics

Pain or agitation will exacerbate ICP hypertension, and analgesia is recommended. Human patients (even those subjected to pharmacologic paralysis) are often routinely treated with a reversible opioid analgesic (e.g., morphine). Pharmacologic paralysis is a therapeutic modality that is more applicable to human patients or veterinary patients in a critical care environment. Paralysis is used to prevent muscle activity (particularly in intubated patients, such as those on ventilators), which can contribute to increased ICP. Paralysis is often, however, combined with sedation; the latter can preclude effective neurologic evaluation.^{235,236} The impact of phenothiazine tranquilizers was previously discussed with regard to epilepsy.

Armitage-Chan and coworkers have reviewed the use of anesthetic agents in canine patients with traumatic brain injuries.²⁴⁶ A number of anesthetic agents have been cited for protective effects in patients with head trauma. Althesin is a rapidly acting steroidal anesthetic that, during CRI, can decrease ICP while maintaining cerebral perfusion pressure. Its tendency to cause anaphylaxis in human patients led to its removal from the market in the United States.²³⁹ Propofol can provide protective effects when used at a rate of infusion that induces coma.²⁴¹ Etomidate is an imidazole anesthetic agent somewhat similar to barbiturates in action. It causes electroencephalography burst suppression, decreased cerebral blood flow, and decreased ICP in human patients with severe head injury.235,236,239 Etomidate may provide some cytoprotective effects induced by hypoxia. Finally, it appears to have antiseizural effects induced through gabaminergic actions (see earlier discussion of anticonvulsants). For humans, however, a single report of interference with the adrencortical axis and stress response after CRI led to its exclusion as recommended therapy for increased ICP. Controlled clinical studies regarding the efficacy of etomidate for the patient with increased ICP have yet to be performed.

Miscellaneous Drugs or Compounds

Lidocaine decreases CNS synaptic transmission (either directly or as a result of the blockade of sodium channels) and may cause vasoconstriction. The net result is a decrease in cerebral oxygen and glucose consumption. Lidocaine appears to be effective in minimizing increased ICP caused by intubation and surgical stimulation and, in dogs, decreases hypertension after acute cerebral ischemia. Risks associated with lidocaine include myocardial depression and lowering of the seizure threshold. Thus it is generally recognized to be ineffective in treating patients with increased ICP.

Acute Thoracolumbar Disk Extrusion

Chondrodystrophoid breeds of dogs are predisposed to disk extrusion. The intervertebral disks of these breeds contain more collagen, fewer proteoglycans, and hence less water in the nucleus pulposus. Poor biomechanics of the degenerating disk result in disruption of the annulus fibrosus and the eventual eruption of calcified disk material into the spinal cord. Demyelination and necrosis of the spinal cord develop as a result of the secondary injury mechanisms. These include decreased spinal cord flow, increased intraneuronal calcium, and increased free radical formation. Despite predilection for the chondrodystrophoid breeds, acute disk extrusion can occur in a large number of nonchondrodystrophoid breeds as well. The clinical manifestations vary with the severity of extrusion. Medical management is indicated for animals with grades 1 and 2 thoracolumbar disk protrusion. This includes animals with spinal hyperesthesia and ataxia that is mild enough to allow weight bearing.²⁴⁷ Surgical intervention is indicated for animals that cannot ambulate, regardless of the perception of pain. The loss of deep pain sensation for more that 24 hours is, however, associated with a poor prognosis.²⁴⁷ Smith and Jeffery²⁴⁸ described spinal shock as a component of severe spinal injury. A common manifestation in humans, the pathophysiology may be sufficiently different in dogs that it is often overlooked. However, unexplained neurologic abnormalities caudal to the anatomic localization may support the diagnosis. Further research may be warranted to identify differential therapies targeting the pathophysiology in animals that endure spinal shock.

Medical Management

Nonpharmacologic therapy of thoracolumbar disk extrusion is appropriate for mild to moderate cases of prolapse and focuses on strict immobilization (i.e., cage or crate) for at least 3 weeks.^{249,250} This time is intended to allow resolution of spinal cord inflammation, reabsorption of extruded disk material, and fibrosis of the ruptured annulus fibrosus. Physical therapy with both passive and active exercises is indicated. Urinary catheterization may be necessary for some dogs. Pharmacologic therapy should focus on control of the inflammatory response to the extruded disk material. Muscle relaxants (e.g., methocarbamol; see Chapter 25) may be helpful. For thoracolumbar disk protrusion, the success rate in ambulatory dogs treated with medical management ranges from 82% to 100%; the success rate in nonambulatory dogs ranges from 43% to 51%.²⁴⁹ Because the intervertebral disk function depends on glycosaminoglycans, compounds used as disease-modifying agents (e.g., glucosamine, chondroitin sulfates) might be considered for long-term prevention or treatment.

KEY POINT 27-33 Pharmacologic therapy of disk protrusion focuses on control of accompanying inflammation.

Among the drugs to control inflammation are glucorticoids and nonsteroidal antiinflammatory drugs (NSAIDs). Mann and coworkers²⁵¹ reviewed some of the advantages and disadvantages of each. Low doses of corticosteroids (0.5 mg/kg prednisolone or prednisone orally twice daily) are intended to control spinal cord edema, inflammation, and pain and improve spinal cord blood flow. Methylprednisolone at high doses (30 mg/kg intravenously, repeated at 2 and 6 hours at 15 mg/kg intravenously, if indicated) presumably provides the additional advantage of free radical scavenging generated by lipid peroxidation (see Chapter 29). However, some drugs may impair healing of the annulus fibrosus. Both glucocorticoids and newer NSAIDs are more potent toward cyclooxygenase-2, the cyclooxygenase isoform more consistently associated with promotion of healing. Thus both classes of drugs might be associated with a adverse effect. However, an advantage to glucocorticoids might be inhibition of collagen contraction, which has been demonstrated for dexamethasone and hydrocortisone. Timing of drug therapy is important, with neurologic recovery greater in humans for which methylprednisolone was initiated within 8 to 12 hours of recovery. However, this and other recommendations in human medicine are complicated by limitations in supportive study designs.^{251a}

A number of prospective or retrospective studies have addressed the role of glucocorticoids in the treatment of intervertebral disk disease. Bush and coworkers²⁵² prospectively studied the functional outcome of 51 nonambulatory dogs weighing less than 15 kg. Dogs had undergone hemilaminectomy. By 10 days after the operation, 90% were ambulatory, 98% pain free, and 82% continent. The numbers improved to 100%, 94%, and 86% by 6 weeks based on phone interviews. All dogs had received a myelogram as part of their presurgical diagnostics. Levine and coworkers²⁵³ demonstrated that 20% of dogs receiving no glucocorticoid and 69% receiving dexamethasone developed urinary tract infection (UTI) in association with hospitalization and surgical correction of disk prolapse. Factors other than immunosuppression that may have contributed to UTI were not addressed. The incidence associated with long-term management is less clear. Wyndaele²⁵⁴ and Igawa and coworkers²⁵⁵ reviewed the role of catheterization in the cause or prevention of UTI in humans with spinal injuries; much of the information may be relevant to dogs. In humans UTI is among the complications associated with long-term intermittent catheterization.²⁵⁴ Identifying the need for antibacterial treatment is difficult in humans because of differences in evaluation, prophylactic antibiotics, and other methods. However, asymptomatic bacteriuria is not necessarily an indication for treatment. The incidence of bacteriuria in human ranges from 11% to 25% asymptomatic to 53% symptomatic (3% with major symptoms). Indwelling catheters increased the risk of infection both during acute and chronic phases of treatment and increase the risk of sepsis. Trauma associated with catheterization (which is not unusual, particularly if someone other than the patient is catheterizing) does not appear to lead to long-term complications. Prophylaxis is helpful and does not necessarily include antibiotics. Indeed, antimicrobials should be reserved for symptomatic patients: Use of ciprofloxacin eradicated susceptible organisms from the urinary tract in humans, only to be replaced shortly thereafter by resistant gram-positive isolates.

Controversy exists regarding the best methods of UTI prevention. Urine can be kept sterile for 15 to 20 days during acute stages of spinal cord injury without prophylaxis and up to 55 days if prophylaxis is implemented. Predictive factors for infection in humans include gender (female), age (young),

and neurogenic bladder dysfunction; in male patients low frequency of catheterization was a risk factor. Prostatitis may also be present and increases the risk of recurrent infections. Increased residual volume also is a risk factor; the incidence of infections increased in humans when the frequency of catheterization was reduced from sixfold to threefold. Bacteriuria was a risk factor for clinical infection. Use of dipsticks to detect bacturia other than pyuria alone is recommended to detect bacturia. E. coli is the predominant infecting organisms. Technique and materials, but particularly education of the catheter team, were the most important factors associated with prevention of complications. The use of hydrophilic catheters has been proposed to lower the risk of urinary strictures or false passages (more likely if urethra bleeding has occurred), complications associated with intermittent catheterization. Instillation of colistin-kanamycin at the end of catheterization decreased the incidence of bacteriuria by 50% in humans. Alternatives to standard antimicrobial use also include intravesicular administration of kanamycin-colistin coupled with low-dose nitrofurantoin therapy. The role of adjuvant therapies, including vitamin C, cranberry juice, and polysulfated glycosaminoglycans, are not supported by convincing evidence but warrant consideration in lieu of or in addition to antimicrobial therapy.

KEY POINT 27-34 Glucocorticoid therapy (particularly dexamethasone) for intervertebral disk disease may be associated with a higher risk of urinary tract infection.

Mann and coworkers²⁵¹ retrospectively examined the recurrence rates of dogs with Hansen type I intervertebral disk disease managed medically with either glucocorticoids or NSAIDs. Dogs were scored according to the level of spinal hyperpathia and neurologic defects; recurrence occurred at least 4 weeks after the initial episode and was identified through communication with owners. Of the 78 dogs studied, 39 (50%) experienced recurrence. Schnauzers were less likely to experience recurrence than any other breed. Recurrences were less likely with methylprednisolone (n = 12; four recurrences) or NSAIDs (n = 36; 12 recurrences) compared with with other glucocorticoids (n = 30; 23 recurrences). The specific NSAIDs or alternative glucocorticoids were not delineated. Timing of methylprednisolone therapy was not an important risk factor; however, only 16 dogs were treated with methylprednisolone, and it is not clear whether the sample size was sufficiently large to detect a difference. The study supports a clinical trial that compares NSAIDs and methylprednisolone.

Levine and coworkers retrospectively reviewed the medical management of cervical and thoracolumbar disk disease.^{256,257} One veterinary teaching hospital and several emergency clinics in the same state were involved. Inclusion criteria focused on ensuring that presentation and clinical condition were related only to intervertebral disk disease. A prospective client questionnaire was included in assessment. Animals were classified as to success, recurrence, or failure in regard to initial therapy. For thoracolumbar disease (n = 223),²⁵⁶ response to NSAIDs and glucocorticoids was studied. Antiinflammatory drugs

used included deracoxib (n = 25), carprofen (n = 42), and others (n = 80) versus 143 dogs receiving none. Glucocorticoids used (n = 105 compared with none in 118) included prednisone (51), dexamethasone (n = 46), and methylprednisolone (n = 8). Glucocorticoids were associated with a lower qualityof-life score, contributing to a lower success score in animals that did, versus did not, receive glucocorticoids. No predictive factor for success could be identified with regard to the specific drug chosen, dose, or duration. In contrast, NSAIDs were associated with a higher quality-of-life score; the success rate between treatment and no treatment with NSAIDs did not differ. For cervical disease (n = 88),²⁵⁷ use of NSAIDs (n = 43, compared with n = 45 receiving no treatment) was associated with success. The most common drugs used included deracoxib (n = 21) and carprofen (n = 18). Glucocorticoids (30) receiving, 58 not) did not influence success or quality of life.

KEY POINT 27-35 Further clinical studies are indicated for comparison of nonsteroidal antiinflammatory drugs versus glucocorticoids for treatment of disk protrusion.

Glucocorticoids and Other Antiinflammatory Drugs

Glucocorticoids have been used extensively to control the inflammatory response to disk extrusion. Additional potential benefits include reduction of edema and improved spinal cord blood flow. Controversy, however, surrounds efficacy, the proper drug, and the proper dosing regimen (including route, dose, interval, and duration of therapy). Dexamethasone stands out among the glucocorticoids as the one most likely to be associated with severe and potentially fatal gastrointestinal complications when used to treat dogs with disk extrusion.²⁵⁸ Potential complications include gastrointestinal hemorrhage, ulceration, pancreatitis, and colonic ulceration and perforation.

Methylprednisolone may be the preferred glucocorticoid for treatment of disk extrusion. At high doses (30 mg/kg intravenous bolus followed by 5.4 mg/kg per hour), it inhibits oxygen radical formation and thus inhibits lipid peroxidation.²⁵⁹ In humans neurologic function appears to improve after treatment with methylprednisolone within 8 hours of the injury (compared with placebo). At higher doses (60 mg/ kg), however, lipid peroxidation appears to be promoted. Cats with experimentally induced spinal damage underwent neurologic recovery more rapidly with methylprednisolone than with other drugs.²⁶⁰A more recent study using a similar model in dogs failed to show a significant difference in neurologic improvement with administration of either methylprednisolone or lazaroids, but the model of spinal cord damage may not have been sufficient for evaluation of the drug.²⁶¹

Levine and coworkers²⁵³reported on a retrospective comparison of the adverse events associated with dexamethasone (n = 49) versus no treatment (n = 80) and other glucocorticoid therapy (primarily methylprednisolone sodium succinate but also prednisone [n = 23]) for treatment of acute thoracolumbar intervertebral disk herniation in dogs. Two teaching hospitals were involved in the study. All treatments were implemented by the referring veterinarian within 48 hours of admission, and dogs treated with glucocorticoids within the month preceding the episode were excluded. Episode duration was less than 7 days, and surgeries were performed within 36 hours of admission. Of the 161 dogs studied, 87 were dachsunds. No signalment differences occurred among treatment groups. Median duration was less at 5 days for the dexamethasone group compared with the other treatment groups at 6 days, but this difference was not significant when corrected for confounding factors. Likewise, client cost was least (by just under 20%) for the alternative glucocorticoid group compared with the no-treatment group (most expensive), but the differential was negated by confounding factors. The mean dexamethasone dose was 2.25 mg \pm 4.28 m/kg (range 1 to 30 mg/kg; dose was not associated with adversity, although the power to detect a relationship was not clear). Doses of the other glucocorticoids were not provided. The dexamethasone group tended to be characterized by a smaller proportion of immediate improvement compared with the other groups, but no difference was found among groups in short-term outcome (29-day follow-up). Adversities that were greater in the dexamethasone group compared with the no-treatment group (with the alternate group generally tending to differ) included vomiting and diarrhea (packed cell volume was lower, but patients were not anemic). UTIs also were more frequent in the dexamethasone-treated patients (11 of 16 that were evaluated); not all patients were tested for infection. Female dogs were more likely to develop UTIs. Less than 20% of dogs examined were positive for UTIs in the other groups. Overall, the dexamethasone group was 3.4 times more likely to develop an adverse effect compared with other groups, with 45 of 49 developing complications compared with 53 of 80 for the no-treatment group. Interestingly, dogs at one institution were 6 times as likely to develop an adverse effect compared with those at the other institution. It is not clear if this was a reporting differential or a true effect.

Side effects associated with methylprednisolone may be rare unless animals have previously been treated with NSAIDs or glucocorticoids.²⁶² Methylprednisolone should be administered after disk extrusion, including before surgical decompression (assuming other antiinflammatory drugs have not been administered), by way of slow intravenous injection within 8 hours of spinal trauma. The initial dose of 30 mg/kg should be followed at 2 and 6 hours with 15 mg/kg intravenously.²⁶²

Other drugs that have been recommended for treatment of disk extrusion include prednisolone sodium succinate, dimethylsulfoxide, NSAIDs, and narcotic antagonists. Clinical studies have not been performed with these drugs. Mannitol is not recommended for animals with disk extrusion because of its risk of increased hemorrhage in the gray matter of the spinal cord.

In animals with severe spinal hyperesthesia, 3 to 5 days of oral prednisolone *or* (not *and*) NSAIDs can accompany confinement therapy. The risk of gastrointestinal ulceration is a cause for concern. In addition, decreased inflammation may lead to increased activity, with subsequent need for surgical intervention.²⁶²

Postoperative analgesics should include opioids. NSAIDs can be used for 3 to 5 days postoperatively; carprofen may

be the drug of choice because of its apparent relative cyclooxygenase-2 specificity. The use of drugs that decrease bladder sphincter hypertonicity (phenoxybenzamine, 5 to 15 mg every 24 hours) are discussed elsewhere.

Miscellaneous drugs. A phase I trial in dogs (n = 39) with naturally occurring traumatic paraplegia or paraparesis investigated the ability of 4-aminopyridine (4-AP) to restore conduction in (presumed) demyelinated nerve fibers. Injuries generally (77%) reflected thoracolumbar degenerative disk disease resulting in chronic, complete paraplegia. Treatment (0.5 to 1 mg/kg intravenously) of 4-AP generally improved hind limb (n = 18) increased response to pain (n = 10) and partial recovery of the cutaneous trunci muscle reflex (n = 9). Effects became evident in 15 to 45 minutes but reversed within a few hours of administration. Remaining animals (36%) either did not improve or exhibited slightly improved hind limb reflex tone. Although higher doses led to more dramatic improvement, side effects, including diazepam-responsive seizures and hyperthermia, occurred.²⁶³ N-acetylcysteine (NAC) is among the drugs studied for its impact on oxygen radicals. Baltzer and coworkers²⁶⁴ found no effect of pretreatment with intravenous NAC in dogs (n = 70) with acute spinal injury on urinary concentrations of 15F2t isoprostane, a prostanoid metabolite, or neurologic function 42 days after surgery, when compared with placebo.

OCULAR PHARMACOLOGY

Relevant Anatomy, Physiology, and Drug Preparations

Treatment of ocular disease can be implemented both locally and systemically. Local administration includes both topical (cornea or conjunctival sac) and directed therapy, the latter including intraocular (aqueous [anterior] or vitreal [posterior] chamber), subconjunctival (targeting anterior chamber and its associated structure), and retrobulbar (targeting the posterior chamber or choroids) routes. Although movement into the eye from topical or local delivery is facilitated by the ability to use higher drug concentrations in the vehicle, delivery might be offset, regardless of the route of administration, by intraocular pressure (IOP), which causes consistent outflow of fluid and any drug that it contains. Although inflammation will facilitate drug penetration in both the anterior and posterior ocular chambers, resolution of inflammation (or, potentially, severe inflammation) may be associated with reduced drug penetrability. Inflammation also may alter penetrability by virtue of its impact on pH (discussed later).

Directed (local) ophthalmic therapy is appealing for three reasons: (1) As with other sites, topical therapy allows use of drugs at concentrations that are likely to be therapeutic but likely to be associated with adverse effects if the drug is applied topically, thus limiting the effective use of the drug. (2) Adversity is reduced with topical administration. Examples include the antimicrobials polymyxin B, bacitracin, and neomycin, each of which is characterized by a high incidence of nephrotoxicity with systemic administration. Drugs that cause agonistic or antagonistic sympathetic or parasympathetic effects in the eye can cause profound cardiovascular and other systemic side effects when given systemically at doses necessary to cause a therapeutic ocular response. The safe use of antiinflammatories such as NSAIDs and glucocorticoids is facilitated with topical delivery. However, even if glucocorticoids are topically applied, sufficient drug may reach systemic circulation to affect the adrenal axis. (3) Ophthalmic delivery avoids the blood-eye barrier at both the ciliary and retinal epithelium presented to systemically delivered drugs. However, as with the skin, drugs applied topically with the intent of intraocular effects must penetrate a protective barrier. Most drug is absorbed through the corneum; this is balanced by drug flow from the sclera in response to a constant outward pressure. The cornea comprises several layers that vary in their chemical nature and thus drug penetrability. The lipid-soluble epithelium is several layers thick and presents the major barrier to penetration of topically applied drugs. Ingredients added to ophthalmic preparations with the intent to facilitate drug delivery include surfactants that increase the permeability of the corneal epithelium. The next deepest layer is the watersoluble stroma, followed by the innermost lipid-soluble endothelium. Topically applied vehicles and the drugs they carry must balance water and lipid solubility to ensure not only dissolution of the drug but also its movement into and through the different layers of the cornea. Drug pKa and environmental pH directly influence drug ionization as well as drug dissolution (and, as discussed later, drug stability), both of which will alter drug penetrability; changes in vehicle or local pH may change drug penetrability. Inflammation may change the slight alkalinity of the tears (7.4) to become more acidic, which will ionize and thus reduce penetrability of the drug.

Drugs intended for ophthalmic preparations are most commonly prepared as either solutions (drops) or ointments. Although easier to administer (facilitating owner compliance) and more rapid in onset (greater immediate contact over a larger surface area), the effect of drops is reduced by a shorter contact time; solutions are characterized by rapid dilution with tears. The volume of the subconjunctival sac, which acts as a reservoir for the drug, can expand to 30 to 50 µl. The optimal drop size for ophthalmic delivery is 20 µl. Whereas tear turnover is 15% in the nonirritated or untreated eye, it becomes 30% with drug delivery or in the inflamed eye; 80% of tears containing diluted drug exiting through the lacrimal duct. As such, a 5-minute contact time can be expected with drops applied 4 times or more a day (recommended). Further, the optimum time before adding a second drop is 5 minutes. Contact time of the drug with the cornea can be prolonged by increasing the concentration of the drug (often prepared as 1% or 100 mg/dL), preparation viscosity, or addition of surfactants that increase corneal epithelial permeability. Drug movement into the eye also can be facilitated by manipulation of the pH: Because tears are slightly alkaline (7.4), increasing the pH such that it is slightly basic will decrease the un-ionized and thus absorbable proportion of a basic drug. Devices such as canulas allow more effective topical subpalpebral or nasolacrimal administration of solutions in selected species. Ointments allow a longer contact time and thus thrice-daily

administration. Less drug enters the lacrimal passages, which may be an advantage for some drugs. However, disadvantages of ointments include the potential for reduced owner compliance (more difficult to administer compared with solution) and slower onset of action. Indeed, drug movement through the ointment into the cornea may be so slow that concentrations may remain subtherapeutic. Other disadvantages of ointments include impaired vision, impaired penetration of other drugs simultaneously administered ophthalmic ally (particularly solutions), and potentially impaired corneal healing.

The advantages of topical ophthalmic drug delivery are offset to some degree by drug safety considerations. More so than other topically applied drugs, the vehicle of ophthalmic preparations must be formulated such that adverse (ophthalmic) drug reactions are minimized. Considerations include tonicity (must be similar to tears, such as 1.4% NaCl; reasonable range is 0.7 to 2%), which is often accomplished using phosphate buffer. The pH (generally buffered at 3.5 to 10.5) must be appropriately balanced, yet altering pH for safety considerations may alter drug delivery. Not only might lipid solubility (because of changes in ionization) be affected (see previous discussion), but dissolution and stability also may be affected, with positive changes in one often causing negative changes in the other. As with many drugs in solution, ophthalmic preparations may lose potency with storage, and strict adherence to expiration dates is indicated. Tonicity and pH are less important for drugs prepared as ointments. Although stability tends to be better overall in ointments, stability may nonetheless be reduced, particularly in water-based ointments. In contrast to solutions, a disadvantage of ointments is their potential to cause inflammation should the vehicle (not the drug itself) penetrate intraocular tissues. In contrast to drugs administered on the skin, ophthalmic preparations generally should be sterile. All should be prepared aseptically, although this does not ensure sterility. Methods that might facilitate sterility include autoclaving, filtering, and adding preservatives (e.g., benzalkonium chloride, phenol, and merbromin); however, each can be irritating to intraocular tissues and may interfere with diagnostic (culture) procedures. A major disadvantage of compounded ophthalmic preparations is the absence of quality-control procedures documenting product stability, potency, and sterility.

Drugs Targeting Ocular Tissues

Anesthetics

General anesthetics, with the exception of ketamine, generally lower IOP. In contrast, opioids generally increase IOP. Local anesthetics block sodium channels, thus impeding impulse conduction through nerve fibers. Their duration is variable and is affected by pH as well as manipulation of chemical structure. The presence of an ester in topically applied preparations shortens duration of action, whereas the addition of an amide prolongs anesthetic effects. Esters include proparacaine (0.5%; 15-second onset; 20-minute duration), tetracaine (longeracting but more toxic), whereas amides, which are generally applied as local (rather than topical) drugs, include lidocaine (5-minute onset, 2- to 4-hour duration) and bupivacaine (≥20-minute onset, 6- to 8-hour duration). Other topical products include benoxinate, butacaine, phenocane, dibucaine, and piperocaine. All local anesthetics inhibit blood vessel formation and corneal epithelialization and may cause minute punctate corneal ulcers. Some can actually cause systemic toxicity with topical administration because of rapid (i.e., conjunctival) absorption. The loss of sensation removes protective reflexes; therefore these drugs should be used only under direct veterinary supervision (i.e., not sent home with clients).

Autonomic Nervous System

Autonomic drugs are generally, but not exclusively, used to treat glaucoma and control associated ocular pain through paralysis of ciliary muscles.

Stimulation (contraction) of the constrictor muscle of the iris is mediated by the parasympathetic (cholinergic; acetylcholine) system, leading to miosis. Flow of aqueous humor is subsequently facilitated. The cholinergic system also controls formation of aqueous humor at the level of the ciliary body. Longitudinal contraction of the ciliary body also occurs and may help lower IOP (e.g., glaucoma) possibly by distending the trabecular meshwork; some miotics may actually decrease outflow by effects on other ciliary sites. Parasympathomimetic drugs include pilocarpine (0.5 to 6%), which directly interacts with cholinergic receptors as well as stimulates secretory glands (which is why it is used for treatment of keratitis sicca); echothiophate (0.03 to 0.25%) or demecarium bromide (0.125 and 0.25%; the most toxic) and isoflurophate (0.025%) are parasympathomimetics are irreversible inhibitors of acetylcholinesterase. The use of these drugs in animals wearing anticholinergic flea preparations should be done cautiously. Echothiophate is among the most effective drugs, in part because it is irreversible and therefore can be used only twice daily. Carbachol (3%) is both act both directly and indirectly, with a longer duration of action than pilocarpine (allowing thrice-daily treatment). Pilocarpine must be given several times a day and may cause pain on application. The use of a 4% pilocarpine gel in dogs has not been reported. Miotics should not be used in the presence of inflammation of the anterior chamber (i.e., anterior uveitis) because of the risk of anterior synechia.

Parasympatholytic drugs relax the cilary body, causing cycloplegia and mydriasis. Drugs include **atropine** (1%; up to 4% to 5% in horses; longest acting), homatropine (0.5% and 2%; intermediate acting), scopolamine (0.3 to 0.5%; used primarily before intraocular surgery), and **tropicamide** (1%). Topical anticholinergics are much more effective than systemic drugs. These drugs are not used to treat glaucoma and, in fact, are contraindicated in some types of glaucoma. Rather, because these drugs cause cycloplegia, they are useful in the relief of pain associated with spasms of the ciliary muscle, which often accompany anterior uveitis. Tear production may be decreased by parasympatholytic drugs. Tropicamide is rapid in onset and of short duration (2 to 3 hours, although mydriasis and cyclopegia may last up to 12 hours in some cats and dogs); therefore it is often used for ocular examinations.

Contraction of the dilator muscle is mediated by the sympathetic (epinephrine) system by way of alpha receptors, leading to mydriasis (dilation) and, as with parasympathomimetic drugs, as a result of constriction of ciliary body vasculature, decreased formation of aqueous humor and decreased IOP.

Sympathomimetic drugs include epinephrine (which does not penetrate the eye well), which directly interacts with alpha more than beta receptors (used as a 1:1,000 dilution to control conjunctival or scleral hemorrhage or to prolong effects of local anesthetics), phenylephrine (0.125% solution for vasoconstriction; 10% as mydriatic; onset of action in 1 hour, duration up to 24 hours), largely limited to alpha receptor stimulation (30- to 60-minute onset with 4-hour duration), and dipivefrin, a lipid-soluble drug that acts indirectly by causing epinephrine release (used to decrease IOP; 30 to 60 minutes to onset). Sympatholytics include alpha antagonists (thymoxamine) which inhibits the dilator muscle, causing miosis. Beta antagonists, represented by timolol (0.5%) (others include Optimpranolol, 0.3% and Betagan, 0.5%), act to decrease IOP by decreasing aqueous humor production. These drugs may be limited in their usefulness although may be effective for treatment of ocular hypertension.

Prostaglandins

The newest class of drugs developed to treat glaucoma are the topically applied prostaglandins. These drugs target the trabecular meshwork or collagen of the ciliary body such that outflow obstruction is decreased. Examples include bimatoprost and travoprost.

Direct Impact on Aqueous Humor

In addition to the impact of drugs targeting the autonomic nervous system, reduced production of aqueous humor can be accomplished by carbonic anhydrase inhibitors, which also have diuretic effects (the latter probably has limited effect on aqueous humor formation). Topical products include dorzolamide and brinzolamide. Systemic drugs include acetazolamide and the newer drugs, methazolamide and dichlorphenamide. These drugs can reduce aqueous humor production by up to 50% and are often used in combination with autonomic drugs. Aqueous humor production is also rapidly decreased by osmotic diuretics, including mannitol and glycerin. Mannitol (given intravenously) is limited to emergency therapy (two treatments) of glaucoma or to reduce IOP before surgery. Additional potential benefits of osmotic agents include reduction in vitreous humor volume (a potential advantage with lens disruption) and resolution of corneal edema (topical only). Glycerol has the disadvantage of being less effective than mannitol but can be administered (orally) at home by the pet owner; care must be taken to avoid emesis.

Antiinflammatory and Immunomodulatory Ophthalmic Preparations

Drugs used to treat ocular inflammation include glucocorticoids (systemic and local) and NSAIDS (topical). Drugs that act to modulate the immune system (e.g., cyclosporine; topical or systemic) also control the inflammatory response. Glucocorticoids target in situ mediators (eicosanoids: prostaglandins and leukotrienes), preformed biogenic amines (histamine, serotonin), and the immune system (macrophage processing, T-cell expansion). Additionally, glucocorticoids are antiangiogenic (inhibit vascularization). Glucocorticoids are indicated for any inflammatory condition of ocular tissues (e.g., conjunctivitis, blepharitis, episcleritis, keratitis, iridocylitis). Glucocorticoids inhibit healing, increase the potential for infection, and also stimulate collagenase. Collagen breakdown in the stroma can result in corneal perforation, and therefore glucocorticoids are contraindicated in the presence of an ulcer. Topical glucocorticoids are available in solution, suspension, and ointment. Preparations include hydrocortisone, 0.1% dexamethasone, and 1% prednisolone acetate (generally the drug of choice).

In contrast to glucocorticoids, NSAIDs principally target eicosanoids and thus are more limited in their control of inflammation (although they may have other effects). However, topically applied NSAIDs also can decrease inflammation; examples include flurbiprofen (0.03%) and diclofenac (0.1%), which are available as topical preparations. Cyclosporine specifically targets T-helper cells and thereby controls the immune response. Available as a 2% solution, cyclosporine is indicated for the treatment of keratitis sicca, pigmentary keratitis, and other ocular immune-mediated disorders.

Antihistamines rarely are useful topically, although systemic therapy may be helpful with allergic ocular reactions.

Antiprotease Drugs

Proteases responsible for tissue destruction and perpetuation of inflammation are produced by ocular epithelial and stroma cells as well as inflammatory cells and select bacteria (e.g., *Pseudomonas*). Acetylcysteine is an effective protease inhibitor that also is monolithic; consequently, it is useful for treatment of keratoconjunctivitis sicca. The low pH must be buffered before topical administration (7 to 7.5); although it can be used as a 20% solution, 5% would be less irritating.

Antiinfective Drugs

Because of the ability to administer high concentrations of antibiotics, traditional classification of bacteriostatic versus bactericidal (fungistatic or fungicidal, virostatic or virucidal) may not be relevant to antiinfective drugs.

Topical antibacterial drugs are available as single or multiple antibiotic agents. Drugs that target gram-negative organisms include the water-soluble, weakly basic aminoglycosides (also effective against Staphylococcus spp.) tobramycin (0.3%; drug of choice for treatment of Pseudomonas), gentamicin (available with the glucocorticoid betamethasone), and neomycin (generally available only in combination with other antibiotics). Polymyxin B also is a water-soluble drug that is notable for its nephrotoxicy when given systemically. The fluorinated quinolones also target gram-negative organisms, including Pseudomonas as well as Staphyloccoccus. In contrast to the aminoglycosides, the fluorinated quinolones are lipid soluble. Drugs include ciprofloxacin and ofloxacin and its congener levofloxacin. Note that systemic fluorinated quinolone has been associated with retinal degeneration in cats; a similar finding has not been reported after topical use. Drugs that target grampositive organisms include the lipid-soluble erythromycin (0.5%; bacteriostatic), the efficacy of which is limited by resistance, and the water-soluble bacitracin, which, like polymyxin B, is most known for its nephrotoxicity associated with systemic therapy. Triple antibiotic combinations include neomycin, polymyxin B, and bacitracin. Broad-spectrum topical antibiotics include chloramphenicol (prohibited for use in food animals), tetracyclines (drugs of choice for ocular *Mycoplasma* or *Chlamydia*), and the sulfonamides. Each is lipid soluble.

Topical antifungal antimicrobials include the polyene natamycin. Its spectrum includes all fungal agents except dermatophytes. The imidazoles (i.e., miconazole, fluconazole, and itraconazole) must be compounded from intravenous solutions. Their spectrum includes opportunistic, dimorphic fungi and dermatophytes.

Antiviral drugs are indicated for treatment of herpes keratitis. Drugs indicated for acute therapy include trifluridine (1%; probably the most effective); idoxuridine (0.1%; intermediate efficacy; must be compounded), and vidarabine (least effective and least irritating). These drugs tend to be irritating but must be administered no less than 5 times a day. For chronic therapy (chronic carrier state), betadine can be diluted (1:30); failure to dilute may be caustic to the eye.

Protectants and Lubricants

Aqueous solutions may be insufficient for replacement of tears because they cannot adhere to the epithelium. Polyvinylpyrrolidone (1.67%) is an artificial mucin that replaces mucopolysaccharides in the precorneal tear film and thereby stabilizes the film. Bicarbonate-based buffer will normal maintain pH, thus facilitating healing. Artificial tears are indicated to compensate for insufficient tear production, decrease loss of fluid from the cornea resulting from evaporation, and facilitate penetration of water-soluble drugs. Other protectants include methylcellulose (0.5 to 1%); hydroxyethyl cellulose; hydroxypropyl methylcellulose; and polyvinyl alcohol (1.4%), which may be too irritating.

Solutions that might be used for intraoperative flushing (rinsing or a wetting agent) include eye washes (commercial formulas preferred), povidine–iodine (2% to 4% in saline), and benzalkonium chloride (1:5000; incompatible with fluoresceine, nitrates, salicylate, and sulfonamides). Zinc sulfate (0.2% and 0.25% solution; 0.5% ointment) is a mild astringent and antiseptic that can be used for mild conjunctivitis.

DEFINITION OF PAIN AND ITS RECOGNITION

Classification of Pain

The International Association for the Study of Pain (IASP) defines *pain* as an unpleasant sensory and emotional experience associated with actual or potential tissue damage.¹ During the past several decades, the importance of pain has evolved from being underestimated, to being recognized for its contributions to morbidity and mortality. In 2000 the Joint Commission on Accreditation of Healthcare Organizations² mandated that hospitals for humans consider pain as the fifth vital sign, thus ensuring its inclusion in the routine evaluation of all patients.

Pain has been classified in several ways. Severity (mild, moderate, and severe) is among the most common, but this categorization also includes an emotional component of pain. As such, in veterinary medicine this classification requires interpretation by either the clinician or owner. Pain also is classified according to its source. Physiologic pain is a protective mechanism, leading the animal to withdraw from a potentially damaging stimulus. In contrast, pathologic pain reflects tissue damage. Unresolved physiologic pain eventually can lead to pathologic pain by causing neurologic damage (also classified as neuropathic pain). Neuropathic pain is also classified according to the location at which the damage occurs (e.g., neurologic damage), with nociceptive pain reflecting tissue damage. Pain might also be localized to the body site: visceral pain is associated with abdominal or thoracic pain, whereas somatic pain originates from musculoskeletal damage. Either of these locations can be further divided as superficial or deep. Pain also is described by duration. Acute pain is abrupt in onset and resolves in 24 to 72 hours, whereas chronic pain is slow in onset and generally persists for several weeks to months. Acute pain is more protective in nature (compared with chronic pain) and indicates that something is going wrong, whereas chronic pain reflects disturbed homeostasis. Acute pain results from traumatic, surgical, or infectious events and generally is conducive to resolution with analgesics. In contrast, chronic pain is a long-standing physical disorder or emotional distress and includes pain associated with degenerative joint disease and some types of cancer. Chronic pain may not respond to traditional analgesic therapy, with tranquilizers or behaviormodifying drugs combined with environmental manipulation and behavioral conditioning commonly implemented. The transmission of chronic pain increasingly is being understood, with knowledge regarding neural pathways elucidating possible targets of therapy. Accordingly, newer drugs are increasingly being identified for their potential efficacy.³

KEY POINT 28-1 Whereas physiologic pain is protective, pathologic pain indicates tissue damage and if unresolved can lead to neurologic damage or neuropathic pain.

KEY POINT 28-2 Chronic pain may be more amenable to nontraditional analgesic therapy.

Transmission of Pain

Nociceptive Pain

Nociception refers to a neural response of nociceptors to a noxious stimulus.¹ Nociception is a normal nervous system function that serves as a warning of danger or credible threat. The nociceptive response comprises a nociceptor and three neuron chains, originating in the peripheral tissues and ending in the cerebral cortex. Nociception is unique among sensory nerves because nocicpetors must detect a wide range of stimuli, including physical and chemical signals, heat and cold, and acid and mechanical pressure. Nociceptors are located in every tissue of the body, originating from a group of neuronal bodies in the dorsal root ganglia (Figure 28-1). Nociception varies with location (peripheral versus central) and organ. Nociception in the skin occurs at the surface (i.e., is somatic), resulting in sharp, defined, localized, and limited pain. In contrast, internal, or visceral, nociception is generally diffuse, dull, and often referred.⁴ The action potential stimulated by a nociceptor crosses the synapse in the dorsal horn and stimulates the second order neurons in the gray matter of the spinal cord. There the signal is transmitted to the brain, where it is processed and interpreted. The transmission of pain from nociceptors is carried by either small, myelinated A delta fibers, smaller unmylelinated C fibers, or A a fibers. A delta fibers are fast, being responsible for sharp and acute pain, and transmit somatic and parietal pain. Because these receptors are discrete,

Pathophysiology of neuropathic pain

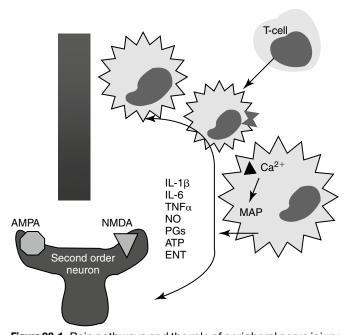

Figure 28-1 Pain pathways and the role of peripheral nerve injury in the emergence of neuropathic pain. See text for the transmission and perception of pain (left). The right side demonstrates mechanisms whereby neuropathic pain might emerge. The lower left diagram delineates the impact of peripheral nerve injury on sensory neurons. Injury is followed by recruitment and proliferation of non-neuronal elements (including Schwann cells, mast cells, macrophages, and T cells). Cells release proinflammatory and other chemicals (TNFa tumor necrosis factor-alpha], IL[interleukin]-1, IL-6, CCL2, PGs (prostaglandins) and NGF [nerve growth factor]). Sensory abnormalities are initiated and maintained either locally at the site of damage or with retrograde transport to cell bodies in the dorsal root ganglion, where neuronal gene expression is influenced. Increased intracellular calcium results in activation of the p38 and MAPK/ERK pathway. Perpetuation of the response is maintained through recruitment of inflammatory cells in general and T-cells in particular. In the spinal cord (upper right), microglia surrounding primary afferent neurons contribute to self-propogation of neuropathic pain after activation by chemicals or the influence of other primary afferent neurons. Subsequent mediator release may presynaptically or postsynaptically modulate pain. Examples include but are not limited to TNF-a, IL-1, IL-6, nitric oxide (NO), ATP, and PGs and excitatory neurotransmitters (ENT). AMPA, amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; NMDA, N-methyl-p-aspartate; MAP, mitogen-activated protein kinases.

animals can localize this pain. In contrast, C fibers are slow, transmitting dull, aching, burning, or throbbing pain that is difficult to localize. A fibers also are slow, transmitting stimuli associated with vibration, stinging, or tickling. However, because they are not able to discriminate between painful versus nonpainful stimuli, they are not pure nociceptor neurons.

Chemical mediators are important components of the nociceptor reflex and offer a target of pharmacologic modulation. These include but are not limited to adrenocorticotropic

hormone, glucocorticoids, vasopressin, oxytocin, brain opioids, catecholamines, angiotensin II, endorphins/enkephalins, vasoactive intestinal peptides, substance P (centrally), eicosanoids (prostaglandins, leukotrienes), tissue kininogens (bradykinin), histamine, serotonin, potassium, and proteolytic enzymes.⁶ Several of these mediators are also associated with stress. Several neurotransmitters associated with nociception and transmission of peripheral pain also function in the dorsal horn, the first site of signal processing. Spinal neurotransmitters include but are not limited to peptides (e.g., substance P, calcitonin gene-related peptide), excitatory and inhibitory amino acids (aspartate, glutamate, gamma-aminobutyric acid [GABA]), nitric oxide, prostaglandins, adenosine-5'-triphosphate (ATP), endogenous opioids, monoamines (serotonin, norepinephrine), protons (acids), and neurotrophins. Opioid peptides are synthesized by interneurons in the superficial dorsal horn; they regulate further neurotransmitter release, probably through decreased calcium conduction. Glutamate, the primary excitatory nociceptor neurotransmitter, is released in response to calcium, following depolarization. Subsequent postsynaptic binding to N-methyl-D-aspartate (NMDA) receptors influences pain transmission, hyperalgesia, allodynia, and neurotoxicity, thus providing the rationale for combination analgesic therapy that includes NMDAreceptor antagonists.

KEY POINT 28-3 N-methyl-D-aspartate receptors and products of cyclooxygenase activity promote several aspects of neuropathic pain.

The IASP definition of pain includes both a sensory and emotional component.² Indeed, of all the sensory systems, the nociceptive system is most able to elicit an arousal response in the brain. The emotional portion of pain occurs at the level of the limbic system (emotional), cortex (cognitive appraisal), and frontal lobes. Stimulation in the reticular formation results in emotional reaction to pain (anxiety, depression, suffering), whereas stimulation in the cerebral cortex leads to conscious perception and interpretation of pain. Transmission of central pain reflects a "gate control" phenomenon. The dorsal horn cells modulate the patterns of incoming information transmitted to the brain, which ultimately produces response and perception. The brain, in turn, can enhance or counter nociception. For example, when pain is sustained, released opioid peptides bind mu receptors in the brain and spinal cord, decreasing pain. Modulation regulates pain response, thus maintaining homeostasis.7 In addition to central transmission of pain, the first-order neuron can also synapse with neurons that cause a local reflex. The reflex can be myoneural or sympathetic in action (e.g., release of norepinephrine, smooth muscle spasm, vasoconstriction). Voluntary reflexes require conscious pain perception, whereas nociceptive reflexes do not.

Not surprisingly, a variety of mechanisms transduce nociceptive signals.⁸ At least two classes of channels are involved: One class detects noxious stimuli or products of tissue damage, and another sets the threshold necessary for a nociceptor

action potential. Channels that detect noxious stimuli include transient receptor potential (TRP) channels, acid-sensing ion channels (ASICs), and the ATP-gated P2X receptor family. Of these, the TRP channels are emerging as the dominant channels transmitting nociceptor signals. The TRP channels are general receptors, able to sense multiple types of noxious stimuli. Their actions are complex, with channels having different roles in different tissues. Further, each channel is able to respond to more than one stimulus and with overlapping sensitivities. Four of the nine currently described nociceptive TRP channels respond to heat. The TRP receptors are regulated through a number of kinases (e.g., kinase C, kinase A, calcium/calmodulin-dependent kinase). In contrast to the general TRP channels, ASIC channels are specialists, able to detect only acidity, as might occur with bone cancer (high levels of acid leak into surrounding tissues), inflammation (local pH can drop to 5.5), and ischemia (resulting from metabolites such as lactic acid). Because extracellular ATP is a major product of inflammation, P2X channels are also drawing interest for their potential role in inflammatory pain, particularly visceral pain.7

The second type of channels that transmit nociceptor signals set thresholds and include newly discovered voltagedependent sodium channels. Unlike other sodium channels, these channels are resistant to blockade by tetrodotoxin (TTX), which serves as a method of identifying and classifying the channels. Normally, these channels set the nociceptor threshold very high. However, in the presence of pathology, thresholds are decreased such that nociceptors respond to much weaker stimuli. Thus, unlike most sensory systems, channels responsible for nociception become more sensitive, rather than less sensitive, to stimuli. The TTX-resistant sodium channels tend to be redistributed after tissue injury.

Neuropathic Pain

Pathophysiology. Nociception is not limited simply to transmission of acute (nociceptive) pain; it also contributes to neuropathic pain. Both acute and unrelieved chronic pain can shift from nociceptive to neuropathic pain. Neuropathic pain includes hyperalgesia (overreaction or increased sensitivity to painful stimuli), allodynia (reaction to an innocuous stimulation), or reflex sympathetic dystrophy. The latter is a complex disorder of pain, sensory abnormalities, abnormal blood flow, sweating, and trophic changes in superficial and deep tissues.⁷ Failure to control development of acute pain and hyperalgesia can lead to chronic pain; progressive and prolonged stimulation can lead to a "wind-up" phenomenon that reflects increased excitation of neurons in the dorsal horn. The windup phenomenon is manifested as a pain response outside the site of injury and can persist beyond resolution of the inciting cause (pathologic pain). Dysesthesia is another example of neuropathic pain characterized by an unpleasant spontaneous or provoked sensation. Dysesthesia has been described in humans as a burning or shooting sensation reflecting damage to peripheral nerves. Excess stimulation of pain fibers, or reduced activity of non-nociceptive sensory pathways contribute to an imbalance between painful and nonpainful inputs to the central nervous system (CNS).⁹ Examples include phantom pain, a centrally mediated pain manifested as an intense burning sensation at the nerve ending of a damaged, paralyzed, or missing extremity. Another example is "stump" pain, a peripheral neuropathic pain secondary to neuroma formation at the site of amputation. These are examples of pain without any obvious noxious input. Further, for some chronic or persistent pain disorders, pain does not necessarily originate at the periphery.⁴

Heightened pain sensitivity is probably a protective response, reducing tissue exposure to further risk of tissue damage, and normally resolves when the tissue is healed. Both local and spinal changes contribute to neuropathic pain. Tissue damage intensifies the sensation of pain by recruitment of otherwise silent receptors. Chemical mediators are produced and released by both neuronal and nonneuronal cells (e.g., fibroblasts, mast cells, neutrophils), increasing nociceptor sensitivity. Local injury causes release of inflammatory mediators (cyclooxygenase-2 [COX-2], interleukins [ILs], leukotrienes [LTs], H+, K+, histamine, bradykinin), generating a slightly acidic inflammatory milieu that lowers threshold sensitivity (allodynia) by facilitating chemical binding to nociceptors. Activation of the nociceptors initiates neurogenic inflammation, leading to the release of substance P and peptides, which in turn perpetuate inflammation.⁵ Dysesthesia may reflect spontaneous activity originating in the regenerating, primary, nociceptive neurons (myelinated, small afferent fibers). Changes in dorsal root Na+ channels also have been reported. Dysesthesia may thus reflect a focal inflammatory process as opposed to axonal damage. Further, potential involvement of (fast) Na+ channels that generate ectopic discharges supports the use of local anesthetics (Na+ channel blockers) as part of a combined analgesic approach.9

Heightened sensitivity also involves retrograde signals from the site of injury to the neuronal cell body; signals alter neurotransmitter release and receptor transcription and expression. Among the mediators of hypersensitivity are mitogen-activated protein kinases (MAP: p38, ERK and JNK), which may initiate changes in the microglia of the dorsal horn.⁶ These changes may persist for weeks. Other mediators released and associated with hypersensitivity in the spinal cord include but are not limited to the proinflammatory cytokines tumor necrosis factor (TNF), IL-1 and IL-6, prostaglandins, and reactive oxygen species. Microglial cell bodies also hypertrophy and multiply, a reaction that, along with release of proinflammatory cytokines, may be inhibited by minocycline. Interestingly, chronic morphine administration may activate microglial cells and thus exacerbate hypersensitivity, an effect that might be reversed by minocycline or pentoxifylline, exemplifying the complexities of hyperalgesia.¹⁰

A role for NMDA receptors has not yet been identified in normal spinal cord transmission. However, a role might be suggested in transmission of pain. Both glutamate and aspartate are major excitatory neurotransmitters in the CNS that bind to NMDA receptors. After tissue injury, impulses from sensitized nociceptors of C fibers stimulate glutamate and other chemical release (e.g., neurokinins) in the primary afferent in the spinal cord. Calcium influx and activation of early genes leads to the development and maintenance of hypersensitivity or the wind-up phenomenon and hyperalgesia. Hyperalgesia associated with opioid use may involve NMDA receptors (see later discussion). Another mediator group that may be involved with changes in response to pain is prostaglandins (PGs). Induced COX-2 prostaglandin E (PGE) has been associated with hyperalgesia in either the spinal cord (primary hyperalgesia) or peripherally at nociceptors (secondary hyperalgesia).¹¹ Induction of spinal COX-2 in the dorsal horn has been associated with central sensitization.¹¹⁻¹³ Finally, PGs may potentiate the effects of other chemical mediators involved in pain or inflammation (e.g., histamine, bradykinin, substance P, nitric oxide), neurotransmitters (e.g., inhibition of glycine or potentiation of glutamate), or other receptors (e.g., NMDA), although this role in central sensitization and hyperalgesia has yet to be determined.

Nociception may awaken long dormant processes. For example, GABA is normally inhibitory, but it becomes excitatory in the spinal cord after peripheral nerve injury.⁷ Further, if the inciting cause is sufficient, quiescent nociceptors will be recruited; output of non-nociceptive neurons (e.g., touch receptors) may be interpreted as nociception by second-order neurons in the spinal cord.⁵

Preemptive control. Successful preemptive analgesia prevents the development of increased central nociceptive pathway responsiveness that is triggered by intense afferent neural activity. Surgery involving limbs exemplifies the importance of preemptive analgesia. For example, local anesthetic blockade of exposed nerves before transaction presumably protects the spinal cord from a sudden, massive impulse surge from nociceptors. Further, ghost phantom pain can be reduced through epidural analgesia or adequate prevention of postoperative pain, particularly during the first 72 hours after surgery.

KEY POINT 28-4 Effective preemptive analgesia decreases the emergence of neuropathic pain.

Meta-analyses of human studies that focused on timing of analgesia in surgical patients warrant review for their implications with regard not only to timing but also to the importance of effective pain control.^{14,15} One meta-analysis examined randomized, double-blinded, controlled trials that addressed either preemptive or postoperative analgesia for acute or chronic postoperative pain relief. Analgesic protocols that were reviewed studied the following: Twenty of the clinical trials reported the analgesic efficacy of NSAIDs (n=20; diclofenac, ketorolac, ketoprofen, ibuprofen, flurbiprofen, and naproxen [endodontal]), opioids (n=8; morphine, fentanyl, alfentanil, sufentanil, meperidine), and NMDA antagonists (n=8; ketamine, dextromethorphan). Further, epidural, caudal, or intrathecal (n=20) or local anesthetics (n=20) were considered. Outcome measures included comparison of pain scores before and 24 hours after surgery, time to the need for analgesics, and the need for supplemental analgesic therapy.

In general, meta-analysis concluded that pre-emptive timing did not alter the magnitude of postoperative pain, although the consumption of analgesia and the time to request additional analgesics were reduced. For NMDA antagonism, preemptive use of ketamine (as part of combination analgesic therapy, generally with opioids) uniformly did not cause a statistical difference in postoperative pain (a finding substantiated by both meta-analyses), whereas dextromethorphan did, although only two trials were reviewed. For epidural analgesia 7 of 11 trials using opioids indicated potential benefits, although the authors concluded that clinical relevance would be improved if epidural analgesia continued for a longer postoperative period. In general, preemptive nonsteroidal antiinflammatory drug (NSAID) therapy provided no difference in pain relief, leading the authors to conclude that the risks associated with preemptive NSAID therapy (e.g., bleeding, renal compromise) may not be justified; the power of the study to detect a significant difference is not known. Only one of the trials addressed the advent of chronic (6 months) pain after a surgical procedure. This trial found chronic pain to be significantly reduced in patients receiving preemptive analgesia. The overall conclusions by the authors was that preemptive analgesia may not be an effective method for reducing postoperative pain. However, the authors also suggested that future studies should not focus on the timing so much as on the approach to prevention of postoperative pain. Specifically, studies might address the importance of aggressive control, including the use of combinations designed to prevent neuropathic pain. Indeed, the lack of evidence of effective preemptive analgesia for control of postoperative pain reported in this study may reflect failed actions that occur in clinical patients. Because even abbreviated sensory events may initiate events leading to central sensitization, effective prevention may be dependent on continuous sensory blockade-that is, throughout the presence of the stimulating nociceptive event. Further, the success of afferent blockade may depend on blockade of input from small nonmyelinated C fibers or spinal, rather than peripheral, analgesia. Indeed, the metaanalysis indicated that neither systemic morphine nor small doses of intrathecal opioids had an effective preemptive impact. However, larger intrathecal doses of morphine were effective. Thorough regional blockade may also be paramount to the success of preemptive operative analgesia.

PHARMACOLOGIC CONTROL OF PAIN

Analgesia reflects the selective interruption of the transmission of injury signals (real or potential) between primary sensory neurons, the spinal cord dorsal horn, the rostroventral medulla, and the cortex opioids.⁵ The paradigm for the approach of pain control in both human and veterinary medicine has been shifting with the increasing realization that uncontrolled pain is not only bad but also avoidable.^{16,17} Appropriate pain management is part of the practice of good medicine: For human patients, analgesic control is associated with more rapid clinical recovery, shorter hospital stays, fewer readmits, and improved quality of life.¹

CONTROL OF PAIN

Assessing Response to Pain and Stress

One of the more difficult aspects of acceptable control of pain for the clinician is detection or recognition of pain.¹⁹⁻²¹ Scientists agree that all animals feel pain, although the level of nociception may vary between vertebrates and invertebrates and among classes of animals.²² Animals may feel pain as easily as human patients; any stimulus that is likely to cause pain in a person will cause pain in animals. Animals differ from people, however, in their response to pain. Indeed, the laws of behavior in wild animals require that abnormal behavior associated with pain be avoided. Avoidance, escape, or control of pain and distress are responses to pain that are important for (wild) animal survival and allow animals to adapt to a new or changed environment. Animals showing weakness, pain, and distress become targets for predators. Ill or injured animals tend to be abandoned by others so that an entire stock is not jeopardized. This evolutionary process makes clinical recognition of pain in animal patients difficult. For example, a critical patient is often unable to manifest pain and unwilling to care for itself; the clinician must be diligent to recognize the likelihood of an underlying disorder in causing pain. Increase in heart rate usually is caused by the underlying pathology, not in response to pain. The more severe the illness, the more important the need for analgesics.

Response to acute and chronic pain varies and includes both physiologic and behavioral changes. If pain is too severe for the animal to accommodate, a state of distress can develop.²³ Beyond protection, pain rarely has any useful function and is associated with dramatic and potentially life-threatening physiologic changes.²⁴⁻²⁶ Physiologic responses to distress include gastrointestinal lesions, immunosuppression, and hypertension. In human patients failure of response to treatment, hospitalization duration, and hospitalization costs can be positively correlated with failure of effective pain control. The sensation of pain can be associated with a marked adrenergic (catecholamine) release, which may cause life-threatening hypertension or cardiac arrhythmias. Response to acute pain includes physiologic changes such as tachycardia, tachypnea, mydriasis, and salivation and behavioral responses such as guarding, protection, vocalization (especially with movement or palpation of painful area), licking, biting or scratching, shaking, restlessness or insomnia, and recumbency.

Failure to control acute pain can stimulate changes at the level of the nociceptor and CNS; nociceptive pain may progress to neuropathic pain. Neuroplastic changes such as hypersensitization or allodynia worsen the stress response that often follows surgery. The response is adaptive and is mediated by behavioral, neural, endocrine, immune, hematologic, and metabolic changes that attempt to restore homeostasis. However, the combined effects can prove detrimental to the patient. Potential sequelae include cardiovascular instability, hypercoagulability, insulin resistance, increased metabolic rate and protein catabolism, and immunosuppression. As such, effective control of pain is paramount in the postoperative or otherwise stressed patient. Responses to chronic pain include limping; licking, perhaps to the point of self-mutilation (of an associated region if an animal can reach it, an unassociated one if not); reluctance to move; loss of appetite; changes in personality; physiologic dysfunctions such as dysuria, tenesmus, and diarrhea; changes in appearance of hair coat and degree of eye brightness; failure to groom; discharges from eyes and nose; decreased food and water intake; and behavioral changes such as aggression or docility, agitation, cringing, and extreme submissiveness. The well-trained clinician or pet owner can detect subtle changes in gait or posture.

Variability among animals in response to stress also makes diagnosis of pain difficult (Box 28-1).

The American Veterinary Medical Association reviewed the major consensus concepts generated by the Cross-species Approach to Pain and Analgesia workshop that took place in 2002.²² In addition to recommendations regarding the use of animals in research involving pain, the review provides guidelines for development of a pain assessment tool. The guidelines stipulate that a numeric (1-10) scale, based on observable behaviors and quantifiable biological markers, be used. Factors that are likely to alter assessment include animal factors such as species (and strain), stage of development (including prepartum and postpartum development), gender, previous experience to pain; environmental factors; and the type of pain. Other factors, such as nutrition, drugs, concurrent disease, and owner social status, should also be considered. The American Society of Anesthesiologists developed a painscoring system (for humans) based on several categories, each scored from 1 to 15. Included are behavior (depressed = 1, normal = 3, apprehensive = 5, and excited or aggressive = 10), preexisting pain (none = 1, minimal = 5, moderate = 10, and severe = 15), surgically induced trauma or pain (minimal = 5, moderate = 10, and severe = 15), duration of surgery (less than 1 hour = 5, 1 to 2 hours = 10, and >3 hours = 15), and patient health (normal = 1, mild disease = 2, severe disease = 3, moribund = 4, and life-threatening = 5).

Appropriate analgesic combinations for any pain group, regardless of score, include opioids, local analgesics, NSAIDS

Box 28-1

Types of Biologic Response to Pain

Types of biologic response to pain vary with genetic, age, or physiologic state or makeup:

- Age: Young animals may exhibit reduced tolerance to acute or physical pain. Lack of learned or conditioned responses thus may be less likely to lead to emotional stress or anxiety associated with anticipated painful experience.
- 2. Sex: Females appear to be less sensitive than males to pain.
- 3. Health: Healthy patients are less sensitive to pain, and severely debilitated animals are less able to respond to pain.
- 4. Species variation: Compared with cats, dogs tend to be stoic. Interestingly, however, cats appear to be treated with analgesics less commonly,²³ perhaps out of concern for adverse reactions.
- 5. Breed differences: Working and sporting breeds of dogs tend to be more stoic than other breeds.

and (for surgical candidates) epidural analgesic therapy. For opioids scores less than 20 might warrant less aggressive control of pain (i.e., mixed agonists–antagonists or partial agonist opioids), whereas scores of 20 to 30 might require more aggressive analgesia (pure opioids) and scores of 30 the most aggressive therapy (e.g., constant-rate infusion [CRI] of pure opioids). The use of NMDA-receptor antagonists should be considered for members of the latter two groups. The prudent clinician might consider assessing pain using a numeric scale at intervals appropriate for the management of the pain and reassess therapy as indicated by the scale. This may be particularly important for prevention or treatment of chronic pain.

Levels of Consciousness

Marked species differences exist in response to drugs intended to control or help control pain. Analgesia is defined as the absence of pain. This may be harder to define in animals than in people. Tranquilization (ataxia, neurolepsis) is a state of behavioral change in which the patient is relaxed and unconcerned by surroundings. Generally, the state is not accompanied by drowsiness, analgesia, or unconsciousness. Targets of tranquilizers include the hypothalamus and reticular activating system. The tranquilized animal feels pain but frequently is indifferent to minor pain. Tranquilizers may act synergistically with analgesics in the control of pain. Sedation reflects a mild degree of central depression. Sedated animals are calm, awake, and possibly drowsy. Sedatives target the cerebral cortex. With anesthesia, light to complete unconsciousness is realized and is accompanied by loss of feeling or sensation. General anesthesia is both a loss of consciousness and a loss of pain; it is also characterized by muscle relaxation, hyporeflexia, and amnesia. However, the loss of pain induced by general anesthesia may not be sufficient to preclude the intraoperative use of analgesics.

Two other states of consciousness may be associated with drugs that also provide analgesia. *Hypnosis* is a state of artificially induced unconsciousness (sleep) from which the patient can be easily aroused. *Akinesia* is simply the absence of muscle movements and is generally induced by neuromuscular blocking drugs. Pain may best be controlled with a balanced combination of drugs, each of which targets a different site in the nociception pathway.

Endogenous and Exogenous Pain Control

Endogenous opiates (opiopeptins) provide analgesia when released in high concentrations in selected regions of the brain. These include enkephalins, dynorphins, and endorphins (Figure 28-2). Each opiopeptin is derived from a larger precursor molecule. Each of the precursor molecules has a characteristic anatomic distribution that is not limited to the CNS. The precursor for endorphin (β -endorphin) is pro-opiomelanocortin, which is also the precursor of melanocyte-stimulating hormone as well as adrenocorticotropic hormone and beta-lipotropin, suggesting a strong link between the opioid system and stress hormones.²⁷ Endogenous recognition sites for these chemicals are also the targets of the exogenous drugs. A variety of other neuropeptides also have been implicated in endogenous analgesia

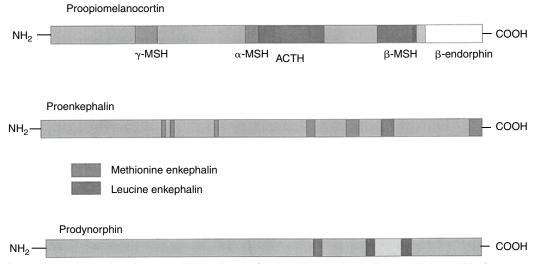

Figure 28-2 Endogenous opiopeptins that provide analgesia (endorphins, enkephalins, and dynorphins) are synthesized from precursor molecules. Each opiopeptin is derived from a larger precursor molecule. Each of the precursor molecules has a characteristic anatomic distribution that is not limited to the central nervous system The precursor for endorphin (β -endorphin) is proopiomelanocortin, which is also the precursor of melanocyte-stimulating hormone (MSH). Endogenous recognition sites for these chemicals are also the targets of the exogenous drugs.

(e.g., vasopressin, neurotensin, cholecystokinin, substance P). Some of these act in concert with other chemicals to stimulate nociceptors. Most notable are the eicosanoids (PGs, LTs), substance P, and bradykinin. The inflammatory process involves the release of a number of these chemical mediators either from the tissues at the site of infection or from the inflammatory cells themselves. Control of pain caused by these mediators is often largely dependent on controlling the inflammatory process. Nociceptin (NC, orphanin FQ, or OFQ) is a novel endogenous opioid peptide named for its ability to lower some pain thresholds. The NC/OFQ system is non-opioid, characterized by behavioral and pain modulator actions that differ from the classical opioids.²⁷ Nocistatin is a related protein of the NC/OFQ system.

KEY POINT 28-5 Exogenous opioids target receptors for endogenous compounds.

Factors such as emotional state, expectation, attention, blood pressure, stress, counterirritation, and drugs can modulate pain, possibly by activating analgesia systems. In humans national, religious, and cultural backgrounds and ethnicity also influence pain. Emotions also modify pain: Human patients function better when they believe that they have some control over pain, an aspect that may be lost or is difficult to assess in animals.²

Pain may be relieved or its intensity reduced by environmental (e.g., soft bedding) or behavioral (e.g., petting) manipulation and by the administration of drugs (Table 28-1).²⁸ With environmental control, emphasis is placed on the wellbeing of the animal. For dogs with osteoarthritis, this has centered on controlled exercise, although this method may be an inappropriate anthropomorphism. The single action for dogs most responsible for stress relief appears to be socialization (with humans). Factors such as emotional state, blood pressure, stress, and drugs can modulate pain, possibly by activating endogenous analgesia systems such as the opiates. The endogenous opiates, such as the enkephalins and endorphins, provide analgesia when released in high concentrations in selected regions of the brain.

The best treatment for pain is removal of the underlying cause. Control of pain often includes nonpharmacologic modalities. For example, the goal of pain control with chronic wounds in humans includes availability of both local and systemic analgesics but also removal of all nonviable, locally infected tissue and elimination of cellulitis, identification of wound pathogenesis, and assessment of objective improvement through the periodic use of an analgesic scale. Notably, the most important aspect of pain control in humans is objective assessment coupled with assuring the patient that pain will be resolved. The importance of the latter in animals is not known, nor is the ability of veterinary clinicians to provide such assurance.

At one time analgesics were categorized by their major site of action-that is, whether they acted centrally or peripherally. This categorization is limited because of the shared signals between the two locations (see Figure 28-1). Multiple target sites are available for drugs in both the peripheral nervous system and CNS; additionally, a large number of specialized receptors exist in the skin and other tissues that signal chemical, thermal, and mechanical changes. However, redundancies in their activation generally lead to compensatory effects by one system on blockade of another. This is particularly true for TRP channels and ASICs. As such, targeting sites of signal convergence may be more effective. Examples include sodium channels specific to the peripheral nociceptive afferents, glutamate receptors in the spinal cord, and their homologs in the trigeminal system (e.g., NMDA receptors that are uniquely activated by persistent input).4

OPIATES

- . .

Among the most effective and potent drugs used for controlling pain in animals, particularly acute pain, are the centrally and peripherally acting opioid analgesics.

Definitions

Opiates, including morphine, codeine, and a number of semisynthetic or synthetic derivatives, are drugs derived from opium. A number of drugs are derived from thebaine, a component of opium. Opioids include all drugs that exhibit morphinelike activity, as either agonists or antagonists (Figure 28-3).²⁷ This includes all naturally occurring and synthetic drugs. The term narcotic, from the Greek word for stupor, is most appropriately used for any drug that induces sleep. The term has, however, become more associated with powerful opioid analgesics (which are more likely to be associated with sedation). Interestingly, endogenous opioid peptides exist in many animals, where they act as neurotransmitters and appear to act as modulators of neurotransmission or neurohormones. Their complete physiologic role has yet to be described; however, their existence was demonstrated in part by the ability of naloxone to reverse endogenous analgesia.²⁷ In addition to the endogenous opioids, several opium derivatives found in nature are also found in mammalian cells, usually conjugated or bound to proteins. These include morphine, codeine, and some related compounds.29

Mechanism of Action

Receptors

The existence of multiple opioid receptors was postulated on the basis of in vivo canine studies.³⁰ The pharmacologic effects result from interaction with one or more of three major opioid receptors named based according to the first letter of the first compound that bound to each receptor: mu (μ ; morphine), kappa (κ ; ketocyclazocine), and delta (δ). Receptors are similar in structure, expressing at least 40 homologies. The NC/ OFQ receptor is a fourth member of the class whose similarity to opioid receptors is based on receptor homology. As with sigma receptors, they do not bind to classical opioid ligands. However, changes in as few as four amino acids would allow the nociceptin receptors to bind to classical opioids. Sigma receptors are no longer considered opioid receptors; they bind to and are activated by drugs completely unrelated to opioids. Opioid receptors also are chronologically classified, with OP-1 (δ) discovered first, followed by OP-2(κ), and OP-3 (μ) (the most recently discovered). The Committee on Receptor Nomenclature and Drug Classification has indicated a final designation: MOP, DOP, and KOP, reflecting mu (μ), delta (δ), and kappa (ĸ) opioid receptors, respectively.27 This latter classification will predominate in this chapter. Nociceptor receptors are classified as OP4 or NOP. Other opioid receptors (e.g., epsilon) may reflect splice variants or diamers.

Each of the opioid receptors is subtyped: μ -1, μ -2, κ 1-3, and δ 1 and δ -2, with differences in structure probably generated after translation. Receptors vary in several characteristics that complicate predictive responses. The μ -1 or MOP₁ receptors are described as very high affinity receptors that do not discriminate well between μ and δ . Dimerization among the receptors may play a role in their differential effects; thus far, both $\delta \kappa$ and $\delta \mu$ diamers have been identified. Differential affinity of the heterodiamerized receptors compared to homodiamers for selected ligands (endogenous peptides or drugs) markedly alters the pharmacologic response. Further, binding

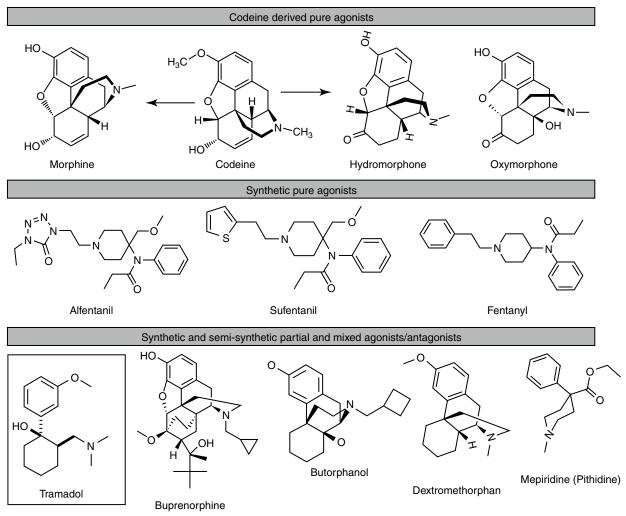

Figure 28-3 Structures of selected opioids.

sites of peptides are different from those of alkaloids (drugs): The latter appear to fit completely inside or at the mouth of the receptor core, whereas peptides appear to bind to extracellular loops. Differential binding sites allows for differential ligand effects, influencing conformation and subsequent responses. Opioid receptors differ from many other receptor systems in that a large number of endogenous ligands interact with a small number of receptors, potentially limiting the precise control that characterizes most systems.²⁷ However, mechanisms whereby distinct responses to endogenous opioids might occur despite the lack of apparent substrate specificity include differences in duration of action, activation of multiple receptors or their heterodimers, production of endogenous opioids with unique activation profiles (perhaps in part through differential responses at the level of intracellular signaling), and differences in intracellular trafficking of the receptors themselves (see the discussion of adaptation). These mechanisms offer means by which pharmacologic interventions might be designed to generate the desired opioid response.

Opiate receptors occur throughout the body but are in high density in the dorsal horn of the spinal cord, where they are responsible for modulating pain reception. The NC/ OFQ system is distributed in the hippocampus, cortex, and selected sensory sites and is responsible for complex behavior.²⁷ Peripherally, receptors also are located in the spleen, kidney, intestine, vas deferens, and retina.³¹ These include effects on drug reward and reinforcement, stress responsiveness, and feeding behavior. The system is closely related to stress processes. Lester and Traynor³² demonstrated in vitro that the effect of commonly used opioids correlated to their binding of opioid or NOP receptors throughout the brain and spinal cord of dogs.

Pharmacodynamics

It is likely that species differences in receptor number, location, and specificity or sensitivity to the various drugs are important to differences in response to the opiates. Additionally, the type of interaction between ligand and opioid receptor influences the response. Ligands may act as *agonists* (which bind and stimulate) or *antagonists* (which block and inhibit the effect). Endogenous antagonists generally have no direct effect but occasionally may inhibit normal functions (e.g., appetite or release of selected hormones). For example, agonists increase whereas antagonists decrease appetite effects of endogenous opioids. *Mixed agonists* exhibit variable binding specificities at each receptor type, with some sites being agonistic and other sites antagonistic (e.g., butorphanol is a KOP agonist and MOP antagonist). *Partial agonists* do the same as mixed agonists, but their positive interaction with the receptors occurs with less than full activity at some of the receptors. The magnitude of each ligand–receptor interaction is likely to vary among species.

KEY POINT 28-6 Predictability in opiod response is confounded by receptor subtype and species differences in receptor type or subtype, tissue distribution, and receptordrug interactions.

The cellular mechanism and the pharmacologic effects of the opioids probably reflect several different effector mechanisms. All three opioid receptors are coupled to G proteins. Accordingly, they inhibit adenylyl cyclase activity and activate receptor-linked potassium currents while decreasing voltagegated calcium currents. The proposed, but as yet unproven, analgesic mechanism thus may reflect hyperpolarization of the neuronal resting membrane potential. Further complicating the understanding of their mechanism is their potential to affect other secondary messenger systems. They may activate MAP kinases and phospholipase C (PLC) mediated cascades that lead to formation of inositol triphosphate and diacylglycerol. Other actions include inhibition of neurotransmitter release (acetylcholine, glutamic acid, dopamine, serotonin, substance P [particularly peripherally], norepinephrine), or modulation of a potassium channel. Control of pain appears to occur without diminution of other senses. The NC/OFQ receptors also are linked to G proteins, as has been demonstrated in dogs.³¹

The pharmacologic effects of opioid derivatives, including the degree of analgesia, depends on the receptor bound, the location of receptor and drug in the body, and the type of interaction between the opioid and the receptor (Table 28-2).29 Opioids act centrally to elevate the pain threshold and alter the psychologic response to pain. The opioids also act peripherally. The primary pharmacologic effects of all opioids are analgesia, euphoria, and sedation (without loss of consciousness).²⁹ MOP receptors give rise to analgesia and sedation above the spinal cord (MOP_1) or in the spinal cord (MOP_2) ; interaction with central MOP receptors might provide greater analgesia than interaction with spinal MOP receptors. For example, morphine causes analgesia primarily by way of MOP₁ receptors when given systemically.²⁹ However, administration of morphine at both spinal and supraspinal sites results in synergistic analgesic effects, with a tenfold reduction in the total dose of morphine necessary at either site alone.²⁹

KEY POINT 28-7 Analgesia, euphoria, and sedation reflect interaction with MOP or KOP receptors.

Table 28-2 Opioid Receptors, Their Pharmacodynamic Effects, and the Impact of Drug–Receptor

MOP, KOP, DOP, are mu, kappa, and delta opioid receptors, respectively. NE, No effect.

Interaction with MOP receptors also causes euphoria, respiratory depression, and physical dependence.³³ MOP receptors located in the gastrointestinal tract mediate the pharmacologic effects characteristic of opiates in this body system. KOP receptors (three subtypes) are responsible for analgesia that is spinal in origin and stimulate miosis and sedation. Interestingly, stimulation of KOP receptors appears to cause effects antagonistic to MOP receptors, including analgesia, tolerance, and reward.³³ DOP receptors (two subtypes) are located on smooth muscle and lymphocytes, in addition to the CNS. Interaction with DOP receptors appears to modulate, among other effects, emotional behavior and immunomodulation (see Chapter 26). Sigma receptors interact with a selected synthetic opioids; positive interactions between drugs and these receptors provide no analgesia but do cause adverse events including dysphoria, hallucinations, respiratory stimulation, and some of the vasomotor responses.

The pharmacologic effects of opioids extend beyond control of pain. For example, nonanalgesic pharmacologic effects account for many of the side effects associated with the use of these drugs for control of pain. The effect of opioids on the immune system is discussed in Chapter 31. The cardiovascular system in particular offers an example of the nonanalgesic pharmacodynamic effects of opioids. Opioid receptors regulate the cardiovascular system centrally (hypothalamus and brainstem) and peripherally (cardiac myocytes and blood vessels). In the heart both KOP and DOP, but not MOP, receptors have been identified.³⁴ Appetite is influenced by all three receptor types, with agonists increasing and antagonists decreasing response (see Chapter). DOP opioid receptors interact (by way of the G protein) with several K+ cardiac channels, and KOP opioid receptors interact with calcium cardiac channels.34 Opioid receptors appear to be involved both in the physiology of the normal myocardium and pathophysiology of disease. DOP receptors appear to attenuate adrenergic response and decrease cardiac performance yet also inhibit acetylcholineinduced vagal bradycardia; suppress baroreceptor responses; and increase inotropy, chronotropy, and blood pressure. In contrast, KOP have been associated with arrhythmias. The impact of opioids on the myocardium is, not surprisingly, complex. On the one hand, opioids appear to facilitate arrhythmias and other disturbances associated with circulatory shock, congestive heart failure, and myocardial ischemia and reperfusion injuries. Yet, opioids appear to protect the heart (and several other organs) from hypoxic or ischemic insults. For example, large amounts of endogenous opioids are released in the heart in response to a number of stimuli, including ischemia, leading to a cardioprotective effect. During acute myocardial ischemia, morphine attenuates neutrophils and endothelial activation and reduces adhesion molecules.34 Indeed, opioids (endogenous) appear to be involved in ischemic preconditioning. This phenomenon involves the protective effect of coronary artery occlusion before a prolonged ischemic insult; irreversible tissue damage is prevented, and ATP depletion is reduced.34

Administration of nociceptin (FOQ ligand) causes a broad range of physiologic changes, with the often contradictory responses depending on the site of administration. These include antinociception or pronociception, anxiousness, altered appetite and cardiovascular effects (depression).³¹ Nociceptin also influences transmission at GABA receptors.³⁵

Pharmacokinetics

Most opiates are well absorbed after oral, subcutaneous, or intramuscular administration (see Table 28-4 later in this chapter). In an attempt to reduce side effects without loss of analgesic activity, while improving the convenience of opioid administration, a number of alternative routes of administration have been studied. Oral, transmucosal (transbuccal), and rectal routes are examples discussed with individual drugs. Additionally, intranasal administration of opioids has been reviewed in humans.³⁶ First-pass metabolism precludes oral as a reasonable route of administration for most opiates. Oral administration can be facilitated with a higher dose (if safe), slow-release products, or generation of active metabolites. For example, morphine is only 25% bioavailable in humans after oral administration. However, it is used effectively through oral administration for control of cancer pain in humans.²⁹ In veterinary medicine use of oral opioids has been limited to codeine (60% bioavailability), hydrocodone, and (at high doses) butorphanol but more recently includes morphine. Morphine is also available as a slow-release oral (and limited injectable) preparation. Buprenorphine (including compounded products) has been used successfully after oral administration. Naltrexone is a pure antagonist, similar in actions to naloxone, which is also orally bioavailable. Selected drugs, including morphine, are available as rectal suppositories.

Drugs for which intranasal pharmacokinetics have been described include fentanyl, pethidine, butorphanol, oxycodone, and buprenorphine. In contrast to other mucosal routes of administration, lipophilicity does not appear to be a major determined of drug absorption through the nasal mucosa; indeed, nasal bioavailability of the opioids studied in humans ranges from a low of 46% for buprenorphine to a high of 71% for fentanyl and butorphonal, with the time to maximum concentrations generally being as little as 5 minutes and less than 50 minutes. Adverse effects were drug- (opioid-) related effects, rather than damage to the nasal mucosa. Limitations to this route of administration include the volume (limited to 150 µl per nostril) and pharmacokinetic variability, which tended to exceed that for intramuscular and subcutaneous administration. Both of these limitations may have reflected the use of the intravenous preparations: administration of an appropriate dose at times required a volume that exceeded that recommended, leading to pharyngeal delivery and subsequent swallowing (oral administration). Current interest in this route as a method of patient-delivered analgesia may lead to approval of products prepared with the intent of intranasal administration.

Transdermal preparations are available for systemic delivery of selected very lipid-soluble products (e.g., fentanyl patch.). In general, transdermal gels have not been successful in the systemic delivery of opioid analgesics, although limited efficacy may ultimately be demonstrated for selected lipidsoluble opioids (e.g., buprenorphine: unpublished work by the author). Epidural or intrathecal administration results in penetration of the spinal cord with limited systemic effects. Drugs that are more lipid soluble (e.g., fentanyl) tend to move rapidly across the dura into the spinal tissue and thus have a rapid, albeit local response. Drugs that are less lipid soluble, such as morphine, do not distribute rapidly into the spinal cord. Therefore they are more likely to diffuse up or down the spinal cord, potentially providing a larger area of analgesia. However, the use of epidural opioids alone for control of postoperative analgesia might be reconsidered for some patients. In children continuous epidural infusion of fentanyl and bupivacaine was found to be superior to intermittent epidural morphine in children undergoing major abdominal or genito-urologic surgery, as is supported by other human studies.37

KEY POINT 28-8 First-pass metabolism that precludes oral absorption of most opioids and a desire to avoid intravenous administration have led to a number of alternative routes of opioid delivery.

Distribution of the opioids from blood into the CNS varies. Most opiates are sufficiently lipid soluble to distribute into the CNS, although the rate into and out of the CNS is variable. Generally, onset of action occurs most rapidly for the highly lipid-soluble drugs (heroin, codeine) but is countered by rapid movement out of the CNS and thus resolution of pharmacologic response. The amphoteric opioids such as morphine move less rapidly, take longer to be effective, and generally act longer. Some opiates, such as loperamide, are designed to poorly penetrate the CNS with the intent of having peripheral (e.g., gastrointestinal) effects only. In the developing fetus, opioid derivatives pass more easily into the CNS because the blood-brain barrier is not fully developed. In humans the developing fetus can suffer severe depression induced by opiates, despite no evidence of depression in the pregnant mother.

Most of the opioids are biotransformed by the liver. Glucuronide conjugation is a common metabolic pathway. In some species metabolitesmay be active, including glucuronide metabolites. Cats may be deficient in some of these pathways, contributing to the increased risk of overdose that occurs with this species. Hepatic elimination for many drugs is "flow limited," meaning that hepatic blood flow determines the rate of elimination. Thus liver disease, particularly that associated with portal to systemic vascular shunting, renders a patient susceptible to adverse reactions (toxicity). Hepatic metabolites are renally excreted. Elimination of the bile and enterohepatic circulation for some drugs may, however, prolong pharmacologic effects. In general, the opioids are very rapidly eliminated in normal animals, with elimination half-lives ranging from 30 minutes to 2 hours and duration of action being less than 2 hours in many animals for many of the drugs. For selected drugs (morphine, oxymorphone, buprenorphine), pharmacologic effects may remain for up to 6 hours, depending on the

type of pain, species, and route of administration. Formation of active metabolites also affects (prolongs) duration of effect. Adherance to receptors may play a role in duration of affect of some drugs (e.g., buprenorphine).

Altered response to the opioids should be expected among species, in very young and very old patients,³⁸ and in patients suffering from hepatic, cardiovascular, or respiratory disease; hypotension; cranial trauma; and (in cats) hyperthyroidism. The duration, but not the extent, of analgesia increases with age in human patients,²⁹ presumably because of changes in hepatic metabolism and hepatic blood flow. Doses are decreased up to 75% in some patients, particularly geriatric patients or those with liver disease. However, prolonging the interval, rather than decreasing the dose, should be a more effective means of compensating for the effects of opioids normally characterized by a short half-life unless volume of distribution changes result in higher plasma concentrations as well. An exception is with CRI, for which doses should be decreased. Both liver disease and renal disease can alter the disposition of opioids, leading to adverse effects. Renal disease affects the elimination of morphine, codeine, and meperidine, in part because of the accumulation of active metabolites.29

Adverse Effects

Central Nervous System

The major disadvantages of opioids reflect general CNS depression, including dose-related respiratory depression and, to a lesser degree, cardiac depression. CNS depression tends to preclude the use of opioids in syndromes such as shock, severe cranial trauma, and diseases associated with respiratory compromise. Synthetic opioids were designed to induce analgesia with minmal undesirable side effects (i.e., sedation, respiratory depression).

Sedation is common with opioid use, depending on the drug and its target receptors, and the species (i.e., MOP and to a lesser degree KOP receptor stimulation in the dog) and can be a disadvantage or an advantage, depending on the clinical situation. Species differences in response to the sedative effects of opioids can be profound. "Morphine mania," typical of that described in cats is manifested as dysphoria and psychomotor activity. It may reflect sigma receptor stimulation for selected opioids or simply may reflect overdosing. Opioids tend to cause release (rather than inhibition) of some neurotransmitters (e.g., dopamine, acetylcholine), and this may occur in cats with high doses. When opioids are used in combination with phenothiazine derivatives (which block many of the neurotransmitter actions), the incidence of adverse effects appears to be reduced in cats. Dogs also are subject to dysphoria, as is exemplified by a series of three cases reported by Hofmeister and coworkers.³⁹ Dysphoria was manifested as vocalization that began within 5 minutes of administration of either hydrocodone, morphine, or fentanyl in association with postoperative analgesia. Clinical signs abated with administration of naloxone.

KEY POINT 28-9 Synthetic opiods are designed to minimize cardiovascular or respiratory adverse effects without sacrificing analgesic efficacy.

Respiratory depression usually is the cause of death in humans who succumb to opioids. The mechanism is reduction in the responsiveness of the brainstem respiratory centers to carbon dioxide, the primary stimulation for respiration. Centers that regulate respiratory rhythm are also depressed.²⁹ Depression, manifested as a slow respiratory rate, is discernible at doses lower than those associated with sedation and increases as the dose increases. Rate, tidal volume, and minute volume all decrease. Respiratory depression is, however, rarely a clinical concern except in cases of overdose or in the presence of pulmonary dysfunction in cases of standard doses.²⁹ Opioids should be used cautiously in patients with compromised respiratory function. Patients may appear to be handling the drugs well but in fact may be using compensatory mechanisms such as increased respiratory rate.29 Concentrations of CO₂ may be increased, and respiratory centers may already be less sensitive to CO_2 . The administration of an opioid may be dangerous in such situations. Use of opioids in the pregnant animal can lead to marked respiratory depression in the developing fetus, with little to no effect on the mother, because of the underdeveloped blood-brain barrier in the fetus.²⁹

KEY POINT 28-10 "Morphine mania" in cats may simply reflect neurotransmitter release at relatively higher doses.

Opioids have precipitated attacks of asthma in human anesthetized patients, probably as a result of histamine release. The importance of this in animals is not clear.

Opioids increase intracranial pressure as a result of increased concentrations of CO_2 and cerebral vasodilation. Cerebrospinal fluid (CSF) pressure also increases.²⁹ These effects may be exaggerated after head injury. The effects on intraocular pressure are not clear and may vary with the species. In humans accommodation is increased, with a decrease in intraocular pressure. Opioids cause miosis in humans, and mydriasis occurs in some species. Mydriasis may impede vision in cats; cats will be sensitive to light until mydriasis resolves.⁴³

Convulsions occur in some species when opioids are administered in high doses. Mechanisms probably include inhibition of GABA and may be more likely with morphinelike drugs.²⁹ The convulsant effects of some opioids can be reversed by naloxone,²⁹ suggesting that drugs with antagonistic actions (e.g., butorphanol, buprenorphine) at some receptors might be preferred in the patient having seizures. The impact of opioids on epileptic patients is not clear.

Morphine and related opioids directly depress the cough center at concentrations lower than that required for analgesia. Respiratory depression and cough suppression do not appear to be related. Thus antitussive opioids do not necessarily cause respiratory depression.²⁹

KEY POINT 28-11 Morphine and related drugs directly suppress cough without causing respiratory depression.

In contrast to depression, opioids directly stimulate the chemoreceptor triggering zone and thus may cause nausea

and vomiting. Individual differences in the emetic response to opioids are marked in humans, but the amount of variability is not clear in animals.²⁹ In human patients in whom opioids cause emesis, after subsequent administration, opioids act as antiemetics, blocking further response by the chemoreceptor trigger zone to opioids. Actions at the vestibular apparatus may also be responsible for emesis. The emetic effects that typify administration of opioids as sole agents do not typically occur in the postoperative, sick, or pain-ridden patient. Butorphanol has been used in some species as an antiemetic to control vomiting induced by cisplatin.⁴⁴ In the awake dog, at doses associated with sedation, MOP agonists (morphine, fentanyl, and methadone) prevent emesis induced by apomorphine and copper sulfate. At lower doses morphine was able to cause emesis. KOP agonists also blocked the apomorphine emetic response at sedative doses. Antiemetic effects were blocked by naloxone. In contrast, DOP agonists did tend to cause emesis, leading the authors to conclude that delta receptor stimulation is associated with emesis, but MOP and KOP receptor stimulation with antiemesis.45 Nausea, vomiting, and salivation are associated with morphine or hydromorphone administration in cats. Buprenorphine, butorphanol, or meperidine are unlikely to be associated with these side effects.43,46 Decreased appetite may occur after several days of continuous opioid treatment in cats.43 Urinary retention has been described for MOP-active opioids in animals, although effects may vary with species.47 Mechanisms may reflect a centrally mediated vasopressin effect on the kidneys. Alternative mechanisms may include opioid-induced hypotension, which is probably more likely with morphine. Anderson and Day⁴⁷ demonstrated that both fentanyl and morphine decreased urine output in normal and traumatized dogs.

Both long- and short-term use of opioids has paradoxically been associated with hyperalgesia. A biphasic, dose-dependent effect has been described and may reflect an initial increase in excitatory neurotransmitters. The hyperalgesic effects of opioids may involve NMDA receptors. Opioids appear to increase NMDA neural currents, providing a rationale for the combination of opioids with NMDA antagonists for enhanced analgesia. Several types of opioid hyperalgesia have been described both experimentally and clinically. At low doses, probably a reflection of disinhibition, intrathecal opioids induce an excitatory effect, which is otherwise masked with the sedation typical of larger doses. In contrast, very high intrathecal doses stimulate allodynia. With single-dose opioids, increased nociception may appear as the opioid effect diminishes. This may be manifested as an increased postoperative need for analgesia in patients receiving short-acting opioids intraoperatively. Reversal of opioids with naloxone often produces marked hyperalgesia. Hyperalgesia has also been associated with chronic use; among the clinical sequelae might be marked hyperalgesia with opioid withdrawal.48-50

Changes in body temperature reflect altered thermoregulatory response. Hypothermia is more common in dogs, whereas hyperthermia is more common in cats.⁵⁶ Opioids most commonly associated with hyperthermia in the cat include hydromorphone (at 3 times the dose) and meperidine; buprenorphine is unlikely to be associated with hyperthermia in cats.^{43,57,58} Experimentally, hydromorphone (1 mg/ kg intravenously) increased body temperature (range 104° to 108° F) 1 to 5 hours after anesthesia. Doses at or less than 0.05 mg/kg had no effect, whereas 0.1 mg/kg was associated with increased skin temperature.

Prolonged exposure of opioid receptors to ligands results in adaptation to their presence at multiple cellular levels.³⁰ Cellular tolerance is translated to animal adaptation manifested as tolerance, physical dependence, sensitization, and withdrawal. However, their emergence is not a reason to forgo opioid use. Tolerance refers to a decrease in drug efficacy associated with repeated administration. Acute tolerance (i.e., tachyphylaxis) may reflect short-term receptor desensitization, perhaps owing to phosphorylation of MOP or KOP receptors. Long-term administration of MOP ligands causes superactivation of adenylyl cyclase, the mechanism traditionally assumed to be associated with long-term tolerance. Different ligands appear to initiate acute or chronic tolerance through different mechanisms. Examples include internalization of receptors (MOP or DOP but not MOP), truncation of receptors or other changes. Adaptation by one response may mitigate adaptation by downstream responses; indeed, this sequela (i.e., failure to initiate downstream adaptations) has been proposed as a mechanism of failed desensitization that characterizes some drugs.²⁷ Accordingly, the ability of different ligands to initiate tolerance differs. Changes in nitric oxide or neurotransmitters or their pathways have been implicated as contributors to the development of tolerance.²⁹ Tolerance will most likely develop for analgesia, euphoria, sedation, respiratory depression, nausea or vomiting, and suppression of cough.

KEY POINT 28-12 Opioid therapy may be associated with both tolerance and physical dependence in animals, leading to controlled status for many of the drugs.

Physical dependence occurs when continued administration is necessary to prevent clinical signs characteristic of withdrawal. Physical dependence on opioids occurs as exogenous opioids replace endogenous opiates. Opioids affect numerous physiologic systems that become imbalanced before drug administration. A new balance or equilibrium is established in the presence of the drug,²⁷ and abrupt discontinuation of the drug requires rapid readjustment to a new equilibrium, predisposing the patient to withdrawal. Care must be taken to discriminate between dependence, which is associated with physical withdrawal, and addiction.

Addiction to opioids may reflect attenuation of the inhibition of dopamine release in the nucleus accumbens. This region of the brain has a central role in the reward circuit; dopamine promotes desire. The prevalence of addiction in humans using opoids is high. ⁵¹ Abrupt discontinuation of opioids after chronic dosing leads to symptoms of withdrawal, with the severity and duration reflecting the rate of onset and clearance of the opioid. Withdrawal is generally manifested as sign opposite to the original effects caused by the drug and

reflects CNS hyperarousal as readaptation to the absence of the drug occurs.²⁷ Symptoms in humans include nausea and diarrhea, coughing, tearing, yawning, sneezing, rhinorrhea, profuse sweating, twitching muscles, abdominal and muscle pain and cramps, piloerection, and dysphoria. Hyperthermia, tachypnea, tachycardia and hypertension also may occur. Pharmacokinetic variables may be helpful in the prediction of withdrawal.²⁷ Morphine dependence has been described in dogs.⁵² Mixed agonists-antagonists or partial agonists are associated with the least risk of dependence; among the opioids studied, buprenorphine appears to be the least likely to cause dependence in dogs.53 Opioids can be discontinued in drug-dependent human patients without causing signs typical of withdrawal by decreasing the dose 25% to 50% every couple of days. In human patients suffering from withdrawal, clonidine, an α_2 -adrenergic agonist, minimizes the autonomic symptoms of opioid withdrawal.27

It is the advent of tolerance and physical dependence that has led to the scheduling or classification of most opioids as potential substances of abuse. The actual class designated varies among the states. Pure agonists tend to be scheduled in class II or III; mixed or partial agonists tend to be scheduled in class IV or V, depending on the abuse potential. Both butorphanol and burpenorphine have been rescheduled from class V to class IV.

Cardiovascular System

The effects of opioids in the myocardium have been described. Cardiac depression (particularly bradycardia) is caused by selected opioids; pretreatment with atropine can reduce the incidence. The risk of hypotension is increased with drugs that also cause histamine release.

Those opioids most likely to be associated with histamine release are morphine (but not oxymorphone) and meperidine.^{40,41} Histamine release caused by buprenorphine has been demonstrated only in vitro; fentanyl, oxymorphone, and butorphanol do not cause histamine release in dogs (as reviewed by Guedes and coworkers).⁴¹ Hydromorphone was associated with an apparent type I allergic reaction when used preoperatively in a dog (Chapter 2). However, species differences should be anticipated. Histamine antagonists (H₁) partially block morphine-induced hypotension; naloxone completely blocks it in human patients.^{29,42} Fentanyl and its congeners are less likely to cause hypotension associated with surgery in part because they do not cause histamine release.²⁹ Volume replacement should be instituted before administration of morphine derivatives that causes histamine release in patients that are at risk for hypovolemia. Allergic phenomena in general (including bronchoconstriction) and those manifested in skin may be exacerbated with opioid use if morphinelike drugs are used. In humans opioids cause vasodilation of cutaneous vessels, probably because of histamine release. Pruritis may occur, in part because of histamine but also because of direct effects on neurons.²⁹

Gastrointestinal Tract

In addition to effects at the chemoreceptor trigger zone, opioids have direct effects in the gastrointestinal tract. Hydrochloric acid secretion is generally decreased but occasionally may be increased.²⁹ Tone of smooth muscle in the antral portion of the stomach and upper duodenum will increase, despite decreased gastric peristaltic motility. Passage of endoscopic or other equipment through the stomach can be precluded for up to 12 hours after administration. Drug or food movement through the stomach likewise can be delayed.²⁹ In the small intestine, and particularly in the upper small intestine, resting tone (segmental) is increased, and propulsive activity is markedly decreased.²⁹ Initial stimulation of gastrointestinal motility may result in defecation; subsequent depressed gastric motility may cause constipation with prolonged use.

Opioids also decrease small intestinal secretions, and water absorption increases. In the presence of secretory diarrheas, morphinelike opioids inhibit movement of electrolytes and water into the lumen, probably through inhibition of the stimulatory effects of PGE₂, acetylcholine, or vasoactive intestinal peptide.²⁹ Because of increased transit time allowing more complete absorption of luminal contents, opioids may be contraindicated in patients suffering from obstructive gastrointestinal diseases and those associated with bacteria or toxin production. Opioids also decrease biliary and pancreatic secretions.²⁹ Morphinelike opioids, however, cause contraction of the sphincter of Oddi and increased bile duct pressure.^{29,54,55}

KEY POINT 28-13 Mechanisms that cause opioids to be effective for treatment of diarrhea may also cause constipation.

Other Effects

Ureteral tone may increase and the voiding reflex of the bladder may be diminished as a result of the increased tone of the external sphincter and increased volume of the urinary bladder. Morphine appears to have antidiuretic effects.²⁹ Inhibitory effects on uterine tone may prolong labor; hyperactivity induced by oxytocin can be normalized with morphine. Neonatal health may be impaired by use of morphinelike drugs during parturition; the neonate appears to be particularly susceptible to respiratory depression induced by opioids, in part because of a poorly developed blood–brain barrier.²⁹

Opioids appear to inhibit cytotoxic activity of natural killer cells. Selected opioid compounds, however, appear to enhance macrophage and killer cell activity, possibly through a novel opioid receptor (see Chapter31).²⁹

Drug Interactions

The depressant effects of opioids can be exacerbated by other CNS depressants. Several CNS depressants prolong the effects of opioids, including the phenothiazines and tricyclic antide-pressants (TCAs). Although some phenothiazines may reduce the amount of opioid necessary for analgesia, others may increase the amount of opioid.²⁹ Among the drug interactions associated with opioids are those at the receptor level (pharmacodynamic) – a interaction often intended for the purposes of reversal of undesireable clinical effect. These interactions are discussed with antagonists.

Drugs. Improvements have altered the state of the interaction between the opioid and the receptor. A useful categorization largely reflects the potency of the opioids at receptors whose ligands control pain: The more powerful drugs tend to be those interacting principally with MOP; as such, they provide the most effective analgesia but the greatest incidence of side effects. Drug companies have attempted to improve the effects of opioids by enhancing the desired pharmacologic effect while minimizing undesirable effects through chemical alteration of the natural opioids. Semisynthetic drugs are made from simple chemical changes of morphine (codeine) or thebaine (e.g., oxycodone, etorphine, and naloxone). Other morphine derivatives include apomorphine (an emetic), hydrocodone, and oxymorphone.²⁹ These changes have allowed for differential effects, perhaps by rendering a full agonist to a partial agonist or antagonist.

POWERFUL PURE AGONISTS

Morphine

Morphine is considered the prototypic narcotic. A class II drug, morphine targets primarily MOP and to a lesser degree DOP and KOP receptors. Morphine frequently is studied as morphine sulfate, for which 1 mg will provide 0.76 mg active base.

Morphine causes profound sedation and analgesia for up to 6 hours in the dog. Its effects are reversed with narcotic antagonists. Morphine can cause cardiac depression;⁵⁹ in addition, hypotension may reflect histamine release or CNS (vasomotor) depression.^{40,60} Morphine can cause respiratory depression,⁶¹ particularly in neonates,⁶² and can cause acute pulmonary edema resulting from histamine release.⁶⁰ Therapeutic uses include premedication for surgical anesthesia (reducing the amount of other potentially irreversible CNS depressants) and analgesia. Morphine is also used in cases of acute, fulminating pulmonary edema because of its ability to reduce cardiac preload through hepatic venous constriction and splanchnic pooling.

KEY POINT 28-14 Profound sedation and analgesia associated with morphine is amenable to reversal in the dog.

The minimum effective concentration of morphine associated with analgesia is variable: in humans, it ranges from from 9.1 to 40 ng/mL, but increases to as high as 364 ng/mL with chronic administration (as reviewed by Kunakinch et al).⁶⁶ A common target for pharmacokinetic studies in dogs is 20 ng/ml. Establishing the minimum target concentration is complicated by the formation of active metabolites. Morphine-6-sulfate (M6S) is metabolite characterized by a thirtyfold greater potency compared with morphine in mouse models, similar to the active morphine metabolite morphine-6 beta-glucuronide (M6G). Its analgesia also is reversed by 3-methoxynaltrexone.⁶³ However, the major metabolite of morphine with clinical significance is morphine-6- β -glucuronide (M6G). It is characterized by pharmacologic activity equal to that of the parent compound in some species.

Drug	Dose	Onset (min)	Duration (hr)	Comments
Morphine	0.1	20 to 6	16 to 24	62-hour duration has been reported for a sustained-release encapsulated product
Meperidine			1 to 4	
Methadone	0.7 to 1	Rapid	4	
Oxymorphone	0.1		10	
Fentanyl				Only as adjunct to other epidural analgesics
Butorphanol	0.25		3	No advantage to epidural
Buprenorphine	0.0125	60		
Xylazine		30	3	Large animal information available only
Medetomidine	0.01 to 0.015		4 to 8	Lower dose for cats; cats are likely to vomit
Ketamine	0.4		1.5	Dog; must be preservative free
Lidocaine 2%	0.22 mL/kg	10 to 15	1 to 2	with 1:200,000 epineprhine. Lower dose (0.17 ml/kg) for Ceasarean section
Bupivacaine 0.5%	0.2 ml/kg	20 to 30	4 to 6

.

Jones 2001

Although more potent than morphine, the metabolite cannot cross the blood–brain barrier as effectively.²⁹ However, with chronic morphine dosing, drug concentrations will accumulate, and the metabolite is likely to contribute more than the parent compound to control of pain in humans. It appears to be associated with fewer gastrointestinal side effects.⁶⁴

A role for M6G in analgesic efficacy of morphine in dogs is not clearly evident. A study of morphine disposition in dogs⁶⁶ demonstrated that M6G was not detected (<25 ng/mL) after either intravenous (0.5 mg/kg) or oral (approximately 1.5 mg/kg, extended release) administration of morphine in normal Beagles (n = 6). This is in contrast to Jacqz and coworkers,⁶⁷ who did detect glucuronidated morphine in dogs. They described a significant (but not exclusive) role of extrahepatic tissues in the formation of the metabolite, which appeared within 5 minutes of administration. Garrett and Jackson⁶⁸ also detected formation and renal excretion of morphine monoglucuronide in dogs. The differences in metabolite detection between these studies may reflect differences in the actual metabolite itself, and particularly the position of the glucuronide. The impact of the glucuronidated metabolite to analgesic control in dogs may not be clear.

Disposition of Morphine

In contrast to cats, parenteral and epidural administration of morphine is generally well established in dogs and multiple studies are available to describe its disposition; several studies also address its metabolites (Tables 28-3 and 28-4; see also Table 28-1). Numerous studies using variable preparations, routes and doses in dogs are summarized in Table 28-4 and below. ⁶⁵⁻⁷⁵ Multiples studies have focused on more convenient routes of administration (other than IV), including oral (including extended release products), rectal and epidural. Much of the IV data has been generated in studies that focus on alternate routes of delivery or in the context of determining analgesic concentrations. Peak morphine concentration has been determined in several studies after intravenous, IM and SC administration. Morphine clearance appears to be dose dependent in the dog, with an elimination half-life of 83 ± 8 minutes at doses ranging from 7.2 to 7.7 mg/kg versus 37 ± 13 minutes at 0.019-0.07 mg/kg intravenously.⁶⁸ Bioavailability of intramuscular morphine is high (119%) but variable (57% to 161%), and elimination half-life approximates 90 minutes.

Studies focusing on the nociceptive concentration of morphine revealed an effective 50% concentration of 29.5 ± 5.4 ng/mL in dogs.⁷² The authors indicated that an intravenous infusion of 0.15 mg/kg/hr or multiple doses of 0.5 mg/kg every 2 hours for 3 doses provided significant nociception. The short half-life of morphine may require administration as a CRI in dogs. Because steady state may require 3 to 5 hours, a loading dose may be indicated. No differences in either analgesia or adverse reactions were detected in dogs undergoing exploratory laporatomy treated with morphine administered either intramuscularly (1 mg/kg at induction and extubation and every 4 hours thereafter) or CRI (0.12 mg/kg/h). Steady-state serum morphine concentration after CRI was 30 ± 2 ng/mL. The power to detect a significant difference was not addressed.

Morphine has been studied in dogs subcutaneously prepared as a solution and as a sustained-release gel (N,O-carboxymethylchitosan polymer) product⁶⁹ given either subcutaneously or orally⁷⁰ (it is not clear if the sustained oral preparation is the same as that approved for use in humans). After subcutaneous injection at 1.2 mg/kg, peak concentrations for the solution and sustained product were 488 and 180 ng/mL, respectively, with time to peak concentrations being 10 and 55 minutes, respectively. Variability among animals was large. Elimination half-life was 79 (solution) and 108 (gel) minutes. The duration of analgesia was reported to be between 1 and 2 hours but appeared longer clinically. Emesis should be anticipated.⁵⁶

Oral administration of morphine in humans generates effective systemic concentrations, although first-pass metabolism

requires oral doses that are two to six times parenteral doses. A sustained-release oral morphine preparation (Morphelan) has been approved for use in humans in the United States. The product is designed for both immediate and extended release. Because several days are required for steady-state kinetics to be reached, an initial loading dose of twice the intended subsequent daily dose has been recommended to achieve steady-state concentrations within 2 days of initiation of therapy.⁷¹ However, the role of oral administration of morphine in providing effective analgesia in dogs is not clear. The formation of M6G after oral administration of approximately 1.6 mg/kg, morphine sulfate extended release in dogs was previously discussed. In their study, KuKanich and coworkers ⁶⁶ compared the disposition of intravenous morphine (morphine sulfate 0.5 mg/kg) and orally administered morphine as a commercially available extendedrelease tablet $(1.6 \pm 0.1 \text{ mg/kg})$ in Beagles (n=6) (see Table 28-4). One dog vomited after oral administration. Oral absorption of the extended-release tablet was poor (5%) and erratic, achieving a C_{max} of morphine of 5.0 ng/ml (variability not provided); this low concentration presumably reflects poor oral absorption rather than high first pass metabolism in that M6G was not detected. This compares to an extrapolated (after distribution) peak concentration of 60 ± 10 ng/ml after IV administration of 0.5 mg/kg. Accordingly, for effective analgesia, a dose of 0.5 mg/ kg intravenously every 2 hours was recommended.

More recently, Aragon and coworkers⁷⁴ reported the disposition of morphine (1 and 2 mg/kg) as either an immediate or oral sustained-release product in dogs (n=14). Although drug concentrations were detectable for 24 hours, concentrations were considered too low and too variable to be of clinical use.

Rectal administration may be a viable alternative route of of administration in dogs. After rectal administration in dogs, morphine is approximately 20% bioavailable,⁷⁵ achieving peak concentrations of 28 ng/mL when 2 mg/kg is administered as a solution and 20, 21, and 51 ng/mL when administered as a suppository at 1, 2, and 5 mg/kg, respectively. Elimination half-life (minutes) ranged from 65 (solution) to 98 (suppository) (see Table 28-4). Vomiting was common (five of six animals) with a 5-mg/kg rectal suppository.

Morphine was studied in dogs after intramuscular and rectal administration, the latter as either a solution or suppository (see Table 28-4). Median peak concentrations were reported at 5 minutes. The duration that drug concentrations were above a target of 20 ng/mL were 120 minutes for the intramuscular dose, 5 to 30 minutes for the rectal solution, less than 40 minutes for the low (1 mg/kg) and medium (2 mg/kg) suppository dose, and 120 minutes for the high suppository dose (5 mg/kg morphine sulfate).⁷⁵

Morphine also has been studied in dogs after epidural administration of the solution $(0.1 \text{ mg/kg})^{76}$ and as a sustained-release encapsulated preparation (experimental; 10 and 30 mg in 3 mL saline).⁷⁷ Both appear to prolong analgesia while avoiding side effects. King and coworkers⁷⁸ demonstrated that epidural morphine (0.07 mg/kg, containing 0.1% sodium metabisulfate) was not associated with histologic damage to the spinal cord in dogs (n=16). Morphine has been studied in Beagles after repetitive epidural administration (30 mg at 10

mg/mL) as a sustained-release multivesicular liposome preparation (DepoFoam drug delivery system).⁷⁹ Adverse reactions were limited to moderate, transient behavioral and physiologic changes, consistent with morphine administration, at each injection. A modest effect on cord histopathology was not associated with changes in CSF or neurologic signs.⁷⁹

Morphine also has been studied intravaginally in humans. When this route was used, pain was effectively reduced in one patient, although close monitoring was necessary.⁸⁰ Morphine has been studied in both dogs and cats after transdermal administration as a pluronic lethicin organo (PLO) gel. Drug was not quantifiable in either species when administered at 1.6 to 2 mg/kg.⁶⁵

Adverse Events and Drug Interactions

Adversities of morphine were discussed as a class. Morphine appears to cause more sedation than transdermal fentanyl when used as a postoperative analgesic.⁷⁶ Guedes and coworkers⁴¹ demonstrated that morphine was associated with variable histamine release in conscious dogs at 0.3 and 0.6 mg/ kg load followed by 0.17 or 0.34 mg/kg/hr, although the difference from placebo was statistically significant only for the higher dose. Flushing of the skin occurred within 5 minutes of 60% and 100% of dogs receiving the lower and higher dose, respectively. Although no adverse cardiovascular events were detected, adversities might be anticipated in at-risk patients.

Intrathecal administration of morphine at 0.15 mg/kg has been associated with a number of adverse effects in dogs, including bradycardia, hypotension, myoclonus, and urinary retention (as reviewed by Novello and coworkers).⁸¹ However, Novello and coworkers⁸¹ demonstrated in clinical cases undergoing cervical or thoracolumbar laminectomy that a low intrathecal dose of morphine (0.023 to 0.034 mg/ kg) administered at the lumber level 25 to 65 minutes before surgery reduced the dose of fentanyl (1.2 µg/kg/hr) needed to maintain a steady-state heart rate and arterial blood pressure when compared with a placebo group (4.2 µg/kg/hr fentanyl infusion). Ketamine was also administered to all animals (0.5 mg/kg every 60 minutes starting 10 minutes before surgery). Induction and fentanyl protocols differed among animals in the study; it is not clear if both methods were distributed similarly among treatment groups.

Vomiting is relatively consistently associated with morphine administration in dogs. Vomiting occurred after intravenous (0.5 mg/kg) or intramuscular (1 mg/kg) administration in one study (five of six dogs) at a mean morphine concentration of 66 ng/mL, and heart rates were significantly lower.⁷⁵Drug interactions with morphine appear to be limited. KuKanich and Borum⁷³ found morphine disposition in Greyhounds was not affected by ketoconazole. The simultaneous combination of morphine with the pure antagonists naltrexone did not affect the disposition of either drug in dogs.⁸²

Therapeutic Use

Morphine has been used in the dog and cat effectively as a premedicant or a perioperative analgesic⁵⁶ using a variety of routes. Lucas and coworkers⁸³ found no differences in the

analgesic efficacy of morphine when administered as a CRI (0.12 mg/kg/hr) or intramuscularly at intubation, extubation, and every 4 hours in dogs (n=20) undergoing exploratory laparotomy. Morphine can be administered safely epidurally, although preparations made specifically for epidural administration are preferred. Epidural administration appears to be effective when given either epidurally^{84,85} or locally (intraarticularly)⁸⁴ for control of some orthopedic pains.

The postoperative analgesic effects of epidural morphine (0.1 mg/kg) or morphine combined with medetomidine (0.005 mg/kg) have been compared in dogs (n=6/group) undergoing cranial cruciate repair. No differences were detected in control of pain (power of the study not reported), although the combination drug consistently had a lower numeric score. Increasing sample size may have resulted in statistical signification. Likewise, no differences were detected in plasma morphine concentrations between the two treatment groups (peak concentrations of approximately 4 ng/mL).⁸⁶ The effect of morphine on healing corneal ulcers has been studied in dogs after administration of an ophthalmic preparation. Both MOP and DOP receptors have been identified in the canine cornea. Topical 1% (but not 0.5%) morphine provided good corneal analgesia with no apparent adverse effects.⁸⁷

Morphine (0.2 mg/kg subcutaneously) was compared with buprenorphine (0.02 mg/kg subcutaneously) and methadone (0.2 mg/kg subcutaneously) in cats (n=8) subjected to mechanical and thermal stimulation. Morphine provided the best analgesia.¹²⁶

Oxymorphone

Oxymorphone is a semisynthetic drug (class II) that has been used in both dogs and cats, It is characterized with 10 times the potency of morphine. Receptor interaction is similar to that of morphine. Unlike morphine, however, it does not appear to be associated with histamine release in dogs.⁴⁰ It has been a common component of neuroleptic analgesia. Oxymorphone is effectively antagonized by naloxone and partially antagonized by butorphanol.^{56,88} Its duration of action is 4 to 6 hours, which may exceed that of its reversal agent, naloxone.⁸⁹ Like fentanyl, it is associated with marked auditory sensitization, altered thermoregulation, and bradycardia (pretreat with atropine). Decreased heart rate may still occur with epidural administration.⁹⁰ Oxymorphone is used primarily to induce neuroleptanalgesia or reduce the amount of barbiturate needed for surgical anesthesia. It also, however, has been commonly used to control postoperative pain in small animals, although use has been curtailed by limited availability and increased use of alternative opioids.²³ Oxymorphone has been studied with and is approved for use in the dog⁹¹ and cat. It remains an excellent analgesic for both young and old patients and for debilitated patients.

Oxymorphone has been studied in normal dogs after intravenous and intramuscular use (Table 28-4).⁹² Oxymorphone also has been studied in Beagles after administration as a subcutaneously administered slow-release liposome-encapsulated [LE] preparation.⁹³ A dose of 0.5 mg/kg LE preparation yielded concentrations comparable to 0.1 mg/kg of standard morphine achieving a (plasma C_{max} of approximately 37 µg/mL using an enzyme-linked immunosorbent assay (ELISA) that measures both parent compound and glucuronide metabolite; however, the elimination phase appeared to be similar (elimination half-life not reported). Sedation and physiologic scores were comparable at these two doses, suggesting no benefit in pharmacologic effects when morphine or its metabolite are delivered as LE preparations compared with standard preparations.

Hydromorphone

Hydromorphone is a pure MOP agonist with a potency (in humans) 5 to 7 times that of morphine suggesting effective concentrations to be 2 to 3 ng/mL. A minimum effective concentration of 4 ng/mL has been suggested (as reviewed by Guedes and coworkers).94 It has been administered for control of pain by a number of routes in humans, including parenteral, transmucosal, and epidural. Hydromorphone (0.1 mg/kg intravenously) disposition and its association with analgesia have been described in the cat.95 Peak plasma concentration was of 94.25 ± 8.40 ng/mL after intravenous administration of 0.1 mg/kg; median concentrations extrapolated from the terminal phase were 25 ng/mL (range 8 to 35). Despite a short elimination half-life (median 100 minutes; range approximately 60 to 140) leading to nondetectable concentrations (less than 1 ng/mL) by 6 hours, analgesia as measured by thermal threshold was maintained for 7.5 hours.95 No behavioral side effects were reported; most cats became nauseated, but none vomited. Mydriasis and "tail tucking" were observed in all cats.

The impact of hydromorphone on nociception has been studied in cats. Hydromorphone at 0.1 mg/kg provided thermal antinociception for 230 minutes (as reviewed by Guedes and coworkers.)94 A dose-dependent effect was evident between 0.025 and 0.1 mg/kg. In contrast to dogs, hyperthermia is associated with hydromorphone treatment in cats. Analgesic effects, based on thermal thresholds, of hydromorphone (0.1 mg/kg intramuscularly), butorphanol (0.4 mg/kg intramuscularly), or the combination have been studied in cats.96 The duration of analgesia was approximately 3 hours for butorphanol, 6 hours for hydromorphone, and 9 hours for the combination. However, the initial intensity of hydromorphone and, to a lesser degree, butorphanol analgesia was substantially reduced when the combination was used. Side effects included dysphoria (butorphanol only) and vomiting (hydromorphone only).97

The pharmacokinetics of hydromorphone have been described in Beagles at 0.1 and 0.5 mg/kg intravenously or subcutaneously (see Table 28-4).⁹⁹ The short half-life (30 to 60 minutes) led the authors to recommend that treatment should occur at 2-hour dosing intervals for either route of administration or that a CRI be used. Hydromorphone was also studied in Beagles after administration in a controlled-release LE product at 0.5 intravenously or, 1, 2, and 3 mg/kg subcutaneously using a randomized design with a 14- to 28-day washout.¹⁰⁰ Serum drug concentrations corrected for dose ranged from 19.41 to 25 ng/mL at 0.19 to 0.27 hour. Concentrations

approximated 4 ng/mL for 6 to 72 hours at 2 mg/kg; at 3 mg/kg, concentration exceeded 4 ng/mL for 96 hours.

Guedes and coworkers⁹⁴ also described the pharmacokinetics (see Table 28-4) and pharmacodyanmics of intravenous hydromorphone (0.1 or 0.2 mg/kg) in dogs (n=5; 2 Beagles) and coupled their studies with pharmacodynamic assessment of analgesia. Antinociceptive effects (based on towel clampinduced withdrawal) and sedation were compared with those of morphine (0.5 and 1 mg/kg). Hydromorphone clearance surpassed hepatic blood flow reported for dogs, leading the authors to suggest extrahepatic clearance. Both drugs were associated with more antinociception and sedation compared with placebo, but differences were not detected between doses or drugs. The authors suggested that lack of dose dependency may reflect achievement of the maximum effect at the low dose. The lack of differences between drugs was interpreted as confirmation of the potency of hydromorphone compared with morphine. However, the power of the study to detect significant differences was not reported. Analgesic concentrations of 0.5 to 4 ng/mL were suggested on the basis of their work as well as that of others, including studies of humans. Other differences compared with placebo were increased respiratory rate, with return to baseline occurring more rapidly for the hydromorphone compared with morphine group. Body temperature decreased in a dose-dependent manner for both drugs, although changes were significantly different only when compared with placebo. Hydromorphone provided clinically relevant antinociception for at least 2 hours.

Fentanyl

Fentanyl is a synthetic opioid (class II) with a potency 100 times that of morphine and 500 times that of meperidine. Doses are cited in $\mu g/kg$ rather than mg/kg. Fentanyl is a pure MOP agonist, but it also positively interacts, although to a lesser degree, with DOP and KOP receptors. In contrast to morphine, fentanyl is associated with minimal hemodynamic changes or cardiac suppression. Historically, fentanyl has been recognized as a drug used to induce neuroleptanalgesia (when combined with droperidol). After parenteral administration, however, it causes profound sedation and respiratory depression. Auditory sensitization and altered thermoregulation (leading to panting) may occur. Pretreatment with atropine is indicated when administering the drug parenterally. Because it undergoes redistribution (as with thiobarbiturates), repetitive administration may result in accumulation of the drug in fat and prolonged duration of effect.

Pharmacokinetics and Pharmacodynamics

Fentanyl has been studied in dogs and cats using several different methods of delivery. Using a thermal threshold response, fentanyl concentrations greater than 1 ng/mL have been recommended for therapeutic analgesic effects in cats.¹⁰¹ A dose of 10 μ g/kg intravenously provided analgesia (measured by thermal response) for approximately 2 hours in cats.

In normal dogs the elimination half-life approximates 3 hours and the volume of distribution 10 L/kg (see Table 28-4); μ g/kg was 1.5 and 2.8 ng/mL, respectively; elimination half-life

was approximately 2.5 hours.⁶⁵ In normal cats the elimination half-life also approximates 3 hours, but volume of distribution appears to be smaller.^{102.} A half-life approximating 2.5 to 3 hours in either species potentially supports the use of a CRI, although a loading dose is indicated. An infusion rate of 0.4 $\mu g/kg/min$ after a loading dose of 5 $\mu g/kg$ is recommended in cats. For dogs, fentanyl has been studied after an intravenous loading dose, and an intravenous loading dose (10 µg/kg) followed by CRI (10 µg/kg/hr) for 1 to 3 hours (see Table 28-4).¹⁰³ Concentrations declined to below 1 ng/mL by 20 minutes after the intravenous loading dose and reached 1 ng/mL again by about 2 hours, with steady-state concentrations at 1, 3, and 4 hours of infusion being 1.0 ± 0.7 , 1.11 ± 0.4 , and 1.25 ± 0.7 ng/mL, respectively. Variability in concentrations was marked. The elimination half-life of fentanyl after the CRI was discontinued was 151 ± 61 (2.51+1 hours) to 182 ± 68 (3+1 hours).

Fentanyl is among the drugs for which alternative routes of administration have been developed,¹⁰⁴ several of which have been studied in dogs and cats. Transdermal delivery of 10 or 30 µg/kg as a PLO gel yielded no detectable plasma fentanyl nor any analgesia in cats in one study.¹⁰¹ However, a second study (unpublished data by author) found a C_{max} of 8.8 ± 5 ng/mL at 10 ± 19 hours after transdermal delivery of a PLO gel (5 mg/mL) to cats (n=3) at a mean dose of 0.08 ± 0.03 mg/kg (80 ± 30 µg/kg). Potentially therapeutic concentrations persisted throughout the duration of the study: concentrations of 4 ± 5 ng/mL were measured at 61 hours. In contrast to cats, fentanyl was not detected in dogs after administration of 0.88 mg/kg (880 µg/kg) as a transdermal PLO gel.⁶⁵

KEY POINT 28-15 Fentanyl is such a potent pure MOP agonist that it is dosed in micrograms rather than milligrams.

Fentanyl (2 μ g/kg) has been studied after oral and intranasal administration in cats. C_{max} (ng/mL) 5 minutes after oral administration was 0.96 and 2 minutes after intranasal administration, 1.48 ng/mL.¹⁰¹ Although not yet studied in dogs or cats, nn humans, after administration as an aerosol (50 μ g/mL solution aerosolized for 5 minutes), fentanyl concentrations were approximately 25% of that achieved after 100 μ g intravenously (1.4 ng/mL versus 4.4 ng/mL, respectively), suggesting aerosolization as a possible route of administration.¹⁰⁵

Fentanyl has been available for about 10 years as a transdermal drug delivery system intended for control of pain (Figure 28-4). Issues surrounding transdermal drug delivery in animals have been well reviewed. ¹⁰⁶ The transdermal patch system has proved safe and effective for delivery of fentanyl to both dogs and cats. The transdermal drug delivery system provides slow, continuous drug delivery that is intended to provide a fairly constant plasma fentanyl concentration. Peak and trough concentrations, which might cause toxicity and therapeutic failure, respectively, are thus avoided. The fentanyl transdermal patch system has been approved for control of cancer pain in humans. The system consists of a patch with an adhesive layer that attaches to the skin. A "release" membrane controls the rate of release of drug from the reservoir. Because the amount of drug that is released is proportional to the size

Figure 28-4 The transdermal fentanyl patch system. The dermis is the site of microcirculation and thus drug absorption.

(area) of the patch,¹⁰⁷ the dose delivered is the amount of drug (in μ g) released per unit time (hour). The system is available in four sizes: 25, 50, 75, and 100 μ g/hr. Drug delivery through the stratum corneum can be influenced by a number of factors that vary among patients. These include thickness of the stratum corneum and epidermal layer, skin appendages (e.g., number of sweat glands), body temperature, hydration status, and diseases that might alter the permeability of the stratum corneum.

Species difference mandate that the fentanyl patch system be studied in the target species before use. Peak concentrations occur within 24 hours in the dog and can occur in as few as 3 to 5 hours in the cat. The commercially available fentanyl patch has been studied in both dogs^{102, 108,109} and cats.¹¹⁰ With the 50 µg/hr patch, drug delivery approximated 37 µg/hr (range of 13.7 to 59.8 μ g/hr) in dogs, and the patch was found to be an effective means of constant, slow drug delivery.¹⁰⁸ A comparison of drug delivery from different patch sizes found the average fentanyl concentration from 24 to 72 hours to be 0.7 ng/mL (50 µg/hr), 1.4 ng/mL (75 µg/hr), and 1.2 ng/ mL (100 μ g/hr) in dogs weighing approximately 20 kg.¹⁰⁹ The elimination (disappearance) half-life ranged from 3.6 hr (50 μ g/hr) to a low of 2.5 hr (100 μ g/hr). Variability among dogs was marked, making duration of analgesia difficult to predict in individual animals.

Fentanyl delivery has been studied after administration of a 25 µg/hr patch in cats.¹⁰² Delivery was approximately 8.5 µg/hr

(36% of the predicted) with mean steady-state concentrations of 1.58 ng/mL being achieved at 12 to 100 hr; the maximum concentration of $3.6\pm$ 0.8 was achieved at 44 ± 12 hr. Concentrations dropped below 1 ng/mL in four of six cats within 12 hours of patch application and in all cats within 36 hours. The amount of drug delivered through a fentanyl transdermal patch can be reduced by decreasing the surface area contact with the skin. The most accurate approach probably is removal of only a portion of the protective lining cover of the patch, although the proportion of drug delivery will not be exactly proportional to the amount of lining removal. Folding half of a 25 µg/hr patch in cats yielded mean peak concentrations of 1.14 ± 0.9 ng/mL compared with 1.8 ± 0.9 ng/mL (38% reduction) for full patch exposure. ¹¹⁰

Robertson and coworkers¹⁰¹ determined the pharmacodynamic response of fentanyl either intravenously or as a PLO (10 µg/kg) applied to the inner pinna. Plasma fentanyl concentrations greater than 1 ng/mL were required for effective analgesia. The only value reported in the study was C_{max} (rather than extrapolated γ intercept) for fentanyl after intravenous administration. However, mean concentrations appeared to be above 1 ng/mL for approximately 60 minutes after intravenous administration. Elimination half-life estimated from the plasma drug concentration versus time curve approximated 15 to 30 minutes. Cats tolerated fentanyl administration well, with most cats exhibiting euphoria. Fentanyl was not detected after PLO administration when administered at 30 µg/kg. In this same study, Robertson and coworkers¹⁰¹ studied fentanyl after oral or intranasal administration of 2 μ g/kg, yielding C_{max} values of 0.96 and 1.48 ng/mL at 5 and 2 minutes, respectively. Cats receiving the drug orally or intranasally salivated profusely and were difficult to restrain. Thermal antinociception differed from saline control for approximately 2 hours.

The rate of drug release from the patch and skin can vary with environmental factors that alter delivery through the stratum corneum. Most notable is temperature; fever or a heating pad will increase drug movement. Body temperature was shown to influence fentanyl concentrations when delivered using a fentanyl as a transdermal patch in cats undergoing isoflurane anesthesia. Peak concentrations were 1.8 ± 0.6 ng/mL in normothermic patients compared with 0.6 ± 0.3 ng/mL in hypothermic cats.¹¹⁴ In another study, experimentally induced hypothermia (35° C) was associated with a decline in plasma fentanyl concentrations of 33% (0.6 ng/mL) compared with that at baseline (1.8 ng/mL).¹¹⁷ Patches had been applied 24 hours before anesthesia. In contrast, hyperthermia may increase the risk of fentanyl overdose.¹¹⁵

Therapeutic Use

Only a few clinical trials have compared non-transdermal fentanyl to alternative opioids. Anderson and Day⁴⁷ compared the effects of morphine (0.12 mg/kg/hr), fentanyl (3 µg/kg/hr) administered by CRI with those of placebo on urine output in healthy (n = 23) and traumatized (n = 18) patients. All animals received a similar rate of fluid infusion. Both fentanyl and morphine decreased urine output in both the trauma and healthy groups (approximately 0.7 to 0.76 mL/kg/hr in all groups compared with 1.2 mL/kg/hr in the untreated group).

Several studies have demonstrated efficacy of the fentanyl transdermal patch system in cats.^{110,111,113} Fentanyl administered as a 25 µg/hr patch was effective on controlling pain associated with ovariohysterectomy in cats.¹¹¹ Fentanyl was more effective than butorphanol (0.4 mg/kg intravenously) in cats undergoing ovariohysterectomy or onychectomy.¹¹³ A number of studies have documented analgesic efficacy of transdermal fentanyl in dogs. Analgesia did not differ from produced by intramuscular oxymorphone (0.05 mg/kg), but fentanyl was associated with less sedation when used in canine patients undergoing ovariohysterectomy.¹¹² Robinson and coworkers⁷⁶ compared the efficacy of transdermal fentanyl (100 µg/hr; placed 24 hours before surgery) with that of epidural morphine (0.1 mg/kg) at induction of anesthesia in dogs (n=10) undergoing major orthopedic surgery. Fentanyl provided superior analgesia. The fentanyl patch system was equal to or better than epidural morphine (0.1 mg/kg) in canine patients undergoing orthopedic surgery⁷⁶.

KEY POINT 28-16 The transdermal fentanyl patch system has proved to be an effective method of analgesia delivery in dogs and cats.

The fentanyl transdermal patch appears to be a reasonable alternative to pain management for dogs and cats, but with

several caveats. Patches can cause irritation. Because the time to peak therapeutic concentrations of the drug may be up to 24 hours,¹⁰⁹ the need for shorter-term control of pain (e.g., for postoperative pain) should be anticipated. Patches should be applied 12 to 24 hours before the anticipated need for analgesia. Likewise, after the patch is removed, a similar 12- to 24-hour period must elapse before the drug is no longer detectable in the patient. Analgesia is provided for 24 to 72 hours, although variability among animals can be marked, making use of the patch for the individual animal less predictable. Intravenous fentanyl (30 µg/kg has been recommended for dogs) can be given at the time of patch application as a loading dose for patients in need of immediate analgesia. Other opioids also can be given intravenously, intramuscularly, or subcutaneously until the patch is effective. Although a pure opioid (morphine, oxymorphone) is probably preferable, a mixed or partial drug (butorphanol or buprenorphine, respectively) can be given. Because both of the latter drugs have some MOP antagonist effects, however, the MOP effects of fentanyl from the patch will be blocked until the antagonist is eliminated. This may be more problematic with buprenorphine, which has a very tight affinity for MOP receptors.113a

The transdermal delivery of fentanyl appears to be very useful in small animals experiencing pain, including postoperative pain, cancer pain, and pain associated with trauma. The patches can be dosed as follows on the basis of body weight: 5 to 10 kg: 25 µg/hr; 10 to 20 kg: 50 µg/hr; 20 to 30 kg: 75 µg/hr; and more than 30 kg: 100 µg/hr.115 The dose of fentanyl administered by a transdermal patch can be decreased in animals ≤ 5 kg by folding the adhesive membrane such that only a portion of the patch is exposed to the skin or by cutting away half of the seal (but not the patch itself). However, variability in concentrations will complicate effective use. Exposure of the second half of the patch may not provide equivalent analgesia if applied to a different cat or after all fentanyl has been eliminated. For animals larger than 30 kg, multiple patches can be applied. Patches can be used on an outpatient basis. Heating pads should not be placed at the site of a patch. Patches generally are placed on the dorsum of the neck, which first must be clipped and dried. The patch must come in close, snug contact with the skin. A bandage should be applied to keep the patch in place and prevent the animal or people (especially children) from disturbing the patch.

If the patch is prescribed, veterinarians should apply the patch to, and on completion of analgesia remove it from, the animal rather than allow the client to do so. Clients should be warned that the patches are not approved for use in animals. Patches that are sent home with the patient should be collected when removed from the animal to minimize the risk of drug abuse by pet owners.¹¹⁶ Animals occasionally remove the patch and swallow it; however, the risk of drug toxicity is minimized because it is unlikely that the close contact necessary for drug delivery will occur between the mucosa and the patch. In addition, first-pass metabolism of any fentanyl that is absorbed will limit the amount of drug that reaches systemic circulation. This will not be true if the patch is chewed such that absorption through the buccal mucosa occurs.

Sufentanil

Sufentanil is a thiamylal derivative of fentanyl. It is 5 to 10 times as potent as fentanyl but is apparently associated with fewer cardiac or respiratory side effects. Its half-life is shorter than that of fentanyl, but its onset of action is much more rapid. It has been used as an effective analgesic in dogs.¹¹⁸

Meperidine (Pethidine)

Meperidine (pethidine) (2 to 10 mg/kg intramuscularly every 2 hours [dogs]; 2 to 4 mg/kg intramuscularly every 2 hours [cats]; class II) induces analgesia that is about one fifth that of morphine and lasts approximately 1 to 2 hours. Its sedative properties, however, are useful for preanesthesia. It undergoes marked first-pass metabolism and is eliminated rapidly in dogs. Meperidine reduces the heart rate and systemic arterial pressure in dogs partly through peripheral vasodilation. Bronchoconstriction also occurs in the dog. It is a potent initial stimulant of the gastrointestinal tract. Rapid intravenous injection can cause peripheral vasodilation. Diphenoxylate (the active opioid ingredient in Lomotil) is a derivative of meperidine. In a randomized, blinded, multicenter clinical trial, meperidine (postoperatively, 3.3 mg/kg intramuscularly; n = 57) provided analgesia equal to that of carprofen (preoperatively, 4 mg/kg subcutaneously; n = 59) in cats.¹¹⁹ However, the duration of analgesia was longer for the carprofen group. Millette and coworkers¹²⁰ studied the effects of meperidine (5 mg/kg intramuscularly) on various nociceptive thresholds in cats (n = 8). Both thermal and mechanical thresholds changed with meperidine.

KEY POINT 28-17 The short duration of action of meperidine largely limits use to preanesthesia.

MILD TO MODERATE PURE AGONISTS

Codeine

Codeine is 60% bioavailable in humans after oral administration. Although effective concentrations reach circulation after oral administration, the potency of codeine as an analgesic is less than that of morphine. Codeine has a very low affinity for opioid receptors, and its analgesic effects are primarily due to metabolism (demethylation) to morphine.²⁹ Only a small percentage (10%) of morphine is formed, however, and its antitussive effects probably reflect direct interaction with codeine receptors.²⁹ In dogs, even less codeine appears to be converted to morphine. Its antitussive effects require lower plasma drug concentrations than expected for analgesia. Currently, its primary indication for small animals is as a cough suppressant (2.2 mg/kg [dogs]) or antidiarrheal. Outpatient use of this drug as an analgesic, particularly when combined with a non-narcotic analgesic (i.e., NSAIDs or acetaminophen) is increasing. Codeine is scheduled as class II.

The disposition of codeine (20 mg/kg) after subcutaneous administration was briefly described in dogs.^{121,122} The elimination half-life of the free form approximated 2.5 hours, and the conjugated form 4 hours. Urinary excretion was the major route of elimination (approximately 50% to 70% of total dose) as either the conjugated (approximately 50% of total dose) or free form (up to 11%). Morphine was not detected.

Methadone

Methadone is an MOP receptor agonist similar to morphine in action. Analgesia is largely due to the l-methadone isomer, which is eightfold to fiftyfold more potent than the d-isomer. The -d-isomer is characterized by antitussive activity.²⁷ Its extended duration of action is useful for its suppressant effects on withdrawal in physically dependent humans. Further, effects persist with repeated administration. Its ability to block tolerance induced by morphine may reflect its mild antagonism of NMDA receptors, also a function of the d isomer.¹²³ In humans it is characterized by an elimination half-life of 15 to 40 hours, resulting in its designation as a long-acting drug. Side effects are similar to those produced by morphine; tolerance develops to the gastrointestinal (including anorexia), sedative, miotic, and cardiac and respiratory effects but not to the constipative effects. Its overall abuse potential is similar to that of morphine in humans.

Methadone has been used as an analgesic in dogs. The disposition of methadone (0.5 mg/kg; 0.45 mg/kg free base) has been described in Greyhounds¹²⁴ and Beagles.¹²⁵ Interestingly, the disposition is different between the two breeds. A larger volume of distribution in Greyhounds (Table 28-4) was attributed by the authors to potentially reflect pH partitioning of methadone (pKa of 7.4) from plasma (pH 7.39) into muscles (pH 6.9). Methadone was well tolerated in Greyhounds at the dose, although dogs panted and defecated shortly after administration. Because clearance is twice the volume in Greyhounds compared with Beagles, elimination half-life is similar between the two breeds despite the larger volume of distribution in Greyhounds. The antinociceptive effects of methadone apparently have not yet been determined in dogs. The impact of the CYP and P-glycoprotein inhibitors ketaconazole and omeprazole on the disposition of oral methadone (2 mg/kg) was studied in Beagles.¹²⁵ Oral methadone was not detected in any dogs, with the exception of one that was also receiving ketaconazole. Methadone (0.2 mg/kg subcutaneously) was compared with buprenorphine (0.02 mg/kg subcutaneously) and morphine (0.2 mg/ kg) in cats (n = 8) subjected to mechanical and thermal stimulation.¹²⁶ Analgesia associated with methadone was better than that associated with buprenorphine and compared favorably with that produced by morphine, although it was not quite as effective.

Miscellaneous Drugs

Oxycodone (Percodan, class II), *hydrocodone* (Hycodan, class III), and *propoxyphene* (Darvon, class IV) are used to varying degrees in veterinary medicine. Among them, hydrocodone is most commonly used for suppression of cough. *Diphenoxylate* (class II as a sole agent; when combined with atropine to control substance abuse as Lomotil, class V) is used to control diarrhea because of its effects on the gastrointestinal tract.

Loperamide is similar to diphenoxylate, but it does not penetrate the blood-brain barrier as effectively and therefore is associated with no CNS side effects.

MIXED AGONISTS AND ANTAGONISTS

Butorphanol

For decades, but orphanol had a nonscheduled designation by the Food and Drug Administration, but it has since been redesignated as class IV. Butorphanol (0.4 to 0.8 mg/kg intramuscularly, subcutaneously, intravenously every 3 to 6 hours [dogs, cats]; oral [antitussive in dog]: 0.5 to 1 mg/kg every 12 hours) is a KOP agonist and a MOP antagonist, although it may have moderate MOP agonistic actions. It is three to five times more potent (KOP agonist) than morphine and about 50 times less potent than naloxone as an antagonist. Butorphanol has been used as both a preanesthetic and a perioperative analgesic in dogs and cats. Historically, it has been one of the three most commonly used opioids for control of postoperative pain in small animals,^{127,128} the other two being buprenorphine and oxymorphone.²³ However, the short duration of analgesia provided by butorphanol increasingly is limiting its use to pre-operative in nature. Butorphanol also is approved in dogs for use as an antitussive.¹²⁹

The duration of analgesia after intravenous or subcutaneous administration in dogs is 30 to 45 min at 0.4 mg/kg^{130,131} although analgesic effects can last up to 4 to 6 hours in some animals. The duration of analgesia is shorter than sedation.¹³⁰ Limited information is available regarding pharmacokinetics in dogs (see Table 28-4).^{132,133} In dogs the elimination halflife is 1.65 hours.¹³² At high doses butorphanol provides some relief of somatic pain. Butorphanol may be an effective analgesic for mild to moderate pain. For postsurgical pain, butorphanol should be administered 10 minutes before the end of surgery. In general, the efficacy of butorphanol as an analgesic in dogs does not compare favorably with that of NSAIDs. For example, butorphanol (0.2 mg/kg intravenously) was less effective than carprofen, etodolac, or meloxicam for control of pain associated with experimentally induced acute synovitis in Beagles despite the small sample size (four dogs per treatment group).¹³⁴ In this study butorphanol was different from control only at 3 and 4 hours after treatment of the 6-hour study period. Butorphanol (0.4 mg/kg) was ineffective as an analgesic in dogs (n = 22) undergoing laparotomy or shoulder arthotomy.135 The intent of the study was to compare butorphanol with ketorolac or flunixin meglumine; oxymorphone was subsequently substituted.

KEY POINT 28-18 The short duration of efficacy of butorphonal limits its use as a primary analgesic.

The oral preparation of the drug has been dispensed for 1 to 2 days in patients released from the hospital; higher oral doses compared with parenteral doses are required because of its reduced bioavailability after oral administration (0.5 to 1 mg/kg every 12 hours). However, there is no evidence that this is an effective analgesic dose.

Butorphanol may act synergistically when combined with acetaminophen (dogs only) for control of pain.¹³⁶ Although safe, epidural administration of butorphanol does not provide sufficient duration of action to be clinically useful.^{137, 138} As such, the short duration of action (and mechanism of action of butorphanol) should be questioned with regard to efficacy in most cases of pain control.

An advantage of butorphanol is its MOP antagonistic effects. Butorphanol (0.4 mg/kg) can be used to partially reverse the sedative or respiratory depressant effects of oxymorphone⁸⁸ (and presumably other pure opioid agonists). Some of the analgesic effects of the pure opioid will also, however, be reserved. An advantage of butorphanol as a reversal agent is its apparent efficacy as a reversal agent in cats, which is in contrast to naloxone. For example, the initial intensity of hydromorphone and, to a lesser degree, butorphanol analgesia was substantially reduced when the two drugs were used in combination. Side effects included dysphoria (butorphanol only) and vomiting (hydromorphone only).97Although butorphanol does cause respiratory depression, a ceiling apparently is reached beyond which additional dosing does not cause further depression (a MOP antagonist).¹³⁹ Butorphanol causes less biliary spasm than does morphine, supporting the postoperative use of butorphanol.54

Butorphanol appears to be safe in cats if used cautiously, although again, its analgesic efficacy is questionable.¹⁴⁰ Butorphanol has been studied in cats (n = 6) after intramuscular and buccal transmucosal administration of 0.4 mg/kg.141 The relative bioavailability of butorphanol transmucosally compared with intramuscularly was 38%. The duration of potential antinociception was quite variable at 155 ± 130 minutes based on the duration that concentrations were at or above 45 ng/mL. The latter was the target concentration based on a review of the literature. The antinociceptive potential of butorphanol was studied in cats (n = 6) at 0.2, 0.4, or 0.8 mg/kg.¹⁴² No dose-response relationship was detected, although this likely reflected the small number of cats in the face of small changes in dose. Analgesia began at 15 minutes and persisted for 90 minutes after injection. Mydriasis and dysphoria were frequent. Lascelles and Robertson⁹⁶ demonstrated that hydromorphone prolonged the antinociceptive effects of butorphanol (or vice versa).

Johnson¹⁴³ compared the antinociceptive potential of intramuscular butorphanol, buprenorpine, or the combination in cats (n = 6). Marked variability was recorded in terms of duration of response: 1 to 8 hours for butorphanol, 0.5 to 5 hours for buprenorphine, and 1 to 8 hours with the combination. This variability contributed to the lack of significant differences among the opioid treatment groups.

Buprenorphine

Buprenorphine (0.005 to 0.03 mg/kg intravenously, intramuscularly, subcutaneously, epidurally [dogs]) is a class IV thebaine derivative with potent analgesic effects 25 or more times greater than those of morphine.¹⁴⁴ It is a KOP antagonist and a MOP partial agonist–antagonist.¹⁴⁵ It is metabolized to norbuprenorhpine, which, as with buprenorphine, is then glucuronidated. The metabolite has approximately ¹/₅₀ the analgesic effect of the parent compound (in rats) inpart because of poor penetration of the blood–CSF or blood–brain barrier as well as low intrinsic activity compared with buprenorphine.¹⁴⁶ Buprenorphine has a long duration of activity which reflects, in part, tight adherence to its target receptors.¹⁴⁶

Buprenorphine is one of the three most commonly used opioids for control of pain in small animals,^{127,128,147} and it has been recommended as the most generally useful analgesic for controlling pain in laboratory animals (including dogs).¹⁴⁸ Although its onset of action is longer than that of morphine, its effects last much longer (in humans). In dogs buprenorphine appears to have a 42-hour half-life.¹⁴⁹ Because of its high lipophilicity, buprenorphine has a very high volume of distribution (33 L/kg) and appears to be sequestered in tissues. The long half-life may contribute to its longer duration of action compared with butorphanol. It is metabolized by CYP3A4.

KEY POINT 28-19 Buprenorphine may be the most generally useful analgesic in dogs and cats.

Several studies have addressed the disposition of buprenorphine via alternative routes of administration. Sublingual use has been noted as impossible because of local pH inactivation. However, buprenorphine is approved as a sublingual product in the United Kingdom; sublingual bioavailability in humans ranges from 16% to 94% compared with 40% to 90% after intramuscular administration.¹⁵⁷ Greater doses are claimed to be associated with longer duration of analgesia with no increase in sedation, yet increased doses have been associated with lethal respiratory depression in humans. The intravenous disposition has been reported in cats¹⁵⁸ and dogs by a number of investigators (see Table 28-4).¹⁵⁹⁻¹⁶¹ Among them are oral and transmucosal routes. Abbo and coworkers160 described the disposition of buprenorphine (20 and 120 µg/kg) in dogs (n=6) after oral transmucosal administration. The bioavailability was 38 ± 12 % and 47 ± 16 %, respectively, for the two doses. Robertson and coworkers¹³⁸ described the disposition of buprenorphine after oral transmucosal (transbuccal) administration (0.01 mg/kg administered as 0.033 mg/kg) in cats. Peak concentrations of 7.5 mg/mL were achieved at 15 minutes.

Like morphine, buprenorphine induces dose-dependent respiratory depression, which may be delayed in onset. Like butorphanol, a ceiling is reached in respiratory depression but not analgesia in humans.¹⁵⁰ The differential effect may reflect full agonistic actions at analgesic receptors and partial agonism at receptors controlling respiratory depression. The differences may also reflect differences in receptor number. Although respiratory depression has not been a problem in human patients receiving the drug, it is noteworthy that these effects are not fully reversible with antagonists such as naloxone. The risk of respiratory depression associated with buprenorphine is markedly increased when used in combination with other CNS-active drugs. Adversities, including deaths, have been reported in humans simultaneously taking opioids (drug addicts taking buprenorphine as substitution therapy),¹⁵¹ fentanyl,¹⁵² or ketorolac as part of balanced analgesia and diazepam;¹⁵³ only mild interactions have been reported with amitriptyline.¹⁵⁴

Cardiovascular side effects of buprenorphine are limited. The cat may respond to buprenorphine with mydriasis and agitation at doses exceeding 0.2 mg/kg. An added advantage of buprenorphine is its ability to reverse opioid-induced sedation while maintaining analgesia. It has been recommended as the reversal agent of choice (i.e., instead of naloxone) for human patients receiving neuroleptanalgesics.

Naloxone, when combined with buprenorphine at a 1:4 ratio, has no antagonistic effect when administered sublinqually in humans.¹⁵⁵ However, it causes withdrawal signs in humans physically dependent on opioids and is combined for such purposes to prevent abuse.

Buprenorphine has proved to be a very effective analgesic. For example, in humans buprenorphine (intravenously) was found to provide superior analgesia and improved hemodynamic indices compared with fentanyl (intravenously) in human patients undergoing spinal surgery.¹⁵⁶ A plethora of anectodal information exists regarding the use of buprenorphine in animals.

Buprenorphine is the most popular opioid used in small animal practice in the United Kingdom.¹³⁸ It may provide 6 hours of analgesia after intramuscular administration (0.01 mg/kg), although onset of action may take 2 hours.¹³⁸ Robertson and coworkers138 a determined the analgesic threshold of buprenorphine in cats after intravenous or transmucosal administration of 20 µg/kg. Bioavailability of the transmucosal route was 113%. Thermal thresholds did not differ by route; peak effect occurred at 90 minutes. The authors concluded that transmucosal was as effective as intravenous administration, providing analgesia for 6 hours. Buprenorphine also has been studied in cats (n = 6) after administration as a transdermal patch.¹⁶² Peak buprenorphine was 10 ± 0.81 ng/mL, but thermal thresholds did not change throughout the 72-hour test period. Steagall¹⁶³ evaluated the antinociceptive response of IV buprenorphine in cats using both thermal and mechanical stimulation. Cats (n = 8) were treated with 0.01, 0.02 or 0.04 mg/kg using a randomized three-way crossover design with a week washout period between treatments. Response among cats was markedly variable and was not correlated with coat color or group. Cats (1 in the middle dose and 2 in the high dose) exhibited marked euphoric behavior. Thermal antinociceptive response was noted within 15 minutes at any dose, lasting from 2 to 4 hours at the low and middle dose and 8 hrs at the high dose. The medium and high doses were associated with greater MT antinociception. Slingsby and coworkers¹⁶⁶ compared the difference between a 4-hour 10 µg/kg dose or a second 6-hour 20 µg/kg postoperative dose of buprenorphine in dogs (14 dogs per group) undergoing castration; both groups received buprenorphine (10 or 20 mg/kg) preoperatively. Dogs were studied using a parallel randomized design. Pain scores were low for both groups, decreasing again with the second dose. A trend towards better analgesia occurred with the higher dose and longer interval. Sedation was also effective in both groups. Three dogs at the low dose and 1 dog at the high dose required carprofen rescue analgesia.

A number of prospective clinical trials have examined the analgesic efficacy of buprenorphine compared with other drugs. Changes in thermal threshold for buprenorpine (0.01 mg/kg) was compared with those for morphine (0.2 mg/kg), butorphanol (0.2 mg/kg), and placebo.⁴⁶ For butorphanol the threshold increased at 5 minutes but decreased by 2 hours. The duration for morphine was 4 to 5 hours and for buprenorphine 4 and 12 hours. Johnson and coworkers¹⁴³ compared the antinociceptive response of intramuscular buprenorphine, butorphanol, or the combination thereof to placebo in cats using a thermal threshold method. Each treatment provided analgesia greater than that in the control group, but no differences could be demonstrated among treatment groups (power of this study not addressed). Duration of analgesia was from 35 minutes to 5 hours for buprenorphine and 50 minutes to 8 hours for butorphanol or the combination. Steagall and coworkers¹²⁶ also compared the analgesic efficacy of methadone (0.2 mg/kg subcutaneously), morphine (0.2 mg/kg subcutaneously), and buprenorphine (0.02 mg/kg) in cats (n=8). Cats were studied using a four-way crossover design; mechanical and thermal antinociception was studied. Response to buprenorphine provided the least analgesia, which was attributed in part to subcutaneous administration. Bosmans and coworkers¹⁶⁴ compared the combination of tepoxalin and buprenorphine to buprenorphine alone during the 24-hour period after cruciate repair in dogs (n=20; 10 per group). Animals were studied using a parallel randomized, blinded design. Pain was assessed using visual analog scales and a multifactorial pain scale. No statistical differences were found in either control of pain or side effects. However, the ability to detect a difference is likely to have been limited by the small sample size. Shih and coworkers¹⁶⁵ compared the analgesic efficacy of buprenorphine (0.02 mg/kg) alone, carprofen (4 mg/kg) alone, and carprofen combined with buprenorphine in dogs (n=20 per group) undergoing ovariohysterectomy. A randomized parallel design was used. Anesthetic protocols were the same for all animals. Efficacy was based on a dynamic visual analog scale, and wound swelling was assessed. The carprofen-treated group required more propofol for induction compared with the other two groups. All three treatments provided effective analgesia at 6 and 24 hours, but the pain and wound management scores were superior for the groups treated with carprofen. Buprenorphine also has been compared to local analgesics (e.g., bupivacaine) (see later discussion).

The partial receptor effects of buprenorphine have proved therapeutically beneficial in the detoxification and maintenance treatment of heroin and methadone addicts. The potency of buprenorphine complicates kinetic studies because the low concentrations associated with analgesia are difficult to detect and thus difficult to characterize. The role of buprenorphine as a reversal agent in dogs or cats apparently has not been studied.

Pentazocine

Pentazocine (2 to 3 mg/kg intramuscularly every 2 hours [dogs] or every 4 to 5 hours [cats]) induces analgesia that is one third as potent as that induced by morphine. It is not, however, associated with as severe cardiovascular and respiratory

depression. It is effective only as a visceral analgesic. Its utility is limited by its short duration of activity (30 minutes) and its tendency to cause undesirable behavior.¹⁴⁰

Nalbuphine

Nalbuphine is a nonscheduled opioid that was at one time used as an analgesic for small animals. It is an MOP receptor antagonist and KOP receptor agonist with minimal cardiovascular effects. Butorphanol and buprenorphine have largely replaced the use of this drug.

NARCOTIC ANTAGONISTS

Antagonists are used to provide quick reversal in the event of an overdose or serious respiratory depression or if ambulation is desirable after use of an opiate. Depending on the antagonist and the receptors with which it interacts, analgesia will be reversed along with the undesirable side effects. This is particularly true of pure antagonists. Like agonists, antagonists can be considered pure or partial in their effects. The use of butorphanol as an antagonist was previously discussed. Antagonists generally are not scheduled. The use of MOP opioid antagonists as behavior-modifying drugs is addressed in Chapter 26.

Naloxone

Naloxone (is a pure antagonist with 30 times the potency of nalorphine and 50 times the potency of butorphanol. It is approved for use in the dog but not the cat. As a pure antagonist (0.04 mg/kg intramuscularly, subcutaneously, intravenously every 2 hours or as needed [dogs, cats]; dilute dose in 10 mL of saline and administer to effect intravenously; give remaining dose subcutaneously), it is not regulated by the Controlled Substances Act. Its ability to block each of the opioid receptor types varies; indeed, receptor type can be based somewhat on response to naloxone. MOP receptors are the most sensitive to naloxone antagonism, sigma receptors the least. High doses of naloxone will reverse both DOP and KOP receptors. Reversal with naloxone also depends on the affinity for naloxone and the target receptor being greater than that of the drug to be reversed and on the receptor. Among the opioids, buprenorphine is characterized by a very high affinity for receptors that exceeds that of naloxone; thus buprenorphine is not reversible by naloxone.155

After successful reversal with naloxone, respiratory, sedative, and cardiovascular effects of opioids are reversed for 1 to 4 hours. Repeat administration may be indicated, depending on which opioid agonist was used. For example, the effects of oxymorphone may last longer than those of naloxone.⁸⁹ Reversal of undesirable opioid side effects with naloxone can be accomplished while maintaining opioid analgesia by mixing 0.1 to 0.25 mL/kg of 0.4 mg/mL naloxone with 10 mL saline. The diluted solution is then administered at 1 mL/minute until unwanted affects are eliminated.¹⁶⁷ Dosing may need to be repeated at 30-minute intervals.

KEY POINT 28-20 MOP receptors are most conducive to antagonism, and in dogs more so than in cats.

Naloxone should be administered slowly when given as an intravenous bolus because of possible cardiovascular stimulation that manifests as increased sympathetic nervous system activity.¹⁶⁸ The increased sympathetic nervous system activity presumably reflects the sudden reversal of analgesia and thus the perception of pain. In human beings this increased sympathetic nervous system activity may be demonstrated as tachycardia, hypertension, pulmonary edema,169,170 and cardiac dysrhythmias (including ventricular fibrillation). Naloxone induces hyperglycemia in cats, similar to that caused by morphine.¹⁷¹ Naloxone antagonizes the effects of nonopiate depressants and alters dopamine and GABA actions in the CNS.⁵⁶ It has also been studied for its ability to alter detrimental physiologic response in circulatory and septic shock; however, this therapeutic use, which was once considered a benefit, appears to provide no decrease in mortality rates and may cause detrimental effects. Diltiazem may impair the pharmacologic actions of naloxone (statement in abstracts of drug interactions with buprenorphine). Naloxone is not approved as a reversal agent in cats, and cats do not appear to react predictably to reversal with naloxone. Recovery and survival were not improved in kittens in which opioids were reversed.¹⁷²

Nalorphine

Nalorphine is a partial agonist and as such is a class III drug. Sedation and analgesia are maintained, and CNS (including respiratory) depression is reduced.

Nalbuphine

Nalbuphine (Nubain) (1 mL of 20 mg/mL solution to 9 mL saline, as with naloxone) is discussed as a mixed agonist– antagonist. Like butorphanol and buprenorphine, nalbuphine has been used as a partial antagonist to induce reversal of CNS depression but not as an analgesic.

Naltrexone

Naltrexone is an orally bioavailable pure antagonist that has been used to treat lick granulomas in dogs (see Chapter 26).

THERAPEUTIC USE OF OPIOID ANALGESICS

Opioids are used in veterinary medicine to control pain; as adjuvant anesthesia, emetics (apomorphine), antitussives, and antidiarrheals; and for chemical restraint. In 1954 the optimum dose of opioids as defined in human medicine was described as "that which provided the desired therapeutic effects with a minimum of undesirable side effects".¹⁷³ Yet caution was encouraged when opioids were used to control pain because of their unpleasant, dangerous side effects and the risk of addiction. Hence a 4- to 6-hour dosing interval has largely been followed, even though subsequent studies in humans have shown this approach to be largely ineffective. For human patients suffering from pain, a sophisticated method of opioid self-administration (patient-controlled analgesia [PCA]) is available; interesting observations have been generated from users of PCA regarding the effectiveness of opioids to control pain; many of these observations can be applied to the control of pain in animals.^{173,174}

In patients using PCA, the method preferred by patients, the dose varies eightfold to tenfold among those within a given age group. Additionally, the analgesic needs of any patient are rarely constant; rather, temporary increases in the dosage of opioids are necessary for "incident" pain such as that caused by ambulation and wound dressing. As expected, the dose declines each day after the surgery. The use of visual analogs reduces the risk of underdosing. The sedative effects of the opioid that occur at high doses appear to prevent the risk of self-overdose. Excessive sedation is an earlier and better indicator of respiratory depression; reduced respiratory rate is a late and unreliable indicator of overdosage. Older patients require less drug than younger patients. Indeed, age is a better predictor of the initial dose than is body weight, although this likely reflects similarities in weight among people, a characteristic that would be more variable in animals. Opioid addiction occurs very rarely when these drugs are used to control postoperative pain.173

Comparisons of opioids have been based on potency, with morphine generally serving as the prototypic drug for comparison. Interestingly, the thermal threshold for a variety of opioids in cats approximates 50 ng/mL.135 Factors determining potency include lipid solubility (and movement into and out of the CNS), affinity for receptor sites, and other factors. As such, fentanyl and its congeners and buprenorphine are among the most potent drugs and thus are dosed in µg/mL as opposed to mg/mL. In contrast to potency, efficacy is affected by relationship to receptors and pharmacokinetics that describe absorption, distribution (including rate and extent), and elimination. Therefore elimination half-life will play a role in the selection of the drug. Generally, lipophilic drugs move rapidly into the CNS, but duration is short because of rapid movement from the CNS.¹⁷³ In human patients the plasma elimination of the opioids varies from twofold to fourfold. Uptake and elimination from the CNS also may vary. Thus differences among patients should be anticipated, underscoring the importance of a visual pain-scoring system when evaluating patient need for opioid dosing.

Pain is generally best controlled with sufficient fixed doses at short intervals (generally 2 to 4 hours).^{23,29} Intramuscular doses will usually prolong the duration of analgesia. However, a transdermal patch or CRI can be used to provide prolonged analgesia without peak and trough effects of marked fluctuation in the plasma drug concentration. Epidural administration achieves analgesia at doses that are a fraction of parenteral doses.

Indications of opioid analgesics include but are not limited to trauma, postoperative pain, and thermal injuries. Postoperative analgesia is best achieved if the drug is administered before anesthetic recovery; preanesthetic administration may be indicated if postoperative analgesia is anticipated. Control of chronic pain with opioids may be difficult in part because tolerance and physical dependence may complicate therapy. Although long-term opioid therapy may be very effective, alternative therapies such as local nerve blocks, acupuncture, and behavioral modification also are implemented for human patients. Other drugs that might be used include antidepressants and NSAIDs. NSAIDs should also be considered in combination with opioids, particularly for orthopedic pain associated with cancer. For example, butorphanol and acetaminophen appear to act synergistically for control of pain.¹³⁶ Constipation should be anticipated with chronic use of opioids, and mild laxatives or stool softeners may be necessary.

Rotation of opioids remains a therapeutic option for control of pain in humans.¹⁷⁵ Drugs most commonly used are morphine, fentanyl, 1-methadone, and buprenorphine. The most common indications for change included insufficient control of pain (most common at 43%) and intolerable side effects or both. Change is successful in controlling pain in 65% of patients for which initial opioid choice failed. Intolerable side effects tend to reflect individual differences in response rather than dose dependency. Unpredictable and incomplete cross-tolerance among the drugs requires careful titration whenever one opioid replaces another.¹⁷⁵

OTHER CENTRALLY ACTING DRUGS

Tramadol

Structure Activity Relationship

Tramadol (Ultram) is a synthetic analog of codeine currently marketed as a racemic (1:1) mixture of \pm enantiomers. Tramadol appears to have multiple mechanisms of analgesia, with interaction among the pathways perhaps contributing to its efficacy. Opioid analgesia reflects agonistic interaction with MOP receptors; additionally, tramadol enhances spinal pain inhibitory pathways through inhibition of neuronal reuptake of serotonin (5-HT) and noradrenaline (NA) and release of 5-HT. As such, tramadol might be indicated for a broad array of conditions associated with pain, including chronic pain: Studies suggest that the analgesia associated with 5-HT_{1A} receptor agonists increases with chronic or repeat administration.⁴⁸

KEY POINT 28-21 Tramadol has multiple mechanism of analgesic efficacy. However, its metabolite may provide most of the efficacy, contributing to variability in response among animals.

Both tramadol stereoisomers are associated with analgesia, although receptor interactions appear to differ between the isomers. Tramadol is de-ethylated by CYP2D6 to an active metabolite, O-desmethyltramadol (ODT, M1). Opioid MOP receptors are bound by both tramadol (low affinity) and ODT (higher affinity). Studies in CYP2D6 deficient or inhibited states suggest that the majority of analgesic activity (at different receptor types) reflects ODT. In animal models ODT is 200 times as potent as tramadol in MOP-opioid binding and up to 6 times more potent as an analgesic (sponsor information). However, the potency of ODT is still 6000 times less than that of morphine. Differences in enantiomer and receptor interactions with opioid and nonopioid drugs have been described for both tramadol and ODT. (+)-Tramadol and ODT interact with opiate (MOP, KOP, and DOP) receptors, alpha (2) receptors, and (tramadol) serotonin reuptake and receptors, whereas (-)-tramadol and ODT interact with norepinephrine uptake and alpha (2) receptors.¹⁷⁶ Although ODT may be responsible for the majority of analgesic activity, tramadol appears to act synergistically with ODT, which may explain its apparent efficacy in dogs despite the apparently small contribution of ODT to tramadol metabolism.¹⁷⁶

Minimum effective plasma concentrations for tramadol and ODT are quite variable, ranging from 298 (\pm 171) to 590 (\pm 410) for tramadol and 39.6 (\pm 29.5) to 84 (\pm 34 ng/mL) for ODT in postoperative human patients.¹⁷⁶ The efficacy of tramadol as an analgesic is dose dependent, with efficacy described as being between that of codeine and morphine and similar to that of meperidine (pethidine), or about 10% to 20% of that of morphine.

Disposition

The volume of distribution of tramadol in humans (and dogs; discussed later) is large, and in rat models the drug crosses the blood-brain barrier. Hepatic metabolism of tramadol produces a number of metabolites. As noted, hepatic demethylation of tramadol by CYP2D6 (an enzyme characterized by polymorphism in humans) yields ODT (M1), which also exists as a racemic mixture. Tramadol also is metabolized by CYP3A4 and CYP2B6, with parent drug and metabolites excreted renally.

The disposition of tramadol and its active metabolite ODT have been studied in normal Beagles;¹⁷⁶ ODT was studied after both intravenous and oral administration of tramadol or ODT (1 mg/kg IV) (see Table 28-4). The proportion of tramadol metabolized to ODT in dogs is approximately 15% after intravenous administration. After an oral dose of 11 mg/kg, plasma C_{max} (ng/mL) of the parent compound is 1403 ± 695 occurring at 1.04 ± 0.51 hours. Oral bioavailability of tramadol is of $65 \pm 38\%$. Elimination half-life of tramadol is approximately 2 hours (1.8 ± 1.2) . The volume of distribution of tramadol appears to be larger than that of ODT. However, clearance also is faster for the parent compound compared with that for the metabolite, resulting in an elimination or disappearance half-life that is similar for both. Although the volume of distribution of tramadol is similar in humans compared with dogs, the elimination half-life of both tramadol and ODT is shorter in dogs compared with humans (approximately 6 and 7 hours, respectively for humans), suggesting that a more frequent dosing interval is indicated for tramadol in dogs. Simulated oral dosing regimens based on kinetics determined in the dog indicate that 5 mg/kg every 6 hours or 2.5 mg/kg every 4 hours should yield tramadol and M1 plasma concentrations associated with analgesia in humans. After intravenous administration of ODT (1.1 mg/kg), nausea and sedation occurred in all dogs (n=3), probably reflecting the MOP 1 agonistic properties. However, even though the area under the curve for ODT after intravenous administration of 1.1 mg/kg approximated that achieved after tramadol at 11 mg/kg, no side effects to tramadol were reported.

The disposition of tramadol and ODT after either intravenous (2 mg/kg) or oral (5 mg/kg) administration of tramadol also has been described in cats (n=6 see Table 28-4).¹⁷⁷ The area

under the curve of active metabolites is equal to or surpasses that of the area under the curve of the parent compound compared with dogs, for which it reaches about 30% of the parent compound in dogs (see Table 28-4). The elimination half-life of both parent and ODT is approximately twofold higher in cats. Cats tolerated tramadol by either route, although they exhibited euphoria for several hours. A 5 mg/kg oral dose achieves for tramadol and well exceeds for ODT the minimum effective analgesic concentrations suggested in humans. It is not clear if a similar level of analgesia would be expected in cats, but based on the higher concentrations of ODT in cats, a dose of 2 mg/kg twice daily is a reasonable starting dose.

Adverse Events and Drug Interactions

Side effects of tramadol appear to be unusual and generally reflect either overzealous use or overdosage. The risk of overdosage is increased in both renal and hepatic disease owing to prolonged elimination of both parent and metabolite. Cirrhosis is associated with a threefold to fourfold increase in elimination time in humans (sponsor information); the impact in the dog—in which the half-life is shorter—is not known. Dosage adjustment is recommended if hepatic or renal function is significantly impaired; for dogs prolongation of the interval may be more appropriate than reduction of the dose. Gender and age differences do not appear to play a major role in overdosing. Overdosage in humans is associated with significant neurologic clinical signs, including seizures, coma, and respiratory depression. Internet resources addressing safety of tramadol for human use indicate that seizures generally reflect overzealous use of tramadol, are of short duration, and are easily treated. Inappropriate (overzealous) administration of naloxone (an appropriate antidote to toxicity) may increase the risk of seizures. CNS side effects may emerge when tramadol is combined with other drugs or compounds that increase serotonin (e.g., behavior modifying drugs, s-adenosyl methionine [SAMe] or silymarin; see also Chapter 26).^{177a} Cardiovascular signs, even with overdosage, tend to be limited to mild tachycardia and hypertension. Respiratory depression is unusual, although the risk may be increased with renal disease, with retention of ODT implicated as a cause in review references. Gastrointestinal motility disturbances typical of opioids, such as postoperative ileus and constipation (including that associated with chronic use), generally are not associated with tramadol. The incidence of nausea and vomiting appears to be similar to that of opioids in humans. However, vomiting did not occur in Beagles (n = 6) receiving tramadol intravenously, whereas it did in those treated with ODT;¹⁷⁶ ODT may have a greater presence in humans compared with dogs, thus explaining the potential lack of this side effect in dogs.

Despite its widespread use, clinical trials demonstrating efficacy of tramadol as an analgesic are lacking in dogs and cats. Steagall and coworkers¹⁷⁸ studied the antinociceptive effects of tramadol (1 mg/kg subcutaneously) with or without acepromazine (0.1 mg/kg) in cats (n=8) subjected to thermal stimulation. Animals had only a limited response to tramadol, although the effect was increased when tramadol was combined with acepromazine.

N-methyl-p-aspartate Agonists

Ketamine

Ketamine is a noncompetitive antagonist of NMDA receptors in the spinal cord and consequently may help prevent or reduce neuropathic pains such as hyperalgesia or wind-up pain. Norketamine is an active metabolite that also binds to NMDA receptors.¹⁷⁹ Three "levels" of ketamine use can be discriminated in dogs or cats: a high dose associated with anesthetic effects, a low dose that targets analgesia and prevention of wind-up pain (hyperalgesia), and a subanalgesic dose that, when combined with other analgesics, provides analgesic dose-sparing effects. Ketamine combined with opioids appear to provide superior analgesia compared with either drug alone.¹⁸⁰ Ketamine and other NMDA-receptor antagonists may impart a neuroprotective effect after reperfusion of ischemic tissues. The local anesthetic effects of ketamine are described later.

After intravenous ketamine (15 mg/kg) administration in dogs,¹⁸¹ the volume of distribution of the central and peripheral compartments were 0.52 and 1.95 L/kg, respectively; clearance was 32 mL/min/kg. Elimination half-life was 61 minutes. The drug was 53% protein bound. Ketamine was converted to ketamine I (62%) and II (11%). The N-demethylketamine metabolites were measured and determined not to accumulate sufficiently to interfere with anesthesia.

A number of studies have examined the efficacy of ketamine as an analgesic when included in combination therapy. The targeted minimum anesthetic concentration is 3 μ g/mL. The addition of ketamine or magnesium enhanced tramadol analgesia in humans undergoing major abdominal surgery.¹⁸² Subanesthetic doses of ketamine were useful in controlling complex regional pain syndrome in humans. Complete resolution of pain occurred in 76% of 33 patients; partial pain relief occurred in another 18%. Side effects included a feeling of inebriation, hallucinations, and light-headedness.¹⁸³ The analgesic benefits of ketamine have been demonstrated in dogs. Dogs presenting for elective forelimb amputation associated with neoplasia and receiving fentanyl (2 µg/kg intravenous bolus followed by 2 µg/kg/hr intravenously) and ketamine by intravenous infusion (0.5 mg/kg before surgery and 2 µg/kg/hr at 12 and 18 hours postoperatively) had lower pain scores and more rapid return to activity postoperatively compared with dogs receiving fentanyl and a saline infusion.¹⁸⁰ Administration of a subanesthetic dose of ketamine (2.5 mg/kg intramuscularly) preoperatively or postoperatively delayed the onset of postoperative wound hyperalgesia in dogs undergoing OHE compared with dogs receiving no ketamine.¹⁸⁴ The use of subanesthetic doses offers the advantage of minimal side effects. The same is true when administered as a CRI (an initial loading dose of 0.25 to 0.5 mg/kg of ketamine, followed by an infusion of 10 mg/kg/min for dogs). Because ketamine can be given by essentially any route, including oral administration,¹⁸⁵ consideration might be given to its oral use in the control of neuropathic pain. A variety of dosing regimens are described for ketamine when used in combination with other analgesics such as lidocaine, morphine, and fentanyl.

KEY POINT 28-22 Combination analgesia might reasonably include a drug that targets N-methyl-D-aspartate receptors.

Amantadine

According to its package insert, amantadine is an antiviral drug with an unknown mechanism of antiviral replication action. It is approved to treat influenza A virus, but it also is useful for treatment of Parkinson's disease in humans and drug-induced extrapyramidal effects. Its mechanism of action in Parkinson's disease is not known, but proposed mechanisms included increased extracellular concentrations of dopamine (increased release or decreased uptake) at presynaptic neurons, direct simulation of dopamine receptors, or increased sensitivity of the receptors. Additionally, at concentrations considered to be in the low range, amantadine inhibits NMDA-receptor-mediated stimulation of acetylcholine release (rat striatum; probably at the MK-801 site). Although a dose of 31.5 mg/kg in dogs (equivalent to an approximate human dose of 15.8 mg/kg based on body surface area conversions) is not associated with anticholinergic actions, it nonetheless does cause anticholinergic-like side effects, including dry mouth, urinary retention, and constipation.

The drug is well absorbed in humans, with peak concentrations of about 0.22 mg/mL occurring at 3 hours after an oral dose of 100 mg (about 1.4 mg/kg). In humans saturation kinetics occur at 200 mg; after 15 days at this dose, C_{max} doubled in healthy human patients. Volume of distribution is large and variable in humans (3 to 8 L/kg), indicating tissue binding. The acetylated metabolite accounts for up to 80% of a dose in about 40% of humans, with the metabolite not occurring in the remainder; only 5% to 15% of this metabolite occurs in the urine. It is not known if this metabolite is active or toxic. Because the dog is deficient in metabolic reactions involving acetylation, extrapolation of human kinetics to dogs is questionable. The drug is cleared as either the parent compound or its metabolite in the urine. The half-life of the drug in adult humans is approximately 15 hours but 29 hours in elderly patients because of smaller clearance; the reason for the differences in clearance is not known. Renal clearance was also higher in human male patients compared with that in human female patients. Renal disease results in at least a proportional decrease in amantadine clearance. Acidification of urine pH is likely to increase renal clearance of amantidine.

Amantadine has been associated with lethal acute intoxication in humans, with the lowest reported acute lethal dose being 1 gram (approximately 14 mg/kg) in humans. However, anticholinergic effects do not occur in dogs receiving 31.5 mg/kg (package insert). Acute toxicity may be attributable to the anticholinergic effects of amantadine. Drug overdose has resulted in cardiovascular (arrhythmias, including tachycardia, and hypertension), respiratory, renal, or CNS (behavioral changes, seizures) toxicity. A less common but life-threatening manifestation is neuroleptic malignant syndrome, which is characterized by fever or hyperthermia, muscle rigidity, involuntary movements, and altered consciousness or other mental status changes. Other disturbances, such as autonomic dysfunction, tachycardia, tachypnea, hypertension, or hypotension may occur; clinical pathology changes include increases in serum creatine phosphokinase activity, leukocytosis, myoglobinuria, and increased serum myoglobin. Treatment of acute intoxication has included dopamine agonists (e.g., bromocriptine) and muscle relaxants (e.g., dantrolene), but their efficacy has not been scientifically demonstrated. Doses should be adjusted for both liver and renal disease. The drug should not be used in conjunction with other anticholinergics, and extra precautions should be taken when combining with any other CNS-active drugs. Anecdotally, amantadine has been used safely in both dogs and cats as part of combined analgesic therapy.

Using a randomized, placebo controlled, blinded design, Lascelles and coworkers¹⁸⁶ prospectively studied the efficacy of amantadine (3 to 5 mg/kg once daily) when combined with meloxicam (0.2 mg/kg followed by 0.1 mg/kg per day orally) in clinical canine cases (n=31) of pelvic limb lameness associated with osteoarthritis. Animals had not sufficiently responded to NSAIDs alone. Amantadine resulted in more activity compared with NSAIDs alone.

Dextromethorphan

Dextromethorphan is a semisynthetic derivative of opium (the d-isomer of the codeine analog of methorphan) that lacks narcotic, analgesic, or addictive properties. Sedation is unusual after its use. Its antitussive mechanism is not certain. Its onset of action is rapid, being fully effective within 30 minutes after oral administration. Dextromethorphan, which is sold in overthe-counter cough preparations, also is an NMDA-receptor antagonist. It has increased the analgesic effects of opiates and NSAIDs.14 The elimination half-life of dextromethorphan in dogs is approximately 2 hours.¹⁸⁷ After intravenous administration of 2.2 mg/kg, an approximate extrapolated C_{max} (Co) of 800 \pm 400 and 360 \pm 150 occurred before and after the distributive phase, respectively. This compares to a C_{max} of 89.8 ± 47.2 at approximately 1 hour after oral administration, yielding an oral bioavailability of 11% or less. Dextromethorphan is metabolized by CYP2D6 to dextrorphan, which is characterized by pharmacodynamics that are similar to, albeit less potent (25% to 30%) than, that of dextromethorphan. Dextrorphan is a metabolite produced in dogs, although it was detected only as the glucuronide metabolite by KuKanich and Papich.¹⁸⁷ After intravenous administration of 2.2 mg/kg in dogs, adverse reactions to dextrorphan were consistent with NMDA antagonism, ranging from lateral recumbency to nonresponsiveness, including ataxia, sedation, muscle rigidity, urination, and ptyalism. Changes in cardiovascular indices did not occur. Clinical signs resolved within 90 minutes, at concentrations of approximately 100 ng/mL. Oral administration was associated with vomiting in one dog. The role of dextromethorphan as an NMDA antagonist in either dogs or cats is not clear but is worth consideration. Dodman and coworkers¹⁸⁸ reported the potential usefulness of dextromethorphan (2 mg/kg orally) for 2 weeks in dogs (n=12) with chronic allergic dermatitis using a double-blinded crossover placebo-controlled design. The percentage of time abnormal behaviors (self-licking, chewing and biting) were observed and the overall pruritis score were significant lower than that in the placebo group; global assessment improved in 11 of 12 dogs.

Other Tranquilizers and Sedatives

Tranquilizers generally are not analgesic, but they alter animals' response to pain. They are most commonly used in combination with opioid analgesics, with which they may act. Some also may provide muscle relaxation. The common tranquilizers and sedatives are the phenothiazine derivatives (which may also provide antiemetic effects), such as chlorpromazine, promazine, and acetylpromazine, and the benzodiazepine derivatives, such as diazepam and midazolam. Phenothiazines (see Chapter 26) should be used cautiously for hypotensive patients or for patients with cardiovascular disease. The benzodiazepines (see Chapter 27) are particularly useful for geriatric and debilitated animals. Agents from either group can be combined with opioid analgesics.

α₂-Agonists

Canine alpha_{2a} receptors in the brain appear to be closely related to those in humans.¹⁸⁹ Alpha₂ agonists such as xylazine and medetomidine warrant special consideration because they are potent analgesics at doses that do not cause sedation. (see Chapter 24). Xylazine's duration of analgesia is short (0.5 hours), and it has profound cardiovascular effects. Its CNSdepressant effects, however, can be reversed with yohimbine or tolazoline. In addition, xylazine can be used in combination with opioid agonist-antagonists such as butorphanol and as an epidural just before surgery or surgical recovery. Newer α_2 agonists such as medetomidine (0.75 mg/m² intravenously or 1 mg/m² intramuscularly [dogs]) are associated with fewer cardiovascular effects and longer duration of activity than xylazine. Medetomidine provides both sedation and analgesia and is labeled for use in dogs for clinical procedures that require short-term chemical restraint. The effects can be reversed with atipamezole, an α_2 -antagonist, and as such, the drug may be useful for incident pain, such as bandage change. Like xylazine, medetomidine can cause vomiting and cardiovascular suppression. Medetomidine has proved to be an equal or better analgesic than buprenorphine for control of pain in dogs. The safety of the two drugs has not, however, been compared.¹⁹⁰

In dogs the DEX enantiomer of medetomidine appears to be largely responsible for analgesia, sedation, and cardiovascular side effects of medetomidine.¹⁹¹ Although the LEV enantiomer appears to be pharmacologically inactive, it may be involved in drug interactions. The sedative or analgesic (based on withdrawal) effects of medetomidine appear to be characterized by a ceiling effect.¹⁹¹ Plasma concentrations associated with analgesia vary, ranging from 1 to 5 ng/mL, although 9.5 ng/mL was not associated with pain-induced withdrawal in dogs.¹⁹¹ The combination of epidural medetomidine and morphine offered only minimal analgesic benefits compared with epidural morphine alone.⁸⁶

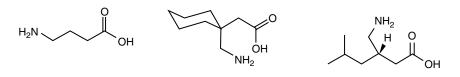

ANTICONVULSANTS AND BEHAVIOR-MODIFYING DRUGS

Anticonvulsants (see Chapter 27) such as carbamazepine, phenytoin, valproic acid, and clonazepam, and more recently, gabapentin and pregabalin have been used by humans to control selected neuralgias.⁵ TCAs (see Chapter 26) have also been used by humans for the treatment of chronic pain. Efficacy of TCAs, anticonvulsants, and antiarrhyhmics requires several weeks and generally requires dose titration.⁹ Amitriptyline and imipramine are considered first-line drugs, particularly for pain that is continuous and aching. Their use for pain control has not been documented in animals, although they have been used successfully for behavioral problems. The sedative and anticholinergic side effects of these drugs may be undesirable. Not all TCAs—and particularly the newer products appear to have analgesic properties. Neuropathic, myofascial, and arthritic pains appear to be most conducive to control. These drugs are contraindicated for patients suffering from urinary retention, heart block, or narrow-angle glaucoma.

Gabapentin and Pregabalin

Both gabapentin and pregablin were initially developed as human antiepileptic drugs. Pregabalin was approved for use for treatment of neuropathic pain in humans, most recently that associated with fibromyalgia. Both are structurally related to GABA; gabapentin is a molecule of GABA covalently bound to a lipophilic cyclohexane ring (Figure 28-5).¹⁹² Although their mechanism of action was intended to be a GABA agonist, pharmacologically, they do not bind to any portion of the GABA receptor, nor do they appear to interfere with degradation or other aspects of GABA receptor activity. Rather, their mechanism of analgesic action appears to occur through binding to $Ca_v\alpha_{2d}$ proteins on voltage-gated calcium channels.¹⁹³ Decreased calcium influx prevents release of neurotransmitters otherwise stimulated by a variety of chemical signals.

A Cochrane review of the ability of gabapentin to control pain covered 14 studies in human medicine, one of which was for management of acute pain.¹⁹⁴ The remaining causes of pain included herpes, diabetic neuropathy, cancer, phantom limb, and spinal cord injury. Gabapentin offered no benefit for control of acute pain. However, for chronic pain 42% of participants improved compared with 19% of patients receiving placebo. Side effects necessitating withdrawal were not considered significant.

Gamma-amino-butyric acid Gabapentin Pregabalin **Figure 28-5** The structure of anticonvulsant-analgesics and gamma-aminobutyric acid.

analgesic effects by itself (concentrations approximating 3.5 mcg/mL) compared to placebo, but morphine analgesia was markedly enhanced (at gabapentin concentrations of about 5.5 mcg/ml). The disposition of gabapentin was altered by morphine, with an increased in AUC by more than 40%. The effect was posulated to reflect increased oral absorption.^{194a} Dosing for control of pain is instituted at approximately 1.25 mg/kg once to three times daily and gradually increased every 1 to 3 days to a dose of approximately 15 to 50 mg/kg total daily dose. The gradual increase is intended to allow accommodation to the drug. Doses were reduced in the presence of renal disease.

Wagner and coworkers194b were not able to detect a significant difference between placebo or gabapentin 10 mg/kg followed by 5 mg/kg bid PO for 3 days prior to forelimb amputation in dogs (n = 30, 15 each group). Other analyses were also used, which along with a small sample size, limited detection of a significant effect.

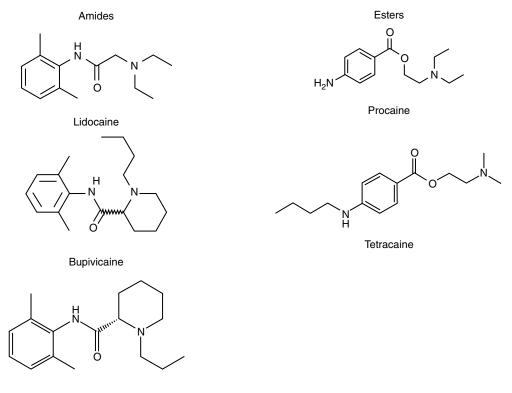

KEY POINT 28-23 Increasingly, gabapentin and pregabalin are proving to be effective alternatives for long-term neuropathic pain control.

LOCAL ANESTHETICS

Local anesthetics act by binding reversibly to a target receptor located in the pore of voltage-gated sodium channels in nerves. Ion movement is subsequently blocked, preventing conduction of the action potential in any nerve fiber. In general, sensation of pain disappears first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function. In addition to effects in the periphery, selective central blockade of afferent evoked activity in the spinal cord also has been suggested as a mechanism of local anesthetics. Further, selected drugs (e.g., lidocaine) may interact with (activate) the endogenous opioid system (as reviewed by Joad and coworkers).⁹ Local anesthetics also bind to other membrane proteins, including potassium, but generally at higher concentrations.

Local anesthetic effects were recognized for cocaine, an ester of benzoic acid. Safety concerns led to the development of synthetic alternative drugs. Local anesthetics generally consist of a lipid-soluble, aromatic component; an amide (e.g., lidocaine) or ester (e.g., procaine) link; and a water-soluble amine (usually tertiary) component (Figure 28-6).¹⁹⁵ Whereas esters tend to be rapidly metabolized by esterases, amides are more resistant to clearance and generally are characterized by longer duration of effect.

The potency, onset of action, and duration of local anesthetic actions depend on lipid solubility, pK_a , and protein binding, respectively. Highly lipid-soluble molecules are more potent and have a longer duration of effect because of their ability to penetrate cell membranes, thus accessing the receptor while avoiding clearance. However, lipophilic drugs also tend to be associated with more side effects. Larger drugs tend to have a longer duration of effect because they are less able to leave the site of action, an important characteristic for rapidly firing cells. Bupivacaine is more lipid soluble and 10 times

Ropivacaine **Figure 28-6** The structure of selected amide *(left)* and ester *(right)* local or topical anesthetics.

more potent than lidocaine. Likewise, tetracaine is more lipid soluble and 40 times more potent than procaine (an aromatic ring is added).

KEY POINT 28-24 The analgesic effect of local anesthetics vary with lipid solubility, pKa, and protein binding.

Drug pK_a also influences drug movement by determining the amount of un-ionized and thus diffusible drug. Local anesthetics are weak bases with pK_a s of 7.7 to 9. In pharmaceutical preparations the pH of the solution tends to be acidic; thus most of the drugs are present in ionized form. Although penetration of tissues is decreased, once penetrated, it is the protonated (cationic) form that preferentially interacts with the receptor. Thus the higher the pK_a , the more drug present in ionized form and the longer the onset of action.

Local anesthetics that are more highly protein bound tend to be attracted to receptors and remain within sodium channels longer. Thus bupivacaine, which is highly protein bound, has a longer duration of activity than procaine. Duration of activity is also affected by the effect of the drugs on local vasculature or the presence of vasoconstrictors (e.g., epinephrine; discussed later).

Local anesthetics should contact the tissue for at least 20 minutes to be effective. Methods include splash blocks or direct infiltration at the surgical site to enhance intraoperative or postoperative analgesia (orthopedic procedures, lateral ear resections or total ear canal ablation, dew claw removal, onychectomy, and ear trims), infiltration of nerves before transection during amputation, regional nerve blocks (e.g., intercostal); intraarticular filtration (analgesic effect may last up to 24 hours), intrapleural infiltration, and epidurals. Lidocaine and bupivacaine are the agents most commonly used (nonophthalmically) in dogs and cats. Lidocaine is characterized by a rapid (5- to 10-minute) onset but a short (1to 2-hour) duration; the pharmacologic (analgesic) action appears longer than its half-life. The lidocaine dose should not exceed 4 to 7 mg/kg. Side effects at 11 mg/kg include restlessness, muscle tremors, cardiac depression, and seizures.

All local anesthetics cause vasodilation, which decreases the duration of action and prolongs the onset of action. Lidocaine is available as a commercial preparation combined with epinephrine designed to prolong anesthetic effects. In humans, after intraperitoneal administration, the time to maximum absorption of lidocaine varies in proportion to the amount of epinephrine (reviewed by Wilson and coworkers).¹⁹⁶ Maximum concentrations occur in approximately 30 minutes when epinephrine is not included. When epinephrine is included, the time ranges from 45 to 60 minutes when epinephrine is added at 1:320,000 (epinephrine) to up to 3 hours when present at 1:500,000. Maximum lidocaine concentrations likewise vary with both the dose of lidocaine and epinephrine; in humans at 400 mg (approximately 3.8 mg/kg), C_{max} ranged from 2.7 to 4.3µg/mL with no epinephrine but approximated only 1.9 µg/mL at 1:800,000 and 2.3 µg/mL at 1:320,000.

Lidocaine (2% lidocaine, with 1:200,000 epinephrine commercial preparation, diluted to a volume of 0.8 mL/kg) has been studied after local (incisional: 2 mg/kg, final epinephrine 1:400,000) and intraperitoneal (8 mg/kg; final epinephrine 1:200,000) administration in normal dogs undergoing ovariohysterectomy.^{196,197} Administration occurred during abdominal closure. The combined administration yielded peak concentrations of lidocaine (n-acetyl metabolite not studied) of 1.45 \pm 0.36 µg/mL at approximately 40 minutes after administration; disappearance half-life was 1.17 \pm 0.11 hour. No clinical signs of toxicity occurred.

The addition of sodium bicarbonate with lidocaine (9:1) has been recommended to minimize pain on injection (one part sodium bicarbonate [1 mEq/L] to nine parts 1% to 2% lidocaine). Bupivacaine likewise can be diluted at a rate of 0.5 mL bupivacaine (0.5%) to 0.025 mL bicarbonate. Alkalinization may affect local anesthetic effect, although impact is likely to vary with the drug. Local analgesia may also potentially be enhanced, perhaps because of either an increase in the unionized local anesthetic or accelerated conversion of local anesthetic from un-ionized to ionized form, with intracellular acidification caused by bicarbonate.¹⁹⁸ However, the risk of precipitation of anesthetic also should be considered and products modified with alkalinizers carefully monitored for changes in anticipated efficacy.

Lidocaine can be applied topically for local effects. A cream approved for use in humans containing 2.5% of lidocaine and prilocaine (eutectic mixture of local anesthetics [EMLA] cream) was found to be effective in awake cats undergoing percutaneous jugular catheterization.¹⁹⁹ The cream (1 mL at 1 g/mL, yielding a 5 mg/kg dose of each anesthetic for a 5 kg cat) was applied to a 2×5 -cm region on the skin at the site of anticipated catheter placement and covered with an occlusive bandage for 1 hour. Six of ten cats were successfully intravenously catheterized without the addition of chemical restraint; struggling was attributed to fear rather than pain. Neither anesthetic was detectable in the plasma of any cat, and methemoglobinemia did not deviate from baseline. The disposition of lidocaine after administration of a liposomal gel (equivalent to 15 mg/kg lidocaine) was studied in cats (n = 6).²⁰⁰ Absorption was negligible in two cats. In the remaining four cats, peak concentrations reached approximately 150 ng/mL at a median time of 2 hours.

Lidocaine is available in a transdermal patch. Lidocaine is contained in a polymer matrix; the amount of drug moving into the system is proportional to the covered skin surface. Weil and coworkers²⁰¹ reviewed their use in dogs or cats. In contrast to fentanyl patches, lidocaine patches can be cut to size. Weiland and coworkers²⁰² described the pharmacokinetics of one 5% lidocaine patch applied to the lateral thorax of Beagles (n = 6). Dogs were either clipped or treated with a depilatory agent. Peak concentrations (ng/mL) of lidocaine were 63 ± 24 and 103 ± 34 respectively (well below the concentration recommended for antinociception, see later discussion), with or without the depilatory. The areas under the curve were 517 and 1128 ng/hr/mL, respectively. The time to maximum concentration was approximately 10 hours for both groups. Ko²⁰³ also reported the impact of two 5% lidocaine patches, each containing 700 mg of lidocaine, applied to the ventral abdominal area of dogs weighing between 18 to 23 kg. Concentrations (ng/mL) increased from 18.5 ± 29.4 at 12 hr to 72.8 ± 65.8 at 24 hrs. Concentrations remained at steady-state for another 24 hrs; at 48 hrs, concentrations declined, reaching to 21.4 ± 24.7 ng/mL by 60 hour and remained detectable (30 \pm 26 ng/mL) at 78 hour but were not detectable by 80 hour. The concentrations approximated 1/10th of that achieved when dogs are given 2 mg/kg IV (as reviewed by Weil).²⁰¹ Ko and coworkers²⁰⁴ also studied the impact of a 700-mg lidocaine patch applied to the lateral thorax of cats (n = 8). Cats were also given lidocaine intravenously at 2 mg/kg. The overall bioavailability of lidocaine in the patch was $6.3 \pm 2.7\%$, with 56% of the patch dose being systemically absorbed. Lidocaine was detectable within 3 hours of patch application and reached steady-state concentration was 103 ± 0.037 (which was approximately 10% of the peak concentration reached with intravenous administration). Peak concentrations occurred at 64 ± 4 hours. Plasma concentrations were still at steady state when the patch was removed at 72 hours.

Toxicity associated with cream preparations has been reported in humans but generally reflects inappropriate administration that facilitates increased rate or amount of absorption. Actions to be avoided include application to a larger-than-recommended surface area, longer contact time, increased body temperature, or application to surfaces not protected by an intact stratum corneum (diseased skin, mucosal membranes).

The use of lidocaine for prevention of reperfusion injury and thus a systemic inflammatory response associated with multiorgan dysfunction syndrome has been reviewed.²⁰⁵ Lidocaine has received considerable attention for its efficacy as a general analgesic when administered systemically. Concentrations of 0.620 to 5.7 µg/mL are recommended for antinociception.²⁰⁶ In human patients 5 mg/kg/hr was used effectively to control cancer pain associated either with the tumor itself or its treatment (e.g., surgery, radiation therapy). Interestingly, general sensation of pain and dysaesthetic, preanesthesia, and nightly exacerbations of pain were significantly decreased in the majority (70% for most symptoms) of patients studied (n=10) for up to 2 weeks.⁹ Unfortunately, the clinical trial was not controlled, and a placebo effect was not assessed. Systemic lidocaine has decreased halothane MAC at antiarrhythmic concentrations in dogs.²⁰⁷ Serum concentrations of 3 to 6 µg/mL have decreased halothane requirements in dogs by 10% to 28%,²⁰⁸ as reviewed by Wilson.¹⁹⁶ In another study²⁰⁹ lidocaine CRI (2 mg/kg intravenously followed by 50 µg/kg/ min as low dose and 200 µg/kg/min as high dose) significantly reduced, in a dose-dependent manner, the MAC of isoflurane in dogs (n=10). The MAC was reduced 19% at the low dose. Lidocaine and metabolite concentrations were (µg/mL) 1.5 µg/ mL (lidocaine), 0.11 (glycinexylidide), and 0.18 (monoethylglycinexylidide). For the high dose MAC was reduced 43% at concentrations of 1.5, 0.18, and 0.47 µg/mL for lidocaine and its metabolites, respectively. No significant cardiovascular effects were observed. Smith and coworkers²¹⁰ prospectively compared the efficacy of systemic lidocaine (1 mg/kg intravenously followed by 0.025 mg/kg/min CRI) to morphine (0.15 mg/kg intravenously followed by 0.1 mg/kg/hr CRI) or saline placebo for control of postoperative ocular pain. Morphine rescue was necessary in all placebo-treated dogs and in 50% of the dogs treated with lidocaine and morphine. The incidence of measures of ocular inflammation did not differ among groups.

Lidocaine pharmacokinetics pharmacodynamics were determined in cats after intravenous administration of 2 mg/ kg. Pharmacodynamics were then based on thermal antinociception.²⁰⁶ Lidocaine at 0.250 to 4.32 µg/mL did not affect the thermal threshold in cats. However, the authors noted that the power of the study was sufficient to detect a thermal difference of 3.75° C as opposed to other studies. Pypendop and Ilkiw²¹¹ also demonstrated that, when used to decrease isoflurane dose, lidocaine (dosed to achieve 3 to 11 µg/mL) was associated with unacceptable adverse cardiac effects in cats. The authors recommended that lidocaine not be used with the intent to lower isoflurane MAC. This may reflect, in part, marked changes in the disposition (particularly reduced clearance) of lidocaine associated with anesthesia compared with awake cats.²¹²

Bupivacaine can be a very effective analgesic. However, in contrast to lidocaine, bupivacaine needs approximately 20 minutes to take effect but provides 4 to 6 hours of analgesia. The bupivacaine dose should not exceed 2.2 mg/kg. Side effects typical of lidocaine occur at 4 mg/kg.¹¹⁵ Diazepam appears to enhance the cardiodepressant effects of bupivicaine.²¹³ When administered locally (around five intercostal nerves), it was equal to epidural morphine for control of pain associated with lateral thoracotomy in dogs.85 Another prospective study in dogs (n=26) undergoing intercostal thoracotomy compared buprenorphine (10 µg/kg intravenously every 6 hours) with bupivicaine (1.5 mg/kg of 0.5% intrapleurally, by slow injection through a pediatric feeding tube placed dorsally, every 4 hours). Dogs were treated for 24 hours, starting 10 minutes before tracheal extubation. Significant changes from preoperative values in pain scores and cardiovascular assessment occurred in the buprenorphine group but not the bupivicaine group.²¹⁴

KEY POINT 28-25 Bupivacaine requires approximately 20 minutes to become effective.

Cardiotoxicity of bupivacaine led to the development of ropivacaine, a nonracemic product consistent of the less toxic S isomer compared with the R isomer. Like bupivicaine, it is long acting, but it is less cardiotoxic. The incidence of arrhythmias and death is lower in animals given toxic doses of intravenous ropivacaine than those given bupivacaine.

A toxicity study in dogs demonstrated better safety for ropivacaine in dogs. Intravenous lidocaine (8 mg/kg/min), bupivacaine (2 mg/kg/min), and ropivacaine (2 mg/kg/min) were administered intravenously. Two of the lidocaine-treated dogs developed lethal hypotension and respiratory arrest. All bupivacaine-treated dogs developed ventricular arrhythmias, with death occurring in five of these, whereas only two of six (one death) dogs developed arrhythmias in the ropivacaine group.²¹⁵ The C_{max} of drugs in nonsurvivors were 469, 70 ± 14, and 72 µg/mL for lidocaine, bupivacaine, and ropivacaine, respectively.

The use of ketamine as an NMDA antagonist was previously discussed. However, ketamine has local anesthetic effects by blockade of Na+ and K+ channels, stabilizing cellular membranes and reducing nerve transmission, similar to that of other local anesthetics. The alkalinization of 5 mL of 1% ketamine solution with 0.5 mEq bicarbonate produced a more consistent and longer-lasting local analgesia (sesamoid block) in horses compared with 1% ketamine solution alone.²¹⁶ However, a greater amount of sodium bicarbonate was associated with precipitation.

MISCELLANEOUS AGENTS

Conotoxins

Conotoxins represent a new class of natural compounds produced by the marine mollusks of the Conus genus. Investigations regarding their therapeutic use in a variety of diseases, including control of pain, are under way. More than 500 species of Conus exist, each capable of producing 100 or more conotoxins (conopeptides); thus more than 50,000 pharmacologically active compounds may be investigated for potential therapeutic use. In their natural environment, conotoxins are used for prey capture (paralysis of fish), defense, and competitor deterrence.²¹⁷ The molecular targets of conopeptides are functionally diverse; some target G protein-coupled receptors, others neurotransmitter transporters; and others are characterized by enzymatic activity. Most of the currently described conopeptides are small, structured peptides that target either ligand-gated or voltage-gated ion channels. Targets identified thus far include Na+, K+, Ca²⁺ or nicotinic acetylcholine channels, serotonergic receptors, and norepinephrine transporters. Most conotoxin families target specific structures: for example, ω -conotoxins target Ca channels, whereas α -conotoxins target nicotinic receptors. Different conotoxins may target the same structure but generally at different sites (e.g., μ and δ conotoxins target different sites on sodium channels). In December of 2004, the Food and Drug Administration approved ziconotide (Prialt), a synthetic peptide that mimics a conotoxin produced by Conus magus. The venom is used by the sea snail to paralyze fish; its analgesic mechanism of action is not clear but appears to reflect blockade of N-type calcium channels. Use is currently limited to intrathecal administration and thus is largely indicted for relief of pain that does not respond to all other options. Currently, because of their ability to discriminate among molecularly similar ion channels, the conotoxins are also being studied for their potential to identify and characterize the role of sodium channels isoforms in diseases, including pain.²¹⁸

Others

Nicotine (e.g., that available in over the counter smokingcessation products) increasingly is being investigated for its ability to relieve pain. Its mechanism appears to target nicotinic acetylcholine receptors, and specifically heteropentameric ion channels activated by acetylcholine. Nicotine may act synergistically with opioids.²¹⁸ Nicotine poisoning as a result of tobacco ingestion has been reported in dogs. Clinical signs in one report were primarily CNS in origin but also include hypersalivation, vomiting, diarrhea, tachycardia, tachypnea, hypertension, and hyperthermia. Animals may present in total collapse, with dilated pupils, slow and shallow respirations, hypotension, tachycardia, and a weak and irregular pulse.²¹⁹

The analgesic effects of marijuana appear to reflect its interaction with cannabinoid (CB) receptors in the CNS, peripheral nervous system, or other tissues. Current efforts are focusing on methods whereby the psychoactive effects, reflecting interaction with CB₁ receptors, are avoided without minimizing interaction with CB₂ receptors (not present in the CNS) associated with acute, inflammatory, and neuropathic pain.²¹⁸

SPECIAL CONSIDERATIONS FOR CONTROL OF PAIN IN ANIMALS

Neuropathic Pain

The use of drugs for treatment of neuropathic pain are also addressed under preemptive analgesia. The most comprehensively studied class of drugs for treatment of neuropathic pain in humans are the TCAs, although anticonvulsants are probably most commonly used.²²⁰ These drugs interact with a number of transporters, receptors, and channels associated with pain. In addition to their impact on synaptic serotonin and norepinephrine, TCAs modulate both sodium and potassium channels and NMDA and ATP receptors. The efficacy of TCAs for treatment of neuropathic pain may reflect closing of sodium channels that inappropriately remain active in response to injury. However, drugs that increase serotonin or other neurotransmitters in the synapse also minimize neuropathic pain, suggesting that multiple mechanisms of action may be important.²¹⁸

Other classes of drugs used to treat neuropathic pain in humans include mexiletine, capsaicin, NMDA inhibitors, clonidine, tramadol, and lidocaine patches. Each has been used with variable success.²²⁰

Gabapentin appears to target neuropathic pain by binding calcium channels, specifically at the alpha₂ delta₁ subunit. As a result, neurotransmitter release appears to be altered.²¹⁸

Cancer Pain

The pathophysiology of cancer-induced bone pain (CIBP) has been reviewed and includes both inflammatory (nociceptive) and neuropathic pain.²²¹ Among the drugs used to control CIBP are the opioids, the mainstay of analgesic control; the NSAIDS, therapeutically appealing in part because of their recently recognized antitumor effects; and the bisphosphonates, which were originally used to treat hypercalcemia.²²¹ Bisphosphonates inhibit the recruitment and activation of osteoclasts, increase osteoprotegerin, induce apoptosis, inhibit cancer cell proliferation, and reduce cytokine production and metalloproteinase secretion. The analgesic effect is delayed several weeks to months.²²¹

Pregnant, Neonate, and Pediatric Animals

In her review, Matthews¹⁶⁷ indicates that opioids are the analgesic of choice in pregnant animals. However, care should be taken in that the fetal blood–brain barrier is permeable to these drugs (see previous discussion). Chronic use (beyond several weeks) is likely to have a negative impact on the fetus, causing lower birth weights and behavioral deficits. The latter may reflect decease nervous system plasticity as a result of opioid effects on neuronal development. In contrast, shortterm use is not considered to present a significant problem. Methadone appears to be safe in humans. Buprenorphine also should be safe, at least with single dosing, because the placenta serves as a depot site from which less than 10% of the drug is transferred to the fetus. In contrast, fentanyl rapidly crosses the placenta. An advantage to opioid use for cesarean section is its reversibility and general responsiveness of neonates to reversal. Repetitive dosing (e.g., 30 minutes) may be indicated if the status of the neonate indicates opioid depression. Animals should respond to sublingual administration. Ketamine also rapidly crosses the placenta. It may contribute to uterine contraction and potentially to discomfort of the mother. The risk of increased uterine tone, respiratory depression in the mother, and altered muscle tone in the fetus warrants careful consideration regarding ketamine use in the pregnant animal. Opioids also are preferred for analgesic control in the nursing mother. Some accumulation should be anticipated in the milk, particularly for the more lipid-soluble drugs. As weak bases, drugs with higher pKa levels may be accumulated to a higher degree. Nursing might be coordinated just before administration of doses. In humans butorphanal concentrations in milk approximated those in serum, whereas little hydromorphone was distributed to milk. Neonates might be observed for evidence of opioid-induced sedation.

NSAIDs should be avoided in pregnant animals for several reasons (see Chapter 29). Fetal defects may occur with administration in the first trimester of pregnancy. The impact of NSAIDs on the reproductive system may adversely affect the pregnancy itself by altering fetal circulation. If administered during labor, they may cause its cessation. Further, the impact of prostaglandin inhibition on the developing fetus (e.g., fetal kidneys) is being elucidated. Postoperatively, a single dose of NSAIDs is acceptable,¹⁶⁷ but unless such administration is demonstrated to offer advantages over opioids, alternative analgesics (e.g., opioids) should be considered in the nursing bitch or queen. Likewise, because of their diffuse effects in the reproductive system, NSAIDs are not recommended for breeding animals.

Analgesic therapy should not be avoided in pediatric patients for fear of adversities. Again, opioids are preferred, although lower doses should be anticipated, particularly in the first 5 weeks of life. Higher volumes of distribution may require higher doses; longer intervals should be anticipated because of both the larger volume of distribution and decreased clearance. Transdermal patches are generally not recommended because of the unpredictable disposition in pediatric patients. NSAIDs should not be used in animals younger than 3 to 6 months unless safety for that particular drug has been demonstrated (see Chapter 29). The package insert for firocoxib states that the drug is not tolerated in juvenile animals, and similar responses might be anticipated for other NSAIDs. Local anesthetics can be used in both neonatal and pediatric patients, although a lower dose is recommended in neonates because of the immaturity of the nervous system.¹⁶⁷ Buffering procedures might be used to reduce pain associated with injection. Topically applied gels might be considered as well.

Geriatric Patients

Because opioids are active in the CNS, the geriatric patient is predisposed to adverse reactions to opioid analgesics.^{38,222,223} Cardiac disease increases the risk of toxicity to opioids or any other CNS-active drug because of increased drug delivery to the brain. On the other hand, decreased receptor sensitivity may result in a reduced response to opioid analgesics. The mentation status of the geriatric animal may complicate interpretation of clinical response to opioids; CNS depression may be difficult to identify. The opioid analgesics decrease central response to increased PCO₂, which is already impaired in the geriatric patient. The opioid analgesics are eliminated from the body by hepatic clearance. Both hepatic blood flow and hepatic metabolism are decreased in geriatric patients. Thus changes in hepatic clearance of these drugs renders the geriatric patient more susceptible to toxicity. Increased response of human geriatric patients to opioid analgesics (who require 60% to 75% less drug than younger patients) has been attributed to changes in drug elimination. Use of opioids that cause minimal sedation (e.g., butorphanol, buprenorphine) should be considered. Alternatively, opioid analgesics that are reversible are indicated for geriatric patients. Buprenorphine essentially is not reversible, as are most other opioid analgesics.

Surgical Pain

Pain associated with surgery is acute, but if it is insufficiently controlled, it can lead to neuropathic pain. The use of preemptive analgesia has been reviewed (see earlier discussion).¹⁴ To effectively prevent neuropathic pain, effective analgesics should be administered as long as the cause of the pain remains. Surgical pain should be managed with a combination of local anesthetics, NSAIDs, opioids, and NMDA antagonists; routes should include local, systemic, and epidural. α_2 agonists are also indicated, although sedative and cardiovascular effects limit their use to epidural administration or as part of combination therapy. General anesthesia alone may not be sufficient to control intraoperative analgesia.

Several opioid analgesics are useful for the control of surgical pain. For animals suffering pain before surgical induction, oxymorphone or butorphanol administered as part of a preanesthetic or anesthetic regimen can both control pain and reduce the amount of general anesthetic. Likewise, animals to be subjected to a surgical procedure that will induce pain that is not likely to be successfully controlled with general anesthetics will also benefit from presurgical administration. Meperidine is generally used as a preanesthetic to minimize the amount of general anesthetic needed for a geriatric or debilitated (e.g., poor cardiovascular system) animal rather than to control pain. In addition, a fentanyl patch can be applied the day before surgery. Opioids might also be given intraoperatively if cardiovascular signs indicate the perception of pain despite a general anesthetic. Agents that can be reversed or those with a ceiling effect should be used to minimize the risk of respiratory or cardiovascular depression.

Postoperatively, any of the opioids can be administered, and the selection should be based on the degree of analgesia desired balanced with the risk of sedation in the postoperative patient (see the section on assessing pain). Those most commonly selected by small animal practitioners include oxymorphone, buprenorphine, and butorphanol, although the indications for butorphanol should be limited.23,127,128 Severe pain indicates the need for pure agonists such as fentanyl, morphine, hydormorphone, or oxymorphone. Fentanyl transdermal patches can be applied postoperatively, but it is likely that the analgesic effects of the patch will need to be supplemented over the short term. Less severe pain may sufficiently respond to buprenorphine or (less ideal) butorphanol. Of the two, buprenorphine can be expected to consistently provide a longer period of analgesia (about 4 to 6 hours). Acepromazine can be combined with either butorphanol or buprenorphine for sedation. Pulse oximetry can be used to evaluate tissue oxygenation and the potential risk associated with a sedating drug, including a pure agonist opioid.

The sedative effects of the opioid may be desirable for some patients but undesirable for others. An advantage of these drugs is that the sedating effects can be reversed if necessary. Note, however, that repeated administration of the reversing agent may be necessary (e.g., naloxone). Alternatively, if a sedating opioid has been used and reversal of the sedating effects is desirable, butorphanol or buprenorphine can be used. A portion of the analgesic effect will also be reversed (because of antagonistic actions at MOP receptors for both of these drugs), but KOP receptors will mediate some analgesia.

NSAIDs can be very effective postoperatively; in addition to their peripheral antiinflammatory effects, NSAIDs may have central actions. Care should be taken with the use of NSAIDs; drugs that are selective for COX-2 are preferred (see Chapter 29). However, the impact of COX-2 inhibition on healing and other physiologic response must be addressed. The availability of several approved COX-1 protective drugs in the dog and meloxicam (COX-protective status unknown in cats) calls into question the wisdom of using alternative NSAIDs. Further, the efficacy of NSAIDs as preemptive analgesics coupled with their inherent risks mandates caution when used perioperatively or intraoperatively, particularly in the unhealthy patient. Fluid therapy during surgery is important to prevent renal complications, and excessive bleeding may occur as a result of the inhibition of thrombogenesis. Combinations of opioids (codeine, butorphanol) and NSAIDs or acetaminophen should be considered to avoid the side effects associated with NSAID use.

Critically III Patients

Stress that is too severe can complicate the care of the critically ill patient. Invasive procedures intended to support the patient produce pain that can be severe, requiring use of sedation, local analgesics, or central analgesics. Procedures that require some type of analgesic therapy include placement of urinary, nasal, and nasogastric catheters; bone marrow aspiration; and drainage or lavage of body cavities. Opioid sedation, or a combination of ketamine (100 mg/mL) and diazepam (5 mg/mL) mixed 1 to 1 and administered at 0.05 to 0.1 mL/kg may limit stress associated with these procedures.^{25,224}

Among the opioids most commonly used to control pain beyond that associated with supportive procedures are morphine, oxymorphone, and butorphanol.²³ Side effects of most concern include respiratory and cardiac depression. Most animals can, however, tolerate mild respiratory depression associated with opioids, and respiratory disease or trauma is not a contraindication for opioid use in animals. For example, morphine can be used for the patient with pulmonary edema secondary to heart failure. In addition to splanchnic pooling and decreased preload to the heart, sedation decreases struggling and oxygen use. Morphine can be given to effect at 0.1 mg/kg every 3 minutes until light sedation has been achieved. Oxymorphone may be the preferred opioid of choice for animals for which systemic hypotension can be life threatening because it is less likely to cause histamine release. Fluid therapy is indicated if hypotension occurs.^{25,224}

The use of local anesthetics for the critically ill patient should not be ignored. The short duration of action of lidocaine leads to its usefulness for short invasive procedures. It has been used intravenously in human patients as a centrally acting analgesic, but in animals it should be administered in conjunction with another analgesic if used centrally (1 to 2 mg/kg loading dose followed by CRI at 25 to 40 µg/kg per minute). The longer duration of action of bupivacaine lends itself to control of pain associated with surgery or trauma. Bupivacaine can be infiltrated in the proximal intercostal nerves for surgical procedures or infiltrated through a chest tube (0.25% to 0.5%, up to 1 to 2 mg/kg every 6 hours) for control of thoracic pain. Sufficient drug can be absorbed to induce toxicity after local administration. Bupivacaine is more cardiotoxic than lidocaine, and cardiac depression is more likely with repeated administration. CNS reactions include depression and stupor, which may precede seizures. Epinephrine can be used to slow absorption of drug into systemic circulation, although this should be used only with extreme caution in critically ill patients.25,224

The use of NSAIDs to control pain in the critically ill is risky because of the gastrointestinal, hematopoietic, and renal and other (often unknown) side effects of these drugs. Until data are available to support their use, however, all NSAIDs, including COX-2 preferential drugs, probably should not be used in the critically ill patient. An exception might be made for patients suffering from endotoxic shock.^{25,224}

Assessment of the patient with cranial trauma can be difficult, complicating the monitoring of analgesic use. Clinical signs vary with the site and extent of brain injury (e.g., concussion, laceration, contusion). Brain trauma can lead to extracranial or intracerebral hemorrhage days after the injury (with clinical signs varying depending on exactly where the hemorrhage occurs), as well as edema (intracellular, extracellular, interstitial, or vasogenic), hypoxia (or ischemia), and increased intracranial pressure. Marked neuronal ion flux (sodium influx, potassium efflux) can lead to anaerobic glycolysis and marked cerebral acidosis. Calcium influx may lead to production of inflammatory mediators; edema is among the consequences of inflammation. The lipid nature of brain tissue renders it prone to damage by oxygen radical generation, which can contribute markedly to neuronal damage. Decreased cerebral blood flow can cause cessation of normal homeostasis, leading to cellular swelling. Loss of autoregulatory mechanisms for blood flow can persist for several days, further contributing to ischemic damage.²²⁵ Cerebral ischemia increases with intracranial pressure. Cerebral arterial PCO₂ increases and PO₂ decreases, causing increased cerebral blood flow. Cerebral blood flow also increases with cerebral metabolism, such as that associated with response to excitement, fear, and pain.^{225,226}

After cranial trauma the blood-brain barrier becomes permeable to small molecules normally excluded by the brain.²²⁵ Maximal permeability occurs several days after the injury. Not only is the patient further predisposed to damage induced by metabolites, but also greater drug distribution into the brain increases the risk of neurologic adverse drug reactions. Conditions that might exacerbate the pathophysiologic sequelae of cranial trauma include systemic hypoxia (associated with pneumothorax, aspiration pneumonia, and adult respiratory distress syndrome), hyperglycemia (increases neuronal damage), and hyperthermia (exacerbating neuronal damage).

Control of pain in the patient with cranial trauma is controversial.^{225,226} Whether or not injury to the brain causes the sensation or perception of pain, the physiologic consequences of pain or the release of endogenous opioids is not clear. Trauma to the brain alone may not be an indication for analgesic therapy. In contrast, the indication for analgesics in patients with other injuries in conjunction with cranial trauma is clear in part because the physiologic consequences of pain may worsen the cranial trauma. For example, hypertension may facilitate cranial bleeding, as might lowered arterial PCO₂ induced by tachypnea. Thus analgesic therapy is indicated for injuries sustained beyond cranial trauma. Among the analgesics, for such injuries the opioid analgesics tend to be preferred because of their efficacy, reversibility, and (compared with the NSAIDs) safety. The physiology of the damaged brain is not, however, well elucidated. Current knowledge has caused neurologists to reconsider traditional therapies such as the use of glucocorticoids (risk of hyperglycemia) and mannitol (increased risk of hemorrhage) for patients with cranial trauma. Even standard therapies such as resuscitative fluid therapy (increased risk of cerebral edema) can worsen damage induced by cranial trauma, and it is likely that neither the positive nor the negative sequelae of analgesics on the traumatized brain have been fully described. Thus caution is recommended not only in the selection of the analgesic but also in the supportive care provided to the patient with cranial trauma.

A number of known disadvantages are associated with the use of opioids in patients with cranial trauma. Altered mentation induced by cranial trauma and neurologic dysfunction associated with damage to the respiratory and cardiovascular systems are the major concerns. Failure to stabilize the patient and masking of worsening mentation induced by trauma with a sedating drug can lead to life-threatening depression. Because of their sedative effects, opioids selected for control of pain in the patient with cranial trauma should be either minimally depressive or reversible if there is risk of life-threatening sedation or continued loss of mentation caused by trauma. The time to maximal detrimental (as well as beneficial) effects of an opioid varies with the route of administration, occurring in most cases within 10 minutes after intravenous administration but up to 30 minutes after intramuscular administration in human patients. Administration of opioids in low doses and titrating the dose to match the patient's response to pain and physical status can minimize the risk of opioid-induced complications.^{225,226}

Opioids have both direct and indirect effects on the brain. Opioids may directly increase cerebrospinal pressure, which may contribute to neurologic damage induced by trauma and its consequences. This may not be reversible with opioid antagonists, and thus increased CSF pressure should be avoided by reserving use of opioids until the CNS status of the patient has stabilized; repetitive, close monitoring is needed after drug administration. The blood–brain barrier is likely to be damaged in the patient suffering from cranial trauma, facilitating drug movement into the brain. Doses of drugs, including opioids, may need to be decreased. In addition, drugs that induce seizure activity, such as meperidine, are not recommended.^{225,226}

All of the opioids are associated with some degree of CNS depression. Pure opioid agonists that act at the MOP receptors are associated with the greatest CNS depressant effect. Drugs predominantly active at KOP receptors (located usually in the spinal cord), such as butorphanol and buprenorphine, are characterized by less sedation. As such, these drugs may be more appealing for the patient with cranial trauma. Buprenorphine, however, has both MOP (supraspinal) agonistic and antagonistic effects, whereas butorphanol only antagonizes MOP receptors. In addition, buprenorphine is not fully reversible at MOP receptors and therefore should probably be avoided until the traumatized patient has been completely stabilized. Once the risk of degrading mental status is minimal, buprenorphine will be safer. Pure opioid agonists such as morphine and oxymorphone can be used, but these drugs are more likely to contribute to CNS depression induced by trauma. An advantage to either of these drugs, however, is their full reversibility by opioid antagonists. Should reversal be indicated, extra caution should be taken to ensure slow reversal, thus avoiding a hyperanalgesic response and its physiologic sequelae. In addition, care should be taken to assess the need for repeated administration of the reversal agent.^{225,226}

KEY POINT 28-26 An advantage of pure opioids as choice drugs for control of pain in special-needs population is their reversibility in dogs.

Direct depression of the respiratory centers, coupled with decreased responsiveness to arterial PCO_2 , are likely to be exacerbated in the patient with cranial trauma. Lung volume

decreases in the normal patient, and depression of the cough reflex (especially morphine) increases aspiration of accumulated secretions and development of atelectasis owing to retention of respiratory secretions. Respiratory rate, depth, and rhythm should be closely monitored during opioid administration. Blood gases should be monitored in patients at risk for respiratory depression. Although pulse oximetry can confirm tissue oxygenation, tissue PCO₂ drives respiratory rate and cerebral vascular responses. Respiratory acidosis may develop despite normal tissue oxygenation. Increased PCO₂ can lead to increased cerebral blood flow, which may exacerbate cerebral hemorrhage. In addition to effects of cerebral vasculature, the respiratory rate may be altered (slowed). In a patient whose respiratory center is threatened as a consequence of cranial trauma, further suppression of the respiratory center by an opioid can be life threatening. Drugs characterized by a ceiling effect on respiratory depression (e.g., butorphanol and buprenorphine) will decrease, but not exclude, the risk of opioid-induced CNS respiratory depression. The use of continuous epidural opiate infusions is recommended for human patients who have sustained multiple pulmonary trauma.^{225,226}

Cardiovascular depression is also a concern in the patient with cranial trauma receiving opioid analgesics. Depression can be mediated through the central centers, directly on the myocardium, or through peripheral effects (particularly opioids such as morphine that mediate histamine release). Again, close monitoring of rate, rhythm, and pulse is indicated during the initial stages of opioid use. Oxymorphone and fentanyl, which are not associated with as much histamine as is morphine, might be preferred over morphine.^{225,226}

Epidural Analgesia

Epidural analgesia was reviewed by Jones.²²⁷ Epidural administration of analgesics can be used to facilitate anesthesia for surgery or provide prolonged postoperative analgesia (see Table 28-3). The efficacy of epidural opioids and local anesthetics in the preemptive control of pain in humans also was reviewed (Jones²²⁷ and Møiniche and coworkers¹⁵). For analgesic effects, opioids, particularly at high doses, are most useful. Opioids cause selective spinal analgesia by binding to opioid receptors in the dorsal horn of the spinal cord segments. The processing of signals sent by nociceptors is modulated. Thus central effects are absent. Opioids most commonly administered epidurally include morphine, oxymorphone, buprenorphine, and fentanyl. Opioids must cross through the dura and pass into the dorsal horn to be effective with epidural use.²²⁷ Bernards²²⁸ reviewed the factors that govern the rate and extent of opioid redistribution from epidural and intrathecal spaces such that target opioid receptors are reached. The specific opioid to be used depends on the targeted region. Pelvic analgesia can be provided by a number of opioids; for abdominal or thoracic analgesia, a drug with a low lipid solubility (e.g., morphine) is indicated to allow more time for cranial diffusion (after lumbosacral administration) before the dura is penetrated. Morphine also has the longest onset of action (up to 90 minutes) but provides the longest duration of analgesia (up to 24 hours) (see Table 28-3). When used to control postoperative pain, it should be administered before surgery. Sibanda and coworkers²²⁹ demonstrated that the combined extradural administration of bupivacaine (up to 1.5 mg/kg) with morphine (0.1 mg/kg) in dogs reduced concentrations of measures of stress, including cortisol and acute phase proteins, in clinical animals undergoing surgical procedures.²²⁹ Fentanyl is very lipid soluble. Its analgesia is very rapid in onset but does not extend more than one to two spinal cord segments from the injection site. Its central effects are more common than those of other analgesics because of its high lipid solubility and rapid absorption into systemic circulation. It can be combined with morphine to provide analgesia as the morphine penetrates the dura.

Pruritus is a common side effect in human patients receiving opioids epidurally. Delayed respiratory depression is a complaint in a much smaller percentage of the human population. Neither of these side effects has been reported in animals. Because opioids cause no paralysis, there is little to no loss of skeletal muscle (motor) function. Weakness of the detrusor muscle and urine retention are not, however, unusual. Among the opioids, buprenorphine appears the least likely to cause urinary retention. Catheterization may be necessary in some patients.

Local anesthetics have been used epidurally in dogs.²³⁰ Local anesthetics provide direct anesthesia at any nerve root with which the drug comes in contact. This effect is spinal if the drug is administered into the CSF. Bupivacaine is more potent and lipid soluble than lidocaine yet has a slower onset of action and longer duration of effect. Motor blockade should be anticipated but can be minimized by use of dilute concentrations (0.0625% to 0.125%). An opioid can be used for diluting bupivacaine 1 to 1 up to 1 to 3 (by volume).

Epidural administration of analgesics is contraindicated for patients with neurologic deficits or injuries and coagulopathies, bacteremia, and severe systemic infections. Despite the lack of reported toxicity, drugs that contain preservatives (e.g., multiple-dose vials) should be avoided because they may contain preservatives that are neurotoxic. The risk of toxicity increases with multiple injections. Products containing sodium metabisulfite should not be administered intrathecally. The use of epinephrine in combination with local anesthetics and particularly bupivacaine also should be avoided because of very prolonged (24 to 48 hours) muscle weakness. Potential complications of epidural analgesia include epidural or intrathecal hemorrhage, spinal nerve root trauma, motor blockage (particularly with local anesthetics), central effects as the drug diffuses to the brain, and weakness or ataxia.

THE PATHOPHYSIOLOGY OF INFLAMMATION

Inflammation can occur in any vascularized tissue. Initiated as a protective mechanism intended to remove the underlying cause, be it chemical, physical, or biological, the acute inflammatory process facilitates return of the inflamed tissue to normal function.^{1,2} With time, however, its unfettered actions can lead to chronic inflammation, which can contribute to harm to the patient. The sequelae of inflammation are manifested as five cardinal signs: redness, heat, swelling or edema, pain, and loss of function. The initial response to vascular damage is vasoconstriction of small vessels in the area of injury, which serves to control hemorrhage within 5 to 10 minutes; however, vasodilation and increased vascular permeability of small venules are evident. Leukocytes, platelets, and erythrocytes in the injured vessels become "sticky," adhering to the endothelium. Leakage of cells and plasma-derived protein-rich fluid is followed by platelet aggregation and fibrin formation. Initially, the predominant cell type infiltrating damaged tissues is the polymorphonuclear leukocyte (PMN), in part because it predominates in circulation. These cells provide a protective response by removing chemicals or other materials that may have initiated the inflammatory response. As the short-lived PMNs die, macrophages become the predominant cell type. The migration and concentration of PMNs to the site of injury is facilitated by chemical mediators that act as chemotactic agents. As PMNs die, the contents of the lysed cells accumulate to form the component of inflammatory exudate commonly referred to as *pus*.

THE ROLE OF CHEMICAL MEDIATORS IN THE INFLAMMATORY RESPONSE

Released mediators perpetuate the inflammatory response (Table 29-1 and Figures 29-1 and 29-2) and are responsible for the clinical signs associated with inflammation, including pain and fever.³ Mediators (see Table 29-1) are derived from both the cells (both preformed and formed in situ) and fluid

that reach the site of tissue damage by way of the bloodstream. Although quantitative differences between species and tissue concentrations of the mediators vary, the effect on and role in the pathophysiology of inflammation that each mediator has are predominantly the same. Leukocytes are a rich source of a variety of chemical mediators of inflammation. These cells, as well as cells of the injured tissues (either at the time of damage or after subsequent damage), perpetuate the inflammatory

Madiatar	Course	Action	Dharmaaalagia Madulatar
Mediator	Source	Action	Pharmacologic Modulator
Lysosomal contents	Phagocytes	Vessel permeability	Glucocorticoids
		Membrane degradation	Dimethylsulfoxide

response and become potential targets of antiinflammatory drugs. Preformed mediators include those located in granules (e.g., histamine and serotonin) and lysosomes and other enzymes. Their release occurs in the earliest stages of inflammation, to be followed by the release of mediators formed in situ. This latter group includes products of arachidonic acid (AA) metabolism, including eicosanoids (prostaglandins [PGs], leukotrienes, and related compounds), and plateletactivating factor, as well as oxygen radicals, and cytokines. The role each of these mediators varies. Although most mediators are proinflammatory in action, antiinflammatory mediators also are formed. Examples include lipoxins, epoxyeicosatrienoic acids (EETs), hydroxyeicosatetranoic acids (HETEs), and epoxyoctadecenoic acids (EpOMEs), selected cytokines, and possibly cyclooxygenase-2 (COX-2)-generated PGs formed in later stages of inflammation (see Table 29-1).^{1,2} The induction of genes responsible for the generation of proinflammatory mediators is an emerging target of interest for antiinflammatory drugs. Among the inducible transcription factors that control inflammatory gene expression, nuclear factor NFkB is of particular interest because of its ability to coordinate soluble proinflammatory mediators such as cytokines and chemokines as well as leukocyte adhesion molecules. Normally, this factor is trapped in the cytosol by an inhibitory protein that hides the signal necessary for nuclear localization. However, in the face of proinflammatory cytokines (e.g., tumor necrosis factor-alpha [TNF-alpha], interleukin-1 [IL-1]), the inhibitory protein is phosphorylated and degraded, thus allowing movement of NF $\kappa\beta$ to the nucleus.⁴ The role of matrix metalloproteinases (MMPs) in the inflammatory process is being increasingly recognized.⁵ The extraceullar matrix has long been recognized as a substrate for these proteolytic tissue-remodeling enzymes. However, other molecules serve as substrates, including cytokines and chemokines. As such, MMPs may act to control or perpetuate inflammation, and the sequelae of their inhibition may lead to adverse reactions as well as therapeutic benefits.

KEY POINT 29-1 The inappropriate inflammatory response reflects an imbalance between proinflammatory and antiinflammatory mediators.

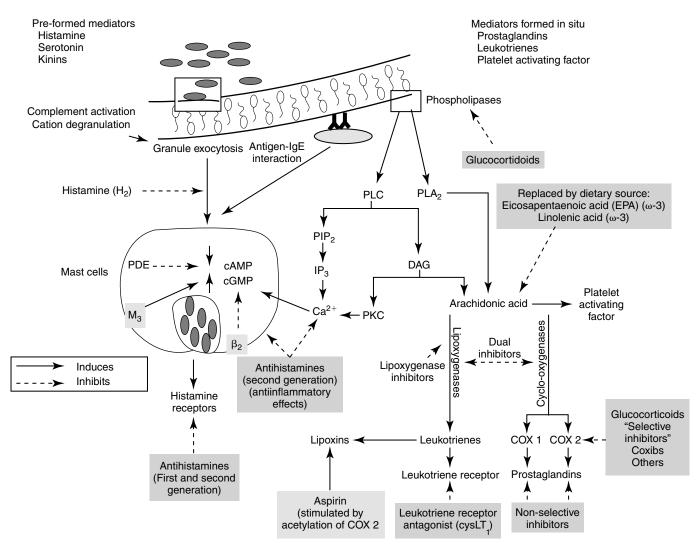

Figure 29-1 Leukocytes are an important source of inflammatory mediators that perpetuate the inflammatory response. Cellular mediators of inflammation include those preformed in granules or lysosomes, such as histamine and serotonin, and those formed in situ from arachidonic acid released by phospholipases in the cell membrane. Muscarinic receptors (M₃) stimulate, and β -adrenergic receptors (₂) inhibit, inflammatory mediator release. Although the phagocytic cell is intimately involved in the inflammatory reaction, it is not the only cell type capable of generating mediators of inflammation. The mediators of cellular origin interact with plasma-derived mediators, further compounding the response. Drugs used to control inflammation generally target specific mediators (see boxes) (see Table 29-1). *cAMP*, Cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *DAG*, diacylglycerol; *IP*₃, inositol triphosphate; *PAF*, platelet-activating factor; *PDE*, phosphodiesterase; *PIP*₂, phosphotipase A₂; *PLC*, phospholipase C.

Plasma-derived mediators also are important contributors to the inflammatory process. These include the kinins (e.g., bradykinin), released from their precursor form after appropriate physiologic or pathologic stimulation; complement and complement-derived peptides, released after activation of either the classic or the alternative pathway; and fibrinopeptides, released during the conversion of fibrinogen to fibrin during the clotting process and subsequent proteolysis of fibrin by plasmin.

Acute inflammation can cause severe organ or lifethreatening damage. Monocytes, which follow neutrophils to the site of inflammation several hours later, release collagenases and elastases, softening local tissues. Interleukin release draws fibroblasts to the area, which in turn deposit collagen at the site. The collagen is gradually remodeled, and new blood vessels continue to form until oxygen tension is normal. If the cause of inflammation is removed, healing is complete. Failure to remove the inciting cause leads to persistent, chronic inflammation. Pharmacologic control of inflammation is oriented toward preventing the release of various chemical or plasma mediators, inhibiting their actions and treating pathophysiologic responses to them. Drugs useful for modulating the activity of chemical mediators derived from cells, plasma, or both are summarized in Table 29-1. Among the most important and frequently used drugs are the nonsteroidal antiinflammatory drugs (NSAIDs), all of which control fever; pain; and, to varying degrees, inflammation. A number of drugs and novel ingredients target inflammation particularly associated

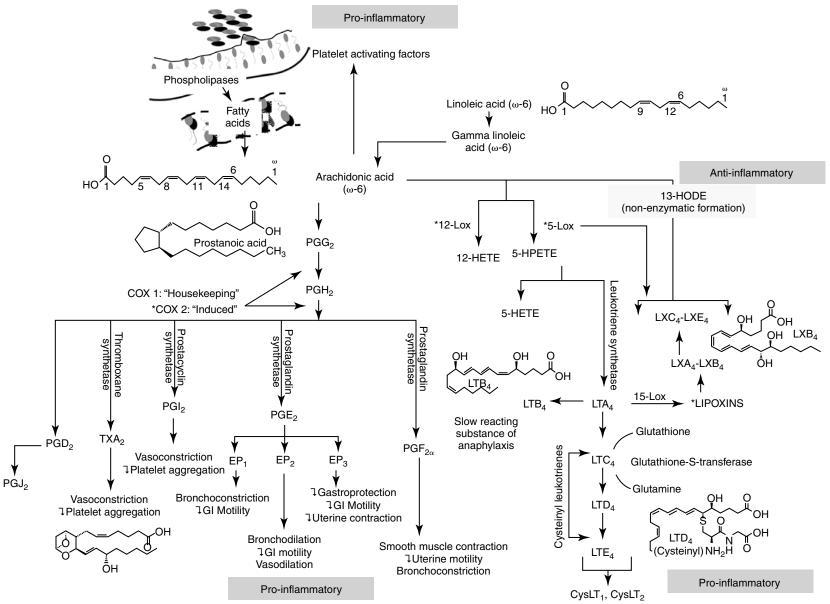

Figure 29-2 The release of arachidonic acid from the phospholipids in cell membranes leads to a cascade of events resulting in the formation of inflammatory mediators. The family of cyclooxygenases (COX) results in the formation of constitutive prostaglandins (COX-1) and inducible prostaglandins (COX-2). The inducible prostaglandins contribute to all cardinal signs of inflammation. Selectivity of nonsteroiodal antiinflammatory drugs (NSAIDs) for COX-2 ultimately may result in marked safety of the NSAIDs. Lipoxygenases result in the formation of leukotrienes, which, along with their precursors, are potent inflammagens in a number of tissues. However, among these products are antiinflammatory lipoxins. The cysteinyl leukotrienes play a major role in type I hypersensitivity and potentially in chronic inflammatory diseases as well (see Chapter 19). Platelet-activating factor also is a potent inflammagen, although some of its actions may be mediated through leukotriene activity.

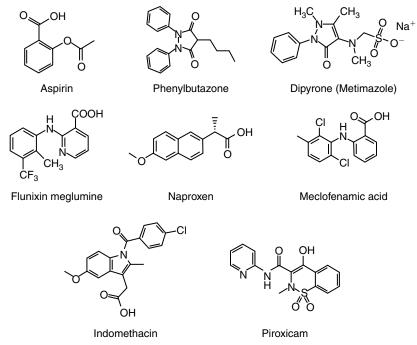

Figure 29-3 Structures of selected "traditional" nonsteroidal antiinflammatory drugs.

with specific conditions including osteoarthritis and septic shock; these are discussed separately. Glucocorticoids engage such a substantial role in the contribution, prevention, and treatment of inflammation that their discussion warrants a separate chapter.

SHARED PHARMACOLOGY OF NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Chemistry

Although NSAIDs have been variably defined, the name is used to describe compounds that are not steroidal and that suppress inflammation. Generally, the classification is restricted to those drugs that inhibit one or more steps in the metabolism of AA, generally at the COX side of the cascade.⁶ The NSAIDs vary in their ability to influence inflammation. The mechanism of action of some of these drugs is not limited to inhibition of AA metabolism.⁷

Aspirin, one of the earliest components of herbal therapy, is the progenitor NSAID, and terms such as *aspirinlike* and *aspirin and related drugs* have been used to refer to NSAIDs,⁶ although this older terminology may become obsolete with approval of newer NSAIDs. Structurally, NSAIDs can be broadly classified as either the salicylate or carboxylic acid derivatives, including the indoles (indomethacin), propionic acids (carprofen, ibuprofen, and naproxen), fenamates (mefenamic acid), oxicams (piroxicam), and pyrazolones or enolic acids (phenylbutazone and dipyrone)(Figures 29-3 and 29-4).⁶ Functionally, NSAIDs increasingly are being categorized by the enzymes they target: conventional (COX-1 and COX-2); newer COX-2–selective (COX-1 protective), which includes the coxibs as well as similarly acting drugs;

more appropriate and dual inhibitors (tepoxalin) (see Figure 29-2). The coxibs include the sulfones and the sulfonamides. However, the term *coxib* refers to a chemical structure (see Figure 29-4) and not pharmacologic action and should not be used to refer to all drugs that might preferentially target COX-2 compared with COX-1. The coxibs are not arylamine sulfonamides (see Chapter 4), and therefore allergic reactions typical of sulfonamides antibiotics (see Chapter 7) may not occur. Nonetheless, several of these drugs are associated with keratitis sicca or suppression of thyroid gland activity.

KEY POINT 29-2 Although all nonsteroial antiinflammatory drugs share a common mechanism of action through inhibition of cyclooxygenase, the drugs vary in the isoform targeted, as well as in nonprostaglandin-mediated effects.

Mechanism of Action

Prostaglandins

Prostaglandin Formation. Eicosanoids, such as PGs and leukotrienes, are 20-carbon chain derivatives of cell membranes. Eicosanoids are potent mediators of inflammation and are particularly important in the later stages.^{3,8} These compounds are synthesized when oxygen reacts with the polyunsaturated fatty acids of cell membrane phospholipids (see Figures 29-1 and 29-2). The most important of these fatty acids is AA, an omega-6 fatty acid, which is released into the cell from phospholipids of the damaged cell membranes. Release reflects activation of phospholipase A_2 (dependent on calcium and calmodulin) located in the cell membrane.⁹ Once inside the cell, AA serves as a substrate for enzymes that generate intermediate and ultimately the final eicosanoid end product.^{8,10} The formation of lipoxygenases and their subsequent

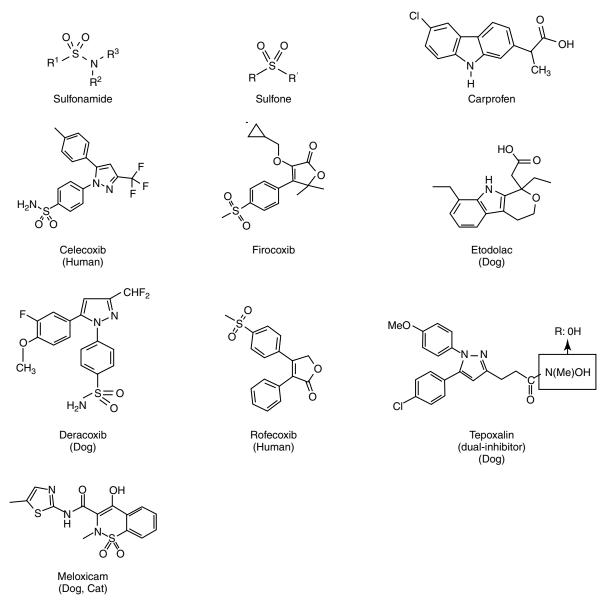

Figure 29-4 Structures of selected newer nonsteroidal antiinflammatory drugs that are more potent toward COX-2 compared with COX-1.

inhibition is discussed under "Miscellaneous Antiinflammtories." COX PG synthase or prostaglandin H (PGH) synthase, located in all cells except mature red blood cells, add oxygen to AA, generating unstable PG endoperoxides (PGG₂). Subsequent peroxidase reactions convert PGG₂ to PGH₂, the precursor of all PGs and thromboxane. The final PG end product depends on the presence of specific isomerase reductase or synthetase enzymes, some of which may be inducible.^{8,9}

The direct effects of PGs are mediated through cell membrane–spanning G protein receptors located on target tissues and cells. At least nine subtypes have been identified, corresponding to each of the COX metabolites: DP1-2 (PGD₂), EP1-4 (PGE₂), FP A, B (PGF₂ α), IP (PGI₂), and TP α , β (TXA₂) (G&G);¹¹ another four have been characterized for PGE₂, opening the potential for selective drug activity.⁹ In addition to their receptor interactions, PGs also act indirectly by enhancing other mediators such as histamine and bradykinin.

The role of PGs in normal physiology as well as in disease might best be understood by considering them as protective in nature, even those associated with inflammation. Their formation is mediated by one of at least two isoforms of cyclooxygenases (see Figures 29-1 and 29-2), located on different genes in humans.¹²⁻¹⁴ COX-1, the "housekeeping" isoform,¹⁴ mediates the formation of constitutive PGs produced by many tissues, including gastrointestinal cells, platelets, endothelials cells, and renal cells. PGs generated from COX-1 are constantly present, providing homeostasis through a variety of normal physiologic effects. These include protection of the gastrointestinal mucosa, hemostasis, and the kidney when subjected to hypotensive insults. COX-2 is the product of an "immediate-early" gene that is rapidly inducible and tightly regulated.¹⁴ Regulation of COX expression is complex, with more sites present on the COX-2 compared with the COX-1 gene. Its expression is tightly restricted (but not absent) under basal conditions,

but it is dramatically upregulated in the presence of inflammation or other diseases.9 Diseases associated with increases include (in humans) rheumatoid arthritis, seizures, ischemia, and (posttranslational) cancer.9 Proinflammatory cytokines such as TNF α and the interleukins stimulate the expression of COX-2 in many cell types, such as synovial cells, endothelial cells, chondrocytes, osteoblasts, and monocytes and macrophages.¹⁴ COX-2 catalyzes the formation of inducible PGs, which are needed only intermittently or under specific situations.^{12,13,15,16} A third COX isoform has been suggested, but it appears to be a variant of COX-1. Originally identified in high concentrations in canine cerebral cortex (hence the term used by some investigators, "canine COX-3"),¹⁷ it is inhibited by acetaminophen (and other NSAIDs). Its inhibition may influence central analgesic effects of NSAIDs.^{1,2} Differential or selective inhibition of COX-2 clearly offers potential some safety benefits by avoiding loss of homeostatic PGs; however, loss of COX-2 activity is also associated with adversities.¹⁴ It is important to note that COX-2 is offtimes constitutively expressed: in the kidney and brain it mediates a cytoprotective effect in damaged or inflamed gastrointestinal mucosa.

KEY POINT 29-3 Cyclooxygenase-2 is consistently, but not exclusively, associated with signals associated with inflammation, pain, and fever. However, it also plays a substantial role in noninflammatory diseases such as cancer and central nervous system diseases

Cyclooxygenases in health and disease. An appreciation of both efficacy and safety of COX inhibition (e.g., NSAIDs) is facilitated by an understanding of the role of COX in healthy and diseased tissues. COX has been described as the most common target of drug therapy with NSAIDs. In general, inhibition of COX-2 is responsible for efficacy, whereas inhibition of COX-1 is responsible for side effects.⁹ However, strict adherence to this simplistic approach will lead to therapeutic failure and increased morbidity with NSAID use. Although COX-1 does indeed appear to be the predominant constitutive enzyme responsible for housekeeping, both COX-1 and COX-2 are constitutively expressed in many tissues. Further, although COX-2 clearly is more active in the promotion of inflammation, COX-1 does appear to have some role.

Inflammation. PGs, and primarily PGE2, induce vasodilation, capillary permeability, and chemotaxis. As such, PGs cause the cardinal and clinical signs of inflammation, including pain and fever.⁸ PGE also modifies both T-cell and B-cell function, in part by inhibition of IL-2 secretion.⁸ Other inflammatory effects of PGE include its regulation IL-6, macrophage colony-stimulating factor, and vascular endothelial growth factor. In general, research consistently indicates that it is COX-2 that predominantly mediates formation of PGE associated with inflammation, pain and fever. For example, whereas COX-1 is largely absent in normal synovial cells, COX-2 is induced in most types of arthritis, including inflammatory arthritis in animals and rheumatoid arthritis in humans. In cartilage COX-2 is associated with IL-1 degradation of proteoglycan and apoptosis of synovial cells.¹⁸ However, not all of the inflammatory actions of COX-2 are undesirable in that COX-2 induction in response to inflammation contributes to tissue healing. For example, COX-2 is associated with healing in ligaments, bone, the gastrointestinal tract, and other tissues. The importance of COX-2 to dermal healing is not yet known.⁹

Central Nervous System. Both COX-1 and COX-2 are consitutively expressed in the brain and spinal cord. Constitutive COX is very responsive to ischemia, immunomodulation, cytokines, toxins, brain damage, and maturation processes.¹⁷ However, although both isoforms are present, COX-2 predominates. PGs of the central nervous system (CNS) play a major role in pain; howevever increasingly they are recognized for roles in other disorders. Among them is the role of COX in the pathogenesis of Alzheimer's disease (AD). Extracellular deposition of fibrillar amyloid β (A β), intracellular accmumulation of abnormally phosphorylated tau protein, and subsequent formation of AB plaques mediating neurodegeneration and dementia in AD are associated with inflammation and COX-2.19 Mediators of inflammation are present throughout all stages of the disease, whereas COX-2 is absent in normal astrocytes or microglial cells. Further, COX-2 is upregulated in acute brain injury and in animal models of AD.^{9,19} Finally, the connection between AD and COX is supported by a lower incidence of AD in patients with rheumatoid arthritis, presumably because of the use of NSAIDs for its treatment.¹⁹ The protective effects of NSAIDs in the AD patient may reflect the antiplatelet properties of NSAIDs; aspirin in particular may decrease the risk of ischemic damage induced by blocked capillaries of the brain. Decreased formation of amyloid β protein also has been proposed,⁹ suggesting a possible role in other diseases associated with amyloid β protein deposition. Finally, COX-2 appears to be involved in the loss of glutamateinduced apoptotic cell death.¹⁹ Because N-methyl-D-aspartate (NMDA) receptors stimulate the arachidonic acid cascade, NSAIDs mute the role of NMDA receptors in pain. NSAIDs may also inhibit NMDA-mediated neuronal cell death by preventing increased extraceullar glutamate.^{19a}

Pain. PGs have been implicated in causing increased pain perception (allodynia) in damaged compared with normal tissues.^{1,2} Induced COX-2 PGE as been associated with hyperalgesia (exaggerated response to pain) at the level of the spinal cord (primary hyperalgesia) or nociceptors (secondary hyperalgesia).¹⁷ Induction of COX-2 in the dorsal horn has been associated with central sensitization, manifested as a change in excitability threshold.^{9,17,18} Currently being descriped is the ability of PGs to contribute indirectly to neuropathic pain through influence on chemical mediators (e.g., histamine, bradykinin, substance P, nitric oxide [NO]), neurotransmitters (e.g., glycine inhibition or glutamate stimulation), or modulation of other receptors (e.g., NMDA).

Gastrointestinal and Other Healing. Both COX-1 and COX-2 are constitutively expressed in the gastrointestinal tract. However, constitutive expression of COX-1 has a predominant role in the protection of the gastrointestinal tract. COX-1 PGs decrease hydrochloric acid secretion, increase mucosal bicarbonate and mucus production, and increase epithelial cell proliferation and mucosal blood flow

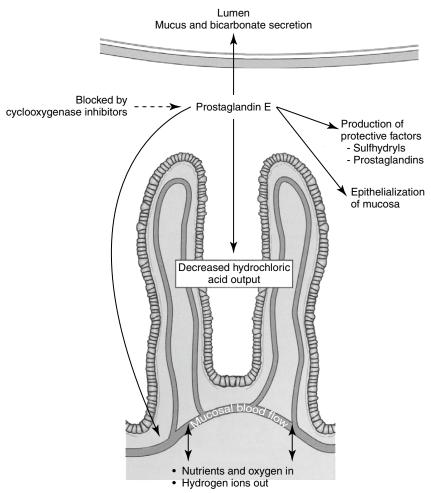

Figure 29-5 Among the many protective functions of constitutive prostaglandins is protection of the gastrointestinal mucosa from acid and other mediator-induced damage. Protective mechanisms include production of mucus and bicarbonate and inhibition of hydrogen ion secretion; epithelial turnover, which ensures rapid replacement of damaged cells; and increased mucosal blood flow, which ensures provision of oxygen and nutrients to the rapidly dividing epithelial cells as well as removal of hydrogen ions that are able to pass into the cells.

(Figure 29-5). The latter effect facilitates delivery of oxygen and nutrients to proliferating cells as well as rapid removal of damaging hydrogen ions that make their way into the mucosa. Drugs that express preferential potency for COX-2 PGs generally are associated with fewer gastrointestinal side effects compared to those targeting both COX isoforms, although the relative protection varies with the drugs. Protection appears to be more important in the presence of high drug concentrations (e.g., high doses).²⁰ COX-2 is critically important to the gastrointestinal tract as well, being important for healing of gastrointestinal damage: COX-2 appears within 1 hour of gastrointestinal damage. Newer coxib PGs will inhibit gastrointestinal healing as has been demonstrated in dogs receiving firocoxib (see the discussion of tepoxalin).²¹ Interestingly, in the pancreas, constitutive COX-2 expression dominates, although the clinical relevance of this is not yet known.²⁰ The impact of NSAIDS on bone healing is an emerging concern. COX influences osteoblast and osteoclast; experimental studies have demonstrated impaired bone healing.^{20a} Their use in controlling pain and limiting ectopic bone growth must be

balanced with the increased risk of impaired fracture healing; conventional NSAIDs might be preferred compared to newer NSAIDs. The impact of NSAID on soft tissue healing (or ligaments) remains to be confirmed; whereas short term use may have minimal negative (and potentially a positive) impact, long term used might be approached cautiously. A recent metaanalysis in humans found no advantage in terms of return to function for coxibs, but recommended caution with long term use.^{20b} A strong association has been reported between NSAIDs and severe necrotizing soft tissue infections.^{20c}

Cardiovascular Disease. The role of PGs in the cardiovascular system is largely beneficial, and the relationship between COX-1 and COX-2 and their respective PG end products exemplifies the complex "ying-yang" balance that characterizes them (Figure 29-6). Platelets contain thromboxane, a synthase, which catalyzes the formation of thromboxane from AA. Thrombosis reflects platelet aggregation and vasoconstriction. The formation of a thrombus is kept in check by the presence of prostacyclin synthase in vascular endothelial cells. This enzyme catalyzes metabolism of AA to prostacyclin

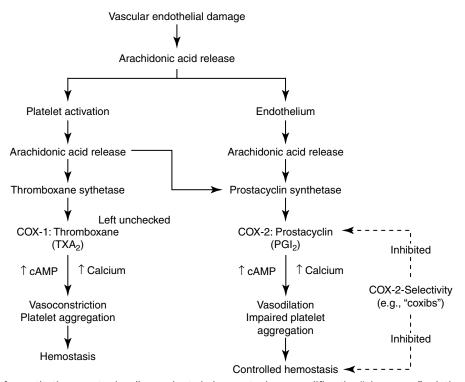

Figure 29-6 The role of constitutive prostaglandin products in hemostasis exemplifies the "ying-yang" relationship that often characterizes their action. Platelet activation in response to the damage is accompanied by the release of arachidonic acid, which is catalyzed by thromboxane synthetase, present in platelets, to thromboxane. Thromboxane causes platelet aggregation and local vasoconstriction. Excessive hemostasis is kept in check, however, by the simultaneous release of arachidonic acid from the damaged endothelial cell surface. Prostacyclin synthetase, located in the endothelial cells, results in the formation of prostacyclin, which is vasodilatory and inhibits platelet aggregation. *cAMP*, Cyclic adenosine monophosphate.

(PGI2), a vasodilatory and platelet-inhibiting PG end product. However, whereas thromboxane A2 (TXA2) is associated with COX-2, prostacyclin synthase co-localizes with COX-1. Thus, whereas drugs that target both COX isoforms will potentially allow the balance to be maintained, drugs that preferentially target only one isoform risk disruption of the balance. Such may be the case with COX-2 selective NSAIDs. Their preferential inhibition of COX-2 may allow thrombus formation to go unchecked, increasing the risk of thromboembolic disorders. Indeed, in a meta-analysis of human clinical trials, two coxib drugs (rofecoxib and valdecoxib) were associated with an increased risk of stroke (see "Adverse Events").^{20d}

Kidney. In the kidney both COX-1 and -2 are constitutively expressed. Both are formed in the macula densa of humans and animals, but COX-2 may have a more important role than COX-1 (Figure 29-7). In animals, inhibition of COX-2 causes sodium and potassium retention in salt-depleted, but not normal, animals. However, in humans COX-2 appears to influence renal vasculature and podocytes. The role of COX in the kidney requires further elucidation before safety can be assumed for any NSAID; sparing COX-1 and targeting COX-2 can be expected to alter renal function. For example, kidneys do not develop in the embryos of COX-2–null knock-out mice.²² The role of COX differs among tissues and species; their impact on adverse reactions are addressed under "Adverse Reactions."⁹

Lungs. The role of PGs in the lungs does not appear to be as important as that of leukotrienes; the impact is primarily in disease, rather than health, for both eicosanoids. However, inflammatory diseases, such as asthma, are associated with smooth muscle proliferation, which is inhibited by COX-2. Thus, as in the gastrointestinal tract, COX-2 appears to have a protective role in the diseased lung. An interesting complication regarding eicosanoids in general is exemplified in the lungs: the increased formation of leukotrienes (LTs) in the presence of NSAIDs, presumably because of the increase availability of AA in the face of decreased PG synthesis.

Reproductive tract. Both COX-1 and -2 play a significant role in the normal reproductive tract. Induction of COX-2 is associated with ovulation, fertilization, implantation, and decidualization, as well as induction of labor.²² Female knock-out mice devoid of COX-2 are largely infertile.²²

Cancer. In the 1990s a reduced risk of colon cancer was associated with consistent aspirin use. Subsequent studies demonstrated a marked increase in COX-2 in a variety of soft-tissue tumors in humans and in transitional cell carcinoma in dogs.²³ These studies suggest that benefits of NSAIDs in cancer may reflect inhibited COX-2.⁹ Mechanisms by which COX-2 may facilitate cancer growth or spread include impaired apoptosis, transactivation of epidermal growth factors or receptors and promotion of angiogenesis.^{9,17} Depending on the model, inhibition of COX-2 by NSAIDS reduces cell proliferation,

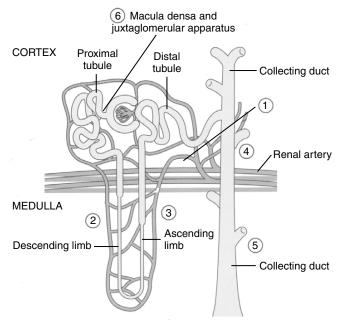

Figure 29-7 Both constitutive and inducible prostaglandins are important to renal blood flow, with the specific effect of each product varying among species. Renal prostaglandins ensure that intramedullary renal blood flow and urine formation will continue in the presence of decreased renal perfusion. Sites of action are noted by numbers and include shunting of blood from the cortices to the medullary intersitium, stimulation of natriuriesis, and inhibition of antidiuretic hormone. The nephrotoxicity of selected drugs reflects inhibition of renal prostaglandins.

increases apoptosis, and reduces metastasis. COX-2 inhibition may also enhance antitumor effects of radiation, although host toxicity also will be increased. Not surprisingly, gastrointestinal toxicity of anticancer drugs is also increased, presumably reflecting a combined toxic effect on the gastrointestinal tract.⁹ COX-1 may also have a role in cancer as is suggested by a decrease in colon cancer in COX-1 knockout mice.²⁴

Cycloloxygenase and nonsteroidal antiinflammatory drugs. NSAIDs (Table 29-2) act to block PG synthesis by binding to and inhibiting cyclooxygenase (see Figures 29-1 and 29-2).⁸ This action is both dose and drug dependent. The planar form that characterizes these drugs is thought to facilitate their binding to COX.^{6,25} Several investigators have shown that some drugs (e.g., phenylbutazone and flunixin meglumine) also reduce later steps of the formation of PGE₂ in inflammatory exudate at therapeutic doses.²⁶ However, both the major therapeutic and toxic effects of NSAIDs have been correlated extensively with their ability to inhibit PG synthesis, with anti-inflammatory potency related to potency of impaired PG synthesis.⁸

The differential effect of NSAIDs on the isoforms of COX presumably contribute to clinical differences in efficacy and safety, $.^{17,27}$ Whereas as a class, NSAIDs appear to inhibit both COX-1 and COX-2, the ratio of the concentration of a NSAID necessary to inhibit the same level of COX-1 vesrus COX-2 activity (e.g., inhibition of 50% or 80% activivity [IC₅₀ or IC₈₀]) compares the potency each drug toward each isoform, and as such, provides a basis for screening predicted relative safety

PO, By mouth; *IM*, intramuscular; *SC*, subcutaneous; *IV*, intravenous. *Note:* Dogs weighing less than 5 kg cannot be accurately dosed. 'The FDA has indicated that meloxicam treatment should not extend beyond a single injectable

and efficacy of each. Thus, a COX-1 to COX-2 ratio greater than 1 (or a COX-2 to COX-1 ratio of less than 1) indicates greater potency for COX-2 which is desirable in that formation of inflammatory PGS should be inhibited preferentially to the housekeeping PGs.^{12,13,15,16} Inhibition of platelet activity is commonly used to measure in vitro COX-1 inhibition whereas inhibition of PGs released from macrophages stimulated with endotoxin is used to measure COX-2. A number of drugs associated with *in vitro* COX-2 selectivity in humans, including rofecoxib (Vioxx) and celecoxib (Celebrex); others include etodolac, meloxicam, and nimesulide; the newest drugs are valdecoxib, etoricoxib, and (soon to be approved) lumiracoxib.⁹ Drugs approved for use in animals include carprofen (the first) followed by etogesic; deracoxib; meloxicam; and, most recently, firocoxib.

Although the gene for COX-1 is about 3 times as large as that for COX-2, the two COX proteins, which are membrane bound, share about 60% homology.9 Differences in NSAID selectivity for these two enzymes reflects smaller amino acids at two positions in COX-2 compared with larger amino acids at the same site in COX-1. The result is a larger and more flexible "pocket" into which the newer drugs insert and inhibit the COX-2 isoform.9 For example, "coxib" drugs contain a sulfonamide group that interacts through hydrogen bonding to arginine of COX-2 but not histidine in the same position in COX-1.28 Despite the usefulness of the COX-1:COX-2 ratio in screening drugs for safety or efficacy, its applicability to clinical use is questionable. Further, comparing results among studies is difficult. For example, whereas some studies focus on the IC_{50} others determine the IC_{80} , the latter probably being more clinically relevant. Assay methods contribute to variability in ratios among investigators for the same drug in the same species (Table 29-3). In vitro assasys based on cell culture or recombinant enzymes are easier to perform, but it is the ex vivo whole blood assays (as opposed to in vitro cell culture assays) that generally are recognized as the most representative of the clinical patient.¹ However, even whole blood assays do not take into account different distribution patterns to different tissues.^{18,22} Extrapolation among species should be avoided.²⁹ For example, wherease the COX-1 to COX-2 ratio of etodolac is much better than that for carprofen in humans,^{20,30} the opposite is true in dogs. Indeed, Wilson and coworkers³¹ have demonstrated that, wherease critical residues in the active sites of canine COXs are identical with human homologs, amino acids differ (up to 54) at in active sites and may contribute to differences in activity that preclude extrapolation among species (see Table 29-3). Further complicating extrapolation among and within species is the fact that NSAIDs generally exist and are largely marketed as enantiomers (see Chapter 1), each with a possible different ratios. For example, Ricketts and coworkers³² found the COX-1:COX-2 ratio of carprofen to be 129 for the racemic mixture but 181 for the S isomer and only 4.19 for the R isomer. Little information is available regarding COX selectivity in cats.^{33,34} Much of the information that is available is based on manufacturer-sponsored studies and as such might potentially reflect reporting bias. For example, in Table 29-3, drugs that generally performed best in each study tended to be the drug manufactured by the sponsor of the study. As such, COX ratios might be considered a screening procedure^{1,2}

KEY POINT 29-4 The markedly diverse role of multiple prostaglandins in normal physiology and the balance among prostaglandins that maintain homeostasis mandate extra caution when using nonsteroidal antiinflammatory drugs in unhealthy animals.

KEY POINT 29-5 Cyclooxygenase-1 to cyclooxygenase-2 ratios that assess potency of a nonsteroidal antiinflammatory are to be species specific and may not reflect clinical efficacy.

Other Mechanisms of Action

Inhibition of eicosanoid formation is not the sole antiinflammatory mechanism of action of NSAIDs. The NSAIDs also appear to alter cellular and humoral immune responses and suppress inflammatory mediators other than PGs.⁷ As a group, all NSAIDs are planar and anionic, thus able to partition into lipid environments, including neutrophil cell membranes. As a result, cell membrane viscosity is altered, even at low concentrations.¹⁰ At higher concentrations, NSAIDs appear to uncouple protein-protein interactions within the plasma membrane and thus interfere with a variety of cell membrane processes. Examples include oxidative phosphorylation and cellular adhesion.¹⁰ Response of inflammatory cells to extracellular signals is impaired by affecting signal transduction proteins (G proteins).¹⁰ Neutrophil adherence and activation is inhibited, as is subsequent release of inflammatory cellular enzymes, including collagenase, elastase, hyaluronidase, and others.⁷ The extent of these effects varies with the drug. Whereas piroxicam inhibits superoxide ions and lysosomal enzymes release, ibuprofen does neither.¹⁰ All NSAIDs appear to inhibit neutrophil adhesion. Some NSAIDS directly block PG receptors. Inhibition of nuclear transcription factor NF-B, is responsible for expression of many genes linked to inflammation. Modulation of peroxisome proliferator-activated receptors (PPARs), heat shock proteins (HSPs) and mitogenactivated protein kinases (MAPK cascades), and impaired induction of nitric oxide synthase (iNOS) are among the COXindependent effects of the class of NSAIDs.^{2,28,35} Selected drugs (e.g., celecoxib but not rofecoxib) directly inhibit signaling needed to promote angiogensis, invasiveness, and proliferation of neoplasias.28 Interestingly, sulfone coxibs (see Figure 29-4) are pro-oxidant, whereas sulfonamide coxibs are not.²⁸ Connective tissue metabolism may also be affected.⁷

NSAIDs are immunomodulators by virtue of their effect on several PGs and LTs as immunomodulators.⁸ Nonsteroidal antiinflammatory cells indirectly influence lymphocyte activity through altered PG formation.⁷ Selected NSAIDs appear to enhance cellular immunity by inhibiting PGE₂, a mediator that dampens the immune response.⁷ This effect appears to be more important in the immunosuppressed animal.

Pharmacokinetics

Shared Pharmacokinetic Properties

Each drug will be discussed in depth; however, the NSAIDs share a number of pharmacokinetic properties as a class. Package insert data for dog and cat contains selected information for some drugs, although the information often is not comprehensive, with content tending to vary, in part based on the requirements implemented by the FDA at the time of drug approval. The United States Pharmacopeia has provided a series of monographs providing pharmacokinetic information regarding the use of NSAIDS in species; information will be addressed for individual drugs. As weak acids, the NSAIDs tend to be well absorbed after oral administration. Bioavailability can vary between animals but has not been established for many drugs because of the lack of intravenous preparations.³⁶ Solutions of selected injectable preparations tend to be alkaline and can cause necrosis or pain if perivascular leakage occurs Food can impair the oral absorption of some NSAIDs or contribute to drug interactions.^{37,38} The drugs are lipid soluble. Whereas the volume of distribution tends to be small (approximating 10%) when based on total drug as a result of \ge 90% binding to serum albumin³⁹ the volume of distribution of unbound drug is consistent with distribution to extracellular fluid (Table 29-4). Only a small portion of pharmacologically active drug reaches peripheral tissues. Displacement from albumin (e.g., due to competition with other substrates for binding sites or from decreased serum albumin concentrations) may result in higher than expected concentrations of pharmacologically active drug and thus predispose the patient to drug-induced adverse effects. Although this increase is likely to be transient as the elimination of of unbound drug increases,^{36,40} adversities might yet emerge particularly in patients at risk (e.g, decreased hepatic or renal function). Clearance of unbound drug is likely to be reduced in geriatric patients. The volume of distribution of unbound drug in pediatric animals is twice that in adults, which will contribute potentially to longer half-life.³⁶ For this and other reasons, (see metabolism), NSAIDs should not be used in the pediatric patient.

Most NSAIDs are eliminated primarily by both phase I and II hepatic drug-metabolizing enzymes. Clearance differs in both rate and extent among drugs and species. Differences in clearance are largely responsible for differences in drug half-life among animals.³⁶ Failing to anticipate these differences may contribute to adverse reactions. Conjugated parent drug or metabolites are eliminated through the bile or urine, depending on the drug. Stereoselective metabolism plays a profound role in species, gender and age differences. Saturation of drug metabolizing enzymes may occur at doses higher than recommended clinically for some drugs as has been demonstrated for phenylbutazone and derocoxib (package insert). Genetic polymorphism has been described in dogs for at least one NSAID (celecoxib)⁴¹ and is likely to occur for others. Several drugs, or their enantiomers, undergo extensive enterohepatic circulation, again with differences among species (e.g., naproxen, meclofenamic acid, and the S enantiomer of carprofen in dogs), increasing the risk of gastrointestinal toxicity.⁴² Renal active tubular secretion occurs for some parent drugs. Naproxen, carprofen, ketoprofen, and celecoxib are among the drugs which exemplify pharmacodynamics and pharmacokinetics differences in safety and efficacy among species.³⁶ Whereas allometric scaling generally can accurately predict systemic clearance and volume of distribution (based on body weight) of NSAIDs, allometric scaling generally cannot predict differences in pharmacodynamic indices (e.g., inhibition of TXB2 and PGE₂ synthesis).⁴³

KEY POINT 29-6 Predicting nonsteroidal antiinflammatory drugs half-life is complicated by enantiomers and differences in rates of metabolism among animals.

Integration of Pharmacokinetics and Pharmacodynamics

Pharmacologic Effects

The pharmacologic effects of this class of drugs include analgesia, antipyresis, and control of inflammation. Antithrombosis also occurs, but this effect is variable, being the greatest for aspirin and the least to absent for newer COX-2 selective drugs. The effects are dose and drug dependent and include antithrombosis (when present), which occurs at the lowest concentrations (relatively lower for aspirin compared to all others); followed by antipyresis, analgesia and antiinflammation, with the latter occurring at the highest concentrations, although an exception appears to occur again for aspirin.^{10,} ^{43d} Studies that compared efficacy and safety traditional or newer NSAIDs are generally are based on in vitro or ex vivo methods, with clinical trials limited. Yet, differences should be anticipated even among the newer NSAIDs. The mechanisms by which NSAIDs inhibit (interact with) COX are responsible, in part, for the variable antiinflammatory effects that characterize these drugs. Although several NSAIDs are characterized by a short plasma elimination half-life, the clinical response may last for over 24 hours after a single dose or up to 72 hours after multiple doses. These differential durations reflect, in part, drug-receptor interactions, with irreversible binding to COX most likely contribute to a longer biologic response.44 Lees and co-workers have reviewed the relationship of NSAID effect and dose, emphasizing the advantages of PK-PD modeling as a basis of dose design.^{44a} Inhibition of COX-1 has been described as simple competitive inhibition, whereas that for COX-2 has been described as a slowly reversible, contributing to a longer biologic versus plasma half-life.⁴⁵ Aspirin binds reversibly to the COX activity site on PGH synthase and then irreversibly inactivates the enzyme by acetylating a serine residue.¹⁰ Both thromboxane and prostacycline synthase are impacted. However, platelets cannot produce additional thromboxane synthase; as such, platelet activity depends on new platelet production in the absence of aspirin. In contrast, endothelial cells are able to synthesize more prostacyclin synthetase and are less susceptible to the inhibitory effects of low dose aspirin.¹⁰ In contrast to irreversible binders of COX, ibuprofen binds reversibly with COX and thus competes with AA for binding. In laboratory

animals and humans, a relative potency (not to be confused with efficacy) has been established for selected conventional NSAIDs and COX: meclofenamic acid >indomethacin >naproxen >phenylbutazone >aspirin.⁴⁴ However, differential potency for COX-1 versus COX-2 varies among the NSAIDs and their enantiomers. In addition to drug-receptor interaction, prolonged elimination of NSAIDs from inflammatory exudate compared with plasma may also result in differential effects among the drugs and species.^{37,44}

Along with inhibition of PGs, disruption of cellular signaling is responsible for all three pharmacologic effects (antiypresis, analgesia, anti-inflammation) that characterize all NSAIDs.¹⁰ The antipyretic effect of NSAIDs may or may not be of benefit. Indeed, in human medicine little scientific support exists for the use of antipyretics for relief of discomfort or reduction of morbidity and mortality associated with fever.⁴⁷ Fever may have a beneficial effect on the outcome of bacterial or viral infections and often inversely correlates with the severity of lesions or the time to resolution. Thus the antipyretic effects of NSAID may be of most benefit when increased metabolism induced by fever might prove detrimental, such as with septicemia.⁴⁷ Central analgesic effects have been suggested for some but not all NSAIDs because NSAIDs can provide analgesia at very low intrathecal doses.^{15,16,46}

The impact of COX on disease has led to a number of new applications for NSAIDs. The antiendotoxic effect of selected NSAIDs has been known (see the discussion of flunixin), but newer mechanisms are being examined. For example, several NSAIDs (carprofen, flunixin meglumine, and phenylbutazone) may specifically inhibit activation of the proinflammatory transcription factor nuclear factor kappa B (NF- κ B) and on lipopolysaccharide (LPS) induction of iNOS. Using a mouse macrophages line, carprofen and flunixin, but not phenylbutazone, inhibited iNOS, whereas carprofen and, to a lesser degree, flunixin, inhibited NF-kappaB activation.³⁵

Because NSAIDs are commonly first-choice treatments for arthritis, a focus on the effects of NSAIDs on cartilage is warranted. NSAIDs have been shown to inhibit proteoglycan synthesis in vitro, and for the salicylates this is supported by in vivo studies.⁴⁸ This effect has been attributed to inhibition of uridine diphosphate glucose dehydrogenase, an enzyme important in proteoglycan synthesis.⁴⁸ Hyaluronic acid synthesis, also dependent on this enzyme, does not appear to be as affected. The clinical effects of NSAIDs on cartilage are controversial. Some NSAIDs may, in fact, favorably modify the metabolism of proteoglycans, collagen, and matrix and may decrease the release of proteases or toxic oxygen metabolites.⁴⁸ This may reflect, in part, control of inflammation. Thus, whereas several NSAIDs have documented adverse effects on normal cartilage, ranging from decreased proteoglycan synthesis (e.g., aspirin) to chondrocyte death (phenylbutazone), others (e.g., naproxen, piroxicam, ketoprofen, and possibly carprofen) are recognized for their chondroprotective effects. Dual inhibitors have been noted for their potential efficacy to slow the progression of arthritis.48b

KEY POINT 29-7 Newer nonsteroidal antiinflammatory drugs are less destructive to the cartilage at therapeutic concentrations than older nonsteroidal antiinflammatory drugs.

The use of NSAIDs in the control of acute pain is evolving. Preemptive use (just before and immediately after surgery) has been demonstrated in humans to be more effective than either placebo or control,¹⁷ and similar findings have been reported in the clinical use of COX-1–sparing drugs in animals. Drugs that target COX-2 (NSAIDs) offer a morphine-sparing effect for control of postoperative pain.¹⁷ Their use in multimodal analgesia is increasing.

NSAIDs are currently being investigated for their potential antitumor effects. Knapp and coworkers⁵⁰ found piroxicam to be clinically useful in reducing tumor size and increasing survival time in dogs with transitional cell tumors of the urinary bladder. The result does not appear to reflect direct cytotoxic effects.⁴⁹⁻⁵¹ NSAIDs may be beneficial when combined with other anticancer drugs.⁵² The effects of drugs inhibiting COX-2 cancerogenesis may be dose dependent: At least for aspirin, the maximum anticancer effect occurs at a dose less than that associated with control of inflammation but similar to that associated with antiplatelet effects.⁹ Mechanisms other than COX inhibition contribute to NSAID antitumor effects.^{51a} In addition to the inhibition of cancer growth, the use of COX-1–sparing drugs may improve gastrointestinal tolerance of anticancer drugs.

Drug Interactions

The NSAIDs can be involved in a variety of drug interactions during any phase of drug disposition (see the discussion of individual drugs). Trepanier⁵³ has reviewed some of these interactions. Displacement of only a small percentage of bound drug from albumin can increased the concentration of pharmacologically active drug in tissues. Few, if any, adverse reactions resulting from drug displacement have been reported, in part because of the failure to recognize the combination as problematic. In addition, the increase in pharmacologically active drug is only transient: Clearance of the unbound drug by both the liver and kidneys will increase.^{36,40} However, the impact of changes in protein binding in patients with altered liver function may be problematic; accordingly, attention to the possibility that protein-binding drug interactions may worsen risks associated with liver disease might be prudent. Several NSAIDs can induce or inhibit drug-metabolizing enzymes and thus the clearance and half-life of other drugs cleared by the liver.³⁶ Phenylbutazone can both increase and inhibit selected drug-metabolizing enzymes depending on the second drug, whereas salicylates increase metabolism.³⁶ Renal competition with other organic acids for active renal tubular secretion in the proximal tubule has been documented for aspirin and other drugs, although the clinical relevance of this is not clear.

KEY POINT 29-8 Among the less appreciated drug interactions involving nonsteroidal antiinflammatory drugs are pharmacodynamic interactions that impair normal physiologic responses.

KEY POINT 29-9 Nonsteroidal antiinflammatory drug–induced gastrointestinal adversities should be anticipated and clients counseled regarding their advent.

Drug interactions also occur at the level of pharmacodynamics and may increase the risk of adversities. Most notable is the combinations of NSAIDs or glucocorticoids, which increase the risk of gastrointestinal toxicity (discussed later). Also notable are those drugs that, like NSAIDs, alter renal blood flow, and potentially renal autoregulation, thus increasing the risk of nephrotoxicity (e.g., aminoglycosides, angiotensin-converting enzyme inhibitors, amphotericin B). NSAIDs, in turn, may blunt response to diuretics and hypertensive drugs. NSAIDs may also block endogenous responses to hypertensive drugs (e.g., alpha adrenergics such as phenylpropanolamine), thus increasing the risk of hypertension, although this is more likely a risk only in animals for which primary hypertension is a concern.⁵⁴ The impact of combining NSAIDs with other drugs that affect platelet function or coagulation proteins is complicated by the differences in mechanisms of action between nonselective and preferentially selective drugs. Nonselective drugs would be expected to potentiate platelet function defects or deficiencies, whereas preferentially selective drugs would not. Prudence dictates that NSAID use ideally be avoided in patients with metabolic, hematologic, cardiovascular, or other disorders that put the patient at risk. NSAIDs are more likely to cause CNS effects if combined with fluorinated quinolones with unsubstituted piperazinyl rings (ciprofloxacin) at position 7.55 It is not clear if the interaction occurs at the level of CNS (at the level of the gamma-aminobutyric acid receptor) or as a result of altered clearance.56

Selective serotonin reuptake inhibitors increase the risk of upper gastrointestinal hemorrhage based on a meta-analysis of the human-medicine literature.⁵⁷ The risk is greater in elderly patients; those drugs most selective for reuptake are associated with a higher risk. Among the proposed mechanisms is depletion of platelet serotonin and loss of platelet aggregation.

Adverse Reactions

All NSAIDs induce undesirable and potentially life-threatening side effects. In general, side effects tend to be predicted by toxicity studies implemented during the approval process,58 although the small number of animals tends to limit their prediction to only the most common side effects. The role of drug interactions in causing adverse events was previously described. Accidental poisoning has been described for several NSAIDs, with the most common among the conventional drugs being ibuprofen, acetaminophen, aspirin, and indomethacin;⁵⁹ decreased use of these drugs as newer NSAIDs are used decreases relevancy. The most common clinical signs of toxicosis were vomiting and diarrhea followed by CNS depression, and circulatory manifestations.⁵⁹ Most adverse reactions reflect the inhibitory effects of NSAIDs on PG activity. Acute intoxication by selected drugs can be fatal; the more common adverse drug events are discussed along with their prevention and treatment below.

The adverse event reporting site of the Food and Drug Administration (FDA) is publically acceptable and can be reviewed for adverse drug events associated with NSAIDs in animals.^{59a} However, effective epidemiologic assessment is limited and cause and effect between drug and adverse

drug event may not exist. Further, the FDA is not provided information regarding the number of units sold precludes standardizing incidence of adverse drug events among drugs. Among the greatest contributing limitations to the adverse event reporting site may be failure of veterinarians or clients to report adverse events.

Transitioning from one NSAID to another in an attempt to reduced toxicity (or improve efficacy) should be based on elimination half-life (plasma or biological, whichever is longer). For those that reversibly impair COX, 3 to 5 elimination half-lives of the current NSAID should elapse prior to initiating the second (see Table 29-4). Prudence dictates that prophylactic measures be implemented during transition for at-risk patients.

Toxicity as a result of overdosing should be treated as with other overdoses (i.e., removal of ingested drug, supportive therapy). Treatment generally should continue for at least 3 to 5 half-lives of the ingested NSAID; longer may be necessary, particularly if the intoxicating amount is sufficient to saturate drug metabolizing enzymes. The risk of saturation kinetics is greater in age extremes, for selected drugs (e.g., phenylbutazone, deracoxib), and in the presences of liver disease. For NSAIDs characterized by enterohepatic circulation, administration of cholestyramine should be considered. The drug binds to at least several NSAIDs, thus preventing enterohepatic circulation, decreasing half-life as well as gastrointestinal exposure.⁶⁰ Treatment of other specific disorders is addressed with the adverse drug events.

Gastrointestinal

Mechanism of Gastrointestinal Adverse Events

Gastrointestinal damage is the most common and serious side effect of the NSAIDs. Dogs are described as being "exquisitively sensitive" (see package insert for meclofenamic acid, Fort Dodge) to NSAID-induced gastrointestinal ulceration. The incidence of gastrointestinal side effects associated with NSAID use in dogs (or cats) is not known. However, essentially every NSAIDs (conventional and new) used in the dog has been cited literature, at the FDA adverse event reporting site, in manufacturing package inserts, or other sources as causing gastrointestinal adverse drug events.⁶¹⁻⁶⁶ Gastrointestinal ulceration should be anticipated in dogs receiving these drugs, and clients should be counseled regarding the side effects and potential treatments for ulcerative injury. The incidence of side effects associated with new NSAIDs approved for use in animals has led the inclusion of client information sheets (as part of package inserts) to be distributed to clients when NSAIDs are dispense to animals for at home therapy.

The mechanism of gastrointestinal damage is not completely understood. A review of the FDA-CVM adverse event website reveals gastrointestinal adversities to be the most common for most, if not all, NSAIDs for which adversities are reported. In the cat, gastrointestinal adversities are the first, or more commonly second, adverse event reported for most NSAIDs. It is likely that several mechanisms act in concert to cause adversities; the mechanisms and risks as they are perceived in human medicine have been reviewed.⁶⁷⁻⁶⁹ Several mechanisms offer a

target for prevention and treatment. Gastroduodenal erosion and ulceration reflect, in part, inhibition of COX-1-stimulated PGE₂-mediated bicarbonate and mucous secretion, epithelialization, and increased blood flow.⁷⁰⁻⁷¹ Breakdown of small blood vessels resulting from a deficiency of mucus may be the initiating lesion.⁷² Enhanced LT synthesis from AA shunted from the COX pathway to the lipoxygenase pathway exacerbates damage: due to vasoconstriction-induced mucosal damage as well as platelet aggregation and neutrophil activation. Dual inhibitors which target LTs as well as PGs may be less ulcerogenic. Direct irritation contributes to gastrointestinal mucosal damage for acidic drugs: ⁷⁰ ion trapping in the mucosa precipitates hydrogen ion diffusion from the lumen of the stomach to the mucosa.^{70,73} The lack of a sensitive indicator of gastrointestinal damage complicates assessment of gastrointestinal adverse drug events caused by NSAIDs. Boston and coworkers⁷⁴ as others could not find a relationship appears between the presence of gastric lesions and positive fecal occult blood. A method based on sucrose absorption in the gastrointestinal tract may be successful for detecting NSAID-induced gastrointestinal damage.⁷⁵ Some investigators have gone so far to suggest that endoscopic presence of erosive lesions is not necessarily indicative of ulcerogenic effects of NSAIDs.76 The lack of welldesigned clinical trials assessing detection, risk, prevention or treatment is problematic. Some studies continue to inappropriately ascribe the lack of statistical differences among treatment groups as evidence of no treatment (diagnostic) effect. Yet, failure to detect a significant difference (type II statistical error) often reflects the small sample size characterizing these clinical trial and caution is recommended to not overinterpret "lack of significant difference" as "sample populations are similar".

Prevention and Treatment of Gastrointestinal Adverse Events

Prevention of gastrointestinal toxicity is based on identifying those patients at greatest risk; avoiding NSAIDs drugs, if possible, in these patients; and if this is not possible, selecting the safest drug (i.e., COX-1–sparing drugs) and using it in a dosing regimen that results in the lowest exposure necessary for efficacy. Prevention also includes co-treatment with prophylactic drugs, including those that prevent gastric acid secretion or those that replace PGs.⁷³ The use of other therapies that might decrease the need for NSAIDs (e.g., combination analgesic therapy, cartilage-supportive disease-modifying agents) also is indicated.

KEY POINT 29-10 Patients at risk for nonsteroidal antiinflammatory drug–induced gastrointestinal adversities should be identified before implementation of therapy, and preventive measures should be taken, if warranted.

Risk factors for NSAID-induced gastrointestinal adverse events. Several risk factors for NSAID-induced gastrointestinal adverse events identified in humans are applicable to animals. No chemical characteristic predicts the likelihood of gastrointestinal toxicity by a particular conventional NSAID.^{70,72} Drugs that undergo enterohepatic circulation (e.g., naproxen, carprofen, etodolac) may be associated with a greater incidence of gastrointestinal upset. Other risk factors include advanced age (altered disposition coupled with decreased ability to protect damaged mucosa),⁷⁷ concurrent use of glucocorticoids (increasing the risk 4.4-fold in humans) or other NSAIDs (the exception might be low-dose aspirin, as discussed later), or anticoagulants. Comorbidity (renal, cardiovascular, or liver disase) is also a risk factor.⁷³

The combination of steroids and NSAIDs causes worse lesions than either drug alone, as has been demonstrated for flunixin meglumine or dexamethasone.74,78,79 Further, the FDA adverse drug events site indicates that the risk of gastrointestinal toxicity is greater when drugs are given with glucocorticoids. In a restrospective study of gastrointestinal perforation associated with deracoxib, a risk factor was combination with glucocorticoids (or other NSAIDs) within the past 24 hours.⁸⁰ Other NSAIDs appear to shift use of AA from the COX pathway to the production of cysteinyl LTs and LTB4, eicosonoids that promote leukocyte migration, break down the mucosal barrier, and stimulate gastric acid secretion. Inhibition of COX-2 may preclude angiogenesis critical to the healing ulcer.⁸¹ Persons with previous history of gastric ulcer disease also are predisposed to NSAID-induced gastrointestinal adverse drug events. Although peptic ulcer disease is unusual in animals, prudence dictates that evidence of any gastrointestinal disease associated with mucosal damage (e.g., inflammatory bowel disease) that might require COX-2-mediated healing be considered a potential risk factor.

Dose-dependent toxicity has been demonstrated during the approval process essentially for all NSAIDs as is indicated by product package inserts (Table 29-5). The single most common cause of NSAID-induced toxicity found by a review of NSAIDinduced adverse drug event reports by the FDA is overdosing, in particular failure to adhere to the recommended dosing regimen. Overdosing was associated with an increased risk of NSAIDinduced gastrointestinal perforation in dogs.⁸⁰ Drugs for which low-concentration preparations are not available increases the risk of toxicity because of inaccurate dosing. Use of compounded preparations (for which oral bioavailability is not known) should be implemented with extreme cautions; increasing bioavailability will result in a proportional increase in drug concentrations. The risk for overdosage is greater for selected drugs for which higher doses may result in zero-order elimination (e.g., deracoxib, phenylbutazone). For such drugs half-life is no longer germane, and the risk of drug accumulation dramatically increases.

The relationship between dose and risk of toxicity remains complex, even for NSAIDs, as is exemplified by aspirin. At low doses (concentrations), aspirin blocks COX activity and thus shunts AA into the lipoxygenase pathway. Although gastrotoxic LTs are produced (cysteinyl LTs and LTB4), aspirin also simultaneously triggers lipoxin (aspirin-triggered lipoxin [ATL]) formed by lipoxygenase-15. Lipoxin is antiinflammatory and thus inhibits the gastrotoxic leukocyte recruitment and activation caused by cysteinyl LTs, as well as mediates the antiadhesive platelet effects of aspirin. As such, low-dose aspirin tends to be both cardioprotective as well as safe to the gastrointestinal tract. However, at higher doses production of LTs is sufficient that the protective effects of lipoxin are masked and gastrotoxicity emerges. Interestingly, COX-1–sparing (COX-2

[‡]No placebo reported.

preferential drugs) inhibit the formation of lipoxin, contributing to the toxicity of the newer drugs when combined with low-dose aspirin.⁸¹ Theoretically, whereas COX-inhibiting drugs should not be combined with low-dose aspirin, dualacting NSAIDs, which do not target lipoxygenase-15 (see the discussion of dual-acting NSAIDs), should not inhibit lipoxin and thus should maintain the low-dose aspirin gastroprotective and cardioprotective effects.⁸¹

In general, conventional NSAIDs are associated with a greater risk of gastrointestinal adverse drug events in humans, but exceptions may occur. For example, in humans (but not dogs) ibuprofen, which is essentially equivalent in its COX-1 versus -2 selectivity, is ranked as low risk, along with the COX-1–sparing drugs celecoxib, rofecoxib, meloxicam, and etodolac.⁷³ Comparison in dogs of gastrointestinal safety among newer NSAIDs, including both COX-1–sparing drugs and dual-acting NSAIDs, might be based on toxicity data generated during the approval process and available on package inserts. This latter source includes both targeted safety studies (the dose is multiplied by 3, 5, or 10) and field studies (clinical trials at recommended doses under conditions of anticipated use) (see Table 29-5).

Comparison of clinical safety among NSAIDs ideally should reflect nonmanufacturer-sponsored, well-designed clinical trials involving a sufficient number of animals such that the power is sufficient to detect a significant difference. Placebo controls are imperative; positive responses have been reported in 40% or more of placebo-treated animals.⁸² However, such studies in veterinary medicine are few and far between. Data that do exist thus far support the safety of the newer drugs compared with conventional NSAIDs. For example, using a placebo-controlled, parallel, randomly assigned design in dogs (n = 6/group), Reimer and coworkers⁸³ found that buffered aspirin caused endoscopic gastric lesions within 5 days of starting therapy compared with no or minimal lesions in animals treated with carprofen or etodolac (sample size may have limited the ability to discern a difference between the two groups); all drugs were administered at mid-recommended doses. Endoscopic lesions followed the same relative pattern among drugs throughout the 28-day study period, indicating that aspirin is more commonly associated with lesions in the canine gastrointestinal tract compared with the COX-1-sparing drugs. A separate study found no differences in gastrointestinal lesions in animals receiving ketoprofen (nonselective), carprofen, meloxicam, or placebo. However, the power of this latter study to detect a significant difference was not reported.

Pharmacologic prevention and treatment. Future pharmaceutical manipulations designed to deliver NSAIDs by alternative routes may decrease risk of gastrointestinal adverse drug effects, although their application to veterinary patients should not necessarily be assumed. For example, formation of nitroso derivatives of conventional NSAIDs may improve the safety margin of these drugs as a result of in vivo release of NO that provides gastroprotection while improving antiinflammatory and analgesic potency.² However, NO also has been associated with the pathogenesis of osteoarthritis, thus exemplifying the continuously complicated nature of designing safe NSAIDs (see later discussion).²² In contrast to current drugs that only slowly dissociate with COX-1, newer NSAIDs appear to be weak and rapidly reversible binders of COX-1, thus enhancing safety.^{17,45}

Topical (including transdermal) NSAID administration is appealing because it avoids direct contact between the drug and target tissue. Indeed, a meta-analysis of clinical trials comparing topical NSAIDs to placebos and oral NSAIDs in humans found this route to be effective, with no difference in response compared with oral. Topical administration was safe, although not necessarily safer than oral. Of the NSAIDs reviewed, ketoprofen was described as the best.84 Thus far, topical NSAID administration has not proved to be a vital means of avoiding gastrointestinal adverse drug events in small animals, primarily because of failed drug delivery. Because the amount of drug delivered cannot be predicted, administration of NSAID in novel drug delivery systems offered by compounding pharmacists is not recommended unless the amount of drug delivered by that system has been scientifically demonstrated, as would occur for an approved drug. Enteric coatings, combination drugs (e.g., with gastroprotectants), and other approaches may be of some benefit for some drugs (e.g., aspirin) and, if currently available, are discussed with the individual drugs.

Both the prevention and treatment for gastrointestinal toxicity focus on, in order of priority, control of gastric acid secretion, replacement of the missing PGs, and (for treatment) protection of the damaged mucosa.^{64,85} The two major categories included antisecretory drugs and the PG analog misoprostol; cytoprotectants, such as sucralfate, also play a role in treatment.

Among the antisecretory drugs, proton pump inhibitors (PPIs) generally have proved more effective than H₂ receptor blockers for prevention and treatment of NSAID-induced gastrointestinal adverse drug events. An exception has been demonstrated in humans for famotidine, but only when it is administered at higher than recommended doses (40 mg twice rather than once daily).73 Boulay and coworkers86 demonstrated that cimetidine did not protect the gastric mucosa from developing lesions in dogs receiving nonbuffered aspirin (35 mg/kg every 8 hours). PPIs appeared to be more effective, as well as better tolerated, compared with misoprostol. In one human study, close to 30% of persons reciving misoprostol could not tolerate the full dose.⁷⁶ Omeprazole generally is the PPI of choice, although lansoprazole may also be a reasonable choice. Although lansoprazole was not found to be superior to misoprostol for prevention of gastrointestinal adverse drug events in humans, improved compliance and better tolerance made it the preferred PPI drug in humans. However, the use of PPI will not prevent ulcers in all patients, as has been demonstrated in humans. Symptoms of GI side effects still occur in 20% of human patients receiving omeprazole.⁷³ Although routine use of PPI in nonrisk animals receiving NSAIDs is not indicated, strong consideration should be given to their use in at-risk animals. As a class, the PPIs are inhibitors of drugmetabolizing enzymes, and care should be taken to review drug interactions before their use. Among them, esomeprazole may be the least likely to impact metabolizing enzymes.^{86a}

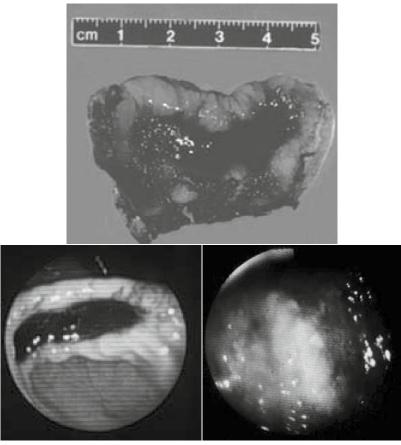

Figure 29-8 A gross (top) and endoscopic view of two gastric ulcers in dogs treated with aspirin and glucocorticoids. The bottom ulcer responded to treatment with misoprostol, sucralfate, and ranitidine.

However, PPI also have been shown to induce selected CYP45O enzymes (P45OIA1 and A2) but this impact appears to be most clinically relevant to (human) poor metabolizers that are deficient in enzymes.^{86b}

KEY POINT 29-11 Among the antisecretory drugs, proton pump inhibitors generally have proved more effective than H₂ receptor blockers for prevention and treatment of nonsteroial antiinflammatory drug–induced gastrointestinal adversities.

Misoprostol is a synthetic PPGE analog that both prevents and helps heal gastrointestinal ulceration caused by NSAIDs.⁸⁷ The efficacy of misoprostol has been well established in human patients suffering from NSAID-induced ulceration,⁷¹ and studies support similar benefits in dogs.^{88,89} Combination NSAID– misoprostol products have been approved for use by human patients,⁹⁰ supporting its their combined use. Interestingly, misoprostol, when combined with an NSAID, also appears to enhance the antiinflammatory effect of the NSAID.⁹⁰ Indeed, misoprostol inhibits IL-1, TNF, and thromboxane release from macrophages, and it is the most potent inhibitor of histamine release from human mast cells.⁹⁰ Misoprostol has potentiated the antiinflammatory effect of a variety of compounds in animalsand appears to have analgesic effects, although at high concentrations, acting synergistically with other NSAIDs.⁹⁰ Finally, misoprostol may be more effective in the presence of agents that decrease gastric acid secretion.⁶⁴

Gastroprotective drugs include sucralfate and potentially glucosamine-chondroitin products (Figure 29-8). The benefits of sucralfate in the treatment of NSAID-induced adverse drug events include binding to and thus protecting damaged mucosa, as well as increasing PG synthesis, angiogenesis, and sulfhydryl (oxygen radical scavenger) production at the site of damage. Despite the fact that sucralfate binds only to damaged mucosa, it nonetheless consistently performs better than placebo in the prevention of gastric or duodenal ulcers in human patients receiving NSAIDs. Sucralfate is minimally effective than antisecretory drugs in preventing stress ulcers (e.g., critical care patients).^{90a} The combined use of NSAIDs and disease-modifying agents (glucosamine and chondroitin sulfates) for treatment of osteoarthritis is discussed later. An added advantage of their combined use is the potential gastroprotection that might be realized because of enhanced mucopolysaccharide production.⁹¹ Interestingly, metronidazole has been ascribed a protective effect on the gastrointestinal tract when combined with NSAIDs, presumably through removal of the microbial impact on neutrophil chemoattractant.⁹²

KEY POINT 29-12 Although sucralfate will not prevent gastrointestinal ulceration, it can protect and facilitate healing of damaged mucosa once it emerges.

The Canadian Agency for Drugs and Technologies in Health (CADTH) sponsored an in-depth analysis of the literature in an attempt to identify the most cost-effective gastroprotective strategies in persons receiving NSAIDs.93 In their report, based on Monte-Carlo modeling, investigators considered patients receiving a nonselective NSAID (diclofenac) alone, a COX-2 preferentnial NSAID alone (celexocib); or either group of the NSAIDS with misoprostol, an H₂ receptor blocker (ranitidine), or a proton pump inhibitor (omeprazole). In their 2007 report, they found that no prophylaxis and treatment with a traditional NSAID; but no gastroprotection was least costly but least effective in avoiding adverse events. Of the combinations, PPI consistently was more effective than no prophylaxis; further, the most cost-effective strategy was the combination of nonselective NSAIDs with PPIs. Combination of nonselective NSAIDs with H₂ receptor antagonists also reduced the risk of gastrointestinal complications, but at a higher cost (25%). Use of Cox-2 selective drugs or combination with misoprotol were effective (but more costly) alternatives, although combination with misoprostol was associated with increased adversity because of its PG effects. The CADTH investigators further observed the need for a large, prospective, multicentered clinical outcome study that directly compares the efficacy of PPIs with H₂ receptor antagonists to prevent NSAID-associated gastrointestinal adversities.

The use of 5-lipoxygenase inhibitors for prevention of NSAIDs gastrointestinal toxicity might be considered. Lis facilitate ulcer formation by virtue of their effect on platelets and blood vessels; these effects and others also might be inhibited by LT receptor antagonists (see later discussion). Among the approaches in reducing gastrointestinal toxicity associated with NSAIDs is the development of NO-NSAIDs.69 NO has been recognized as an important gastroprotectant. Its mechanism appears, in part, to reflect inhibition of neutrophil adherence to vascular endothelium, which is necessary for mucosal damage to occur. Whereas adverse reactions are likely to preclude use of drugs that promote NO release systemically, NSAIDs that facilitate local release of NO (COX-inhibiting NO donors; NO-NSAIDs) are currently being developed. The drugs contain a NO-releasing moiety; their continuing development has been reviewed.⁶⁹ For example, the addition of the moiety to naproxen has yielded naproxcinod. The gastric mucosa also is protected by the formation of hydrogen sulfide (H_2S) when produced in appropriate quantities. Accordingly, NSAIDs are being designed with a moiety that allows local, limited release of H₂S. In either case (NO- or H₂S-releasing moiety), the antiinflammatory potency of the drug may also be improved as gastric adversity is decreased.

Liver disease should be an anticipated sequela of longterm use of any drug extensively concentrated or metabolized by the liver, including NSAIDs (see Chapter 4).⁹⁴ All NSAIDs approved for use in dogs have been associated with increased liver enzymes; most have been reported scientifically or anecdotally to cause hepatitis. Although their occurrence is discussed with individual NSAIDs, hepatic function tests (e.g., serum bile acids, albumin, urea nitrogen) should be implemented throughout drug exposure in patients at risk (discussed previously). The use of hepatoprotectant drugs (e.g., *N*-acetylcysteine, *S*-adenosylmethionine [SAMe]) should be considered for both prevention and treatment.

Clinical signs indicative of gastrointestinal ulceration may be exacerbated by an increased risk of bleeding induced by NSAIDs. In addition to their antiplatelet effects, selected NSAIDs (e.g., phenylbutazone) have also been associated with bone marrow dyscrasias.⁹⁵⁻⁹⁸ Gastrointestinal bleeding is probably the most common sign of bleeding dyscrasias, in part because of the ulcerogenic properties of these drugs. Epistaxis has also been reported. Because prostacyclin is mediated largely by COX-2, use of COX-2–selective drugs may increase the risk of thrombosis.⁹⁹

Renal

Analgesic nephropathy is a relatively common adverse effect of NSAIDs in human beings.¹⁰⁰ In the kidney both COX-1 and COX-2 mediate renal effects of PGs. Vasodilatory and tubuloactive PGs are protective, ensuring that medullary vasodilation and urinary output continue during states of renal arterial vasoconstriction (see Figure 29-7). The loss of this protective effect becomes important in patients with compromised renal function.¹⁰⁰ NSAIDs inhibit the synthesis of renal PGs and may lead to deterioration of renal function in patients whose kidneys are physiologically stressed.^{100,101} However, some side effects reflect mechanisms other than PG inhibition. Renal side effects include both acute and chronic renal disease, nephrotic syndrome, interstitial nephritis, hyperkalemia, and disturbances in water and sodium movement.

Two different forms of renal disease associated with NSAIDs are generally described: hemodynamically mediated ischemic nephropathy and acute interstitial nephritis.¹⁰² Nephrotoxicity is more common in human patients than in veterinary patients, probably because therapy with NSAIDs is prolonged in the human patient and often occurs without physician supervision. NSAID therapy is also more common in geriatric patients, which is more likely to have reduced renal function as well decreased nephroprotective function. As such, animals that are likely to be predisposed to developing analgesic nephropathy are those that are geriatric, afflicted with conditions that impair renal blood flow (e.g., cardiac, renal, or cirrhotic liver disease), subjected to a hypotensive state (e.g., prolonged anesthesia without fluid support), and receiving nephroactive or nephrotoxic drugs in addition to the NSAID. Patients receiving more than one NSAID, aminoglycosides, amphotericin B, and possibly angiotensin-converting enzyme inhibitors are potential candidates for analgesic nephropathy.¹⁰³ Interstitial nephritis, a less common syndrome associated with NSAID use in human patients, apparently has not been reported in dogs or cats. The cause of this syndrome appears to be a cell-mediated allergic response. Loss of renal PGs may potentiate the disease as inflammation progresses unchecked.

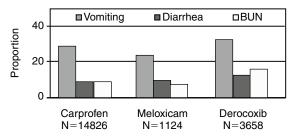

In contrast to gastrointestinal adverse drug events, the risk of renal adverse drug events may not necessarily be reduced with use of newer COX-2–selective drugs compared with conventional NSAIDs. In human medicine clinical trials have demonstrated that the renal effects of COX-1–protective (COX-2–selective) drugs are similar to those of conventional NSAIDs. A low-salt diet may increase the risk: Elderly human patients on a low-sodium diet receiving either single or multiple doses developed reductions in glomerular filtration rate, creatinine clearance, and sodium renal clearance.¹⁰⁴ Acute changes in renal function in humans generally occur within 24 hours, with return to normal by 48 hours.¹⁰⁵

KEY POINT 29-13 The newer nonsteroial antiinflammatory drugs may offer no advantage to older nonsteroial antinflammatory drugs in preventing nephrotoxicity; cats in particularly may be predisposed to adverse renal effects.

A number of studies have focused on the impact of perioperative NSAID use on renal function in dogs. Lobetti and Joubert¹⁰⁶ studied the effects of ketoprofen (1 mg/kg) and carprofen (4 mg/kg) as well as ketorolac (0.5 mg/kg) and morphine (0.1 mg/kg; "control group") on renal function as assessed by serum urea and creatinine concentrations, urine y-glutamyltransferase, fractional renal clearance of sodium, and urinalysis. Measurements were collected before and 24 and 48 hours after ovariohysterectomy in dogs (n=40; four per group, with no placebo control). Fluids were not administered during the surgical procedure, which ranged between 1 and 5 hours in duration. Although all dogs remained clinically normal, transient azotemia was detected in two dogs each (2/4) in the ketoprofen and ketorolac groups, and changes in fractional clearance were detected in all three NSAID groups. Urine specific gravity increased in carprofen-treated dogs, although the clinical relavence of this is not clear.

In their study of carprofen safety in cats, Steagall and coworkers¹⁰⁷ cite a report from the European Union that indicates 50% of the surveyed cases of acute renal failure in cats were associated with NSAID therapy. Gunew and coworkers¹⁰⁸ prospectively studied the effects of long-term (approximately 6 months) treatment of cats with osteoarthritis (n = 46) meloxicam at 0.01 to 0.03 mg/kg using a case-controlled design. Cats were approximately 13 ± 4 years for both groups. Unfortunately, indices of renal dysfunction were compared between groups only at 1 month; no differences were detected at that time. The author has summarized adverse events reported for carprofen and meloxicam in dogs versus cats at the FDA adverse event reporting site for reported after 2006 but before 2009. (Figure 29-9). Although direct numbers of adverse events cannot be compared (no information on units or doses sold for each drug), the proportion of each advent might be compared among drugs. The percent of adverse events related to the kidney suggest that the incidence is clinically relevant in both the dog and cat. However, the data also suggests that the incidence of renal adverse events is generally higher for the cat compared to the dog. Further, the data suggests that the risk of increased BUN and serum creatinine is greater for meloxicam (45 and 46%, respectively) compared to carprofen (24 and 22%, respectively). However, assessment of the more recent data suggests a broader implication. For more recent data, the number of animals for which each specific adverse event occurs has been removed from the site. As such, current comparisons must be limited to ranking of adversities. The rank of increased BUN or serum creatinine is

Proportion of selected ADE associated with NSAID use in dogs

Proportion of selected ADE associated with NSAID use in cats

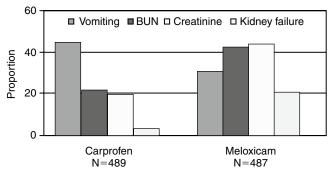

Figure 29-9 The proportion of renal-associated adverse drug events drug for nonsteroidal antiinflammatory drugs (NSAIDs) reported in either dogs or cats. The proportion comes from the total number of adverse events reported for that drug. The total number of adverse events should not be directly compared among drugs because the data cannot be adjusted for the number of units sold or animals treated. For example, a greater number of adverse events in dogs should be expected for carprofen compared with other NSAIDs because carprofen has been approved for a longer time. Further, veterinarians may be less inclined to report adverse events for newly approved NSAIDs if the event is one that is expected of the class. The cause-and-effect relationship for the adverse event and the NSAID was not confirmed but reflects cumulative adverse events reported to manufacturers or directly reported to the Food and Drug Administration (FDA) at the time the data were studied (2007-2008). The data were collected from the FDA's adverse event reporting site from 2006 to 2008 (data were no longer available at time of publication).

higher in cats for each NSAID (approved or not approved) compared to dogs. This includes both meloxicam and ketoprofen (Table 29-6). Accordingly, caution is recommended to not over estimate renal safety of these products in either dogs or cats; further, monitoring of renal function might be indicated in cats receiving NSAIDs long term, particularly if other risk factors for renal disease are present.

Studies have attempted to identify methods to prevent or treat NSAID-induced analgesic nephropathies. Despite some studies supporting its role,¹⁰⁹ misoprostol does not have a recognized role in the prevention or treatment of NSAID-induced nephrotoxicity. Its impact on other drug-induced nephropathies associated with vasoconstriction has been variable (e.g., cyclosporine^{110, 111}). Misoprostol has been used clincally in human patients suffering from clinical conditions

Table 00 C Devilie of the Deat Marter O D - I -

From the Food and Drug Administration Center for Veterinary Medicine Cumulative Adverse Event website: fda.gov/AnimalVeterinary/SafetyHealth/ProductSafetyInformation/ ucm055394.htm), accessed January 2011. The rank for each adverse event (vomiting, increased BUN or serum creatinine) indicates the frequency of reports citing that adverse event for that drug in dogs or cats, where a ranking of 1=most frequent. Numbers in parentheses indicate the number of animals for which adverse events were reported. The absolute number of adverse events should not be directly compared among drugs because it is not correctable for the number of units sold. NR, Not reported; PO, oral; Inj, injectable.

associated with peripheral or renal vasoconstriction; however, its effects may be dose related, with natriuresis, diuresis, and vasodilation occurring at low doses and vasoconstriction and impaired salt and water excretion occurring at high doses. Currently, preventive measures, including therapy with sodium-containing fluids, minimizing of drug interactions, and avoidance of use in patients at risk, appears to be the best method of avoiding the nephrotoxic effects of NSAIDS.

N-acetylcysteine has been studied experimentally for the prevention or treatment of NSAID-induced nephrotoxicity.^{102,112} Proposed mechanisms include vasodilation, although other mechanisms may be relevant. However, although animal models have indicated potential efficacy, clinical trials, including meta-analyses, have thus far failed to provide conclusive evidence of efficacy.¹¹³ Nonetheless, in the absence of effective therapies, N-acetylcysteine is generally recommended (approximately 10 mg/kg or more orally twice daily) preventively for drug-induced toxicity.

Cardiovascular

All conventional NSAIDs are able to impair platelet activity as a result of impaired PG (thromboxane) synthesis, a COX-1-selective action (see Figure 29-6). At pharmacologic doses aspirin selectively and irreversibly acetylates a serine residue of a platelet COX.¹¹⁴ The platelet form of this enzyme is up to 250-fold more sensitive to acetylation by aspirin compared with COX (prostacyclin synthetase) in vascular endothelial cells. Although platelets cannot regenerate more COX, endothelial cells apparently are able to rapidly synthesize and replace impaired COX.¹¹⁴ Platelet aggregation defects caused by aspirin will last until platelets can be replaced, generally 1 to 2 weeks.

KEY POINT 29-14 Cyclooxygenase-2-preferential drugs should be expected to increase the risk of thrombosis rather than hemostasis.

The effect of newer NSAIDs differs from that of conventional NSAIDs. The loss of COX-2-mediated formation of prostacyclin and its antithrombotic effects in the vascular endothelium predisposes (human) patients to COX-1-mediated platelet aggregation, leukocyte activation, and adhesion and accumulation of cholesterol in vascular cells. The potential association of COX-2 inhibitors and an increased risk of thromboembolic disease evolved in the analysis of side effects

in treatment groups receiving selected COX-2 preferential drugs (e.g., rofecoxib or celecoxib compared with placebos or conventional NSAIDs) as part of clinical trials evaluating their use for treatment of cancer, treatment of AD, or association with gastrointestinal side effects. The trials initially were not designed to compare cardiovascular events, and initial evaluation could not discern whether it was treatment with rofecoxib or lack of treatment with naproxen (and thus loss of a cardioprotective effect) that led to the increased risk.¹¹⁵ Subsequent studies that have focused specifically on the risk of thromboembolic events have yielded conflicting results, ranging from a clear increased risk to no detectable increase in risk. The results of these studies have been reviewed,¹¹⁵ but conclusions are complicated by the presence of aspirin. However, neither conventional nor COX-selective NSAIDs are as likely to impair platelet aggregation as well as aspirin does. For platelet aggregation to be impaired, TXA2 must be inhibited by at least 95%, an impact that competitive TXA2 inhibitors cannot achieve; the possible exception is naproxen because of its long half-life. In contrast, aspirin irreversibly acetylates TXA2. Accordingly, both aspirin and naproxen tend to be associated with cardioprotective effects. However, aspirin has the added advantage of stimulating lipoxin, which provides antiplatelet effects.²⁰ A number of NSAIDs, including naproxen, block aspirin's cardioprotective effect, in part by physically binding the serine site of TXA2 acetylation by aspirin. Although this is less likely for newer NSAIDs, they may impair lipoxin, thus impairing antiplatelet effects through a different mechanism. This complicates interpretation of these studies, particularly if groups are not controlled for aspirin dose, duration, and timing. However, in general, review of these clinical trials indicate that COX-2selective drugs do increase the risk of cardiovascular adverse events, particularly in patients already suffering from disease.¹¹⁵

The impact of COX-2 selective drugs on hemostasis in veterinary medicine is not clear, but preferential COX-2 inhibition by endogenous glucocorticoids may help explain the increased risk of thrombogenesis in dogs suffering from hyperadrenocorticism. In a canine model of coronary vessel occlusion, celecoxib decreased the vasodilatory response to AA, leading the authors to conclude that a potential risk exists for acute vascular events in animals suffering from inflammatory disorders and receiving COX-2-selective drugs.¹¹⁶ However, celecoxib also prevents the cardioprotective effects provided by low dose aspirin, contributing to the increased

risk of thromboembolic events in some human patients.^{116a} The lack of unequivocal information regarding COX selectivity of the various NSAIDs in either dogs or cats complicates assessment of risk. As such, NSAIDs should be used only with great caution in animals with comorbidity influencing hemostasis (e.g., heart worm thromboembolis). This may be particularly problematic in the cat (e.g., hypertrophic cardiomyopathy) for which little information regarding COX selectivity among drugs is available.

Miscellaneous

Thyroid

A number of NSAIDs adversely affect thyroid function, primarily through competition for or impairment of binding to carrier proteins. Displacement appears to cause plasma concentrations to rapidly increase, leading to decreased thyroidstimulating hormone; however, with time, increased clearance of the hormone should alter the balance in the opposite direction. The impact of NSAIDs on the thyroid gland may reflect the sulfur moiety present on many of the drugs (see Figures 29-3 and 29-4); it is possible that displacement from proteinbinding sites might increase clearance. Using a randomized crossover design, Daminet and coworkers¹¹⁷ reported that aspirin reduced total T₄ within 24 hours of administration of 25 mg/kg twice daily; thyroid-stimulating hormone and free T₄ were not affected. Ketoprofen at 1 mg/kg once daily had no effect compared with placebo. Whereas etodolac appears to have minimal impact on thyroid function.¹¹⁸ Ferguson (as reviewed by Sauve)¹¹⁹ reported slightly decreased serum T₄ and cTSH in dogs receiving carprofen for 2 to 5 weeks. Sauve and coworkers¹¹⁹ prospectively studied in osteoarthritic dogs (n=62) the effect of meloxicam (n=14; 0.2 mg/kg load followed by 0.1 mg/kg daily for 60 days total), carprofen (n=14; 1.7 to 2.3 mg/kg twice daily for 60 days) and chondroitin sulfateglucosamine-manganese combinations (n=18; 1 to 3 capsules daily for 60 days) compared with placebo on thyroid function. The study was randomized and placebo (n=16) controlled. Thyroid function did not significantly differ among any treatment group across time or between groups; however, free T₄ declined 20% in the meloxicam group. Sample size may have limited the ability to detect differences in other groups.

Lungs

The "allergy" to aspirin described for human asthmatics is generally recognized to reflect increased production of LTs, although the loss of the inhibitory effect on LT production by PGs also has been suggested. Drugs that are COX-1 sparing do not appear to precipitate asthma as do conventional NSAIDs and aspirin in particular, suggesting that the newer drugs are safe in asthmatic patients.²⁰ The impact of low-dose aspirin (which would allow the production of aspirin-induced lipoxin) on pulmonary inflammatory diseases has not been addressed.

Other

Miscellaneous side effects associated with the use of NSAIDs include aseptic meningitis,¹²⁰⁻¹²² diarrhea, and CNS depression.⁵⁹

CONVENTIONAL NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Aspirin: The Prototypic Nonsteroidal Antiinflammatory Drug

The discovery of the mechanisms of aspirin and its elucidation of COX enzyme isoforms was recently reviewed.^{122a}

Structure-Activity and Preparations. Aspirin, the salicylic acid ester of acetic acid, is the prototype of the salicylate drugs, which includes sodium salicylate, bismuth subsalicylate, and others. In addition to inhibition of COX enzyme activity, salicylates inhibit the formation and release of kinins, stabilize lysosomes, and remove energy necessary for inflammation by uncoupling oxidative phosphorylation. Among the traditional NSAIDs, aspirin stands out for its impact on the AA cascade. Its effect on thromboxane synthetase was previously described. Additionally, at low doses, aspirin triggers the formation of lipoxins and their 15-epimers, epoxins.^{123, 123a} The latter are antiinflammatory mediators that counter the proinflammatoroy mediators of the cascade (see Figures 29-1 and 29-2). Aspirin is available in several different preparations, including plain, film-coated, buffered, time-release, and enteric-coated tablets. Capsules and suppositories are also available.⁷⁰ Oral salicylates are also available in preparations intended to treat inflammatory bowel disease.

Disposition. The oral bioavailability of aspirin products may vary because of differences in disintegration, drug formulation, stomach content, and gastric pH.124 Although buffered aspirin is more soluble than plain aspirin, a larger proportion is ionized and less rapidly absorbed. The rate of absorption of both products is the same.⁷⁰ Aspirin undergoes rapid metabolism to the hydrolyzed active product salicylic acid by plasma esterases. This metabolite is not as potent an analgesic or antiinflammatory drug because of the loss of the acetyl group, which is able to acetylate key proteins.⁷⁰ Salicylic acid is between 50% and 70% bound to serum albumin among species.¹²⁵ Hypoalbuminemia may result in transient increases in plasma drug concentrations associated with adverse effects. Distribution of salicylic acid into extracellular fluid is rapid and includes synovial and peritoneal fluids, saliva, and milk. Salicylic acid is eliminated by hepatic conjugation with glucuronide and glycine, renal excretion by glomerular filtration, and tubular secretion.^{125,126} Species differences in the biotransformation and elimination of salicylates are dramatic. Excretion is more rapid in alkaline urine, which might be used therapeutically to treat acute aspirin intoxication. Salicylate can achieve substantial concentrations in milk. Elimination occurs more slowly in pediatric patients.¹²⁷

The disposition of acetyl salicylate appears to be the only salicylate for which data is available in dogs or cats.^{127, 128} Other oral salicylates such as sulfasalazine have been used to treat chronic inflammatory conditions of the bowel (see Chapter 19). Although their mechanism of action is unclear, splitting of the diazo bond by colonic bacteria to yield sulfapyridine and 5-aminosalicylic acid (5-ASA) may be involved. The 5-ASA is considered to be the active moiety.¹²⁹ Both the sulfapyridine and sulfasalazine (up to 25%) are absorbed from the small

intestine, but most of the 5-ASA remains in the colon. That absorbed (approximately 20% in humans) is rapidly acetylated and inactivated by either the colonic mucosa or liver. Newer products composed principally of 5-ASA are being investigated for the treatment of chronic inflammatory bowel diseases.¹²⁹ Alternative methods of delivery of these compounds such that side effects are minimized are also being studied.¹³⁰

Adverse reactions. Aspirin is theoretically characterized by a wide safety margin in most species. The recommended therapeutic range in humans ranges from 100 to 250 μ g/mL,¹³¹ with higher concentrations necessary to control inflammation, particularly that associated with immune-mediated disease. ⁵ Analgesia and antipyresis generally require concentrations of 20 to 50 μ g/mL,⁷⁰ whereas control of inflammation may require concentrations that exceed 50 μ g/mL. Response of rheumatoid arthritis in human beings requires concentrations approximating 200 μ g/mL. Although the drug concentration necessary to achieve an antithrombotic effect has not been established for aspirin in animals, smaller doses have proved efficacious (e.g., 3 mg/kg). These studies did not effectively evaluate safety (gastrointestinal changes). Studies based on gastrointestinal permeability.⁷

Clinical signs of aspirin toxicity may be present at concentrations necessary for clinical response, but they worsen as serum salicylate concentrations exceed 300 μ g/mL. The effects of NSAIDs on cartilage are largely detrimental. Hepatotoxicity and decreased renal function have been reported at 250 μ g/mL. Decreased prothrombin time, deafness, and hyperventilation occur at 300 to 350 μ g/mL, with severe toxicity, including metabolic acidosis, occurring at doses above 400 μ g/mL.¹²⁷

Treatment of acute aspirin toxicity is largely supportive, including increasing elimination. Toxicity (acute) is usually manifested as depression, vomiting, hyperthermia, electrolyte imbalances, convulsions, coma, and death. Toxicity is more likely in cats because of slow metabolism with accumulation. Acute toxicity includes serious acid–base disturbances resulting from uncoupling of oxidative phosphorylation. Hyperventilation resulting from direct stimulation of the respiratory center may be followed by depression at high doses. Bleeding disorders may also be evident,^{70,132} as might dose-dependent hepatotoxicity. Salicylate markedly suppresses augmented proteoglycan synthesis in osteoarthritic cartilage and permeates the damage joint more than the undamaged joint.¹³³

Dogs. In dogs aspirin is distributed to a volume ranging from 0.4 to 0.6 L/kg. Bioavailability probably varies with the manufacturer as well as the preparation and ranges from 68% to 76%.¹³⁴ The bioavailabilities of plain, buffered, and enteric-coated aspirin (25 mg/kg) do not appear to vary markedly, although plasma salicylate concentrations were most variable for the enteric-coated preparation.¹³⁵ Concentrations of 91 to 120 µg/mL are achieved at 25 mg/kg administered at 8-hour intervals.¹²⁷ After several doses of 25 mg/kg at 12-hour intervals, the biological half-life of aspirin is 7.5 hours in dogs. This time increased to a mean of 12.2 hours, however, when the dosing interval was decreased to 8 hours.¹³⁶ In another study the elimination half-life of aspirin varied after intravenous injection of 36 to 60 mg/kg, ranging from 2.2 to 8.7 hours.

One study in clinical patients found that plasma salicylate concentrations correlated with response.¹³⁴ The dose necessary to maintain clinical control of various lamenesses in dogs in one study ranged from 23 to 86 mg/kg twice daily, resulting in plasma drug concentrations ranging from 71 to 281 µg/mL.¹³⁷ Marked individual variability in drug elimination among animals suggests that therapeutic drug monitoring may be useful to ensure that therapeutic drug concentrations have been achieved and that toxic concentrations (>300 µg/ mL) are avoided.¹³⁴ However, when 25 mg/kg is administered at 8-hour intervals, therapeutic concentrations can be expected to be maintained throughout the dosing interval. Gastrointestinal side effects of aspirin in dogs also appear to be dose and preparation related^{62,135} and may be decreased by using special preparations. Doses of 25 mg/kg of plain aspirin caused mucosal erosions in 50% of dogs that received plain aspirin, whereas minimal damage occurred in animals receiving buffered and coated preparations.¹³⁵

Cats. As a phenol, aspirin is a compound for which glucuronidation is generally deficient in cats compared with other species.^{132,138} Its plasma elimination half-life may be dose dependent.¹³⁹ The half-life is 22 to 27 hours after doses of 5 to 12 mg/kg but 45 hours after administration of 25 mg/kg.^{7,128} No clinical signs of toxicosis occurred in one study in which cats were treated with 25 mg/kg every 48 hours.¹³⁸ Clinical signs of aspirin toxicity in cats are similar to those seen in human patients.¹⁴⁰ Subtle changes in liver function may reflect nonspecific hepatitis, the primary histologic lesion.

Flunixin Meglumine

Structure–activity relationship. Flunixin meglumine is a nicotinic acid derivative approved for use in the horse. Described as a potent analgesic agent, it has been used to control pain that might otherwise respond only to opioids. It is particularly useful for visceral pain. In addition to its analgesic effects, flunixin meglumine has been studied and cited for its antiendotoxic effects in experimental models of septic shock in several species.¹⁴¹⁻¹⁴⁵

Disposition. The disposition of flunixn has been studied in dogs and cats (see Table 29-4).^{60,146} Flunixin appears to undergo enterohepatic circulation in cats. Its half-life differs considerably depending on the study, with more recent studies perhaps being more accurate because of a lower limit of detection that allows description of the true elimination phase.⁶⁰ However, because therapeutic concentrations are not known, the true elimination phase may reflect concentrations that are subtherapeutic and may not be clinically relevant. At least two transport systems appear to be involved in the disposition of flunixin in cats (one being organic anion transporter polypeptide-2 in the liver, the other renal in origin),⁶⁰ which may subject the drug to drug interactions.

Therapeutic use. Although the mode of action has not been documented, flunixin is specifically recommended as an analgesic in the treatment of colic in horses and has been useful for control of visceral pain in dogs (e.g., parvovirus) or postoperative pain.⁶⁶ It also has been useful for the treatment (and especially pretreatment) of endotoxic shock.⁴⁴ It prevents many

of the adverse effects caused by administration of endotoxin, TXA2, and PGI2.¹⁴⁶ Flunixin meglumine appears to modulate response to septic shock in dogs.^{141,145,147} In dogs a dose of 1.1 mg/kg flunixin meglumine blocks PGI2 production, and 2.2 mg/kg improves survival times of septic dogs.¹⁴⁶ Newer COX-2–targeting NSAIDs might be similarly effective in the treatment or prevention of endotoxemia. Pharmacokinetics of flunixin in septic dogs does not appear to differ from that of control dogs.¹⁴⁶ Toxicity, most commonly manifested as gastrointestinal upset, limits use of this drug in dogs to 2 to 3 days. Doses at three to five times those recommended caused gastrointestinal disturbances in one study.

Ibuprofen

Ibuprofen is a propionic acid derivative that has been used in dogs. Ibuprofen may be less effective as an analgesic than aspirin, perhaps on account of differences in binding of COX (reversible for ibuprofen and irreversible for aspirin). Ibuprofen remains a popular and effective antiinflammatory drug in humans. The disposition of ibuprofen has been studied in dogs (see Table 29-4). Pharmacokinetics are similar at doses of 5 and 10 mg/kg.¹⁴⁸ A dose of 12 to 15 mg/kg is, however, necessary to achieve therapeutic concentrations, as reported in humans.¹⁴⁸ After repetitive administration of this dose, plasma drug concentrations decrease despite no change in drug half-life.¹⁴⁸

KEY POINT 29-15 Ibuprofen and naproxen should be considered as contraindicated in the dog just as acetaminophen is contraindicated in the cat.

In humans ibuprofen is associated with a low incidence of gastrointestinal side effects and has been compared favorably with even the newer COX-2-selective drugs.73 This may lead clients to assume the same is true for dogs or cats. However, ibuprofen is among the least safe NSAIDs in dogs. Vomiting commonly occurs after several (2 to 6) days of ibuprofen therapy in dogs with either the gelatin- or enteric-coated capsules.¹⁴⁸ Gastrointestinal inflammation and gastric erosions have been documented after administration of 8 mg/kg daily despite the lack of clinical signs of toxicity.^{148,149} Death associated with gastrointestinal hemorrhage occurred in one dog given 3 mg/kg every other day for 6 weeks.¹⁴⁹ These effects occur despite a short half-life for ibuprofen in dogs (less than 5 hours). The COX-1 to COX-2 ratio apparently has not been determined for ibuprofen in dogs. Because gastric lesions occur at doses less than those necessary to achieve therapeutic concentrations, ibuprofen is not recommended for use in dogs.

Ketoprofen

Structure–activity relationship and mechanism of action. Ketoprofen is a propionic acid NSAID approved for use in humans and horses. Because ketoprofen is a strong inhibitor of COX, it has been ascribed powerful antiinflammatory, analgesic, and antipyretic properties. Although not firmly established, the efficacy of ketoprofen has been attributed to its ability to inhibit some lipoxygenases and thus formation of LTs.¹⁵⁰ Ketoprofen is also a powerful inhibitor of bradykinin.¹⁵⁰

Disposition. Ketoprofen is rapidly absorbed from the gastrointestinal tract. Although peak plasma drug concentrations are lower in dogs after oral than intravenous administration, mean residence times (4.59 versus 3.81 hours, respectively) were not different.¹⁵¹ Bioavailability does not seem to be impaired by food. As with other NSAIDs, ketoprofen is approximately 99% protein bound, principally to albumin. Elimination reflects metabolism to inactive metabolites by the liver and excretion as the glucuronide conjugate in the urine.¹⁵⁰ Ketoprofen has a slightly shorter half-life in cats compared with dogs (see Table 29-4). Ketoprofen is sold as a racemic mixture. The R and S isomer are handled differently by the body and induce different pharmacodynamic and pharmacokinetic responses, with variability expected among and within species. Disposition is further complicated by the potential conversion that occurs between isomers, with the extent and sequelae also varying among and within species.¹²⁷ Conversion of the R to S isomer, but not the S to R isomer, has been documented in dogs and cats. Cats may convert up to 37% of the R to the S isomer. Not surprisingly, species differ as to which isomer predominates after administration of the racemic mixture. In dogs the S isomer represented 91% of the peak plasma drug concentration 3 hours after administration of the R isomer.

Drugs that are similar in structure may be markedly different in their pharmacokinetic and pharmacodynamic description, as is exemplified by ketoprofen and a similar drug, fenoprofen, in cats.¹⁵² For ketoprofen the R and S isomers behave similarly: Respective clearance was 235 and 216 mL/ hr/kg, and half-life of each was 0.5 hour. For the structurally similar fenoprofen, clearance for the R isomer was ninefold greater compared with that for the S isomer (980 versus 112 mL/hr/kg), leading to a shorter half-life (0.53 hour) for the R isomer compared with the S isomer (3 hours). Further, 93% of R-fenoprofen was converted to the S-isomer, compared with only 37% of R-ketoprofen.¹⁵² As such, at least for the cat, exposure to either isomer of ketoprofen may be largely equivalent (based on area under the curve) but is approximately sixfold higher for S-fenoprofen (the COX-active isomer) compared with R-fenoprofen.¹⁵² As with disposition, the pharmacodynamic impact of each ketoprofen isomer on inflammation and analgesia is variable among species. The anti-COX effect of ketoprofen (and fenoprofen) reflects the S-enantiomer in cats.

Drug interactions specific for ketoprofen have not yet been documented.¹⁵³ However, in humans adverse reactions to ketoprofen occur in approximately 30% of the patients studied.^{154,155} The most frequent complaint was upper gastrointestinal upset. Other commonly encountered side effects include CNS reactions, such as headaches and dizziness, and nephritis. Side effects were severe enough in one report that therapy was discontinued in approximately 13% of patients.¹⁵³ Alternative preparations, such as rectal suppositories, have been formulated for ketoprofen to reduce the incidence of gastrointestinal toxicity.¹⁵¹

KEY POINT 29-16 Ideally, the preferred nonsteroidal antiinflammatory drug for perioperative use will be one approved for use in the target species and known to be cyclooxygenase-2 preferential in action. Ketoprofen is not approved for use in small animals in the United States but is approved for both dogs and cats in Canada and Europe. It has proved to be an efficacious NSAID in humans and animals. In human patients suffering from rheumatoid arthritis, ketoprofen has been shown to be as efficacious as aspirin, naproxen, aspirin, indomethacin, ibuprofen, diclofenac, and piroxicam.¹⁵⁶ Similar results occurred in cancer patients receiving either aspirin–codeine combinations or ketoprofen.¹⁵⁵ For control of postoperative pain, ketoprofen has proved as effective as pentazocine and meperidine¹⁵⁶ and equally effective but longer in duration than acetaminophen–

profen has been reported to last between 12 and 20 hours.¹²⁷ The use of ketoprofen as an analgesic and antipyretic has been studied in cats. The antipyretic effect of ketoprofen (2 mg/kg subcutaneously followed by 1 mg/kg once daily orally) in febrile cats was rapid, being evident in 4 hours with temperatures normalized at that time.¹⁵⁸ Temperatures did not change in the cats treated with antibiotics only. The use of ketoprofen as an analgesic is variable.¹⁵⁹ In cats subjected to ovariohysterectomy, ketoprofen (2 mg/kg subcutaneously) compared favorably with buprenorphine (0.006 mg/kg or 6 µg/kg intramuscularly) and meperidine as gas anesthesia was discontinued. Response was based on visual analog scores and overall clinical assessment. Response was equal to that of buprenorphine at 4 hours and better at 8 hours. Response was better for both drugs compared with the control at both 4 and 8 hours but still present for buprenorphine only compared with control at 18 hours.

codeine combinations.¹⁵⁷ In dogs analgesia provided by keto-

Ketorolac

Ketorolac is an NSAID approved for use in human patients. In contrast to many NSAIDs, ketorolac is only moderately effective as an antiinflammatory.¹⁶⁰ It is a potent analgesic, however, that has been described as equivalent to morphine. As such, it has been used as a perioperative analgesic in dogs.¹⁶¹ Ketorolac appears to be superior to butorphanol and equal to flunixin meglumine for control of postoperative pain. The disposition of ketoralac is quite variable in in dogs (see Table 29-4) after single intravenous or oral dosing (0.34 mg/kg), although investigators indicate that the disposition was simlar to humans.¹⁶² In humans ketorolac causes gastrointestinal upset, and similar side effects occur in dogs. In one study 1 of 21 dogs developed gastrointestinal ulceration after a single dose.⁶⁶ Therefore recommendations are to limit use to one to two treatments, or 3 days. Other side effects reported in human patients include dizziness, headache, nausea, and pain at the site of injection.¹⁶⁰ Caution should be taken particularly in the perioperative patient, which is more likely to be dependent on renal PGs during the surgical procedure.

Meclofenamic Acid

Meclofenamate is an anthranilic NSAID available as a palatable granular preparation intended to be mixed with food for large animals and as a tablet. It is approved for use in dogs in the United States. Among the NSAIDs, it is noted for its slow onset of action. The package insert associated with the label of this drug describes dogs as being exquisitely sensitive to the gastrointestinal ulcerogenic effects of these drugs. Meclofenamic acid appears to have no clear advantage to other drugs for treatment of osteoarthritis in dogs and may be more likely to cause gastrointestinal upset.

Naproxen

Naproxen is approved for use in humans and is available in over the counter preparations. Although it contains a chiral carbon, it is sold as the pure S isomer. Its disposition has been studied in dogs and, notably, it varies from that in humans. Compared with 12 to 15 hours in humans and 5 hours in horses, the elimination half-life of naproxen after intravenous administration in dogs ranges from 45 to 92 hours.¹⁶³ Peak concentrations in dogs after oral administration of 5 mg/kg were 40 to 50 µg/mL. Tissue concentrations paralleled plasma concentrations, with a peak of 20 to 30 µg/mL; concentrations declined over a period of 200 hours.¹⁶⁴ Extensive enterohepatic circulation has been credited as the cause for prolonged elimination in dogs. Because of its long half-life, naproxen need be given only once daily to every other day. Although a loading dose has been recommended, the gastrointestinal toxicity of this drug in dogs suggests that a loading dose be avoided to minimize the risk of toxicity.

The dog has been described as the animal most sensitive to naproxen.¹⁶³ Its use in dogs does not seem prudent. Gastrointestinal toxicity occurs at doses of 5 mg/kg daily.¹⁶⁵ Toxicity appears most likely when plasma drug concentrations exceed 50 μ g/mL. If this NSAID must be used in dogs, doses initially should be low (1 to 2 mg/kg) and subsequently titrated to the animal's need. Animals should be watched closely for evidence of gastrointestinal upset. Bleeding dyscrasias have also been reported in dogs receiving large doses of naproxen.^{163,165,166}

Naproxen has been cited for a positive protective effect on articular cartilage. In a canine experimental model of osteoarthritis, naproxen decreased the loss of proteoglycans and suppressed metalloproteinase activity.¹⁶⁷

Phenylbutazone

Phenylbutazone is a weakly acidic, lipophilic NSAID approved for use in dogs. Inhibition of the AA cascade by phenylbutazone occurs after conversion to reactive intermediates at the level of PGH synthase and prostacyclin synthase. Prostanoiddependent swelling, edema, erythema, and associated pain are reduced by phenylbutazone.³⁷ Phenylbutazone has been associated with some attenuation of some clinical signs associated with endotoxic shock in experimental models.^{142,144}

Bioavailability after intramuscular administration of phenylbutazone is less than that after oral administration in most species studied because of precipitation in the neutral pH of muscle.^{37,168} Phenylbutazone is metabolized by the liver, with less than 2% of the drug being excreted as a parent compound in the urine in some species. Its major metabolites are oxyphenylbutazone, which is less active than phenylbutazone, and inactive γ -hydroxyphenylbutazone.^{37,169,170} Dosedependent zero-order kinetics has been reported in dogs.¹²⁷ Reported adverse reactions caused by phenylbutazone include bleeding dyscrasias, hepatopathy, and nephropathy (primarily in horses).^{37,96,171,172} Phenylbutazone has chondrodestructive effects.^{173,174}

Dogs. Despite approval of the oral preparation for use in dogs, there is little information regarding the use of phenylbutazone in dogs. The half-life in plasma (7.3 to 18 hours) is shorter than that in tissues (20 hours), although peak concentrations in tissues (13 to 20 μ g/mL) were approximately one third of those in plasma (49 to 75 μ g/mL)¹⁶⁴ after a dose of 15 mg/kg orally. The elimination half-life (in Greyhounds) is 6 to 7 hours.^{169,170} Dogs apparently are more tolerant of phenylbutazone than are humans. When used to treat racing greyhounds, phenylbutazone should be used with caution because of routine drug testing. One study¹⁷⁵ has documented that phenylbutazone can be detected in the urine of Greyhounds after topical administration in a commercially available cream.

Toxicity manifested as hemorrhage, biliary stasis, and renal failure has been reported in one dog receiving close to recommended doses.^{97,172,176} For reasons not explained, the package insert notes a total maximum dose and requires the drug to be discontinued slowly. Bone marrow dyscrasias (including neutropenia) also have been reported.

Cats. Although phenylbutazone has been used in cats, a high incidence of toxicity suggests extreme caution. One hundred percent of cats treated with 44 mg/kg daily became anorectic at 2 to 3 days, with 80% mortality at 2 to 3 weeks. Toxicity occurs primarily in the bone marrow and is characterized by decreased erythroblastic activity and possible interference with myeloid maturation. Gastrointestinal damage, nephrotoxicity, and hepatotoxicity also occur.⁹⁶

Piroxicam

Piroxicam is an oxicam NSAID approved for humans that has been used to treat osteoarthritis in dogs. More recently, it has received attention for its ability to reduce the size of tumors (transitional cell tumors and others) in dogs.^{49,50-52} Piroxicam may interact by an additive or synergistic action with anticancer drugs to cause tumor cell death. Piroxicam is a potent antiinflammatory in musculoskeletal conditions. The disposition of piroxicam has been studied in both the dog¹⁷⁷ and cat.¹⁷⁸ Notably, the half-life of the drug is much shorter in cats (12 hours) compared with dogs (40 to 50 hours). Although the LD_{50} of piroxicam is greater than 700 mg/kg in dogs, gastric lesions and renal papillary necrosis have occurred in dogs receiving 0.3 to 1 mg/kg daily.49,177 The ratio of COX-2 to COX-1 suggests that gastrointestinal toxicity occurs. Little evidence of toxicity (gastrointestinal or bleeding), however, was noted after administration of 0.3 mg/kg every other day.^{49,177} Extrapolation of human use to dogs should be done cautiously because of possible differences in volume of distribution, therapeutic concentrations, or safety margin.

Tolfenamic acid. Tolfenamic acid (Tolfedine) is a nonselective NSAID approved for use in Canada for long-term use in dogs and short-term use in cats. The half-lives in dogs and cats are, respectively, 6.5 hours and 8 hours. The drug appears to undergo enterohepatic circulation.

CYCLOOXYGENASE-1-SPARING NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Because the extent of COX-1 and COX-2 inhibition for many of the newer NSAIDs is not clear, particularly in dogs and cats, the term *preferential COX-2 inhibitors* is preferred in this text to *selective COX-2 inhibitors*, with the former reflecting the potential for inhibition of both isoforms. COX-1 sparing is intended to mean the same. Bergh and Budsberg¹⁷⁹ reviewed the use of coxib NSAIDs in veterinary medicine.

Carprofen

Dogs. Carprofen is a proprionic acid–derived NSAID approved in the United States for use in dogs for the treatment of osteoarthritis.¹⁸⁰ The drug is approved for use in dogs and cats in selected countries outside of the United States. Like other NSAIDs, carprofen has antipyretic, analgesic, and antiinflammatory effects.¹⁸⁰ Its potency is equal to that of indomethacin and surpasses that of aspirin or phenylbutazone,¹⁸⁰ and doses consequently are smaller for carprofen than for these NSAIDs.

The mechanism of action of carprofen is not certain, but, unlike other members of its class (e.g., ibuprofen, ketoprofen, naproxen), it may be relatively selective for inhibition of COX-2. McKellar and coworkers¹⁸¹ reported that it does not inhibit thromboxane activitiy in platelets, PGE₂ (isoform not identified) nor 12-HETE in inflammatory cells. With canine platelet-derived COX-1 and macrophage-like cell COX-2, the ratio of COX-1 to COX-2 IC₅₀ (concentration that caused 50% inhibition) for the racemic mixture (that available in the commercial preparation) was 129; the ratio was 181 for the S isomer (thus the "antiinflammatory" enantiomer) but only 4.19 for the R isomer (see Table 29-3).³² These differences in COX inhibition may explain the apparent safety of carprofen compared with conventional NSAIDs in dogs and with safety in the dog compared to that in humans, for whom the ratio is less than 1.

Pharmacokinetics. Carprofen has been studied in dogs after oral and subcutaneous administration (see Table 29-4). Increases in oral doses generally result in proportional increases in C_{max}, with peak concentrations occurring at approximately 1 hour. Peak concentrations appear to occur more slowly with subcutaneous than with oral administration; the former route may prolong onset of efficacy. Although C_{max} differed between oral and subcutaneous administration, the area under the curve did not, indicating bioequivalence among the two routes after both single and multiple dosing.¹⁸² Like other NSAIDs, carprofen is highly protein bound. Carprofen is metabolized by the liver and in dogs is characterized by a half-life of approximately 10 hours, which is sufficiently long that it has been approved for once-daily administration. Between 70% and 80% of carprofen metabolites are excreted in the feces, with the remainder in the urine.

The dispositions of the two carprofen enantiomers have been studied in dogs.^{181,183} Administration as a racemic mixture yields a C_{max} of the R isomer at 18 µg/mL versus 14 µg/mL

for the S isomer. Conversion apparently does not occur between the R or S isomer in dogs. Both the R isomer (72%) and the S isomer (92%) are extensively excreted in the bile, but enterohepatic circulation appears to be relatively specific for the S isomer (the isomer characterized by a very favorable COX-2 specificity), probably owing to greater glucuronidaseresistant isoglucuronides for the R isomer.¹⁸³ Up to 34% of the S isomer is recirculated.¹²⁷ Because both the clearance and the volume of distribution of the S isomer are greater than those of the R isomer, the mean residence times and half-lives of the two isomers do not differ.¹⁸³ After a single subcutaneous dose of 4 mg/kg either preoperatively or postoperatively, duration of analgesia ranged from 18 to 24 hours.¹²⁷

Adverse reactions. On the basis of toxicity data, carprofen appears to be among the safest of the new NSAIDs approved for use in dogs (see Table 29-5). According to the package insert, dogs dosed with more than 10 times the amount necessary to achieve therapeutic concentrations did not develop gastrointestinal side effects when dosed for 2 weeks or when dosed at almost six times the recommended dose for 52 weeks. In a clinical trial of 70 dogs, 6 of 36 carprofen-treated dogs (2.2 mg/kg orally every 12 hr) developed clinical signs indicative of gastrointestinal upset; three dogs that received placebo also developed gastrointestinal signs.¹⁸⁴

KEY POINT 29-17 On the basis of toxicity and field trial data on package inserts, carprofen appears to be among the safest of the newer nonsteroidal antiinflammatory drugs approved for use in dogs.

Forsyth and coworkers¹⁸⁵ compared the gastrointestinal side effects of carprofen (2 mg/kg orally twice daily for 7 days followed by 2 mg/kg once daily), meloxicam (0.2 mg/kg orally once daily), and ketoprofen (1 mg/kg orally every 24 hours) with those of placebo after 28 days of therapy in dogs. The fewest and least severe gastroduodenal lesions apparent endoscopically were in the carprofen-treated and control group, but there was no statistical significance between the three NSAIDs and the control group, making interpretation difficult. No animals revealed clinical signs associated with gastrointestinal upset. Reimer and coworkers83 found etodolac and carprofen to not differ from the placebo and all three to cause fewer gastric lesions than aspirin when dosed at labeled doses for 28 days. Craven and coworkers¹⁸⁶ also prospectively compared the effects of carprofen (n = 10 dogs; 4 mg/kg days 1and 2, 2 mg/kg daily thereafter) to meloxicam (n = 10 dogs; 0.2 mg/kg daily, 1 then 0.1 mg/kg daily) on gastrointestinal epithelium as measured by sugar permeability tests. Dogs were dosed for at least 7 days and studied for 8. Significant changes across time occurred within the carprofen-treated group but resolved by study end; further, although not significant, changes also appeared to have occurred for at least one sugar test for meloxicam. No significant changes were detected in urinary recovery of any sugar between the two treatment groups; placebo controls were not studied. The impact of this comparison is somewhat limited by the absence of untreated controls, large number of comparisons made (two treatment groups, 3 times, seven sugars; potentially, 42 comparisons), and the small number of dogs studied in the face of the variability of the data; the power of the study to detect significant differences was not reported.

Hepatotoxicity reflecting acute hepatic necrosis has been reported as an unexpected adverse effect of carprofen in dogs.¹⁸⁷ Toxicity studies supporting carprofen approval found only mild changes in liver enzymes when the drug was administered at 25 mg/kg for 13 to 52 weeks (package insert data); serum alanine transaminase (SALT) increased with a dose of 80 to 160 mg/kg per day. However, approximately 1 year after its approval, reports of gastrointestinal toxicity led Pfizer to address concerns regarding side effects in a technical report.¹⁸⁸ Of the 1 million dogs receiving carprofen, an incidence of 0.2% suspected side effects was reported, with 0.02% involving the liver. Although 33% of animals affected in initial studies were Labrador Retrievers, this number was not corrected for the prevalance of this species. Hepatopathy has been diagnosed in all breeds of dogs receiving carprofen clinically. At least 70% of afflicted animals were considered geriatric, suggesting that this age group is predisposed, perhaps because of decreased hepatoprotective function (e.g., glutathione scavenging of metabolites). Although death has occurred in some animals, timely discontinuation of the drug can lead to complete resolution of biochemical abnormalities. Animals with liver disease in one study also had evidence of renal tubular disease.187 MacPhail and coworkers187 studied 21 animals and reported clinical signs of anorexia, vomiting, lethargy, diarrhea, polyuria, polydipsia, and hematuria occurring between 5 and 30 days; however, clinical signs did not occur until as long as 60 and 180 days for two dogs. In this study 13 of the 21 dogs were Labrador Retrievers, with dogs ranging in age from 4 to 15 years. The most common clinical laboratory abnormalities included increased activities of SALT, aspartate transaminase (SAST), alkaline phosphatase (SAP), and bilirubin. Histologic lesions in the liver ranged from mild to severe and consisted of hepatocellular necrosis. Four of the 21 dogs died; those remaining that were hospitalized were treated with supportive therapy, including gastrointestinal protectants.

Hepatic disease associated with carprofen might be minimized by pretreatment evaluation because lesions appear to occur within the first several weeks of therapy. Consequently, monitoring (clinical laboratory tests) for hepatic damage and hepatic function (bile acids) at weekly or biweekly intervals for the first month is recommended, particularly in predisposed (e.g., geriatric) animals. Monitoring should continue at intervals of 2 to 4 weeks for 3 months and perhaps longer in patients at risk for liver disease. Animals receiving phenobarbital have been anecdotally reported to be more susceptible to hepatotoxicity. Induction of hepatic drug-metabolizing enzymes (e.g., phenobarbital, others) may increase the risk of toxicity if associated with toxic metabolites. Use of hepatoprotective agents such as N-acetylcysteine (a glutathione precursor) or SAMe may be beneficial during initial or continued hepatic damage.

The potential for carprofen-induced nephrotoxicity also has been studied in dogs. Crandell and coworkers¹⁰⁵ found

no changes compared with saline placebo in renal function (glomerular filtration rate, serum urea, and creatinine) in young healthy dogs (n = 12) receiving placebo, meloxicam (0.2 mg/kg), or carprofen (4 mg/kg) after 30 minutes of electrically stimulated pain. Dogs were studied using a randomized crossover design; anesthesia consisted of butorphanol and acepromazine as preanesthetics, ketamine and diazepam for induction, and isoflurane for maintenance.¹⁰⁵ The study was designed such that power was sufficient to detect a change in glomerular filtration rate of 0.5 mL/ kg/min, suggesting that the two treatment groups were the same. This is in contrast to the results of Forsyth and coworkers,¹⁸⁹ who found that creatinine clearance was significantly less in dogs 24 hours after undergoing routine castration and receiving either carprofen (4 mg/kg intravenously), ketoprofen (2 mg/kg intravenously) compared to placebo or saline (0.2 mL/kg intravenously) at induction of anaesthesia. The anesthetic protocol is this study differed among animals (drugs included morphine, thiopental, and halothane).¹⁸⁹ Bostrom and coworkers¹⁹⁰ investigated the effect of carprofen (4 mg/kg intravenously) administered either 30 minutes before or 30 minutes after induction of anesthesia (acepromazine-thiopentone-isoflurane) on renal function (glomerular filtration rate) in dogs (n = 6)after experimentally induced decrease in blood pressure to 65 mm Hg. Significant adverse effects were not detected, although the power of the study to detect a significant difference was not assessed.

The impact of carprofen on hemostasis has been studied. Although carprofen was associated with decreased platelet aggregation and increased partial thromboplastin time in one study, all values were within normal limits. Neither buccal mucosal bleeding time nor complete blood count parameters changed after 12 days of dosing at 2.2 mg/kg twice daily.¹⁹¹ Other investigators have found no changes in in vitro indices of platelet function.

The effect of carprofen on cartilage physiology appears to be biphasic.¹⁹² In vitro studies with canine chondrocyte cell cultures revealed that carprofen increases the rate of polysulfated glycosaminoglycans (PGAG) synthesis at synovial fluid concentrations ($\leq 10 \ \mu g/mL$) achieved in human patients receiving a therapeutic dose of carprofen. The S-isomer stimulated PGAG synthesis at a tenfold higher rate compared with the R isomer (United States Pharmacopeia [USP]).¹²⁷ Inhibition of PGAG synthesis, however, occurs at concentrations of 20 $\mu g/mL$ or more.¹⁹² Concentrations that occur in dog synovial fluid after administration of a therapeutic dose of carprofen have not been determined.

Carprofen is approved for use in dogs for control of perioperative pain and treatment of osteoarthritis. It is available as either an oral preparation or an injectable solution intended for subcutaneous injection. Carprofen solution is stable for 1 month if not refrigerated. A chewable table is available, although the risk of accidental overdose may be greater with this product. Although approved for subcutaneous use, injectable carprofen has been given intravenously (4.4 mg/kg) as a single dose with no adverse effects.¹⁹⁰

Carprofen appears to be equally or more effective than many other NSAIDs studied for the control of inflammation, and it has proved effective for control of the pain associated with the inflammation of osteoarthritis¹⁸⁴ and postoperative pain¹⁹³⁻¹⁹⁵ when administered preoperatively. Because carprofen was the first COX-1-protective NSAID approved for use in dogs, approval of subsequent similar-acting NSAIDs generally used it as a positive control. As such, several studies have compared the efficacy of carprofen with that of other NSAIDs, although these studies tend to be manufacturer sponsored. Using a non-placebo-controlled randomized crossover design, Borer and coworkers196 compared single-dose carprofen (0.2 mg/kg intravenously or 4 mg/kg, orally), etodolac (17 mg/kg, orally), or meloxicam (0.2 mg/kg, orally); (n = 12; studied in groups of four at 3-week intervals) in dogs with experimentally induced acute synovitis (monosodium urate injection). Outcome measures included kinetic gait analysis (force plate), orthopedic evaluation, and serum C-reactive protein (CRP) (n = 6). Lameness was assessed on a biomechanical force platform and by orthopedic evaluations of the stifle joints; blood was collected to monitor serum CRP concentration. All dogs in the treatment groups had improved indices of lameness compared with control animals. Although greatest improvement occurred in carprofen-treated dogs, onset was fastest in etodolac-treated animals. Both carprofen and etodolac were associated with lower pain compared with butorphanol, although the authors concluded that meloxicam also was more effective than butorphanol. Serum CRP was not different among groups.196

Carprofen or meloxicam also were compared with a combination glucosamine–chondroitin sulfate (Cosequin) product using a prospective, double-blinded study in dogs (n = 71) with osteoarthritis; the study was supported by the manufacturers of meloxicam. Treatment continued for 60 days, and response was based on force plate analysis and subjective evaluation by owners. Although animals responded to both meloxicam and carprofen, only meloxicam was associated with a return to baseline function. Side effects were minimal, although one dog receiving carprofen developed hepatopathy and one dog receiving meloxicam withdrew from the study because of vomiting.¹⁹⁷

Finally, Aragon and coworkers¹⁹⁸ evaluated the quality of evidence of NSAIDs, including carprofen, or supplements used to treat osteoarthritis in dogs. The FDA's evidence-based ranking was applied to scientific data collected from a review of the literature before 2006. Studies were ranked on the basis of study design, quality, and total body of evidence (quantity of studies or study subjects, consistency among the different reports, and the likelihood that the magnitude of the response was physiologically meaningful). The evidence was then ranked according to strength (high, moderate, low, or extremely low level of comfort). Only 16 clinical trials met the inclusion criteria. Of the compounds studied, the evidence for meloxicam was accorded a high level of comfort (i.e., that efficacy is scientifically valid), and the evidence for carprofen, etodolac, PGAG, and glucosamine -chondroitin-manganese was ranked as moderate. Hyaluronan was ranked extremely low. Care must be taken not to overinterpret this data because of the limited number of studies reviewed

Cats. Carprofen is approved for use in cats in certain countries outside the United States. The disposition of the drug and its enantiomers has been studied in cats at the dose associated with control of inflammation (4 mg/kg; Table 29.4).^{128,199-201} The smaller clearance for carprofen in cats results in an elimination half-life that is at least twice as long in cats as in dogs. The S isomer is cleared almost 3 times as rapidly as the R isomer, resulting in a shorter half-life for S compared with R in the cat

The relative COX-2 selectivity of carprofen that occurs in dogs has not been well documented in cats, although data from Brideau and coworkers³³ suggests relative selectivity similar to that in dogs (see Table 29-3). Clinically, however, this may not be true. The gastrointestinal effects of single-dose carprofen (4 mg/kg intravenously) or aspirin (20 mg/kg intravenously) were studied in cats (n = 5) using endoscopy and a randomized crossover design. Lesions in the stomach and duodenum 8 hours after injection were limited to minor pinpoint erosion in one cat. Clinical laboratory tests were not affected by either drug.¹²⁸ Duodenal perforation has been reported in cats receiving oral carprofen (2.2 mg/kg twice daily for 7 days) after ovariohysterectomy.²⁰² The ulceration may have been exacerbated by the flunixin meglumine and dexamethasone with which the cat was treated before referral.

Parton and coworkers¹²⁸ prospectively compared the gastrointestinal effects of carprofen (4 mg/kg intravenously) and salicylate (20 mg/kg intravenously) in cats using a crossover design. Only a single dose was studied; gastric lesions were scored endoscopically 8 hours after dosing. No differences were found between treatment groups or times, with one exception in the salicylate group for which pinpint erosive lesions were found. Steagall and coworkers¹⁰⁷ also prospectively studied the adverse effects of carprofen, after multiple doses (6 days) of decreasing doses (4 mg/kg on day 1 to 1 mg/kg on day 6). A randomized, blinded crossover, placebo-controlled design was used, with a 4-week washout. Endoscopic lesions were scored before and 7 days after treatment. Changes in biochemistry profiles included decreased albumin but no other abnormalities, including gastrointestinal lesions or changes in renal dysfunction.

As a postoperative analgesic in cats, carprofen compares favorably with pethidine (meperidine), providing equal but longer analgesia (at least 24 hours) when administered at 4 mg/kg subcutaneously postoperatively.²⁰¹ In a clinical trial of cats undergoing ovariohysterectomy, the analgesic effects of carprofen, ketoprofen, meloxicam, or tolfenamic acid were compared. Outcome was based on the visual analog scale and a nociceptive threshold at the incision site, as well as clinical response. No difference was found between treatment groups in providing analgesia. With nine of ten cats responding, all responses were described as good, although none prevented wound tenderness.²⁰³ Taylor and coworkers²⁰⁴ prospectively compared the efficacy of carpofen (4 mg/kg) and buprenorphine (0.01 mg/ kg) as preventives for hyperalgesia in an experimental model of inflammatory pain in cats. Cats (n = 8) were studied using a randomized, crossover, placebo-controlled design. Drugs were administered before (3 hours for carprofen, 1 hour for buprenorphine) anesthesia. Carprofen completely prevented inflammation, and buprenorphine almost completely did so, although hypoalgesia was not realized.

Deracoxib

Deracoxib is approved for use as an oral chewable preparation in dogs. As a coxib, deracoxib would be expected to be COX-1 sparing, which appears to be true on the basis of studies using cloned canine COX enzymes (see Table 29-3). However, specificity is lost at higher concentrations. Deracoxib undergoes extensive hepatic metabolism. At 8 mg/kg (approximately 2 to 8 times the recommended dose [1 to 4 mg/kg]), nonlinear kinetics emerge, increasing the risk of toxicity. As with other NSAIDs, gastrointestinal toxicity occurs with increased doses. The package insert indicates that toxicity occurs at 3 times the dose when a micronized (which differs from the approved product) compound was administered (in a rapidly dissolving capsule) but not when the commercial preparation was administered at the same dose (see Table 29-5). Whether or not derocoxib is more likely than other NSAIDs to reach saturation kinetics is not known. The difference in preparations may have resulted in much more rapid exposure of the gastrointestinal mucosa to drug. The gastrointestinal lesions associated with the micronized material were attributed to a local effect (osmotic, pH, pharmacologic, others) rather than a systemic effect.²⁰⁵ Dose-dependent increases in blood urea nitrogen were reported when dogs received deracoxib at 3, 4, and 5 times the recommended dose (2 mg/kg); variable renal histologic lesions were reported. The disposition of deracoxib has been described in cats after a single oral dose (see Table 29-4). ²⁰⁶ Safety information in cats was not available at the time of this publication other than at the FDA CVM site (Table 29-6).

As a sulfonamide, deracoxib might be expected to be associated with adverse reactions (but not those typical of antimicrobial sulfonamides), including keratitis sicca.

In a study at least partially funded by the manufacturer, efficacy of deracoxib administered as a single dose (0.3, 1, 3, or 10 mg/kg) was compared with that of carprofen (2.2 mg/kg) in 24 hound dogs. Drugs were administered 30 minutes before induction of chemically induced (urate crystal) synovitis, and lameness indices (including clinical scores, force plate analysis, and joint fluid analysis) were measured for 24 hours after induction. Deracoxib was found to be somewhat more effective at 3 mg/kg (determined to be the minimum effective dose) and more effective than carprofen at 10 mg/kg (not a recommended dose) on the basis of outcome measures for lameness which included lameness scores, pain joint effusions, and pain threshold response²⁰⁷; no significant differences were found between carprofen or the placebo group.

Lascelles and coworkers⁸⁰ described a series of cases of gastrointestinal perforation associated with deraxocib administration in dogs (n = 29). The mean age was 6.4 ± 3.2 years. Among the more important points of the report was that 55% of the dogs received a dose higher than recommended on the label; and 59% had received, within the previous 24 hours, either a different NSAID or a glucocorticoid. A total of 90% of the dogs had received one or the other and a total of 20% had received both. Of the dogs, 68% either died or were euthanized. The mean dose in dogs receiving the drug for long-term pain management was 3 ± 1.1 mg/kg/day, ranging from 2.3 to 6.2 mg/kg.

The safety of deracoxib (1.5 mgkg daily) was prospectively compared with that of buffered aspirin and placebo (25 mg/kg orally every 8 hours) in dogs (placebo controlled) based on gastroscopy and clinical scores assessing vomiting and diarrhea.²⁰⁸ Aspirin-related gastric lesions and vomiting were higher than similar lesions in the deracoxib-treated and placebo-treated groups, beginning with the first endoscopic exam at 6 days.

Etodolac

Etodolac is a pyranocarboxylic acid that has shown potent NSAID activity by inhibiting chondrocyte and synoviocyte biosynthesis of PGE₂ COX-1 to COX-2 ratios vary among studies. The ratio using human cells appears to favor safety,²⁰⁹ although studies using canine cells³² reveal the opposite. Ricketts and coworkers³² reported a COX-1 to COX-2 ratio of only 0.517 compared with 129 for carprofen (study sponsored by carprofen manufacturer). In dogs the drug is rapidly absorbed, with food slowing absorption. Its elimination half-life is approximately 14 hours,²¹⁰ which is sufficiently long to allow once-daily dosing. Food may prolong elimination (see Table 29-4). The drug is extensively metabolized, with the majority eliminated in the bile and up to 10% excreted in the urine; enterohepatic elimination is extensive, potentially increasing the risk of gastrointestinal toxicity.¹²⁷ Etodolac is marketed as a racemic mixture, although the disposition of the enantiomers has not been well described in animals. Because it is approved for use in humans, much information is available regarding possible side effects in humans. However, in vitro studies indicate pharmacodynamic effects may differ in animals, and extrapolation of information may be inappropriate. Because of its longer half-life and enterohepatic elimination, etodolac may be associated with a greater risk of gastroduodenal ulceration than other COX-2 preferntial drugs. Toxicity studies also suggest that etodolac may not be as safe as other newer NSAIDs, which might be supported by COX ratios in the dog (see Table 29-3). According to the package insert, six of eight dogs developed gastrointestinal erosions and subsequently died after etodolac was administered at five times the recommended dose for 6 to 9 months (see Table 29-5). Five of six dogs developed excessive bleeding when receiving etodolac at the recommended dose, although the duration of therapy was not clear from the package insert. However, clinically, based on field studies, etodolac does not appear to be less safe than the other COX-2 preferential drugs.

Liver disease in dogs such as that associated with carprofen has not been reported in the literature but has been anecdotally reported and has been seen by the author. Etodolac (mean dose of 13.7 mg/kg orally every 24 hours for 28 days) administration did not significantly affect serum T_4 , T_3 , fT_4 , or cTSH concentrations or serum osmolality in healthy random-source mixed breed dogs (n = 19). However, plasma total protein, albumin, and globulin concentrations were decreased by day 14 of administration; decreases were still evident by day 28 of administration, although all concentrations were within normal limits.¹¹⁸ The effect of etodolac on cartilage metabolism has not been well documented, although one study found it to be associated with more cartilage damage than carprofen.²¹¹ Etodolac has been associated with keratitis sicca. ^{211a} In a series of cases collected from the manufacturer or surveyed veterinary ophthalmologists, lesions were commonly considered severe, occurred in both eyes more than 50% of the time, with remission occurring in 10 to 15% of animals. Remission was 4 times more likely if treatment duration was less than 6 months.

Etodolac is available of an oral capsule prepration for use in dogs. Despite potential gastrointestinal adverse drug events, when dosed at 10 to 15 mg/kg once daily, etodolac was effective yet safe for controlling lameness associated with hip dysplasia.²¹² A clinical trial comparing carprofen and etodolac was previously discussed (see carprofen).¹⁹⁶ Aragon and coworkers¹⁹⁸ ranked etodolac as moderate with regard to scientific evidence of efficacy claims.

Firocoxib

Firocoxib has recently been approved for use in dogs in a chewable tablet form. Its disposition was reported before its approval by McCann and coworkers,²¹³ who reported on COX-2 selectivity (canine whole blood), pharmacokinetic properties (2 mg/kg intravenously and 8 mg/kg orally) in healthy male and female mixed-breed dogs (n = 21). The IC_{90} for COX-2, according to the monograph, is 0.3 µg/mL, compared with a C_{max} of about 0.5µg/mL at the recommended dose in dogs (Table 29-4). In the manufacturer sponsored study, the COX-1 to COX-2 ratio using canine blood was 384, compared with 6 for carprofen and 12 for deracoxib. Although the volume of distribution is larger than for most NSAIDs, clearance also is rapid, resulting in a relatively short half-life compared with that of other NSAIDs (see Table 29-4). Nonetheless, the drug is administered once a day. The oral bioavailability of firoxocib as listed on the package insert at 5 mg/kg is 38% (variability not reported); as such, care may be indicated in anticipating potential differences in oral bioavailability among animals.*

Firocoxib is approved for use in dogs greater than 3.2 kg (smaller dogs cannot be accurately dosed) as a chewable tablet. The package insert overdose data and its impact on gastssrointestinal toxicity for firocoxib are indicated in Table 29-5. The manufacturer of firocoxib was interested in avoiding an age limit to drug administration, and accordingly, studied firoxocib in juvenile Beagle dogs (Table 29-5). Fatty livers were consistent findings in drug-treated juvenile dogs. In addition to the gastrointestinal effects, one juvenile dog given a dose 3 times that recommended developed juvenile polyarthritis, thrombocytopenia, decreased albumin, and elevated liver enzymes. In a separate study, one dog receiving 3 times the dose was euthanized because of poor clinical condition, although no indication was given as to whether adversity was

^{*}Data on package insert provided among the NSAID may differ depending, in part, on requirements of the FDA. As such, bioavailability data may not be available for all drugs. This may preclude accurate comparisons among drugs.

related to the drug. However, 4 of 12 juvenile dogs receiving 5 times the dose either died (n = 1) or were euthanized (on account of a moribund status) as early as day 38 and as late as day 79; two of the dogs had gastrointestinal ulceration. This data should not be interpreted as a greater risk of toxicity to firocoxib as much as a potential indication that NSAIDs should be avoided in animals 6 months or younger.

For the approval process, efficacy of firocoxib was compared at 8 mg/kg with carprofen (2.2 mg/kg) as the positive control in healthy male Beagles (n = 24; eight per group) using chemically induced (urate) synovitis. The drugs were administered either prophylactically (administration 2 hours before induction of synovitis) or therapeutically (administration 1 hour after induction). Both drugs were effective in controlling pain and inflammation when administered either prophylactically or therapeutically; failure to find a difference between the two NSAIDs was attributed to the variability in the data compared to animal numbers studied. Although a treatment effect was found across time for firocoxib compared with carprofen, superiority of firocoxib compared with carprofen was not sufficient to allow label claims as such. Pollmeier and coworkers,²¹⁴ in a manufacturer-sponsored study, reported the results of a multicenter field trial that compared firocoxib (5 mg/kg/day) to carprofen (4 mg/kg/day) using a double-blinded, randomized design in dogs (n = 218) with osteoarthritis. Efficacy was assessed by both owners and veterinarians. Reponse was slightly better for firocoxib at 96% compared with 92% for carprofen.

Meloxicam

Dogs

Structure-activity relationship. Meloxicam, like piroxicam, is a member of the oxicam group of NSAIDs. It is approved for use in tablet and oral suspension forms in the United States, Canada, and Europe in dogs and cats (the injectable form [subcutaneous] only is approved for one time use in cats in the US). The COX-2 to COX-1 ratio for meloxicam, unlike that for piroxicam, favors selective COX-2 inhibition in humans, suggesting that it has a wider margin of safety than most other NSAIDs.²¹⁵⁻²¹⁸ The drug is more potent (although not necessarily more efficacious) than aspirin, indomethacin, and piroxicam; hence its dose is smaller. In a study partially funded by the manufacturer of meloxicam, using in vitro methods, Kay-Mugford and coworkers²¹⁹ determined the ratio of COX-1 and COX-2 activity of meloxicam, tolfenamic acid, carprofen, and ketoprofen using a canine monocytemacrophage cell line. In this cell line, expression of COX-1 is constitutive, but COX-2 is induced in response to LPS. The COX-1 to COX-2 ratios were more favorable for meloxicam than carprofen (see Table 29-3), which suggests that meloxicam is COX-1 protective in the dog.

Disposition. The plasma concentration-time profile for meloxicam in dogs was described as being comparable to that in humans, in contrast to that of selected other species.²¹⁹ Although oral bioavailability is close to 100% in dogs (according to package insert), time to peak concentration is approximately 7 to 8 hours, one of the longest of NSAIDs in dogs (see Table 29-4). Likewise, the elimination half-life is long

compared with that of other NSAIDs (both conventional and new) in the dog, with a minimum of 3 days expected before steady state is achieved. A loading dose of 0.2 mg/kg is suggested in dogs, followed by a maintenance dose of 0.1 mg/kg. Cautious clinicians might consider administering the loading dose themselves rather than allowing the client to do so; this reduces the risk that the client will continue to administer the drug at a dose that is higher than appropriate. The package insert also indicates that disposition of meloxicam changes with chronic dosing, with elimination half-life becoming longer. As with most drugs, the selectivity enjoyed with the mechanism of action of this or any selective NSAID is likely to be lost at high doses.²²⁰

Adverse reactions. The safety profile of meloxicam, as indicated on the package insert, supports its safe use in dogs, although direct comparison with other newer NSAIDs is limited by differences in doses studied (see Table 29-5). Interestingly, in field studies the incidence of vomiting in dogs receiving meloxicam was among the highest of the newer NSAIDs. The safety of meloxicam has been compared with that of carprofen (see the discussion of carprofen). Meloxicam-induced hepatotoxicity has been reported in humans.²²¹

The impact of meloxicam (0.1 mg/kg subcutaneously once daily), dexamethasone (0.25 mg/kg subcutaneously twice daily), or the combination of the two on the gastrointestinal mucosa was prospectively compared with that of saline after 3 days of therapy in Beagles (n = 20). Outcome measures included scores collected from five regions of the gastroduodenal region. Scores were greater for the combination-treated group than for the other groups; additionally, dexamethasone was associated with higher scores than either meloxicam or saline. No significant differences in histologic findings were found among groups, although this may reflect a low power for the study. However, the lack of correlation between gross and histologic gastroduodenal lesions is not unusual. Lesions associated with NSAIDs were greater in the pylorus and pyloric antrum compared with other regions, a finding also consistent with other studies.74

Gastrointestinal perforation associated with the administration of meloxicam was reported in a series of cases (n = 5).²²² Ages ranged from 2.5 to 11 years. Doses associated with vomiting ranged from a single postoperative dose of 0.1 mg/kg (on day 8) to a high dose of 0.2 mg/kg orally as a single or divided daily dose. Onset of vomiting ranged from as early as day 2 to as late as day 8. Predisposing factors such as glucocorticoid or NSAID administration were not evident. Unidentified underlying gastrointestinal disorders were postulated as possible risk factors.

A single case report has described cutaneous and ocular lesions in a 10-year-old 25-kg mixed-breed dog with a history of atopy receiving meloxicam.²²³ Meloxicam (0.1 mg/kg orally once daily) was administered in anticipation of surgery. The patient returned after 3 days of therapy with cutaneous clinical signs consistent with a potential drug reaction and corneal edema. Skin biopsies were collected several days after initial lesions emerged; the patient was treated with glucocorticoids. Skin lesions had resolved by 6 weeks, and ocular lesions persisted.

Therapeutic Use. Meloxicam has been demonstrated to be both safe and effective for treatment of osteoarthritis in dogs.^{82,224} The efficacy of meloxicam in treatment of locomotor disorders in dogs compares favorably with that of other NSAIDs in studies supported by the manufacturer.^{218,225} In their evidence-based review of clinical trials addressing treatment of osteoarthritis, Aragon and coworkers¹⁹⁸ found meloxicam to be the only drug worthy of the highest level of confidence reported in the study in regards to scientific validity of efficacy claims. Several studies have demonstrated efficacy of meloxicam compared to placebo. Doig and coworkers²²⁴ studied 40 dogs (manufacturer sponsored), and Peterson and Keefe⁸² studied 217 dogs with spontaneous osteoarthritis. Duration of therapy was 7 to 14 days, respectively. Placebo effects were reported in up to 38% of animals, underscoring the importance of placebo controls.82 Meloxicam (0.2 mg/kg every 24 hours) and aspirin (25 mg/kg every 12 hours) were compared in a clinical trial using a crossover (randomization not indicated) design in dogs (n = 12) with experimentally induced (cranial cruciate rupture) osteoarthritis of the stifle. Animals were treated for 21 days; outcome measures included measurement of PGE₂, thromboxane B2 (TXB2) in blood and synovial fluid, and endoscopically collected gastric mucosa. Both aspirin and meloxicam administration significantly suppressed PGE₂ concentrations in blood and synovial fluid. Aspirin, but not meloxicam, suppressed TXB2 concentration in blood and PGE₂ in gastric mucosa, leading the authors to conclude that meloxicam behaves in vivo as COX-1 sparing.²²⁶

KEY POINT 29-18 The Food and Drug Administration has indicated that meloxicam should not be administered in cats more than as a single dose.

Meloxicam also has been compared with opioid analgesics for control of perioperative pain. Mathews and coworkers²²⁹ compared the safety and efficacy of preoperative administration of a single dose of meloxicam, ketoprofen, and butorphanol in dogs (n = 36; 12 per group) undergoing abdominal surgery. The butorphanol-treated group received a second dose immediately after surgery. Overall efficacy was rated as good or excellent in 9 of 12 dogs that received either meloxicam or ketoprofen compared with only 1 of 12 that received butorphanol. Analgesic effects of meloxicam were maintained for 20 hours postoperatively. Budsberg and coworkers²³⁰ compared the analgesic effects of meloxicam (0.2 mg/kg intravenously) and butorphanol (0.1 mg/kg) administered immediately after surgery (at incision closure) for control of postoperative pain in client-owned dogs (n = 40) presenting with rupture of the cranial cruciate ligament. Outcome was based on evidence of pain (visual analog scale) and serum cortisol concentrations for a 24-hour period. Differences in pain response did not emerge between the treatment groups until 8 hours later, with the meloxicam-treated group exhibiting less pain 8 to 11 hours after extubation. Failure to detect a significant difference between treatment groups earlier than 8 hrs may have reflected low overall scores for both groups coupled with low animal numbers (i.e., poor power of the study). Overall serum cortisol was less in the meloxicam-treated group compared with butorphanol group. Otherwise, significant differences could not be demonstrated. Using a model of acute inflammation (intraarticular injection of calcium pyrophosphate dehydrate), the effects of meloxicam (0.2 mg/kg intravenously for 3 doses) on proteoglycan biosynthesis in vitro and ex vivo were compared with indomethacin (0.5 mg/kg intravenously for 3 doses). Indomethacin is known to contribute to joint injury in humans in part by inhibiting sulphated proteoglycans., Neither drug contributed to joint damage, but pain and exudates were decreased more by meloxicam than indomethacin.²³¹

Cats

The disposition of meloxicam has been studied in cats. Meloxicam is among the NSAIDs characterized by a shorter half-life in cats than in dogs (see Table 29-4). It is one of the few NSAIDs that appear to be well tolerated in cats. Its use in Canada for several years predated its approval for use in cats in the United States. Meloxicam is the only NSAID approved for use in cats in the United States, with the approved use limited to perioperative single dosing. Meloxicam is approved in cats outside the United States for single dose administration as both an injectable and oral product.

Despite its apparent safety compared with other NSAIDs, the therapeutic margin of meloxicam is relatively narrow. The association between renal disease and NSAIDs, including meloxicam, in cats was discussed previously. Cats do not tolerate multiple doses greater than or equal to 0.3 mg/kg, and gastric ulceration and death have occurred at three to six times the normal dose for 10 days. Several studies support the efficacy of meloxicam in cats. In one study the optimal dose of meloxicam to prevent endotoxin-induced fever in cats was 0.3 mg/kg.²³² The need for a long-term safe yet effective analgesic in cats was supported by a symposium that focused on osteoarthritis in cats.²³³ The safety of meloxicam in cats in regards to renal disease was previously addressed (Table 29-6). A prevalence of degenerative joint disease was found in 34% of cats (n = 218), with previous reports placing the prevalence as high as 90%.

A number of clinical trials have addressed efficacy of meloxicam in cats. In cats subjected to ovariohysterectomy, meloxicam, carprofen, ketoprofen, and tolfenamic acid all were effective in controlling postoperative pain, with 10% of cats in each group requiring opioid rescue.²⁰³ In a comparison of carprofen (4.4 mg/kg subcutaneously) and meloxicam (0.3 mg/kg subcutaneously) in 80 cats undergoing ovariohysterectomy, no difference was found in control of postoperative pain; one cat in the carprofen group and two in the meloxicam group required opioid rescue.²²⁸

The efficacy of meloxicam for treatment of osteoarthritis in cats was reported in abstract form²³³ on the basis of a prospective crossover pilot study (n = 7; mean age 14 years). Cats were treated with either 0.05 mg/kg meloxicam orally for 5 days (first dose 0.1 mg/kg) or placebo (neither washout period nor randomization described). A tendency toward improvement has been described. Lascelles and coworkers²²⁷ prospectively compared the efficacy of meloxicam (0.3 mg/kg orally, followed by 0.1 mg/kg for 4 days orally) to ketoprofen (1 mg/kg orally once daily for 5 days) for treatment of acute or chronic pain associated with locomotor disease in cats (n =69). Although both

drugs were effective in reducing clinical signs associated with pain, meloxicam was considered more palatable.

Robenacoxib

Robenacoxib is approved for use in companion animals outside the United States.^{45,234} The disposition of robenacoxib has been described in dogs after single-dose administration of 1 mg/kg either orally (fasted or fed), intravenously, or subcutaneously²³⁵ (see Table 29-4). Isoform preference in studies supported by the manufacturer indicate a COX-1 to COX-2 ratio (95% inhibition) of 450 using whole blood assays in cats.⁴⁵ The disposition of robenacoxib in cats at 2 mg/kg intravenously has been reported.⁴⁵ Data from the ex vivo and pharmacokinetic studies were subsequently integrated with a model of inflammation in cats (n=10), resulting in a recommended dose 2 mg/ kg dose every 12 hours.

Vedaprofen

Vedaprofen is marketed outside the United States for use in dogs as an oral gel preparation. A document provided by the manufacturer indicates that the racemic mixture is approximately 8 times more potent toward COX-2 than COX-1, with the majority of activity exihibited by the S enantiomer. The pharmacokinetics of vedaprofen, including its enantiomers, are available in the dog (see Table 29-4)²³⁶ after administration either intravenously or as an oral gel preparation. Although volume of distribution was not provided, the elimination (disappearance) half-life was 12 to 17 hours, depending on oral versus intravenous administration. Bioavailability of the gel preparation was near complete. The S and R enantiomers are present generally at a ratio of 1:1, with variability ranging as low as 0.5 (toward the end of the 24-hour dosing interval) and as high as 3.10 (at 2 to 3 hours) after single dosing. After oral multiple dosing for 14 days, the R:S ratio averaged about 1.8 throughout the 24-hour dosing interval. The higher concentration of the R enantiomer appears to reflect more rapid clearance of the S enantiomer (see Table 29-4). The disposition f vedaprofen did not appear to change substantially with 14 days of dosing.²³⁶ The efficacy and safety of vedaprofen were compared with that of meloxicam, which was used as the control during the approval process. Differences could not be detected for either safety or efficacy. Gastrointestinal side effects were reported in approximately 11 to 12% for both groups despite treatment for approximately 15 days (acute) and 40 days (chronic). Both drugs were effective in both acute (approximately 88%) and chronic (approximately 67%).237

CYCLOOXYGENASE-1-SPARING DRUGS APPROVED FOR USE IN HUMAN MEDICINE

Celecoxib

Celecoxib appears to be COX-1 sparing in the dog (see Table 29-3). Its disposition has been studied in Beagles after single and multiple oral dosing, using different (a solution and solid) dosing forms, with and without food.²³⁸ Celecoxib

metabolism in dogs is characterized by polymorphism: Paulson and coworkers⁴¹ described dogs that metabolize the drug poorly (poor metabolizers [PMs]) compared with efficient metabolizers (EMs). The elimination half-life of the drug in PMs is approximately 4 times as long as that in EMs (see Table 29-4). The drug is normally extensively metabolized (principally hydroxylation followed by oxidation). In both EMs and PMs, approximately 80% of the drug is eliminated in the feces. In EMs disposition does not appear to change with chronic (1-year) dosing. Administration of the drug with a fatty meal increased both the C_{max} and the bioavailability. The disposition of celecoxib also has been studied in normal Greyhounds after single (12.5 mg/kg) and multiple dosing. Decreases occurred in C_{max} (22%), elimination half-life (shorter), and area under the curve (40%) after 10 days of dosing at 12.5 mg/ kg per day.²³⁹ The pharmacodynamic and toxic effects of celecoxib have not been well studied in the dog.

Rofecoxib

Rofecoxib is described as a COX-2-selective drug in humans, but no information is available regarding its selectivity in dogs. Its disposition has been studied in dogs (see Table 29-4).²⁴¹ The drug is cleared after oral administration primarily by biliary excretion after extensive hepatic metabolism to hydroxyl and glucuronide metabolites, with some urinary excretion.²⁴¹ The effects of rofecoxib (0.5 mg/kg/day orally) on the canine gastrointestinal tract were compared endoscopically to those of the dual-acting NSAID licofelone (2.5 mg/kg orally twice daily) and placebo after 56 days of dosing.²⁴⁰ Whereas no endoscopic lesions were evident for either the placebo or licofelone, rofecoxib was associated with lesions in both the gastric (six of seven) and duodenal (four of seven) areas. This occurred despite a progressive decline in mean plasma drug concentrations for rofecoxib across time: Baseline concentrations were 110.1 ± 85.8 (2 days) compared with study end concentrations of 65.3 ± 49.1 ng/mL (56 days). Concentrations of licofelone also decreased: 761.0 \pm 413.8 at baseline compared with 307 \pm 106.5 ng/mL at study end.²⁴⁰

Nimesulide

Nimesulide is a COX-2-selective drug approved for use in humans that also appears to act as a COX-1-sparing drug in dogs.^{31,242} The disposition of nimesulide has been studied in dogs (n = 8-10) after single-dose administration of 5 mg/kg intravenously, intramuscularly, and orally and after 5 days of once-daily administration of the same dose (see Table 29-4).²⁴² The terminal elimination half-life after intramuscular administration was longer than that after intravenous administration, indicating a flip-flop model for this route. On the basis of the integration of pharmacokinetics and pharmacodynamics, the authors determined an effective concentration (EC₅₀) to be 2 to 6 μ g/mL, which would be achieved at the studied dose, with some inhibition of COX-1 also occurring.²⁴³ However, the study was performed on Beagles, which may not be generally applicable to the canine population at large. The safety of nimesulide has not apparently been studied in dogs.

MISCELLANEOUS NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Indomethacin

Indomethacin is an NSAID that was developed specifically to abate the inflammatory response to the indolic hormones serotonin and tryptophan.⁶ As a powerful antiinflammatory, it became a standard for comparison with other drugs. In humans toxicities are not serious, but CNS side effects are undesirable.⁶ The incidence of gastrointestinal hemorrhage after administration of indomethacin at doses of 2 to 5 mg/ kg precludes its clinical utility in dogs. In one study all dogs developed melena within 1 week of receiving 2 mg/kg daily; 60% of these animals had gastric ulcers.²⁴⁴ Interestingly, pretreatment with pure 5-lipoxygenase inhibitors prevents the ulcerogenic effects of indomethacin.²

Acetaminophen

Acetaminophen (paracetamol) is a coal tar analgesic used in human medicine as an effective alternative to aspirin for control of fever and pain. Classically, it is recognized to have poor antiinflammatory activity, although this view has become more controversial.²⁴⁵ Although often classified as an NSAID, its mechanism does not involve inhibition of COX. Rather, acetaminophen interferes with the endoperoxide intermediates (PGG₂, PGH₂) of AA conversion. Inhibition of a new isoenzym, COX-3, has been suggested, but studies suggest that this isoform is actually a variant of COX-1.9 Concentrations necessary to inhibit this variant are high, leading some investigators to suggest that its efficacy as an analgesic and antipyretic (but not antiinflammatory) reflect its effects on PGH synthases and glutathione-dependent PGE_2 synthases.^{17} The relatively weak antiinflammatory activity of acetaminophen has been attributed to the high concentrations of peroxides that occur in peripheral inflammatory lesions but may reflect limited COX enzyme activity. Acetaminophen may be more effective against inflammatory conditions in the CNS.

The major disadvantage of acetaminophen use in veterinary patients is the narrow safety margin in cats.¹⁴⁰ The drug is normally conjugated with glucuronide and to a lesser degree with sulfate. Drug that is not conjugated is metabolized by phase I microsomal enzymes to cytotoxic oxidative metabolites (see Chapter 4). Intracellular glutathione normally scavenges the metabolites, but in the case of overdose or glucuronide deficiency (as with the cat), the formation of toxic metabolites overwhelms the glutathione-scavenging system. In cats methemoglobinemia is the most common indication of toxicity, although centrolobular hepatic necrosis may also occur. Treatment of acetaminophen toxicity includes administration of antioxidants, including N-acetylcysteine, a precursor of glutathione, and ascorbic acid (vitamin C).246-248 The administration of cimetidine, a microsomal enzyme inhibitor, will reduce the formation of toxic metabolites and will result in clinical improvement if given within 48 hours of acetaminophen administration.^{249,250} The use of SAMe has been demonstrated scientifically and has been reported as clinically effective in

a case report.²⁵¹ A potential advantage of SAMe is response despite late administration.

Acetaminophen toxicity in cats has been retrospectively described in a series (n = 17) of cases.²⁵² Treatments consisted of emesis induced by apomorphine or xylazine, activated charcoal, intravenous balanced crystalloids, intravenous N-acetylcysteine (140 mg/kg, followed by 70 mg/kg every 3 to 6 hours), and ascorbic acid (30 to 100 mg/kg orally or parenterally every 4 to 6 hours). Cimetidine was administered to three cats and methylene blue with dexamethasone to one. The survival rate was 82%. Responding cats were normal within 48 hours of treatment. Median acetaminophen dose in surviving animals was 170 mg/kg (highest 400 mg/kg) versus 100 mg/kg in nonsurvivors (highest dose 170 mg/kg), suggesting dose was not a determinant of outcome. Ten of 12 surviving cats were treated within 14 hours of ingestion. In four of the five deaths, Nacetylcysteine was not begun until 17 hours after acetaminophen exposure, emphasizing the importance of early treatment.

Acetaminophen can interfere (false increase) with glucose determination on certain bedside glucometers.²⁵³

In humans, according to the American College of Rheumatology, acetaminophen remains the first choice for treatment of patients with osteoarthritis because of its efficacy, safety, and cost. NSAIDs are recommended only after acetaminophen has failed. Among the NSAIDs, it is characterized as among the most able to penetrate the CNS, thus potentially providing better analgesia. Acetaminophen (15 mg/kg every 8 hours) may be as effective as aspirin for the control of postoperative pain and inflammation in dogs. An extended-relief formulation has proved useful (20 to 30 mg/kg every 8 to 12 hours) at a longer interval.²⁵⁴ Acetaminophen also can be combined with opioids, with a commercial preparation available with codeine (dose based on codeine at 1 to 2 mg/kg orally every 8 to 12 hours). Acetaminophen appears to be safe in dogs. At daily doses of 0.5 g every 8 hours (average weight 18 kg, or 28 mg/kg), acetaminophen causes no clinical signs of adverse drug effects.²⁴⁵ Other studies, however, have shown that adverse reactions (e.g., depression, methemoglobinemia, vomiting) can occur at higher (100 mg/kg) doses.^{255, 256} In another study, 900 mg/kg intravenously caused fulminant hepatic failure in dogs.257

Leukotrienes and Their Inhibition Leukotriene Formation

Although COX has been the primary target of NSAIDs, the complex role of lipoxygenases in the inflammatory process increasingly is being recognized and targeted. Further, improved gastrointestinal safety as a result of inhibition of leukotrienes supports their potential use. Goodman and coworkers²⁵⁸ recently reviewed the role of LTs and their inhibition in dogs and cats.

Lipoxygenase enzymes located within cells can also metabolize AA to inflammatory mediators, with lipoxygnases 5, 12, and 17 apparently being the most clinically relevant.^{7,8,17,259} Lipoxygenase enzymes are not as ubiquitous in the body as the COX enzymes, but the enzymes do vary in tissues location. Lipoxygenase-5 enzymes are found primarily in cells of myeloid origin, including macrophages (and all tissues in which they are found) as well as B-lymphocytes. The initial product formed

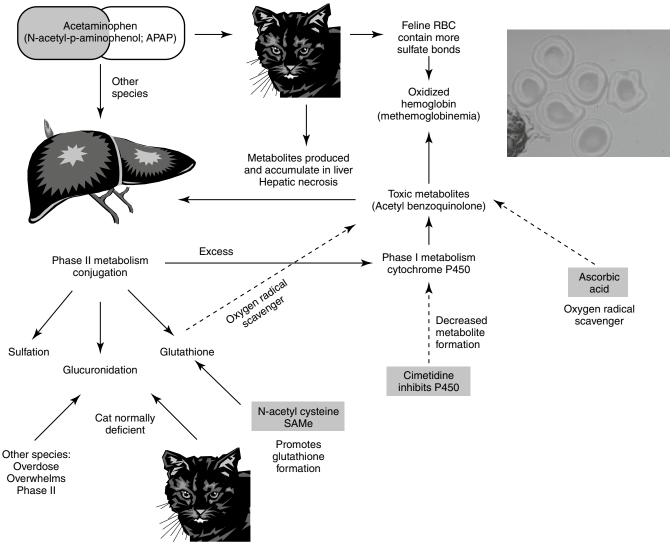

Figure 29-10 Acetaminophen toxicity reflects a cytotoxic type A adverse reaction. Because cats are deficient in glucuronidation, phase II metabolism is easily overwhelmed, and drug is shunted more aggressively back into phase I metabolism. The same process occurs in dogs after an overdose. The products of phase I metabolism are reactive and cause destruction of tissues (liver and red blood cells). Glutathione, an important phase II scavenger, prevents damage but is easily depleted in cats. Supplementation in the form of *N*-acetylcysteine can decrease damage. Cimetidine is useful because it decreases phase I metabolism and thus the formation of phase I metabolites.

from its action on AA is HPETE, followed by LT A4 (Figure 29-10; see also Figures 29-1 and 29-2). Further conversion (by way of hydroxylase) of LTA4 produces LTB4, a very potent chemotactant, and LTC4 (by way of reduced glutathione) or LTD4 (y-glutamyltranspeptidase). From these, LTD4 is further converted to LTE4. LTs C, D, and E are referred to as cysteinyl-LTs (see Figure 29-2).²² A second lipoxygenase enzyme, lipoxygenase-12, occurs in platelets, where it catalyzes the formation of 12-HPETE.7,22 A third enzyme, lipoxygenase-15, catalyzes the formation of lipoxins. In contrast to LTs, lipoxins (LXA₄ and LXB₄) are characterized by *anti-inflammatory* activity.²⁶⁰ Lipoxin formation can occur when 5-lipoxygenase products interact with 12- lipoxygenase or 15- lipoxygenase.²⁶¹ Lipoxins are described as counterregulatory, with a particular focus on those inflammatory responses that resolve inflammation.²⁶⁰ LTs act through membrane receptors located on inflammatory and other cells. Receptors are linked to G proteins, increasing intracellular calcium and decreasing cAMP (see Figure 29-1). For example, LTB4 binds to BLT1 and 2 subreceptor types located in inflammatory cells, whereas cysteinyl LTs (C-E) bind to CysLT1 and 2 subreceptor types located in eosinophils, macrophages, and bronchial smooth muscle.

Leukotrienes in Health and Disease

With the exception of lipoxins, each of the lipoxygenasecatalyzed products is a potent mediator of inflammation. At picomolar concentrations, they are effective in the activation, recruitment, migration, and adhesion of immune cells.²² LTs and other selected lipoxygenase products modulate lymphocyte function.⁸ LTB4 increases production and release of inflammatory cytokines, including activation of NF-kB (transcription factor responsible for expression of proinflammatory

cytokins), and expression of TNF-alpha and IL-1β. In the cartilage these cytokines increase expression of MMPs.¹⁸ Inhibition of 5-lipoxygenase reduces expression of the cytokines, including TNF-alpha.²² In addition to their effect on leukocytes, the cysteinyl LTs are extremely spasmogenic, causing bronchoconstriction (being 100 times more potent than histamine) in the lungs and exacerbation of ulcerogenic effects in the gastrointestinal tract. The cysteinyl LTs are important mediators in hypersensitivity reactions. They are particularly effective chemoattractants for eosinophils; as such, they play important roles in a number of inflammatory and allergic diseases.²⁵⁸ LTB4 most commony is associated with inflammation associated with inflammatory bowel lesions; colonic epithelials cells are able to produce LTB4. A potential role for lipoxygenase in cancer also is emerging: Lipoxygenase-5 is overexpressed in cancer cells; upregulation in pancreatic cancer suggests a potential therapeutic role for lipoxygenase inhibitors.^{24,258,262} The role of LTs in eosinophil signaling and chronic (allergic) inflammatory diseases is discussed in Chapter 31.

KEY POINT 29-19 Although less ubiquitous in the body, leukotrienes also represent a balance of proinflammatory and antiinflammatory signals.

A potential sequela of COX blockade by NSAIDs is shunting of unused AA to the lipoxygenase pathway, resulting in increased production of LTs from AA that would have otherwise been metabolized to PG products.8 For example, aspirin hypersensitivity has been associated with the diversion of AA from the PG to the LT (5-lipoxygenase) pathway and the production of mediators that are more inflammatory than the products of PGH synthetase.^{10,22} Aspirin hypersensitivity also has been attributed to the loss of PGs that might otherwise have specifically inhibited the formation of LTs. The adverse reactions of NSAIDs thus reflect not only loss of PGs but also augmentation of LT synthesis.8 Examples include exacerbation of bronchoconstriction and increasing ulcerogenicity of NSAIDs. Newer NSAIDs that preferentially target COX-2 are not characterized by aspirin hypersensitivity, presumably because AA can yet be metabolized to PGs by way of COX-1.

Lipoxygenase Inhibition

Originally, studies indicated that NSAIDs were not capable of inhibiting LT synthesis. However, the antiinflammatory efficacy of some of the NSAIDs (e.g., ketoprofen)²⁶³ has been attributed, in part, to inhibition of lipoxygenase and thus prevention of LT formation.⁶ However, the ability of NSAIDs to inhibit 5-lipoxygenase is controversial.⁸ More recently, dual-acting NSAIDs, which impair COX-1 and -2 and lipoxygenases, have been approved. These include tepoxalin, which was initially studied in humans, but approved only for use in dogs. The class of di-tert-butylphenol antiinflammatory agents have the added advantage of antioxidant (phenolic properties) and radical-scavenging properties.²² These include tebufelone, darbufelone, and licofelone. Finally, the effects of LTs can be inhibited at the level of the receptor. LT-receptor antagonists include zafirlukast and montelukast (Figure 29-11).

Lipoxygenase Inhibitors

Zileuton is a potent, selective 5-lipoxygenase inhibitor. It is the only drug of this class approved for use in the United States. Use of these drugs has largely been limited by hepatotoxicity; further, efficacy has been limited.

Dual-Acting Nonsteroidal Antiinflammatory Drugs

Despite the advantages of NSAIDs that COX-1-sparing drugs offer, the need for improved gastrointestinal tolerance continues. Because the formation of LTs from AA that might otherwise have been metabolized to PGs appears to contribute to the toxicity (gastrointestinal, repiratory, and other) of NSAIDs (conventional more so than newer drugs), a drug with both COX and lipoxygenase inhibitory effects has been the target of the pharmaceutical industry for some time. However, the presence of an iron atom in the structure of COX or lipoxygenase required that such drugs be redox active in their mechanism. Therefore these drugs tended to inhibit other redox-active enzyme systems, including those in the liver. Consequently, hepatotoxicy has limited the use of dual-acting drugs. Two drugs have been studied in human medicine for their dual actions: tepoxalin and licofelone. The latter is an AA substrate and as such acts as a competitive inhibitor of COX and lipoxygenase without redox activity;81 it is not clear whether tepoxalin similarly avoids redox activity. Neither drugs target lipoxygenase-12 or -15, and thus minimally affect lipoxin formation, further improving potential gastrointestinal tolerance. Further, in the cardiovascular system, because both COX-1 and COX-2 (prostacyclin and thromboxane formation) are inhibited, thrombembolic balance should not be disrupted.

In addition to enhanced safety, enhanced efficacy of dualacting NSAIDs toward inflammatory diseases should be anticipated. As such has been demonstrated for licofelone in experimentally induced osteoarthritis in dogs. Not only are LT and PG formation decreased, but also formation of proinflammatory cytokines is decreased. Their ability to inhibit both COX and lipoxygenase may result in synergistic activity in the control of inflammation.²⁶⁴ Preliminary data suggest that dual inhibitors may slow the progression of osteoarthritis.²⁶⁵ Because of their potential enhanced efficacy and safety, dual inhibiting NSAIDs have been referred to as a class of breakthrough NSAIDs.²² Indications for dual inhibitors include osteoarthritis, the chronic inflammatory allergic diseases asthma and atopy, and chronic inflammatory bowel disease.

Tepoxalin. Among the dual-acting NSAIDs, only tepoxalin has been approved for use in animals. This drug was being investigated in humans, but pharmacokinetics (not safety) precluded further development.¹⁷ It is a potent antiinflammatory and analgesic pyrazole derivative that also inhibits production of IL-1 and suppresses NFkB activation and dependent gene expression.¹⁷ Its dual inhibitory effect has been demonstrated in dogs. For example, tepoxalin inhibited COX-1, COX-2, and lipoxygenase-5 in synovial fluids (stifle) of dogs with osteoarthritis.^{266,267} Tepoxalin, but not firocoxib or meloxicam, inhibited TXA2 in canine blood compared with baseline.²⁶⁷ Its disposition has been reported in both dogs and cats (see Table 29-4). In dogs tepoxalin is approved

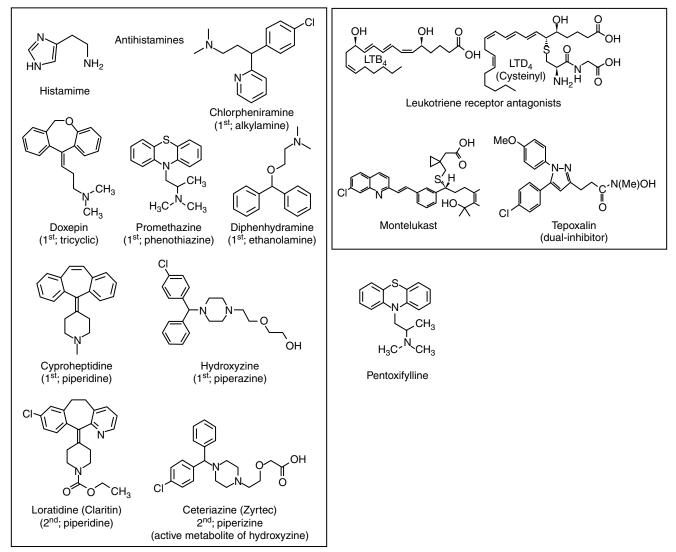

Figure 29-11 Structures of selected drugs used to treat various aspects of inflammation. Antihistamines are generally structurally similar to histamine (upper left).

as a tablet that rapidly disintegrates in the oral cavity, with absorption nonetheless occurring in the intestinal tract. Food enhances oral absorption.¹²⁷ Tepoxalin undergoes hepatic metabolism. It is converted to at least one major metabolite whose activity contributes substantially to its clinical effect in part because its half-life is substantially longer than that of the parent compound. Both the parent compound and its active metabolite are highly protein bound. Chronic administration does not appear to alter either the C_{max} or the elimination half-life of either the parent compound or the active metabolite (USP).¹²⁷ Essentially all drugs or metabolites, either as parent compound or metabolites, are eliminated in the feces. Feeding appears to increase absorption. The toxicity data generated for the approval of tepoxalin suggest that it should be among the safest of the NSAIDs recently approved for use in dogs (see Table 29-4), although gastrointestinal toxicity can occur. Its safety is supported by the study of Goodman and coworkers.²¹ Gastric and pyloric ulcers were monitored endoscopically in dogs (n = 6) treated with tepoxalin, firocoxib, or placebo for 7 days. Animals were studied using a

randomized crossover design. Eicosanoids were determined in plasma and lesion margins, and lesions were scored. The firocoxib lesions were larger than placebo or tepoxalin lesions despite the fact that tepoxalin prostaglandin concentrations in the mucosa were lower than in either group. Safety appears to reflect blockade of LTs whose vasoconstrictive and neutrophil chemotaxis, adhesion, and degranulation effects are necessary for mucosal erosion.²⁵⁸ Agnello and coworkers²⁶⁶ demonstrated tepoxalin inhibition of PGE₂ and LTB4 in the gastric mucosa of dogs. Despite its impact on both COX pathways, in a manufacturer-sponsored study, tepoxalin did not cause significant changes in hemostatic or renal function tests when administered (10 mg/kg orally) to young, healthy dogs (n = 8; 4 placebo) before surgery. Tests of renal function (serum blood urea nitrogen, creatinine and urine gamma glutamyl transferase [GGT] creatinine ratios) were studied for 48 hrs. Hemostatic tests included buccal mucosal bleeding time, as well as bleeding at the site of (experimental) surgical incision. The power of the study was not addressed. In a different study, tepoxalin did not alter renal function when administered with with angiotensin-converting enzyme inhibitors for up to 28 days. 258

KEY POINT 29-20 Dual-acting inhibitors might be expected to be more efficacious toward some inflammatory conditions, particularly those associated with allergies, compared with nonsteroidal antiinflammatory drugs.

Tepoxalin also has been studied in cats. Whereas tepoxalin was well tolerated in cats when administered at 100 mg/kg once daily for 3 consecutive days, saturation kinetics occurred with two doses of 60 mg/kg 4 hours apart. Signs suggestive of CNS adverse drug events occurred (drunkenlike state), a response not recorded in any other species. Tepoxalin is a potent antipyretic agent in cats at doses between 5 and 10 mg/ kg and provides analgesia at least equivalent to that of butorphanol at 10 mg/kg for onychectomy.²⁶⁸

The action of tepoxalin as a dual inhibitor might render it useful for control of pain or inflammation typical of other NSAIDs. This includes a potential added advantage for treatment of chronic allergic diseases for which LTs play a role in cellular signaling. However, preoperative use of tepoxalin may not be prudent, particularly in animals at risk for hemostasis problems. Its postoperative use might be considered. Bosmans and coworkers²⁶⁹ compared the combination of tepoxaline and buprenorphine to buprenorphine alone during the 24-hour period after cruciate repair in dogs (n = 20; 10 per group). Animals were studied using a parallel randomized, blinded design. Pain was assessed using visual analog scales and a multifactorial pain scale. No statistical differences could be demonstrated for either control of pain or side effects.

Licofelone. Licofelone impairs PGE production in a similar manner to conventional NSAIDs, but unlike other NSAIDs, it also prevents the formation of LTB4. Although licofelone has not been approved for use in dogs, its pharmacodynamic effects have been studied in dogs.²⁴⁰ Licofelone appears to have potent antioxidative properties.^{269a} Its effects on the canine gastrointestinal tract (2.5 mg/kg orally twice daily) as measured endoscopically were negligible to those of rofecoxib (see the discussion of rofecoxib) after 56 days of treatment with either drug. In that study, as with rofecoxib, concentrations of licofelone also decreased across time. Baseline concentrations were 761.0 \pm 413.8 compared with 307 \pm 106.5 ng/mL at study end.²⁴⁰ The drug's safety was explained in part because of decreased bioavailability at high doses but also because of prevention of lipoxygenase.² Licofelone has been found effective in the treatment of experimentally induced arthritis in the dog.²⁶⁴

Leukotriene Receptor Antagonists

Zafirlukast and montelukast are competitive cysLT-1 receptor antagonists (LAR) approved for use to treat human asthma. However, their use increasingly is being expanded to treatment of a variety of chronic allergic inflammatory diseases. Interestingly, their use might be considered in combination with NSAIDs to reduce the risk of gastrointestinal toxicity. The currently available LARs are available only for oral administration. Disposition information is not available for dogs or cats. In humans the drugs are rapidly and nearly completely absorbed. Metabolism of zafirlukast is by CYP2C9 and for montelukast by CYP3A4 and CYP29C. Metabolites are not active. Half-lives in humans are 10 hours (zafirlukast) and 3 to 6 hours (montelukast). Maximum efficacy may require 2 to 4 weeks, although an initial response may be evident within several days. The drugs are generally very safe, probably reflecting the limited effects of LTs in the body.²⁷⁰

Pentoxifylline

Pentoxifylline is a methylxanthine derivative of theobromine with minimal bronchodilator activity but with clinically apparent rheologic effects.²⁷¹ It is used to treat human patients with claudication associated with chronic occlusive arterial disease. Mechanisms do not include vasodilation or cardiac stimulatory effects. Its rheologic effects appear to reflect increased flexibility of red blood cells and reduced blood viscosity.²⁷²

The disposition of pentoxifylline is complex, with hepatic metabolism to at least seven metabolites, two of which (I and V) are responsible for most of the pharmacologic effects.²⁷³ Pentoxifylline inhibits the complement cascade, neutrophil degranulation, and cytokine production. Among the cytokines, inhibition of TNF-alpha may be particularly important to its efficacy.²⁷⁴ IL-1 and IL-6 also are inhibited, as is expression of adhesions molecules. Pentoxifylline also increases fibroblast collagenases, decreases collagen, fibronectin, and glycosaminoglycan production.²⁷⁴ Inhibition of phosphodiesterase contributes to its antinflammatory effects.

The disposition of the drug has been studied in normal dogs.²⁷⁵ After a dose of 30 mg/kg orally and 8 mg/kg intravenously (n = 5 dogs), pentoxifylline and its metabolites are characterized by an elimination half-life of 125 ± 192 and 450 ± 533 minutes, respectively, suggesting slow absorption. Peak concentrations were 41 ± 46 and $40 \pm 32 \mu$ g/mL for intravenous and oral administration, respectively. Bioavailability was $76 \pm 78\%$. No side effects occurred in any dog at this dose. Although therapeutic concentrations have been recommended in humans, this is based on the parent compound. However, therapeutic ranges should be based on both the parent drug and its most active metabolites.

In human patients inflammatory conditions for which pentoxifylline has been used include contact dermatitis, systemic vasculitis, and sepsis syndromes.²⁷¹ However, for the latter indication (septic shock), one study demonstrated increased risk of mortality in septic dogs treated with pentoxifylline as a constant intravenous infusion, presumably because of decreased endotoxin clearance.²⁷⁶ Pentoxifylline was able to decrease the extent of esophageal stricture induced by erosive esophagitis.²⁷⁷ Pentoxifylline increasingly is being used to treat dermatolgic disorders in humans.²⁷⁴ The drug has been used to treat Collie dermatomyositis, although animals probably benefit as much from the antiinflammatory effects as from the rheologic effects.

KEY POINT 29-21 The anti-tumor necrosis factor effects of pentoxifylline warrant consideration of its use for treatment or prevention of a variety of inflammatory conditions, ranging from life-threatening septic shock to nonresponsive inflammatory bowel disease.

Antihistamines

Histamine in Health and Disease

Histamine is a low-molecular-weight amine, synthesized from histidine by its decarboxylation. Histidine decarboxylase is ubiquitous in the body, occuring in the CNS, gastric parietal cells, mast cells, and basophils. Upon its formation histamine is stored. Most histamine is stored bound to heparin in granules located in either mast cells or their circulatory counterparts, basophils. Histamine is not the sole mediator of clinical relevance located in mast cells. Because histamine release occurs by mast cell degranulation, it is accompanied by the release of other mediators, including those preformed and stored in granules (e.g., serotonin) and those synthesized in situ (e.g., AA products). Currently, four histamine subreceptors have been identified. The H1 receptors couple to G proteins, activating the PLC-IP3-Ca²⁺ pathway [G&G].²⁷⁸ H₂ receptors link to Gs, activating the adenylyl cyclase cAMP pathway. Both H₃ and H₄ receptors are inhibitory toward adenylyl cyclase; 35% or more homology between the two complicates pharmacologic distinction.

The impact of antihistamines is complex but somewhat predictable based on the location and impact of each receptor. For example, H₁ receptors on vascular endothelium activate calcium mobilization and nitric oxide production (eNOS), causing local vascular smooth muscle relaxation. In contrast, activation of H₁ receptors in smooth muscle will cause contraction (e.g., bronchoconstriction), which is balanced by stimulation of H_2 receptors in the same cells that mediate *relaxation*. Both H₁ and H₂ receptors are distributed throughout the peripheral nervous system and CNS, whereas H₃ receptors are limited to the CNS. The H₃ receptors serve as autoreceptors. In general, their stimulation promotes sleep, and antagonism is manifested as wakefulness. H₄ receptors are located primarily in cells of hematopoietic origin.²⁷⁸ These include granulocytes. Stimulation of H₄ receptors on eosinophils induces a change in the shape of the cell, chemotaxis, and upregulation of adhesion molecules; antagonists therefore may be particularly useful for treatment of chronic allergic diseases.

The effects of histamine on H₁ and H₂ receptors vary with the site and extent of release. In general, histamine affinity for H_1 receptors is probably greater than that for H_2 receptors. In the vasculature both H1 and H2 receptor activation causes relaxation of arteriolar smooth muscle (resistance vessels), resulting in vasodilation. Whereas H₁-mediated responses are rapid, H₂- mediated response are slow and prolonged. In contrast to its effect on smaller vessels, histamine may cause contraction of the smooth muscle, causing hypertension in some species. In the heart contractility and automaticity increase, primarily through H₂ receptors. Endothelial cells of venules contain more histamine receptors than other tissues. In postcapillary venules, H₁ receptors cause endothelial cells to contract and separate, regulating cell-to-cell cytoskeleton interactions.^{278a} The loss of the endothelial barrier results in increased permeability, typical of edema. Passage of inflammatory cells into tissues is facilitated. In nonvascular smooth muscle, H₁ receptors cause contraction, whereas H₂ receptor activation causes relaxation. Thus in the bronchi the predominant effect of smooth muscle contraction is bronchoconstriction; in the gastrointestinal tract, diarrhea may occur. Species sensitivity to these effects vary; for example, histamine does not appear to play a major role in bronchoconstriction associated with asthma in the cat. Release of histamine from mast cells and basophils causes H_2 -mediated inhibition of further histamine release. Gastric acid secretion is mediated by H_2 receptors. The H_1 receptors also stimulate sensory nerve endings; for example, pruritis reflects, in part, stimulation of type C nerve fibers.

The manifestation of the vascular effects of histamine varies depending on the magnitude of response. Local effects in the skin are manifested as the typical wheal and flare response; in contrast, systemic release, if sufficient, may be manifested as hypotensive shock, typical of anaphylactic or anaphylactoid response. The clinical signs vary with the species, depending on the "shock" organ, which in turn generally reflects the tissue with the greatest number of mast cells (lungs in cats, gastrointestinal tract in dogs).

Prevention or treatment of the effects of histamine can be accomplished in several ways: preventing histamine release (e.g., inhibition of mast cell degranulation), targeting the histamine receptor itself, or antagonizing (modulating) tissue response to histamine (e.g., the use of beta antagonists to blunt histamine-induced bronchoconstriction). Of these, the most comprehensive response is likely to occur if mast cell degranulation is prevented. This reflects the fact that histamine is not the only mediator released with degranulation. Others simultaneously released include those stored with histamine, such as serotonin (to which feline bronchial smooth muscle has been described as very sensitive), and those mediators formed in situ (e.g., eicosanoid mediators such as PGs, LTs [LTB4], or slow-reactive substance of anaphylaxis), platelet activating factor, and related compounds (see Figure 29-1)

Inhibitors of histamine release (mast cell degranulation) (see Figure 29-1), are exemplified by cromolyn sodium. It prevents calcium-dependent release of histamine from mast cells (but not basophils). Its mechanism of action may involve inhibition of calcium flux into the mast cell. Because degranulation is prevented, the release of other autacoids released with histamine is also prevented. However, the drug is poorly absorbed orally and can be given only by inhalation. Thus its use is limited to respiratory disease associated with mast cells. Because it prevents degranulation, it is useful only when administered prophylactically.

Structure–Activity Relationship

Anthistamines historically refer to those drugs specific for H_1 receptors. Some of the drugs also inhibit muscarinic, serotonin, or alpha-adrenergic receptors. All H_1 receptor blockers or antagonists are structurally similar to histamine; however, the primary amine of histamine is replaced by a tertiary amine (see Figure 29-11). Previously referred to as *competitive antagonists* at histamine receptors, they are now described as *inverse agonists*. They preferentially bind to the receptor in its inactive state, maintaining the conformation of the inactive state, thus prolonging the state of inactivity.²⁰⁵ Antihistamines are among the most used drugs in human medicine, with over 40 different drugs available worldwide, many of them nonprescription.

Traditional categorization results in six chemical groups: ethanolamines, ethylenediamines, alkylamines, piperazines, piperidines, and phenothiazines. Alternatively, another classification is based on sedative potential, with first-generation drugs being sedating and second-generation drugs being nonsedating.

Pharmacologic Effects

The effects of the H₁ receptor blockers are similar and predictable regardless of the preparation. Specific effects include smooth muscle inhibition in the gastrointestinal tract and respiratory tract; inhibition of histamine-induced vasodilation of resistance vessels in the vasculature (residual vasodilation may require H₂ blockers); and strong antagonism of capillary and venule permeability. In the CNS both stimulation and depression may occur, depending on the drug. However, second-generation drugs (particularly cetirizine or fexofenadine, but less so loratadine) do not penetrate the blood-brain barrier and are less likely to be associated with CNS side effects.²⁷⁹ The difference appears to reflect, in part, whether the drugs are substrates for P-glycoprotein, with second-generation drugs more likely. Effects on anaphylactic (or anaphylactoid) shock vary with species and tissues. Inhibition of motion sickness may actually reflect anticholinergic activity (promethazine). Antiallergic effects of the newer drugs in particular may reflect inhibition of mediator release,²⁰⁵ probably by way of direct inhibition of inward calcium flux through calcium ion channels.

KEY POINT 29-22 The central nervous system–related side effects of antihistamines reflect their ability to penetrate and remain in the brain, a characteristic more consistent among the first-generation drugs than the newer second-generation drugs.

Example drugs include doxepin (marketed as a tricyclic antidepressant), diphenhydramine (antimuscarinic and sedating ethanolamine), chlorpheniramine (first-generation alkylamine; such drugs as a class are very potent and less sedating), hydroxyzine, cyclizine, and meclizine (a first generation piperazines), cetirizine (a second-generation piperazine and active metabolite of hydroxyzine), promethazine (a phenothiazine), cyproheptadine (a first-generation piperazine that also has antiserotonergic effects), and terfenadine (a second-generation piperazine). Dimenhydrinate (Dramamine) and diphenhydramine (Benadryl) are characterized by marked sedation and significant antimuscarinic effects. Tripelennamine is one of the most specific H_1 antagonists and is associated with less sedation but more gastric side effects. Chlorpheniramine is one of the most potent H1 blockers and also is associated with less sedation but more CNS stimulation. Promethazine is the most potent inhibitor of motion sickness. Piperazines are very effective for motion sickness and may have more prolonged action (cyclizine and meclizine). Phenothiazines (promethazine as the prototype) are characterized by considerable anticholinergic activity and prominent sedation but are the most effective for motion sickness.

Pharmacokinetics

Few antihistamines have been studied in animals. Species differences are likely to preclude extrapolation of dosing regimens among species, and particularly between humans and dogs. This reflects, in part, differences in pH of the human skin (4.8) versus canine skin (similar to plasma). As weak bases, antihistamines are likely to accumulate in skin.²⁸⁰ In the ionized form, the accumulated drug will be inactive in human skin. However, the skin may serve as a depot, allowing slow release as the unionized, active form. This may either prolong elimination half-life from plasma or, if concentrations are too low to be detected in plasma, may allow a local pharmacodynamic effect that exceeds the duration indicated by pharmacokinetics. These benefits may not be realized in dogs.

Hydroxyzine is a piperazine antihistaminergic drug that is further metabolized to cetirizine, the active ingredient in Zyrtec. Its disposition has been described in dogs (n = 6) after oral and intravenous administration of 2 mg/kg hydroxyzine, using a randomized crossover design (14-day washout between routes).²⁸¹ The pharmacokinetic study was accompanied by pharmacodynamic response based on immunoglobulin E (IgE) cutaneous wheal formation. Dogs tolerated each dose well. The maximum response to hydroxyzine occurred during the first 8 hours, correlating with plasma cetirizine concentrations that exceeded 1.5 µg/mL, with response attributed almost exclusively to cetirazine. Accordingly, the authors recommended cetirizine at 2 mg/kg twice daily.

In cats the disposition of cetrizine has been described after an oral dose of 0.9 ± 0.2 mg/kg (see Table 29-4).²⁸² Despite the high proportion of bound drug, the effective concentration in humans of 10.5 to 27.3 ng/mL was achieved (based on calculation of free drug) and maintained during a 24-hour dosing period. Cats tolerated the single dose well, despite drug concentrations that are higher than those generally achieved in humans (human dose 10 mg/person).

Clemastine is an ethanolamine antihistaminergic drug. Its disposition and pharmacodynamic response have been described in dogs (Table 29-7).²⁸⁰ Target concentrations in human approximate 0.7 ng/mL. After oral administration bioavailability of clemastine was less than 5%. Although not reported, plasma drug concentrations versus time curves indicate that 0.7 ng/mL is achieved but maintained for less than 3 hours in dogs after oral absorption. Poor oral absorption contributed to poor response to antigen challenge, whereas intravenous administration inhibited wheal formation entirely for 7 hours. Accordingly, the oral dose of the drug should be at least 1 mg/kg every 12 hours or more; in contrast, the intravenous dose of 0.1 mg/kg would be effective twice daily.

Drug Interactions

Antihistamines generally are substrates for P-glycoprotein and other drug transport systems; therefore competition should be expected when they are used in concert with other P-glycoprotein substrates. Selected drugs may also cause the induction or inhibition of drug-metabolizing enzymes.

			Dose	C _{max}	T _{max}	Bioavailability	Clearance			
Drug	Species	Route	mg/kg	μ g/ml	hr	Percentage	mL/min/kg	L/kg	F _{unbound} (%)	Half-Life (hr)
Cetirizine ²⁸²	Cat	РО	0.9±0.2	3.3±1.2	3.1±3.3	NA	NA	NA	88±1.5	10.1±4
Hydroxyzine ²⁸¹	Dog	IV	2	1.1±0.1			5.3±3.5	12.6±7		59±58
		РО	2	0.16 ± 0.05	3±1.1				71±39	17.1±7

*Cetirizine formed from hydroxyzine.

Adverse Drug Reactions and Side Effects

Because side effects to first-generation drugs are problematic, alternative drugs were developed. For example, diphenhydramine adversely affects learning in children and alters cognition and mood. Several drugs cause a level of intoxication similar to that produced by alcohol; chlorpheniramine causes a hangover effect. Gastrointestinal side effects include anorexia, nausea and vomiting, constipation, and diarrhea. Other effects, such as a dry respiratory tract and urinary retention or dysuria, can be attributed to atropine-like (anticholinergic), antiadrenergic, and antiserotonin effects. Newer antihistamines (H_1) do not interact with muscarinic receptors as effectively as did the first-generation drugs, thus avoiding many of these side effects. Side effects in the CNS are not unusual at therapeutic doses. However, they are rarely serious, and adaptation occurs with chronic use. Sedation is affected by pH, lipophilicity, and activity of transport proteins such as P-glycoprotein.²⁸³ Lack of sedation in the newer drugs has been attributed to transport proteins that mediate active efflux from the CNS and thus limit CNS distribution. Collies and related breeds deficient in P-glycoprotein might be expected to manifest more CNS reactions with newer drugs compared with other dog breeds.

Two early second-generation H_1 antihistamines, astemizole and terfenadine, were associated with cardiotoxicity (prolongation of the QT interval: torsades de pointes) as a result of blockade of the rapid component of the delayed rectifier potassium current. More recent drugs, including loratadine, desloratadine (a metabolite of loratadine), cetirizine, and fexofenadine (a metabolite of terfenadine), are not associated with this effect.

Acute poisoning is not uncommon in humans; its occurrence in dogs and cats is not known. There is no specific therapy. Signs include ataxia, incoordination, convulsions, dry mouth, and fever, with treatment being supportive.

Therapeutic Use

Indications for antihistamines include the prevention or treatment of anaphylactic shock (IgE-mediated histamine release) or anaphylactoid response (e.g., cationic drug-induced histamine release), motion sickness (see the discussion of the gastrointestinal tract), particularly dimenhydrinate, piperazines, and promethazine, and allergic disease, including that affecting the skin. These indications are addressed in the relevant chapters. Antihistaminergic drugs have proved variably useful in the control of small animal allergic diseases.²⁸⁴⁻²⁸⁶ This no doubt reflects differences in receptors and drug receptor interactions. However, profound differences also are likely in the disposition of the drugs, including oral bioavailability (e.g., clemastine in dogs). Part of the lack of efficacy also reflects limited actions: Although the effects of histamine at H₁ receptors may be blocked, limited to no effects on mast cell degranulation will result in inflammatory response to other mediators.

TREATMENT OF OSTEOARTHRITIS

Physiology and Pathophysiology

Osteoarthritis Defined

Degenerative joint disease, or *osteoarthritis*, is defined as a loss of articular cartilage and chondrocyte death. In its primary form, it is considered a disease of "wear and tear," and inflammation does not play a significant role in the onset of the disease process.²⁸⁷ Although the role of inflammation in the pathogenesis of the disease is also limited compared with that of other joint disorders (i.e., sepsis or immune-mediated diseases), the role of inflammation have become important that drugs modifying inflammation have become important in the management of degenerative joint disease. However, the concept of chondroprotection in the damaged joint has become a focus for therapy, as have agents that modify the disease process.

Degenerative joint disease is a progressive disease characterized by degeneration and destruction of articular cartilage.^{288,289} Certain conditions are predisposed to cause secondary degenerative joint disease, although it can occur as the primary disorder. Secondary degenerative joint disease can develop as a result of abnormal joint mechanics (e.g., instability) or direct trauma.

Cartilage Physiology and Pathophysiology

In order to understand the potential role of disease-modifying agents in the treatment of osteoarthritis, a discussion of normal and diseased cartilage is warranted. Normal cartilage is avascular and tightly adheres to cortical bone.^{290,291} A loadbearing and gliding surface of the joint is formed such that

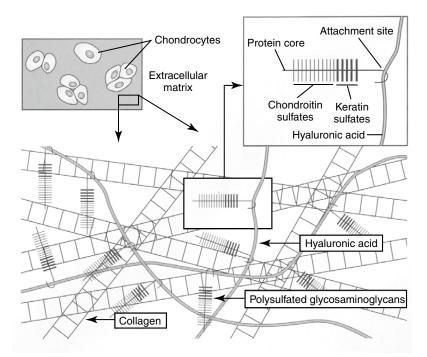

Figure 29-12 Hyaline articular cartilage is characterized by highly metabolic chondrocytes surrounded by an extracellular matrix that they secrete *(inset, top left)*. The matrix is composed of collagen, which provides strength to the joint, and polysulfated glycosaminoglycans (PGAGs). The PGAGs cause retention of water, thus providing a cushion to joint stresses. The PGAGs are composed of a central protein core *(inset, top right)* to which is attached keratin sulfates (base) and chondroitin sulfates. The PGAG attaches to hyaluronic acid.

a frictionless surface occurs throughout the range of motion of the joint. The fibrous capsule of the joint contains a layer of synovial cells that are very vascular and serve as a selective membrane, precluding passage of molecules greater than 12,000 molecular weight. Synovial fluid produced by the cells lubricates and nourishes cartilage. Hyaline cartilage contains a small number of chondrocytes that synthesize the matrix in which they are embedded. The matrix is composed of collagen fibers interspersed in a well-structured manner with proteoglycan aggregates of varying molecular weights (Figures 29-12 and 29-13). Proteoglycans comprise glycosaminoglycans encircling a core protein. The proteoglycan complex in turn is bound (by a link protein) to hyaluronic acid. Chondroitin sulfate is the principal proteoglycan of mature cartilage, with other sulfates (e.g., keratin, dermatan) making up the remainder. Chondroitin sulfates are glycosaminoglycans composed of alternating sulfated residues of a glucuronic acid and a galactosamine. Sources of chondroitin sulfate for commercial purposes include bovine trachea, nasal septum, and shark cartilage. Proteoglycans are large, hydrophilic (containing oxygen, nitrogen, and sulfur) molecules that trap water, thus maintaining the gel-like consistency of cartilage, and act as an elastic shock absorber. Chondrocytes are very metabolically active, constantly breaking down and resynthesizing proteoglycan and collagen. The substrates and energy for these activities are transported to, and waste material from, the cartilage by a synovial "pump" mechanism.

The initial insult leading to cartilage degeneration may vary (i.e., injury, congenital malformation, chronic overload, age), but the sequence of events is similar. The changes occur well before clinical (including radiographic) signs are evident. The initial lesion in osteoarthritis occurs in cartilage. Chondromalacia (softening of the cartilage) occurs early in the course of disease. Collagen turnover is markedly increased by the chondrocytes; reparation may not yield the appropriate (type II) collagen. Ultimately, collagen loss may predominate. Species differences in the repair of collagen are likely to exist. Proteoglycans are also lost as degenerative joint disease progresses. Initially, proteoglycan synthesis is markedly increased, but the normal ratios of high-molecular-weight versus low-molecular-weight proteoglycans may not be maintained. Eventually, proteoglycan synthesis markedly decreases. Hyaluronic acid concentrations also decrease.

The loss of cartilage matrix is mediated, in part, by proteolytic enzymes such as metalloproteinases, including collagenases, stromelysin, and aggrecanases, and lysosomal enzymes released (stimulated by IL-1 or TNF) by synovial cells or chondrocytes.²⁸⁷ IL-1 and IL-6, TNF, and nitric oxide also act as cellular or molecular mediators.^{287,292-295} Mediators (eicosanoids, IL-1, and TNF) act to upregulate catabolic enzymes of destruction while downregulating mediators that inhibit catabolic actions.²⁹³ The catabolic process of cartilage degradation worsens as these enzymes are released. Chondrocyte death may occur early in the process of degenerative joint disease. Synovial cells phagocytize the products of degradation and initiate a (chemical) inflammatory process. Collagen is exposed; fissures develop in the cartilage. Local tissue degradation increases, and leukocytes are activated, eventually leading to a viscous cycle of degradation and inflammation. Synovial fluid amount is increased, which reduces the content of hyaluron.²⁸⁷

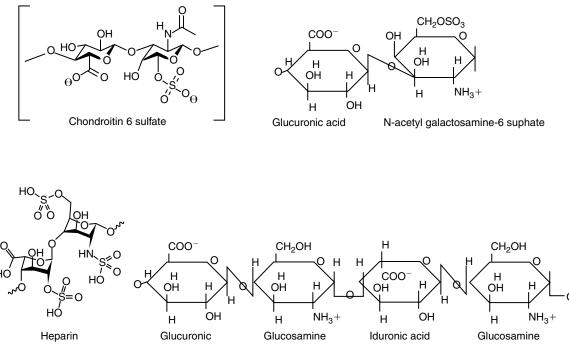

Figure 29-13 Chondroitin sulfates structurally are very similar to heparin and hyaluronic acid (not shown). The negative charges of the repeating units cause retention of water. Inappropriate chemical configuration of the chondroitin sulfates contributes to abnormal stresses on the joint and ultimately continued articular damage.

As cartilage continues to bear weight, mechanical destruction and physiologic changes continue. The damaged cartilage cannot bear weight appropriately, and subchondral bone is exposed to forces that normally would be dampened. Subchondral sclerosis occurs, and apposing articular surfaces become eburnated. Cartilage homeostasis is interrupted, limiting access to fluid-containing nutrients. Fluid released into the synovial joint may not be efficiently absorbed. In addition, mediators of inflammation are released by both chondrocytes and synovial cells. The joint becomes painful as a result. Microfractures and fissures allow synovial fluid to penetrate into the bone, with resulting subchondral cyst formation. The damaged cartilage attempts to repair the damage as it occurs by synthesizing new proteoglycan and collagen. Osteoarthritis probably occurs when the catabolic process overwhelms the repair process.

Therapy with Drugs and Other Agents

The goals of drug therapy for degenerative joint disease should be (1) to control pain, (2) to increase mobility, (3) to prevent continued degradation of the joint, and (4) to provide support to reparative processes. In addition to drug therapy, dietary management (i.e., weight control) and exercise control should be implemented, and surgical options should be considered when appropriate. Mechanisms of therapeutic drugs designed to retard the deterioration of degenerative joint disease include inhibition of synovial cell–derived cytokines and chondrocyte-derived degradative enzymes, inactivation of superoxide radicals, stimulation of matrix synthesis, and enhancement of synovial fluid lubrication.^{296,297}

Advances in the pathophysiology of degenerative joint disease (osteoarthritis) have provided new therapeutic foci.

The progressive degeneration of articular cartilage that characterizes this disease reflects an imbalance between cartilage matrix synthesis and breakdown. The role of inflammation in the pathophysiology of degenerative joint disease is controversial. The impact of NSAID therapy can be a doubleedged sword: The effects may be either harmful or beneficial, depending on the drug. The primary effect of NSAIDs in the disease may be analgesic rather than antiinflammatory.²⁹⁶ A number of other antiinflammatory drugs have been studied for their efficacy in the treatment of degenerative joint disease, and clinical trials addressing their use for treatment of osteoarthritis has been previously discussed with each drug. The dose of NSAID needed to control pain associated with osteoarthritis may vary greatly among animals. Drugs can control pain not associated with inflammation at doses lower than those necessary to control pain associated with inflammation. On the other hand, for some animals pain may be controlled only if inflammation is successfully controlled. The choice of the most appropriate NSAID should be based on both efficacy and safety.

Until relatively recently, little justification existed for the selection of one NSAID over another for treatment of osteoarthritis in dogs. Approval of the newer class of NSAIDs, which are more selective for COX-2 in their inhibition compared with COX-1, has, however, provided a realistic firstchoice drug. Of the conventional NSAIDs, aspirin has been the second drug of choice simply because it is a known entity; phenylbutazone may also be used because it is approved for use in dogs in the US. In countries in which ketoprofen is approved, it may be the second choice. Chondroprotection by the NSAID also should be considered. Differential effects on healthy or damaged cartilage among the newer NSAIDs are likely to exist. For example, etodolac appears to contribute to damage, whereas carprofen appears to facilitate its repair at therapeutic concentrations.²¹¹ Caution is recommended with use of all drugs (or supplements) whose action targets COX, with relative potential toxicity likely being greatest for conventional NSAIDs, less for COX-1-protective (often referred to as COX-2-selective) and least for dual-acting (COX- and lipoxygenase- inhibiting) drugs. Ideally, NSAID use for treatment of osteoarthritis is limited to "rescue" situations in animals with mild to moderate disease, with maintenance therapy focusing on disease-modifying agents (discussed later). NSAIDs might be reserved in such patients for short term treatment of acute conditions (or "flare-ups"). If NSAIDs are required for maintenance therapy, simultaneous use of disease-modifying agents should be considered so that the animal may benefit from any synergistic effect the combination of therapies might have,²⁹⁸ as well as to decrease the amount of time that an NSAID is necessary, to protect the cartilage from any NSAID damage that might occur, and to potentially protect the gastrointestinal tract.⁹¹ Selection of an NSAID for treatment of osteoarthritis in cats is confounded by the lack of data identifying COX-1 protection. Meloxicam and ketoprofen each are characterized by shorter half-lives in the cat (compared with the dog), which may or may not contribute to the relative tolerance the cat has to these drugs compared with other NSAIDs. Further, meloxicam is approved in the U.S. for use in cats. As such, meloxicam might be a first choice for treatment of pain or inflammation associated with osteoarthritis in the cat. However, concerns regarding renal disease indicate the need for pre- and during treatment evaluation of renal function. The FDA has led the manufacturer of meloxicam to state that meloxicam should not be used beyond a single dose in cats, increasing the risk of liability for veterinarians that use the drug off label. Signed informed consent is recommended if meloxicam is used off-lable. Care must be taken that the daily dose does not exceed 0.03 mg/ kg (or 0.1 to 0.15 mg/cat). Time may reveal dual inhibitors to be well tolerated by cats. Although used safely as a platelet inhibitor, the use off aspirin at doses necessary to control pain in cats is likely to be unsafe. Disease-modifying agents also should be used in cats.

The use of glucocorticoids alone for the treatment of osteoarthritis is discouraged. In general, these drugs should not be used for prolonged periods because of their chondrodestructive effects, which are likely to occur at clinically used doses. Rather, use, including intraarticular injections, should focus on short-term management or in patients for which other therapies have failed. The combination of NSAIDs with drugs that control inflammation through mechanisms other than COX inhibition should be strongly considered. These include disease-modifying agents (discussed later). For acute flare ups in animals already receiving the maximum dose of a chosen (safe) NSAID, the use of opioids, tramadol, or NMDA receptor inhibitors (e.g., amantadine) should be considered. Although scientific evidence is needed, gabapentin increasingly is being used based on anecdotal recommendations for control of chronic pain.

DISEASE-MODIFYING AGENTS: CHONDROPROTECTANTS

A number of compounds are able to modify the progression of osteoarthritis, most commonly by supporting the cartilage. These products help achieve the goals of preventing further degradation and providing support for the reparative cartilage.Although variable, evidence exists that supports the use of these products as sole or adjuvant therapy in the treatment of the damaged joint (see the discussion of recommendations regarding the use of disease-modifying agents in the treatment of joint disease). Care should be taken to not overinterpret studies that fail to demonstrate a statistical difference between treatment groups (including placebo); such studies do not demonstrate a lack of treatment effect, but rather, are unable to demonstrate a treatment effect. Commonly, treatment design fails to effectively address the complex nature of the conditions being treated, particularly in terms of sample size.

Injectable Products

Polysulfated Glycosaminoglycans

Efforts to treat osteoarthritis have focused on drugs that favorably shift the balance from degradation to synthesis of cartilage matrix. Two compounds composed of PGAGs are available in the United States and Canada: Adequan and pentosan polysulfate. Hyaluronic acid (e.g., Legend) is also a PGAG but differs in structure sufficiently to be addressed separately. Because of similarities in structure, however, the disposition of these drugs (at least as much as is understood) and their assumed mechanism of action are similar. On the one hand, subtle differences in chemical structure may impact physiologic function (e.g., water retention in cartilage), and thus change efficacy.On the other hand, for products with demonstrated efficacy but presumed different mechanisms of action, combination therapy in the damaged joint. Their use should not be limited to osteoarthritis, but should include any conditions associated with of joint damage-trauma, immune-mediated diseases, septic or drug-induced damage, surgery (including prophylaxis) and others. Further, prophylactic use should be considered in animals predisposed to joint damage (e.g., conformation predisposing to joint damage or intensive sports training). Because PGAGs are responsible for normal functions in a variety of body tissues, their potential applications include disorders other than osteoarthritis (e.g., interstitial cystitis and glomerulonephritis).

Chemistry. A PGAG s a polymeric chain of repeating units of hexosamine and hexuronic acid. Considered a hypersulfated compound, approximately 14% of the drug is sulfated. It is extracted and purified from bovine tracheal tissues.²⁹⁹ Normal cartilage matrix is composed of proteoglycan complexes, collagen, and water. Side chains of glycosaminoglycans (keratin and chondroitin) are attached to the core protein of the proteoglycan molecule by a strand of hyaluronate (see Figures 29-12 and 29-13). Water trapped between these complexes accounts for the resiliency of cartilage. PGAGs closely mimic the proteoglycan complexes found in normal articular cartilage.

Pharmacologic effects. PGAGs appear to be chondroprotective in both in vitro and in vivo models. In vivo models have included chemically and traumatically induced cartilage damage.^{300,301} Cartilage degradation is retarded in the presence of PGAG. Although the mechanisms of these protective actions are not known, chondrocyte proliferation and matrix biosynthesis appear to be important.³⁰¹ Collagen, proteoglycan, and hyaluronic acid syntheses increase.³⁰² In addition, proteolytic enzymes such as collagenase,^{302,303} leukocyte elastase,³⁰⁴ proteases,^{299,305} and lysosomes are inhibited,³⁰⁵ although these actions are likely to be complex.³⁰² Complement activity is also inhibited; the degree of inhibition appears to be related to the sulfate load of the chondroitin sulfate matrix.³⁰⁶ PGAGs appear to have no effect on the ability of IL-1 to stimulate metalloproteinase activity in cartilage.³⁰⁷

Disposition and safety. Deposition of PGAG in normal and damaged cartilage has been demonstrated after parenteral administration. Drug that is not retained in cartilage is excreted primarily by the kidneys with minimal degradation of the parent compound. Toxicity is limited in all species studied. In dogs the LD_{50} is 1000 mg/kg.²⁹⁹ Heparin and PGAG are chemically similar. Adverse effects related to the anticoagulant activity of PGAG have been suggested. One study found coagulation times to be prolonged after administration (see below). This suggests that PGAGs should not be administered at the time surrounding a surgical procedure. Heparin-associated thrombocytopenia, a presumed immunologically mediated decrease in circulating platelet numbers, has been reported in human patients receiving PGAGs.³⁰⁸

At the time of this publication, several injectable PGAG products are being marketed as "generic" Adequan. These products (e.g., Chondroprotec for horses) are not "generic" in that they have undergone no FDA approval process. That such products contain the same ingredients and will provide the same level of response as approved products cannot be assumed without inbiased scientific evaluation. Although a peer review paper disputing the efficacy of such products could not be identified at the time of this publication, a review of the internet reveals testimonial based evidence of the lack of efficacy of these products and the lack of understanding regarding their approval status. Although veterinarians might be legally empowered to prescribe or recommend such products, liability and standard of care concerns should lead to caution regarding their use. Differences in chemistry may be very subtle but may impact efficacy both safety and efficacy. Among the biggest concerns might be the impact of adulteration, as has occurred for heparin, also a PGAG (see Chapter 17). That these products can become unsafe if composed of improper PGAGs has been recently demonstrated.

Clinical use. Adequan has been approved for use in dogs for the treatment of osteoarthritis. The drug might, however, be considered in any situation in which the joint has been or will be injured. This includes trauma, elective surgical procedures, and arthritis associated with immune-mediated or infectious conditions. Additionally, PGAGs should be considered in conjunction with NSAIDs for their chondroprotective effects, as well as with the intent to potentially discontinue

the NSAID. Disease-modifying agents including PGAG or its precursors (see later discussion of nutraceuticals) might also be considered as preventive therapy in animals that are likely to develop osteoarthritis for whatever reason, including conformation problems. Use of these drugs before clinical signs of osteoarthritis develop may prolong the time until NSAIDs are necessary. In patients with osteoarthritis, the time to clinical response is likely to be directly related to the severity of disease. Treatment that is begun before the joint is markedly damaged is more likely to be successful. Adequan may negatively impact hemostasis. Dogs treated at 10 times the recommended dose develop hemotomas and prolonged protime (package insert). Surgical candidates probably should not be treated with Adequan on the day of or prior to surgery unless coagulation studies indicated no effect. Care should be taken to not use Adequan in patients with bleeding disorders (see package insert), which might include patients receiving aspirin. The impact on patients receiving COX-2 preferential drugs is not clear.

KEY POINT 29-23 Injectable polysulfated glycosaminoglycans should be anticipated to act more rapidly than orally administered products.

Pentosan Polysulfate

Pentosan polysulfate (PPS) is isolated from beechwood hemicellulose and synthetically modified by adding sulfates to its repeating units of xylan pyranoses. Thus, unlike Adequan, it is not derived from animal sources. It is available as an injectable product, and an oral product has been approved in the United States for people with interstitial cystitis, a syndrome that may reflect a quantitative and qualitative defect in bladder mucosal glycosaminoglycans.^{309,310} It is approved for use under the market name Cartrophen for treatment of osteoarthritis in dogs in Canada and Europe, where it has been marked for at least 15 years.

PPS has a number of pharmacologic effects. Response of interstitial cystitis (based on resolution of pain in humans) ranges from 6% to 20%. In Europe PPS is used to treat thrombosis and hyperlipidemia, and an application for its use in treatment of osteoarthritis is pending. For cartilage PPS may improve subchondral and synovial membrane blood flow. In addition, it modulates cytokine actions, stimulates hyaluronic acid synthesis, and maintains PGAG content in joints.^{302,311} When PPS was administered intramuscularly (2 mg/kg once weekly) in a model of osteoarthritis in dogs, cartilage damage was significantly decreased. In a double-blind clinical trial in 40 dogs, after 3 mg/kg intramuscularly per week, lameness, body condition, pain on joint manipulation, and willingness to exercise were improved at 4 weeks.³¹² The work of Budsberg and coworkers³¹³ supports the efficacy of PPS in selected surgeries. The investigators prospectively studied the efficacy of PPS in dogs (n = 40; 10 per group) with spontaneous cranial cruciate rupture using a parallel, randomized, blinded, placebo-controlled design. Dogs were divided into four groups on the basis of radiographic score (low versus high) and a

partial meniscectomy was performed. Within each group animals were randomly assigned to receive either placebo or 3 mg/kg PPS weekly for 4 weeks after surgery. Animals were evaluated for 48 weeks, with biomarkers of collagen cleavage, aggrecan activity, and osteocalcin activity measured in serum. Radiographs and gait analysis were included in the postoperative evaluation. A total of 10 response variables were compared among the groups. Although lameness scores did not differ, PPS-treated dogs generally improved faster than placebotreated dogs, and in those dogs with partial meniscectomies, biochemical markers were reduced compared with placebotreated dogs. An oral dose has not been established for dogs.

PPS appears to be safe, but like other PGAG-like compounds, it appears to prolong clotting times and may cause thrombocytopenia. Safety information from the manufacturer available online³¹⁴ indicated an adverse event reporting incident of 0.01% with no signalment predisoposition. Clinical signs considered to be "probably related" to the drug, based on their appearance within 10 to 15 minutes of administration, included vomiting (78% of those reports, or 0.0047% of animals dosed) and a change in demeanor (i.e., quiet, etc; 0.0062% of animals). Experimentally, at 3 mg/kg, PPS increased partial thromboplastin time (PTT) and thrombin time (TT) but not prothrombin time (PT) above baseline in dogs, with the peak effect at 2 hours and resolution by 8 hours. Although hemorrhage has been reported in clinical cases using PPS, few of those reports have been designated as probable cause. Local reactions at the injection site did not occur in experimental studies, even at 30 mg/kg. The posibility that PPS and similar products worsens gastrointestinal hemorrhage induced by NSAIDs has not been addressed; indeed, evidence suggests a protective nature is imparted by related products in the gastrointestinal tract. It should be noted that information provided by the manufacturer of Cartrophen indicates that generic products are not therapeutically equivalent because they differ both chemically and thus in their interation with target proteins. As such, differences in therapeutic response among these products in general might be anticipated.

The use of this product for syndromes other than osteoarthritis in humans (e.g., interstitial cystitis, thrombosis) potentially might lead to similar uses in animals. For example, a study of mouse mesangial cells found that PPS decreased proliferation and net extracellular matrix production, mechanisms that may explain its apparent ability to slow the progression of glomerular sclerosis.^{315,316} PPS inhibits calcium oxalate crystallization in vitro³¹⁷ and is being studied for possible use in vivo. The compound is being studied for its apparently clinically beneficial effects for the treatment of acquired immune deficiency syndrome–related Kaposi's sarcoma in human patients.³¹⁸

Hyaluronic Acid

Hyaluronic acid is a linear polydisaccharide (glucuronic acid combined with glucosamine) that is an essential component of synovial fluid, where it is chemically linked to proteoglycans in articular cartilage. As such, it helps to form large, aggregating proteoglycans in articular cartilage (Figure 16-12).²⁹⁶ Its mode

of action is not certain, but it is assumed to function as a lubricant by increasing viscosity of synovial fluid. It may also act as an antiinflammatory. Studies in horses support its efficacy in the treatment of osteoarthritis. After intraarticular injection, the drug persists in joints for several days. The drug also has been given intravenously; the half-life in horses is 96 hours, but no studies could be found regarding dogs. Hyaluronic acid exists in variable molecular weights. High-molecular-weight hyaluronic acid inhibits phagocytosis, lymphocyte migration, and synovial permeability and stimulates hyaluronic acid synthesis.³¹⁹ Prior treatment with glucocorticosteroids or bony changes limits response. Hyaluronic acid appears to be very safe; side effects tend to be associated with administration of the drug. The drug has been used with variable success after intraarticular injection in horses³²⁰ and dogs.³²¹

The role of viscosupplementation in the treatment of human osteoarthritis has been reviewed.³²² A meta-analysis of 22 studies of hyaluron use in humans found it to have a small effect compared with placebo, but the study also found publication bias.³²² Accordingly, as with glucocorticoids, intraarticular administration of hyaluron tends to be limited in humans to patients who have not responded to other therapies.

Oral Disease-Modifying Agents

Veterinary Nutraceuticals

The use of oral disease-modifying agents (slow-acting diseasemodifying agents)^{323,324} for the treatment of damaged joints remains controversial despite increasing evidence regarding their potential contributions. Currently, with the exception of oral PPS (for which an approved drug version exists), these products can be classified as veterinary nutraceuticals.³²³⁻³²⁷ The North American Veterinary Nutraceutical Council (no longer active) defined a veterinary nutraceutical as "a [nondrug] substance that is produced in a purified or extracted form and administered orally to a patient to provide agents required for normal body structure and function and administered with the intent of improving the health and well-being of animals."^{325,326}

Regulatory considerations. Neither human nor veterinary nutraceuticals, botanicals, herbs or other novel ingredients (including botanicals or biological) undergo any mandated federal approval process, and therefore neither quality, safety nor efficacy necessarily have been documented before they are marketed. Chapter 4 addressed some of the safety issues associated with these products, and particularly those of plant origin. Unfortunately, clients may not realize the lack of regulation of these products, and counseling by veterinarians regarding the implications may be important.

The issues relating to quality, safety, and efficacy of diseasemodifying agents have been reviewed,³²⁷ but the complexity of their nature and the impact the lack of regulation has on products warrant a short review. The FDA historically has held dietary supplements to the same standards applied to foods, requiring evidence of safety as well as evidence that labeling was truthful and not misleading. In 1994 the dietary supplement industry was successful in lobbying Congress to pass the Dietary Supplement Health and Education Act of 1994 such that it addresses these products. The amendment, which legally defines a dietary supplement, effectively restricts the FDA's ability to regulate dietary supplements. Various label claims that refer to effects on structure or function of the body are now allowed on these products. Premarket safety evaluation is no longer required; rather, the manufacturer is responsible for ensuring safety, However, the FDA is responsible for monitoring the safety, despite the lack of a mandated mechanism for adverse event reporting. Rather, all adverse event reporting is voluntary, which may preclude effective safety assessment of products by the FDA. Consequently, the burden of proof that a product is unsafe rests with the FDA. Since DSHEA passage, the FDA has been able to require that manufacturers of hebal products include proper herbal names, and when relevant, the generic drug name for the product (e.g., ma guang for caffeine), and to indicate the part of the plant (e.g, stem, leaf, flower), from which the ingredient is derived.

The Center for Veterinary Medicine (CVM) of the FDA has determined that DSHEA does not apply to animals or animal feeds, including veterinary nutraceuticals. Therefore the term *dietary supplements* does not apply to veterinary products and theoretically should not be used when referring to products marketed for veterinary use. The term animal dietary supplements will nonetheless be used in this document. The CVM believes that public health is better served if the special concessions given to human dietary health supplements by the DSHEA do not apply to those given to foodproducing animals. This reflects their goal of ensuring that harmful residues from either the compound or its metabolite do not reach food intended for human consumption and their concern that extrapolation of information among species receiving novel ingredients is complex and difficult. Most notably, the CVM is concerned that current "production drugs" (i.e., those that increase the production of food) might be considered by manufacturers or users of these products to fall under the lax guidelines of DSHEA, thus increasing the risk of human exposure to unapproved products. Thus, unlike human products, the FDA-CVM has retained its ability to regulate animal dietary supplements, although the lack of resources necessary to adequately regulate their sale will limit regulation. However, in contrast to dietary supplements, states can and do restrict the sale of products for animals through an alternative mechanism. Federal and state feed officials have organized the American Association of Feed Control Officials (AAFCO),³²⁸ whose stated goal is to 'provide a mechanism for developing and implementing uniform and equitable laws, regulation, standards, and enforcement policies for regulating the manufacture, distribution, and sale of animal feeds" such that the use of these products is "safe, effective and useful." Although nonregulatory, the AAFCO nonetheless influences state regulation and thus the marketing of oral products administered to animals in many (although not all) states. For those states that follow the AAFCO's guidelines, a manufacturer seeking the sale of an unapproved oral product in a state must provide information

necessary for the product to be recognized as an "ingredient" that has been "defined" by the AAFCO. Sale of a product that is not a drug, food, or feed additive is more likely to be denied by a state feed official if the product is not listed as a defined ingredient in the AAFCO publication.

The dramatic increase in veterinary nutraceutical use in the last 15 years led the AAFCO to focus more aggressively on the regulation of these products. The National Animal Supplement Council (NASC),³²⁹ based in the United States, has taken an active approach in working with the AAFCO to implement voluntary actions among nutraceutical manufacturers that will cause the AAFCO to respond to their products positively, thus allowing their sale. Veterinarians should be reminded that because DSHEA specifically applies only to human beings and neither dietary supplements (humans) nor novel ingredients (other animals) are not approved drugs, the use or prescription of these products is *not* protected by the Animal Medical Drug Use Clarification Act of 1994, which otherwise legalizes veterinary extralabel drug use.

Quality assurance. Several sources of scientific information indicate the need to focus on those products whose quality assurance can be verified. Chondroitin sulfate products (CDS) offer an example of consistent mislabeling. A University of Maryland study, funded in part by Nutramax Laboratories, found deviations from label claims for CDS in 84% (9 of 11) of the products studied; the amount by which products were mislabeled ranged from 0% to 115%.329a Further, the study found that products costing less than or equal to \$1 per 1200 mg of CDS were seriously deficient (less than 10% of the label claim), which suggests that cheaper products should be avoided. Costliness did not guarantee accuracy, however. Several of the most expensive products also were found in this study to be mislabeled. In contrast to CDS, the glucosamine of only 1 of 14 products was mislabeled in this study. However, another study found glucosamine sulfate to vary 60% to 140% of the label claim.^{329b} ConsumerLab³³⁰ (www.Consumerlabs.com) is a for-profit laboratory (with income based largely on subscription to their site) that offers a seal of "validation" for dietary supplements that are appropriately labeled. The efforts of the laboratory are two fold in origin: dependent, based on requests from a sponsoring manufacturer or independent, that is, an unsponsored investigation. In either case, the products to be tested are obtained from commercial sites (grocery or health food stores) rather than from the manufacturer, thus avoiding manufacturerinduced bias through product selection. The samples are subjected to ingredient analysis by independent laboratories. The "pass" criteria vary for each ingredient but are based on comparing content as determined from ingredient analysis to the labeled ingredients. Criteria include labeling of ingredients by proper name (for herbs, this includes the part of the plant and herbal names); a misatch between the listed and measured ingredients; and lack of contaminants, including toxicants (heavy metals, cleaning agents, and [particularly for herbs] pesticides or insecticides), metabolites, and other degradative products of the active ingredient. Products that pass analysis are allowed to place the ConsumerLab seal on

the product label. Members of the public can read selected information on the ConsumerLab website for a fee (\$23 annual fee at the time of this printing) for ingredients that have been tested. Criteria for passing and failing and reasons for failure for specific ingredients can be viewed, as can a list of proprietary products that have passed. Animal products have just recently been included in the review. A review of the website reveals that an important proportion of both human and animal products fail quality assessment; in general, animal products have fared more poorly than products marketed to humans. Among the passing products are those manufactured by Nutramax Laboratories, although a number of other human products also have passed. The USP¹²⁷ has also recently implemented the Dietary Supplement Verification Program (DSVP), a voluntary standards assessment program for human dietary supplements; veterinary products have not yet been included in their review. Although its activities are nonregulatory, the USP criteria are recognized in the Food, Drug and Cosmetic Act and its amendments, including the DSHEA. The NASC Compliance Plus program offers a potential mechanism for ensuring the accuracy in labeling of veterinary products; however, it is not clear if their program is is based on independent product analysis or if their criteria include the the use of ingredients that meet USP standards.

KEY POINT 29-24 Because they undergo no premarket approval process, dietary supplements for animals or humans often lack in quality.

Assessing Quality. Veterinarians and consumers should fully evaluate a product under consideration.³²⁷ First, the user should establish whether the product has been manufactured according to good manufacturing practices. The label should include the exact amount of each active ingredient; labels that combine metric and apothecary systems may be intentionally misleading because conclusions regarding product content are more difficult to determine. Each product listed on the label should contain a specific dosage. The source of each compound should be noted on the label. Note that products based on whole body tissues (e.g., mussel-containing glycosaminoglycans) will lack milligram contents of specific compounds (e.g., chondroitin sulfate). When individual products are listed, the purity of the compounds is likely to vary among and within products. The stated purity may not be the actual purity, particularly if good manufacturing procedures are not followed. Anderson³²⁴ noted that 70% of products analyzed for glucosamine and chondroitin sulfate did not meet the labeled claims.

Safety and Efficacy Considerations. The lack of efficacy data should not lead to the assumption that the benefits of these products are negligible. Establishing efficacy for many novel ingredients, including disease-modifying agents targeting cartilage, may be very difficult because of the complex nature of their actions and the dependence of their actions on other endogenous molecules.³²⁶ For example, the disease-modifying agents accumulate in tissues and have a carryover effect that requires a minimum of 6 to 8 weeks of therapy, necessitating

long studies.³³¹ A placebo effect of more than 40% mandates the need for controls. Studies that do not demonstrate a significant difference between treatment groups should not be considered evidence of "no effect" unless the power of the study to demonstrate an effect is sufficient. Establishing safety may be easier simply because many adverse events are dose and duration dependent. It should be noted, however, that with poorly manufactured products, harm may occur not only because of the compounds themselves but also because of possible contaminants. Additional harm may occur if the client neglects traditional therapies in the belief that the nutraceutical agent will be sufficiently effective.

Nutraceutical Disease-Modifying Agents

Nutraceutical products that contain various forms of glycosaminoglycans or their component parts (aggregates form proteoglycans, the major constituent of cartilage matrix), such as glucosamines or chondroitin sulfates, appear most promising for treatment of osteoarthritis according to studies supporting their efficacy³³²⁻³⁴⁰ and safety.³⁴¹ Presumably, as precursor nutrients, chondroitin sulfates, glucosamines, and other ingredients that comprise these will be extracted from the serum by chondrocytes and used to synthesize proteoglycans. During periods in which cartilage degradation exceeds cartilage formation, the need for precursor molecules may exceed availability, inhibiting the repair process. The availability of orally administered compounds not only increases the efficiency of the ability of the chondrocytes to repair damaged cartilage, as is demonstrated by increased synthesis, but also leaves less opportunity for formation of inappropriate molecules. The role of glucosamine and chondroitin sulfate, the major component of oral disease-modifying agents, in veterinary medicine has recently been reviewed.^{342, 342a}

Glucosamine

Glucosamine is an amino sugar that is among the aminosugars necessary for synthesis of mucopolysaccharides such as chondroitin, heparin and hyaluronic acid. As such, it is important in chondrocyte synthesis of PGAG. A deficiency of the compound has been implicated as a cause of decreased PGAG synthesis in early osteoarthritis. Alternatively, glucosamine also may stimulate synovial production of hyaluronic acid.³³⁹

Glucosamine is not available in foods. It is derived from either bovine cartilage or chitin, the hard outer shells of shrimp, lobsters, and crabs. Several glucosamine salts are available, including sulfate, hydrochloride, N-acetyl, and hydroiodide; although it is glucosamine that is active, the oral absorption of the salts varies.

After intravenous injection of radiolabeled (at a carbon atom) glucosamine sulfate, about 10% appears in plasma, with the rest rapidly disappearing from plasma as it is incorporated into plasma globulins. After oral administration, at least 88% of the compound is absorbed, with oral bioavailability being only 44%, due to first-pass extraction. Radioactivity remains in the body, with a half-time of approximately 95 hours. Radioactivity rapidly appears in multiple tissues, including articular cartilage. After intravenous administration, 49% of the dose is excreted in the lungs as radiolabled CO₂, presumably after hepatic or other peripheral tissue metabolism. However, another 29% is excreted in the urine.³⁴⁴ A metaanalysis of studies on glucosamine in humans concluded that the compound is well absorbed after oral administration; firstpass metabolism due to incorporation into proteins reduced oral bioavailability to 26%.340,343 Glucosamine sulfate kinetics have been studied in dogs as well and appear to resemble that in humans.^{344,345} After oral administration, absorption was rapid and nearly complete in dogs (87%). Glucosamine hydrochloride also is well absorbed in dogs, with peak concentrations occurring in 1.5 to 2 hours; bioavailability after a single dose is 12% although bioavailability is likely to increase, as it does with chondroitin sulfates, after multiple dosing.³³¹ Glucosamine hydrochloride exhibits a dose-dependent effect on plasma glucosamine concentrations, although, unlike chondroitin sulfates, glucosamine does not appear to accumulate in dogs with multiple dosing.³³¹

KEY POINT 29-25 If only a single disease-modifying agent is chosen, glucosamine is a reasonable first choice because it is the rate-limiting step in polysulfated glycosaminoglycans synthesis; its oral absorption and safety have been demonstrated; and among the supplements, it tends to be one that is labeled appropriately.

The safety and efficacy of glucosamine have been well reviewed in human medicine.^{287, 342a, 343} Glucosamine appears to be safe; an LD₅₀ value cannot be established in mice or rats, even at doses of 5000 mg/kg orally or 3000 mg/kg intramuscularly, or 1500 mg/kg IV. Safety has been established both in the dog and cat after medium to high doses for 30 days.^{341,346} Oral doses ranging from 160 to 2000 mg/kg for up to 180 days were associated with no adverse effects in dogs.³⁴³ Safety in animals with comorbidity may be a concern. The impact of glucosamine on glucose metabolism, particularly through the hexosamine pathway,³⁴³ has led to concern regarding diabetic control. However, glucosamine metabolism follows a different path than radiolabeled glucose,³⁴⁴ and glucosamine does not appear to interact with glucose disposition.³⁴⁷ Diabetes could not be induced in rats genetically predisposed to sugarinduced diabetes mellitus after treatment with glucosamine, chondroitin sulfate, or the combination of the two at 3 to 7 times the recommended dose.³⁴⁸ In a separate series of studies in humans, glucose concentrations did not change and histologic lesions could not be identified as a result of glucosamine administration.³⁴³ Using a placebo-controlled, doubleblinded, randomized clinical trial, human patients requiring medical management of type 2 diabetes mellitus and receiving Cosequin (1200 mg CDS, 1500 mg glucosamine) for 90 days were monitored in an outpatient clinic. Diabetic control did not change in either group during the study period, and concentrations of glycosylated hemoglobin did not differ between treatment or placebo groups.³⁴⁹ With rare to no exceptions, reviews of clinical trials in humans reveal that the

use of glucosamine is not associated with adverse effects in humans.³⁴³ Indeed, some trials find fewer adverse effects associated with glucosamine than with placebo.³⁴³

The use of glucosamine for treatment of osteoarthritis remains controversial despite in vitro and in vivo studies supporting its efficacy in improving lameness scores and mobility in human and animal models of degenerative joint disease. Some of the controversy probably reflects poor design of selected clinical trials.³⁴⁰ However, several meta-anlayses and reviews of clinical trials generally find glucosamine (hydrochloride or sulfate) moderately effective for treatment of osteoarthritis in humans.^{342a, 343} A prospective study found glucosamine to be highly cost effective in the treatment of human osteoarthritis.^{343a}

All glucosamine salts appear to be equally effective,³³⁶ although one in vitro study suggests that the N-acetyl salt may be less efficacious, perhaps owing to less absorption. This is in contrast to galactosamine salts (also found in PGAGs) and glucuronide salts, which do not appear to be effective in damaged joints.³³⁶ Dosing differences should be expected among the glucosamine products. The differences reflect, in part, the different salts, with the molecular weight of the salts being hydrochloride (36.5), N-acetyl (58), and sulfate (96). This compares to a molecular weight of 192 for glucosamine. Thus approximately 16% of the molecular weight of glucosamine hydrochloride is represented by the (hydrochloride) salt, compared with 24% of the N-acetyl salt and 33% of the sulfate salt. Consequently, on the basis of weight alone (of the total salt), the dose of glucosamine sulfate should be 15% higher. An additional adjustment must be made for differences in bioavailability. Some glucosamine salts, including sulfate, are accompanied by sodium or potassium, whose molecular weight also may be included with the active moiety. Sulfate has been proposed as the active moiety responsible for efficacy of glucosamine sulfate insofar as it is required for glycosaminoglycan synthesis. Because sulfate, but not glucosamine, increases in plasma and sulfate concentrations appear in the joint, some investigators believe that it is the sulfate moiety of glucosamine sulfate that is responsible for its effects.³⁵⁰ Therefore the sulfate salt might be the preferred form, but clinical trials comparing the salts are warranted. An injectable glucosamine preparation is available, and the acetyl salt is available as an enema preparation.

A number of studies support the use of glucosamine for treatment of osteoarthritis. In 2001 Reginster and coworkers³⁵¹ reported on the success of glucosamine sulfate in the treatment of knee osteoarthritis in humans in a non-manufacturer-sponsored study. The placebo-controlled, blinded study encompassed 3 years, a sample size that exceeded 200, and included outcome measures that were less subjective to bias (radiographic measurements) compared with clinical assessment. The investigators have since published additional studies³⁵² in different sample populations, with similar success. Glucosamine has been compared to NSAIDs as well. A meta-analysis³⁵³ comparing ibuprofen and glucosamine for treatment of osteoarthritis pain found glucosamine to be a reasonable alternative to or adjuvant with ibuprofen or other NSAIDs.

Chondroitin Sulfate

Chondroitin sulfates are glycosaminoglycans (repeating units of galactosamine sulfate and glucuronic acid) that can be found in many tissues (see Figure 29-13). In cartilage matrix they bind to and support collagen. Differences in molecular weight result in variable oral bioavailability with lower weight molecules being more bioavailable. Chondroitin 4-sulfate is mammalian in origin, and it is the most abundant chondroitin in growing mammalian cartilage. Chondroitin sulfate generally is derived from bovine trachea. Processing is costly and variable, with differences in fractionation, particle size, molecular weight, location, purity (presence of other PGAGs, such as keratan or dermatan sulfate), and degree of sulfation evident among products. As such, products containing CDS are more likely to be mislabeled with regard to CDS content compared with glucosamine, which is less expensive to manufacture.

With age, chondrocyte secretion of chondroitin 4-sulfate may decline, contributing to the initiation of degenerative joint disease. Chondroitin 6-sulfate is derived from shark cartilage and conceptually may be less ideal than chondroitin 4-sulfate. Chondroitin sulfates appear not only to increase synthesis of PGAGs but also to competitively inhibit the actions of metalloproteases in cartilage matrix. They have a variety of other in vitro and in vivo effects on cartilage. In humans (dosed at 1 to 1.5 g/day) they decrease the need for NSAIDs.

Despite its large molecular size, 70% of CDS is absorbed in various sizes ranging from intact chains to monomer subunits after oral administration. In humans more than 70% of radio-activity was absorbed and distributed to urine and tissues after oral administration of radiolabled low molecular weight (14,000) CDS.^{347,354} The presence of intestinal chondroitinases in carnivorous and omnivorous animals has been postulated as the reason for absorption.³³⁶ In contrast to glucosamine, chondrotin sulfate accumulates after multiple dosing (for 7 days); bioavailability of 200% was reported, indicating that a carryover or residual effect might be expected after dosing is discontinued.³³¹

In dogs oral chondroitin increases serum glycosaminoglycans. Because of its ubiquitous location in the body, indications other than joint disease should be considered for chondroitin sulfates, including cardiovascular diseases associated with thrombogenesis and indications previously noted for PPS. Attention should be paid to the source of chondroitin sulfates in nutraceuticals. Syndromes such as interveterbral disc disease (discs are comparised of CDS), tracheal collapse (a hylaline cartilage related problem), and chronic urinary (cystitis) infection may be rationale indications. Purified preparations are expensive, but the amount of chondroitin in whole animal tissues (mussel, shark cartilage, sea cucumber, or sea algae) cannot be determined from the label. Bioavailability of the chondroitin sulfates in such products is not known.

Efficacy of Glucosamine–Chondrotin Sulfate Combination

Glucosamine by itself might be expected to be the most effective of the oral nutraceuticals for the following reasons: (1) It is the rate-limiting step in PGAG synthesis; (2) it is generally labeled more accurately than chondroitin sulfate; and (3) clinical trials have demonstrated a clinical effect using glucosamine alone. However, the combination product might offer some advantages. A number of studies support the efficacy of the combination of chondroitin sulfate and glucosamine.355,356 Many are sponsored by the manufactuer, most commonly Nutramax Laboratories. This should not be surprising insofar as this company holds the patent for their glucosamine-chondrotin sulfate product (Cosamin for humans and Cosequin for animals) and strives to ensure product quality and safety. In a single-center study sponsored by the manufacturer, humans with mild to moderate radiographic damage in the knee improved more when receiving Cosamine compared with placebo after 6 months of therapy.357 Some evidence supports the possible efficacy of combination products in lowerback degenerative diseases. Leffler and coworkers³⁵⁸ reported improvement in Navy personnel (n = 34) afflicted with knee or lower-back cartilage degeneration osteoarthritis after 16 weeks of Cosamin therapy compared with control. A European meta-analysis of studies found a large treatment effect in persons receiving chondroitin sulfate (of similar molecular weight to the Nutramax products Cosamin or Cosequin) and a moderate treatment effect for glucoasmine.359 Fajardo and Di Cesare³⁶⁰ reviewed meta-analyses examining the effect of glucosamine and chondroitin on treatment of human osteoarthritis. In general, the studies revealed that glucosamine provides significant effects on most outcome measures, including structural efficacy (based on radiography of joint spaces), whereas effects of chondroitin tend to be significant for symptomatic outcome measures.

Clegg and coworkers³⁶¹ reported the results of a large multicenter double-blinded clinical trial that compared placebo (negative control), celecoxib (positive control), glucosamine (1500 mg), chondroitin sulfate (1200 mg), and the combination of glucosamine and chondroitin sulfate in humans (n = 1583), with osteoarthritis graded as mild (n = 1229) and moderate and severe (n = 354). The primary outcome measure was a 20% decrease in knee pain by week 24 of treatment. The only treatment that significantly reduced pain compared with placebo was celecoxib; however, the placebo effect was 60%, underscoring the importance of negative control groups. More important, the group receiving the combination therapy tended to respond better than the placebo group (p = 0.09). Further, within the subgroup of patients with moderate to severe pain, the combination product, but no other treatment, was significantly more effective than placebo.

Efficacy also has been demonstrated in dogs using a variety of models, including in vitro studies and experimental and spontaneous disease. Most of these studies also have been manufacturer sponsored. With use of in vitro methods, biosynthetic activity was greater in canine cartilage cores incubated in serum collected from dogs receiving Cosequin for 1 month compared to incubation in serum collected from the same dogs before Cosequin administration.³⁶² Under experimental conditions, in surgically induced instability in rabbits, the combination product was found to be superior to placebo, glucosamine hydrochloride, chondroitin sulfate, or manganese

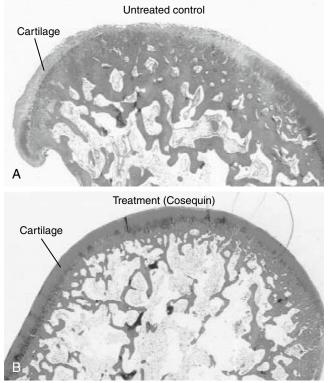

Figure 29-14 Histologic evidence of the clinical efficacy of disease-modifying agents. A surgically induced instability model of osteoarthritis was induced in rabbits. Treated rabbits received 0.38 g glucosamine hydrogen chloride and 0.304 g sodium chondroitin sulfate (Cosequin, Nutramax Laboratories, Inc., Edgewood, Md.) per kilogram body weight per day. Histologic samples were collected at 16 weeks from the center of the medial condyle. Differences in lesions between the groups were significant (p < 0.02). (Photographs courtesy Nutramax Laboratories.)

alone (Figure 29-14). The results of this study led investigators to suggest that the combination product Cosequin was more effective (and perhaps acted synergistically) than individual ingredients. However, the dose that animals received was higher than that recommended. Using an experimental model in dogs, Canapp and coworkers³⁶³ demonstrated a protective effect of Cosequin in dogs when administered 21 days before induction of chemical synovitis. These studies do not reflect a comprehensive review of the literature but nonetheless provide evidence of efficacy.

Other Oral Supplements

Nutritional products for treatment of osteoarthritis were scientifically reviewed in human medicine.³⁶⁴ These studies were randomized (human or animal) clinical trials that focused on osteoarthritis, published in peer-reviewed journals, and based on nonsynthesized (i.e., natural) orally administered products. Because it is considered synthetic, SAMe was excluded (it is not stable in its endogenous form), whereas chondroitin sulfates and glucosamine were excluded because they were already well reviewed. Surprisingly, only of 52 of 2026 potential studies met all criteria. Each was then scored on a scale of -2 (evidence of no efficacy) to 2 (very good evidence of efficacy). Funding sponsorship for the trial as a possible source of bias was not addressed. No positive effects were found in 11 of 52 trials. An example of some of the major nutrients that emerged from the review and their respective scores are as follows: avocado soybean unsaponifiables ([ASU] score 1.58); methylsulfonylmethane (MSM) (1.21), vitamins B₃ or C (0.75); lipids from green-lipped mussels (0.58); boron (a nonmetallic trivalent chemical whose concentration is less in femoral osteoarthritis than in normal osteoarthritis; score of 0.50); cetyl myristoleate (a lipid of sperm whale and beaver gland origin; score of 0.58); ginger [0.42], vitamin E (0.17); hyperimmune milk (-0.9); and collagen hydrosylate (-0.17).

Avocado Soybean Unsaponifiable Lipids

The term ASU lipids refers to the residue left behind after the lipids associated with avocados and soybeans are saponified (ie "soapafied"). Saponification occurs through the addition of an alkali. For ASU the primary ingrediants associated with the beneficial effects are phytosterols. They appear to inhibit cholesterol absorption and endogenous cholesterol biosynthesis.³⁶⁵ Among those present in ASU are beta-sitoseterol, which is particularly potent as an antiinflammatory. Among the anabolic, anticatabolic, and antiinflammatory effects cited for ASU are increased collagen and aggrecan synthesis, decreased collagenase, aggrecanase and matrix metalloproteinase activity, and decreased production of IL-6 and IL-8 and PGE₂ activity. ASU increases transforming growth factor in normal canine synovial fluid. The most common avocado to soybean ratio studied was 1:2; it was the most effective, followed by products with a ratio of 1:1; products with a ratio of 2:1 were less effective. In general, ASU appears to improve symptoms of osteoarthritis after several months and may slow down joint space loss. However, further studies are needed to confirm structure-modifying effects and long-term effects.

KEY POINT 29-26 A variety of nutraceutical ingredients target inflammation. The ideal supplement or supplement combination, however, should always include orally bioavailable glucosamine and chondroitin sulfates.

S-Adenosylmethionine

S-Adenosylmethionine (also addressed in Chapter 19) also is a nutraceutical product, but its mechanism for treatment of osteoarthritis is less clear and probably reflects antiinflammatory effects. It is synthesized in the body from methionine and is responsible for a number of biological reactions, serving as a methyl donor. In the joint it may act to transulfate glycosaminoglycans. Its precursor (methionine) cannot be administered during states of deficiency without toxicity. The product must be prepared as a salt because it is unstable; it is extremely hygroscopic, and the tablet cannot be broken without loss of efficacy. In human clinical trials (controlled and uncontrolled), SAMe has improved lameness scores and mobility. In vitro studies suggest that SAMe increases proteoglycan synthesis and protects the cartilage.³²³ This is being studied in dogs. The human dose is 600 mg daily for the first 2 weeks, followed by 400 mg daily. Clinical response may not be evident for 1 or 2 months.

The efficacy of SAMe for treatment of osteoarthritis in humans compared with placebo or an NSAID was studied through meta-analysis.³⁶⁶ Eleven studies (controlled clinical trials) met the critiera of the study. The authors concluded that SAMe was as effective as NSAIDS in reducing pain and improving function, without the adverse effects traditionally associated with NSAIDs. Limitations of the studies included higher than recommended doses for some studies; a short intervention for most studies (28 to 30 days), which may have underestimated NSAID efficacy; and, in general, study of only osteoarthritis of the knee or hip, which limited extrapolation of data to osteoarthritis of other joints. The mechanisms and other aspects of SAMe are addressed in greater depth in Chapter 19.

Phycocyanin

Phycocyanin (PC) is a phycobiliprotein chromoprotein that is a major pigment of the microalgae Spirulina. Among its function in algae is to harvest light, which also serves to protect the organism from undue damage associated with oxygen radical formation produced by exposure to ultraviolet light. Like many other light-harvesting pigments, it is an effective antioxidant compound. Structurally, it is similar to bilirubin, which also has antioxidant activities.367 Romay and coworkers³⁶⁷ reviewed the evidence supporting PC as a selective COX-2 inhibitor. First, antioxidant properties in general have been demonstrated in vitro, including scavenging of hydroxyl, alkoyl, peroxyl, and peroxynitrite radicals. Lipid peroxidation has been demonstrated, also in vitro. Neutrophil activation is decreased. Antiinflammatory effects have been demonstrated using inflammatory rodent models in a dose-dependent model. Because the models are also used to demonstrate inhibition of COX or lipoxygenase activities, the antiinflammatory effects of PC were considered to potentially reflect inhibition of AA metabolism, as well as prevention of lipid peroxidation. Separating out the direct inhibition f COX or lipoxygenase from inhibition of fatty acid (i.e., AA) release from cell membranes is difficult. Studies in human whole blood have supported COX-2 inhibition, although selectivity was not demonstrated. However, a subsequent in vitro study using cloned human COX-1 and COX-2 does demonstrate selectivity.367 The appropriateness of using COX-1 to COX-2 ratios as indicators of efficacy or safety has already been discussed. By virtue of its antioxidant effects, largely through animal models, PC has demonstrated potential efficacy as a hepatoprotectant and a treatment for arthritis and inflammatory bowel disease. Because efficacy has been demonstrated after oral absorption, it is possible that it is not active as the intact compound. Although its combined use as an antiinflammatory with disease-modifying agents containing glucosamine and chondroitin sulfates is reasonable, issues associated with dietary supplments in general should be addressed, including species differences, safety, and quality assurance of the product. This is particularly true if PC is an inhibitor of COX; its safety should be confirmed in target species, particularly when combined with NSAIDs.

OTHER ANTIINFLAMMATORY DRUGS

Orgotein

Orgotein, or superoxide dismutase, is a copper- and zinccontaining metolloprotein that can be an effective antiinflammatory. As an endogenous intracellular enzyme, it occurs at very low concentrations in many tissues, but particularly the liver, where it scavenges tissue-damaging oxygen radicals. Phagocytic cells (neutrophils and macrophages) generate large amounts of cytotoxic superoxides during the inflammatory process. Among the radicals apparently scavenged by orgotein is peroxynitrite, a long-lasting radical that can contribute to chondrocyte death.³²³ The half-life of phagocytic cells is prolonged in the presence of superoxide dismutase.^{369,370} Approximately 2 to 6 weeks of therapy may be required before therapeutic benefits are realized.

Orgotein is characterized by a wide margin of safety, with the lethal dose being over 40,000 times the therapeutic dose. As a large molecule, efficacy by any route other than intraarticular is questionable owing to poor absorption. The drug has, however, also been administered clinically both intramuscularly and orally.³⁷¹ Absorption of the oral preparation has not been documented. Molecular size limits renal elimination of the drug. After intraarticular administration, orgotein was 94% effective in horses lame for less than 2 months, compared with only 49% efficacy in horses lame for longer than 2 months before treatment.³⁷² The use of orgotein in combination with disease-modifying agents is a rational approach for control of inflammation; however, other antiinflammatories may be necessary for effective control of inflammation.

Dimethylsulfoxide

Dimethylsulfoxide (DMSO) is a hygroscopic solvent derived from wood pulp. It is used as a drug vehicle because of its ability to dissolve drugs that are not soluble in water.^{373,374}

Pharmacologic Effects

As an antiinflammatory, DMSO is a scavenger of free oxygen radicals. Antiinflammatory effects have been reported in acute musculoskeletal injuries and CNS inflammatory processes and after trauma.^{375,376} Chronic diseases are less responsive to the antiinflammatory effects of DMSO. Immunomodulation may be responsible for some of the antiinflammatory effects of DMSO. The drug inhibits white blood cell migration and antibody production. Fibroblast proliferation is also inhibited. The analgesic effects of DMSO have been compared with those of narcotic analgesics. Analgesia has been reported in a variety of situations, including acute and chronic musculoskeletal disorders and postoperative pain. Although nerve blockade has been reported in vitro, it is unlikely that concentrations occur in vivo sufficient to affect this response. Opiate receptors also do not seem to be involved. Other pharmacologic effects include inhibition or stimulation of enzymes, vasodilation (due to either histamine release or anticholinesterase effects), inhibition of platelet aggregation, radioprotection, cryopreservation, and antimicrobial (antifungal, bacterial, and viral) activity.373,375 Diuresis occurs after topical, oral, or parenteral administration, probably because of its hygroscopic nature and ability to pull water into the tubules. DMSO (3 mg/kg in 20% solution) has been reported to protect the kidneys against ischemic insults. A sedative effect has also been reported in several species.³⁷³

Disposition

After oral administration of 1 g/kg, peak plasma drug concentrations occur within 4 to 6 hours, and detectable levels persist in the plasma for 400 hours.375 Within 20 minutes of topical application, DMSO penetrates the skin and can be detected in all organs of the body.³⁷³ Peak plasma drug concentrations occur 2 hours after topical administration.375 Its ability to penetrate the skin is believed to reflect exchange and interchange with water in biologic membranes. Mucous membranes, lipid membranes of cells and organelles, and the blood-brain barrier are similarly penetrated without irreversible membrane damage.³⁷³ Tooth enamel and keratin appear to be the only tissues that DMSO does not penetrate.375 DMSO facilitates penetration of other substances across membranes; cutaneous penetration of steroids, sulfadiazine, phenylbutazone, and other drugs has been documented.^{373,374} Enhanced absorption of therapeutic drugs can lead to toxicity, particularly for anesthetic, cardioactive, and anticholinesterase drugs.

DMSO is partially metabolized by hepatic microsomal enzymes,³⁷³ but the primary route of elimination appears to be in the urine as the parent compound.³⁷⁵ Although a significant amount of DMSO may be eliminated in the bile, most undergoes enterohepatic circulation.³⁷⁵ Hepatic metabolism of a small amount of DMSO (3% to 6%) to dimethylsulfide and subsequent pulmonary excretion of this metabolite accounts for the halitosis that occurs regardless of the route of administration.³⁷⁵

Adverse Effects

DMSO is characterized by a large safety margin. Signs associated with near lethal intravenous doses include sedation, diuresis, intravascular hemolysis, and hematuria. Death is preceded by hypotension; prostration; convulsions; and respiratory distress characterized by dyspnea, tachypnea, and pulmonary edema. Phlebitis and venous obstruction may occur with intravenous dosing. Intravascular hemolysis is concentration and rate dependent, and concentrations less than 10% are recommended for intravenous administration. Susceptibility to hemolysis will vary with species on account of differences in erythrocyte fragility. Nephrotoxicity has been reported in some species. Necropsy lesions include hematuria, hemoglobinuria, and mild tubular nephrosis. Chronic toxicity studies in laboratory animals have documented hepatotoxicity, which may be due to its metabolism by the liver to toxic metabolites. DMSO may also enhance hepatotoxicity of other drugs, as well as hepatic binding and metabolism of selected carcinogens.

Teratogenicity has also been reported in some animals. Ocular toxicity occurs with daily, long-term administration and develops more rapidly in young animals. Lesions occur in the lens and appear as altered lucency, making animals myopic. Histologic abnormalities are not apparent. Such a response was reported in one horse that received 0.6 g/kg daily cutaneously for 2 months. Skin reactions are common, particularly at higher concentrations, and are manifested as erythema, warmth, and local vasodilation. A wheal and flare response and pruritus may also occur. Repeated application may result in drying and desquamation of the epithelium.³⁷³

Clinical Use
