Contents

List of Contributors, vii
Preface, x

Part 1: Basic Physiology

1 Reproductive Physiology of the Female, 2
Bob Robinson and David E. Noakes

2 Reproductive Physiology of Male Animals, 35
Timothy J. Parkinson

3 Puberty and Seasonality, 54
Richard Lea and Gary C. W. England

4 Fertilisation and Development of the Conceptus, 63
Marcel Taverne

5 Pregnancy and Its Diagnosis, 78
Marcel Taverne and David E. Noakes

6 Parturition and the Care of Parturient Animals and the Newborn, 115
Marcel Taverne and David E. Noakes

7 Physiology of the Puerperium, 148
David E. Noakes

8 Pharmacological Agents in the Control of Reproduction, 157
Richard Laven

Part 2: Gestation and Pathology of Gestation

9 Abnormalities of Development and Pregnancy, 168
Peter Windsor

10 Prolapse of the Cervix and Vagina, 195
David E. Noakes

Part 3: Obstetrics and Surgery of the Reproductive System

11 Approach to an Obstetrical Case, 203
Timothy J. Parkinson, Jos J. Vermunt and David E. Noakes

12 Prevalence, Causes and Consequences of Dystocia, 214
Timothy J. Parkinson, Jos J. Vermunt and David E. Noakes

13 Maternal Dystocia: Causes and Treatment, 236
Timothy J. Parkinson, Jos J. Vermunt and David E. Noakes

14 Fetal Dystocia in Livestock: Delivery *per vaginam*, 250
Timothy J. Parkinson, Jos J. Vermunt and David E. Noakes

15 Defects of Presentation, Position and Posture in Livestock: Delivery by Fetotomy, 277
Jos J. Vermunt and Timothy J. Parkinson

16 Defects of Presentation, Position and Posture in Livestock: Delivery by Caesarean Hysterotomy, 291
Jos J. Vermunt, Timothy J. Parkinson and David E. Noakes

17 Disorders of Parturition and the Puerperium in the Gilt and Sow, 315
Olli Aarno Peltoniemi, Stefan Björkman and Claudio Oliviero

18 Manipulative Delivery *per vaginum* in Dogs and Cats, 326
Gary C. W. England

19 Caesarean Hysterotomy in Dogs and Cats, 330
Gary C. W. England

20 Injuries and Diseases Consequent Upon Parturition, 333
Timothy J. Parkinson and David E. Noakes

21 Castration and Cryptorchid Surgery, 349
Neal Ashton

Part 4: Subfertility

22 Infertility in the Cow Due to Functional and Management Deficiencies, 361
Timothy J. Parkinson

23 The Metritis Complex in Cattle, 408
I. Martin Sheldon

VetBooks.ir

24 Specific Infectious Diseases Causing Infertility and Subfertility in Cattle, 434
Timothy J. Parkinson

25 Veterinary Control of Herd Fertility in Intensively Managed Dairy Herds, 467
Chris Hudson, John George Cook and Richard Laven

26 Veterinary Control of Herd Fertility in Pastoral Dairy Herds, 485
Richard Laven

27 Veterinary Control of Reproduction in Beef Herds, 493
Neil Sargison and Colin Penny

28 Fertility and Infertility in *Bos indicus,* 500
Roberto Sartori, Jéssica Nora Drum and Alexandre Barbieri Prata

29 Infertility and Abortion in Sheep and Goats, 510
Peers Davies

30 Management of Breeding in Small Poultry Production Units, 526
Michael Ian Clark

31 Equine Infertility and Stud Medicine Practice, 541
Dale Paccamonti and James R. Crabtree

32 Infertility in the Pig and the Control of Pig Herd Fertility, 581
Olli Aarno Peltoniemi and Bas Kemp

33 Infertility in the Bitch and Queen, 593
Gary C. W. England

34 Pharmacological Control of Reproduction in the Dog and Cat, 613
Gary C. W. England

Part 5: Male Animal

35 Evaluation of the Fertility of Breeding Males, 619
Michael McGowan

36 Abnormalities Affecting Reproductive Function of Male Animals, 635
Timothy J. Parkinson and Michael McGowan

Part 6: Reproduction, Breeding, Reproductive Disease and Infertility in Less Common Domestic Species

37 Old and New World Camelids, 670
Gayle D. Hallowell

38 Buffalo and Related Species, 683
Oswin Perera and David E. Noakes

39 Deer, 693
Geoffrey W. Asher

40 Laboratory and Pet Rodents, and Lagomorphs, 701
Molly Varga and Tim Morris

41 Veterinary Control of Reproduction in Rodent Colonies, 711
Lucy Whitfield, Phil Gibbs and Tim Morris

42 Elephants, 724
Anil Pushpakumara, Chatchote Thitaram and Janine L. Brown

Part 7: Assisted Reproduction

43 Artificial Insemination, 746
Timothy J. Parkinson and Jane M. Morrell

44 Embryo Transfer and Other Assisted Reproductive Technologies, 778
Henrik Callesen, Ingrid Brück Bøgh and Torben Greve

Preface

During the many hours spent revising the book to produce this new 10th edition, as editors/authors we have often thought how previous editions influenced our own professional activities and scientific interests.

The book was first published in the English Language in 1938, as a translation of the original German text by Professor Franz Benesch, who was Professor and Director of the Obstetrical Clinic of the Veterinary High School Vienna, entitled: 'Geburtshilfe bei Rind und Perd', which is literally 'Help with birth in cows and horses'. The English translation, first produced in 1938, was under the editorship of Professor John George Wright, who was Professor of Veterinary Surgery at the University of Liverpool, having previously been Professor of Surgery at the Royal Veterinary College. Both authors were great clinicians with outstanding teaching and practical skills. Thus their writings were based very closely on their personal experiences.

The first English translation of Benesch's original text in German published in 1938 was, as its title implies, almost entirely devoted to a text on dystocia and its treatment in cattle and horses. In the preface to the first joint author edition published in English 1951, it is apparent from comments in the preface that JG Wright, having sought the views and suggestions of others working in the discipline, included these in the new book. The subtitle to the book recognises this, stating: "—Including certain aspects of the physiology and pathology of reproduction in domestic animals". To some extent this underemphasises the scope of the book because in Part 1, for example it describes normal parturition in the sow, bitch and queen cat, whilst in Part 3 there are chapters on the caesarean operation in the bitch and queen cat as well as others on infertility in the mare, cow and bitch. Thus in 1950, when the book was being written, someone with the vision of JG Wright recognised that veterinarians of the future would need to diversify both their interests and expertise.

This change in emphasis and increased diversity has continued in previous editions, and is even greater reflected in this new 10th edition published nearly 80 years after Benesch's first book. Firstly, the diversity of species, these range from small mammals which are kept as pets and for biological research, domestic poultry and camelids, zebu cattle, buffalo and Asian Elephants for example, as well as what are considered to be more traditional domesticated species. Secondly, the wide nationality of the contributors; we have in the 10th edition recruited expert contributors from 14 different countries. Thirdly, whereas in the first edition there was no reference to the use of relatively simple reproductive technology such as artificial insemination, despite the report of the first successful use of the technique in the dog in 1780 and the successful transportation of semen overseas from sheep followed by AI in 1935, in this 10th edition a wide range of advanced reproductive biotechnologies are described and discussed.

As with previous editions, the book is intended primarily for veterinary, veterinary nursing, and animal science/agricultural students, as well as being a source of reference for anyone who has an interest in the biology of reproduction, particularly those species which have been subject to varying degrees of domestication.

We wish to thank all of the authors to the 10th edition for their hard work, and sharing their knowledge and expertise with us, and the subsequent readers of this new edition. It is a reflection of how our knowledge of reproductive biology has expanded since the sole author first edition published in 1938. We would also like to thank our families for their tolerance during the long gestation of the book, which fortunately did not quite become a prolonged gestation, requiring artificial induction.

Finally we would also like to thank Peter Parkinson for redrawing a substantial number of the figures, the staff at Elsevier for their expert help, particularly Ellen Wurm-Cutter in collecting the chapters from authors and latterly Carol O'Connell and Elizabeth Kilgore for the cheerful, professional and efficient way in which they have edited and proofed the chapters to produce a high quality textbook.

Reproductive Physiology of the Female

BOB ROBINSON AND DAVID E. NOAKES

In nature, generally, animals breed once annually, with parturition occurring in the spring at a time that is most favourable for the progeny. As a consequence, the early neonatal period of their life coincides with a period of increasing light and warmth and at the time when food for the mother is most abundant to ensure adequate lactation. The domestication of animals resulted in enhanced feeding and provision of housing such that the breeding season tends to be lengthened; in some species, e.g., cattle, they may breed at any time during the year. However, all domesticated animals show a tendency to revert to the natural breeding season, as evidenced by reduced fertility during summer and early autumn in sows.

For a female animal to reproduce, she must be mated and hence must attract the male and be sexually receptive (she is in oestrus or heat). All domestic mammals show recurring periods of sexual receptivity, or oestrous cycles, which are associated with the ripening in the ovaries of one or more Graafian (antral) follicles (Fig. 1.1), and culminate in the shedding of one oocyte from each ovulatory follicle. If a fertile mating occurs, then pregnancy may ensue.

The Oestrous Cycle and Its Phases

Traditionally, the oestrous cycle is divided into a number of phases.

Prooestrus

This is the phase immediately preceding oestrus. It is characterised by a marked increase in activity of the reproductive system. There are the final maturation stages of follicular growth, alongside regression of the corpus luteum (CL) from the previous cycle (in polycyclic species). The uterus enlarges very slightly, with the endometrium becoming congested and oedematous, and its glands show evidence of increased secretory activity. The vaginal mucosa becomes hyperaemic, the number of cell layers of the epithelium start to increase, and the superficial layers become cornified. The bitch shows external evidence of prooestrus with vulvar oedema, hyperaemia and a sanguineous vulvar discharge.

Oestrus

This is the period of acceptance of the male. The onset and end of the phase are the only accurately identifiable points in the oestrous cycle and hence are used as the reference points for determining cycle length. The animal usually seeks out the male and 'allows' him to mate her. The uterine, cervical and vaginal glands secrete increased amounts of mucus; the vaginal epithelium and endometrium become hyperaemic and congested, and the cervix is relaxed.

Ovulation occurs during this phase of the cycle in all domestic species with the exception of the cow, when it occurs about 12 hours after the end of oestrus. Ovulation is a spontaneous process in most domestic species, with the exception of the cat, rabbit and camelids in which it is induced by the act of coitus.

During prooestrus and oestrus, there is follicular growth in the absence of functional CLs; the main ovarian hormone produced is oestradiol. Prooestrus and oestrus are frequently referred to collectively as the follicular phase of the cycle.

Metoestrus

This is the phase succeeding oestrus. The granulosa and theca cells of the ovulated follicle give rise to lutein (luteal) cells, which are responsible for the formation of the CL. There is a reduction in the amount of mucus secretion from the uterine, cervical and vaginal glands.

Dioestrus

This is the period of the CL. The uterine glands undergo hyperplasia and hypertrophy, the cervix becomes constricted and the secretions of the genital tract are scant and sticky, while the vaginal mucosa becomes pale. The CL is fully functional during this phase and secretes large amounts of progesterone.

The period of the oestrous cycle when there is a functional CL is sometimes referred to as the luteal phase of the cycle to differentiate it from the follicular phase. Because in most of our domestic species oestrus is the only readily identifiable phase of the oestrous cycle, there is some merit in polyoestrous species to divide the cycle into oestrus and interoestrus, the latter including prooestrus, metoestrus and dioestrus. Another alternative division can be into follicular and luteal phases.

Anoestrus

This is the prolonged period of sexual rest, during which the genital system is mainly quiescent. Follicular development is minimal, and the CLs, although identifiable, have regressed and are nonfunctional. Secretions are scanty and tenacious, the cervix is constricted and the vaginal mucosa is pale.

Natural Regulation of Cyclical Activity

Regulation of cyclical activity in the female is a complex process. With the development of techniques, particularly those involving hormone assays and the application of new molecular biological techniques, there is a continual advance in the knowledge and understanding of the mechanisms involved. Although much of the early work was done on laboratory animals – notably the rat and guinea pig – there is now much more information about domestic species, although there are still areas, particularly in the bitch, that are not fully understood.

The central control of cyclical activity is the hypothalamic–pituitary–ovarian axis. At one end of this axis, there is the influence of the extrahypothalamic areas – the cerebral cortex, thalamus and midbrain – and their role in coordinating stimuli such as light, olfaction and touch. At the other end is the influence of the uterus upon the ovary.

Seasonal

The pineal gland plays a critical role in controlling reproductive activity in seasonal breeders by regulating the release of follicle stimulating hormone (FSH), luteinising hormone (LH) and prolactin. Much of the focus has been on the action of melatonin on the hypothalamus and pituitary gland. Melatonin is produced by the pineal gland during periods of darkness, with increasing melatonin secretion driving the reproductive response in 'short-day' breeders such as goats and sheep (Lincoln & Hazlerigg 2010). In 'long-day' breeders such as the horse, the increasing daylight length will 'switch-on' the hypothalamus–pituitary–ovarian–axis. In this case it is decreasing melatonin secretion that drives the stimulation. The integral role that season plays in controlling reproduction in seasonal breeders is extensively discussed in Chapter 3.

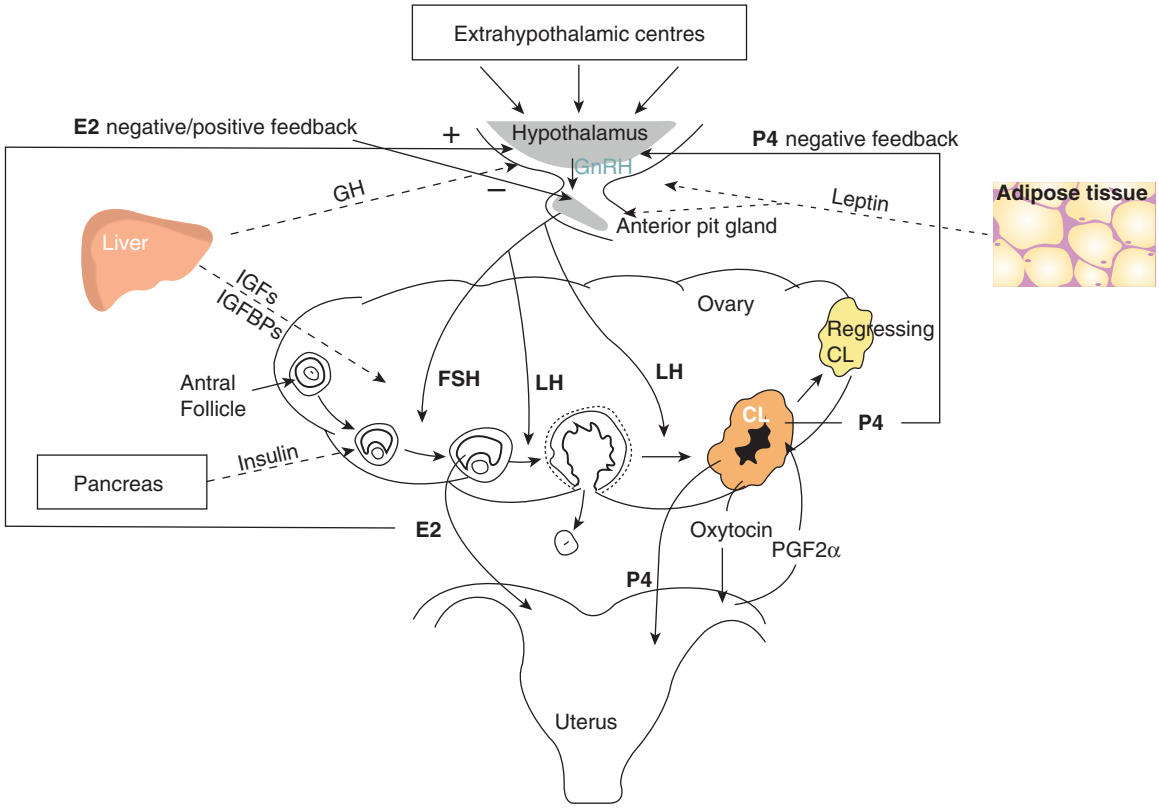
Hypothalamic and Anterior Pituitary Hormones

The hypothalamus is responsible for the control of the release of gonadotrophins (FSH and LH) from the anterior pituitary by the action of specific releasing and inhibitory substances. These are secreted by the hypothalamic neurons and are carried from the median eminence of the hypothalamus by the hypothalamic–hypophyseal portal system. In 1971 the molecular structure of porcine gonadotrophin (GnRH) was determined as being a decapeptide (Matsuo et al. 1971) and subsequently synthesised (Geiger et al. 1971). Over the past decade, a newly discovered neuropeptide called kisspeptin has been shown to act as a 'gatekeeper' for GnRH release. Kisspeptin is secreted from hypothalamic neurons and stimulates GnRH by acting directly on GnRH neurons (Clarke & Arbabi 2016). Kisspeptin is an important regulator of the timing of puberty, as well as the regulation of gonadotrophin secretion in seasonal breeders, and is discussed in Chapter 3.

It is clear that both gonadotrophins (FSH and LH) are located within the same gonadotrophic cell, and the exogenous administration of GnRH stimulates the release of both FSH and LH (Lamming et al. 1979). However, there is strong evidence that there is differential secretion of FSH and LH from the anterior pituitary gland and that it changes in the different stages of the oestrous cycle. It appears that GnRH is critical for the basal and pulsatile secretion of LH, which is particularly evident during the preovulatory LH surge. In contrast, the secretion of FSH secretion is more independent from direct GnRH receptor signalling (Pawson & McNeilly 2005).

There is good evidence that in domestic species the secretion of FSH and LH is controlled by two functionally separate, but superimposable, systems with two hypothalamic centres involved in controlling these two systems (Fig. 1.2). These are: (1) the episodic/tonic system, which is responsible for the continuous basal secretion of gonadotrophin that stimulates the growth of

VetBooks.ir



• **Fig. 1.2** Endocrine control of cyclical reproductive activity. *Solid line,* HPO axis; *dashed line,* extra HPO axis inputs; *GH,* growth hormone; *IGFs,* insulin-like growth factors; *IGFBPs,* insulin-like growth factor binding proteins; PGF_{2alpha}, prostaglandin F_{2alpha}. (Adapted from Lamming et al. 1979.)

both germinal and endocrine components of the ovary; this predominates during the luteal phase when LH pulses are described as high amplitude, low frequency (every 4-8 hours); and (2) the surge system, which controls the short-lived massive secretion of gonadotrophin, particularly LH, and is responsible for ovulation. This is evident at the end of the follicular phase, when high amplitude LH pulses occur more frequently (every 1-2 hours) resulting in a LH surge that is at least tenfold higher than a tonic pulse of LH (Rahe et al. 1980). It is important that this occurs in most domestic mammals as they are spontaneous ovulators. Notable exceptions are the cat, rabbit and camelids, in which ovulation is induced by the stimulation of sensory receptors in the vagina and cervix at coitus. This initiates a neuroendocrine reflex which ultimately results in the activation of GnRH neurons in the surge centre and release of a surge of LH.

There is a precise interplay between the ovary and the hypothalamus–pituitary, as the anterior pituitary not only has a direct effect on ovarian function (e.g., stimulating folliculogenesis, follicular maturation, ovulation and CL formation), but the ovary also has an effect upon the hypothalamus and anterior pituitary. This is principally mediated by oestradiol, produced by the maturing follicle, and by progesterone, produced by the CL.

The episodic/tonic hypothalamic release centre is influenced by the negative feedback effect of oestradiol (below threshold levels) and progesterone. Indeed, progesterone has a profound negative effect on the tonic and surge centres, which appears to be particularly important in ruminants (Lamming et al. 1979). In the cow, ewe and sow (and probably in other domestic species) FSH secretion is additionally controlled by a number of ovarian-derived peptide hormones. The first characterised was inhibin, which is produced by the granulosa cells of large antral follicles and accumulates in the follicular fluid (Fig. 1.1); it is also produced in the testis by Sertoli cells (see Chapter 2). Inhibin and oestradiol act in concert to suppress FSH secretion. Inhibin, which is produced by all antral follicles, has a longer half-life and sets the overall level of negative feedback, whereas oestradiol, which is produced only by those antral follicles that have the potential for ovulation, is responsible for the day-to-day fluctuations (Baird et al. 1991). Two other peptide hormones that have been isolated from ovarian follicular fluid are designated: activin, which stimulates, and follistatin, which suppresses FSH secretion. Over recent years, it has become increasingly apparent that both activin and inhibin have intraovarian functions such as follicle growth and modulating steroid production (Knight et al. 2012).

The positive feedback effect of oestradiol on hypothalamic–pituitary function is well demonstrated in farm animals because the preovulatory surge of oestradiol stimulates the release of LH, which is absolutely critical for the process of ovulation and CL formation. The response of the anterior pituitary to GnRH is influenced by the levels of ovarian steroids so that there is increased responsiveness shortly after the level of progesterone declines and that of oestradiol rises (Lamming et al. 1979). There are probably self-regulatory mechanisms controlling gonadotrophin secretion acting locally within the anterior pituitary and hypothalamus.

Tonic release of gonadotrophins, especially LH, does not occur at a steady rate but in a pulsatile fashion in response to a similar release of GnRH from the hypothalamus. The negative feedback of progesterone is mediated via a reduction in pulse frequency of gonadotrophin release, whereas oestradiol exerts its effect by reducing pulse amplitude. The onset of cyclical activity after parturition,

VetBooks.ir

at puberty or at the start of the breeding season is associated with increased pulse frequency of tonic gonadotrophin secretion. For example, when the ram is in contact with ewes before the start of the breeding season, there is increased frequency of pulsatile LH release, which stimulates the onset of ovarian cyclical activity (Karsch et al. 1984).

Folliculogenesis

The current evidence indicates the formation of follicles is completed during fetal life, such that at birth, there are approximately a half to 1 million follicles. Each follicle will contain an oocyte that is arrested in meiosis I. The majority of these follicles will remain at the primordial stages until puberty when, in cohorts, they will undergo a 'committed' transition into primary follicles (Scaramuzzi et al. 2011). The exact regulation of this process remains unclear but it is likely to involve activation by Kit ligand and mTORC1 (mammalian target of rapamycin complex 1). Conversely, anti-Müllerian hormone (AMH), PTEN (phosphatase and tensin homologue) and forkhead box transcription factors are inhibitory. The protein complex mTORC1 might play an integral role because it is activated by various cues such as nutrients, energy, stress and oxygen (Monniaux 2016). Simultaneously, the oocyte will increase in size and start to form its protective glycoprotein coat called the zona pellucida. The primary follicle cohort will then progress into preantral (secondary) follicles once it has multiple granulosa cell layers alongside the recruitment of the vascularised theca layer. These preantral follicles grow in size, and at 0.1 to 0.5 mm will form a fluid-filled antrum and become antral follicles. Antral follicles are also known as tertiary or Graafian follicles. These early stages of folliculogenesis occur in the absence of gonadotrophin support and are likely controlled by intraovarian growth factors such as insulin-like growth factors (IGF), members of the transforming growth factor beta (TGFB) superfamily, and vascular endothelial growth factor (VEGF) (Hunter et al. 2004, Scaramuzzi et al. 2011). However, it is likely that the development is stimulated by FSH. An emergent concept is that the oocyte plays an active role in regulating folliculogenesis and that there is extensive interplay between the oocyte, granulosa and theca cells. It is widely recognised that the oocyte secretes two important growth factors: growth differentiation factor 9 (GDF9) and bone morphogenetic protein 15 (BMP15). Naturally occurring point mutations in these genes and their receptors (e.g., BMP receptor type 1B) are known to affect ovulation rate in sheep. For example, Booroola ewes will typically yield 4 to 5 offspring as a consequence of an enhanced ovulation rate. In these sheep, the point mutation, known as $FecB^{B}$, was characterised to affect the BMPR1B gene (McNatty et al. 2005). Importantly, the whole process from primordial follicle to ovulation takes 4 to 6 months in ruminants but is slightly shorter in pigs (Hunter et al. 2004), and there is a loss of follicles, and consequently the oocyte, as result of atresia at all stages of folliculogenesis.

The important stage of folliculogenesis from a veterinary perspective is the continuous growth, development and regression (atresia) of antral follicles that occurs throughout the oestrous cycle, during pregnancy and in other reproductive stages. There appear to be two different patterns of follicular growth (Fortune 1994, Scaramuzzi et al. 2011). First, well-organised, wave-like patterns of follicular development occur throughout the oestrous cycle in horses, cattle, sheep, goats and buffalo or, in the case of camelids, during the periods of reproductive activity. Thus there are antral follicles present throughout the oestrous cycle, including the luteal phase, and these follicles are often similar in size to those that are preovulatory. However, in the sow there is no evidence of a wave-like pattern, but there is the presence of 30 to 50 intermediate-sized follicles (2-7 mm in diameter) during the luteal phase. From these, between 15 and 30 will grow and ultimately ovulate once the CL regresses and the follicular phase is initiated (approximately days 14 to 16 of the oestrous cycle). One explanation for such a system of folliculogenesis may be the large number of follicles that ovulate over a very short space of time in this species. The patterns of follicular development in individual species will be described separately below. The following terminology describing folliculogenesis is now generally accepted (Webb et al. 1999):

- **Recruitment**: gonadotrophin stimulation of a cohort of rapidly growing antral follicles
- **Selection**: the process whereby one or more of the recruited follicles are selected to develop further
- **Dominance**: the mechanism whereby one (the dominant follicle) or several codominant follicles undergo further maturation in an environment in which the growth and development of other antral follicles is suppressed

The pattern of follicular dynamics has been expertly described, particularly in ruminant species, by Adams (1999) and is briefly summarised here: The periodic increases in peripheral FSH concentrations are associated with the recruitment of small antral follicles and the emergence of the follicular wave. These follicles will continue to develop under the influence of FSH. This is followed by the selection of a dominant follicle, as the follicle becomes less dependent on FSH and acquires enhanced LH responsiveness. This is associated with the appearance of the LH receptor in the granulosa cells. The dominant follicle secretes inhibin and oestradiol that feedbacks on the hypothalamus–pituitary axis to reduce circulatory FSH concentrations. Thus any antral follicle that is still FSH-dependent will regress and undergo atresia. The dominant follicle will further develop and can remain dominant for several days. It will undergo its final maturation and ovulate if progesterone concentrations decline. However, if progesterone concentrations are maintained, it will regress as progesterone is suppressive to LH secretion, enabling FSH concentrations to increase and the recruitment of a new follicular wave. These periodic anovulatory follicular waves will continue to occur until there is an LH surge. Typically, within a given species there are an increased number of follicular waves when the oestrous cycle is longer. In all species the follicular dominance is enhanced during the first and last follicular wave of the oestrous cycle. The exact mechanism or mechanisms by which follicle becomes dominant and deviates from the subordinate follicles remain a mystery. Originally, it was hypothesised that the follicle with the largest diameter during selection was the follicle that became dominant. The frequent sequential ultrasonographic tracking of individual follicles during the selection and dominance phases has demonstrated that this hypothesis is an over-simplification (Mihm & Evans 2008, Ginther 2016). It is clear that the vascular bed is greater in dominant follicle enabling enhanced gonadotrophin and nutrient uptake. Based on this, Zeleznik et al. (1981) proposed that the degree of vascularisation within the follicle plays a critical role in the selection of the dominant follicle. The use of improved Doppler blood flow technologies has indicated that there is enhanced blood flow to the follicle that becomes dominant prior to deviation in the mare (Acosta et al. 2004) and cow (Ginther et al. 2017). It is widely recognised that the acquisition of LH receptors in the granulosa cell layer is critical for a follicle to achieve dominance. Recent transcriptomic approaches have yielded further insights (Evans et al. 2004, Mihm & Evans 2008, Liu et al.

VetBooks.ir

2009, Hatzirodos et al. 2014). These include the upregulation of transforming growth factor β signalling (e.g., inhibin A, BMP receptors), immune/inflammation signalling, and transcription factor as well as intercellular matrix adhesion.

Even during times such as pregnancy, anoestrus and postpartum, there is evidence of follicular growth and regression. Follicular waves have been identified in pregnant cows, ewes, doe goats, llamas and camels as well as during the puerperium, before the resumption of ovarian cyclical activity. However, the follicles tend to have a smaller diameter than those present in follicular waves of nonpregnant individuals (Evans 2003).

Ovarian Steroids

Progesterone plays a critically important role in the inhibition of the tonic mode of LH secretion (Goodman & Karsch 1980) by reducing LH pulse frequency. Progesterone is a major regulatory hormone that controls the oestrous cycle of domestic mammals. Thus when the circulatory concentrations of progesterone fall (e.g., during luteolysis), there is increased release of LH from the anterior pituitary. The subsequent increased frequency of LH pulses triggers the secretion of oestradiol, and its rapid rise stimulates the hypothalamic surge centre. Consequently, there is a surge of LH that will induce the final stages of follicular maturation, ovulation and the release of oocyte (McNatty et al. 1981).

In some species, notably the cow (see Fig. 1.29), there is also a concomitant surge in FSH, although its significance is unclear; it may be part of the 'ovulation-inducing' hormone complex. For this reason, it is probably incorrect to assign a separate and specific physiological role for the two pituitary gonadotrophins. Although steroidogenesis can be initiated by both FSH and LH, it would appear that only FSH can induce early antral follicular growth, but when the granulosa cells have matured, they are able to respond to endogenous LH; then LH is principally responsible for triggering ovulation.

Ovulation

The preovulatory LH surge triggers a series of cellular and molecular changes in the follicle that culminate in ovulation. Ovulation is a complex process**,** involving the measured destruction of the follicle enabling the release of the oocyte and conversion of the follicle into the CL. The three key events involved in ovulation are: (1) elevated local blood flow (hyperaemia) and increased vascular permeability stimulated by prostaglandin E_2 and VEGF; (2) the breakdown of the connective tissue within the tunica albuginea and the basement membrane of the ovulatory follicle. The activity of proteolytic enzymes (e.g., collagenase, plasmin) is triggered by a local rise in progesterone and PGE_2 production from the theca cells. Collectively, this will increase follicular fluid volume and weaken the apex of the follicle, leading it to protrude and form a stigma; and (3) the contractions of the smooth muscle within the theca externa layer of the follicle. These are stimulated by $PGF_{2\alpha}$ and may increase pressure locally to force the stigma to protrude more and eventually open up to release the oocyte and follicular fluid (Murdoch et al. 2010).

Formation of the Corpus Luteum

The CL is rapidly formed from the Graafian follicle after ovulation, primarily from the luteinisation of the granulosa and thecal cells; this is accompanied with intense angiogenesis. Collectively, this enables the CL to increase its mass to twentyfold over a period of 10 to 12 days (Reynolds & Redmer 1999; Mann et al. 2007). For some time it was assumed that once formed, it remained a relatively static structure. However, it is now known that when it is functionally mature, there is still rapid cell turnover, although there is little change in its size. The fully formed CL consists of a number of different cell types: the steroid-secreting large and small luteal cells, fibroblasts, smooth muscle cells, pericytes and endothelial cells (Woad & Robinson 2016). It has the greatest blood supply per unit tissue of any organ (Reynolds & Redmer 1999). In the ewe, based on volume, the large luteal cells comprise 25% to 35%, the small luteal cells 12% to 18% and vascular elements 11% (Rodgers et al. 1984). Although the CL develops as a result of ovulation, in some species, notably the bitch, there are early signs of luteinisation of the follicle before it has ovulated (Concannon 2011). The stimulus for the formation and maintenance of the CL probably varies within species. The hormones that are most likely to be involved are prolactin and LH, with some evidence that they act in conjunction with each other. The treatment of ewes, cows and pigs with LH antiserum causes a dramatic decline in luteal weight and progesterone content, and therefore prolactin is unlikely to be essential for normal luteal function. However, prolactin plays a critical role in maintaining the CL in rodents and the dog (Niswender et al. 2000, Concannon 2011).

Regression (Luteolysis) of the Corpus Luteum

The presence of a functional CL, by virtue of its production of progesterone, inhibits the return to oestrus by exerting a negative feedback effect upon the hypothalamus. This is most obvious during pregnancy. In the normal, nonpregnant female, oestrus and ovulation occur at fairly regular intervals, and the main control of this cyclical activity would appear to be the CL. Although it has been known for over 80 years that in certain species the uterus influences ovarian function (Loeb 1923), the exact mechanisms are now only just being completely understood (see review by Weems et al. 2006).

It is recognised that, in many species, removal of part or all of the uterus will result in the life span of the CL being prolonged (Du Mesnil Du Buisson 1961, Rowson & Moor 1967). These species include cattle, horses, sheep, goats and pigs. However, in the human, dog and cat the normal life span of the CL is unaffected by the absence of the uterus. In the cow, ewe and goat the luteolytic action of the uterine horn is directed exclusively to the CL on the adjacent ovary (Ginther 1974, McCracken et al. 1999). Thus if the uterine horn adjacent to the ovary with a CL is surgically removed, then the CL will persist. Conversely, if the contralateral horn is removed, then the CL will regress at the normal time.

It was not until 1969 that the substance responsible for luteolysis was identified, when the duration of pseudopregnancy in the rat was shortened by the injection of prostaglandin $(PG)F_{2\alpha}$ (Pharriss & Wyngarden 1969). This same substance is known to have potent luteolytic activity in the ewe, doe goat, cow, sow and mare. Although it has been proved only in ruminants and the guinea pig that $PGF_{2\alpha}$ is the natural luteolysin, it is likely that it is also true for the other species listed.

It appears that the endometrial-derived $PGF_{2\alpha}$ is transported directly from the uterus to the ovary. In the ewe it has been shown that the most likely route for transport of the substance is the middle uterine vein because, when all other vascular structures between the ovary and uterus were severed, there was still normal regression of the CL (Baird & Land 1973).

VetBooks.ir

In the mare no local effect can be demonstrated because, if the ovary is transplanted outside the pelvic cavity, luteal regression still occurs (Ginther & First 1971). It is generally assumed that in this species the $PGF_{2\alpha}$ is transported throughout the systemic circulation. In the sow $PGF_{2\alpha}$ is transported locally, but not exclusively, to the adjacent ovary. It has been shown that, following surgical ablation of segments of the uterine horns and provided that at least the cranial quarter of the uterine horn is left, regression of the CLs occurs in both ovaries (Du Mesnil Du Buisson 1961). In the bitch the mechanisms by which the lifespan of the CL is controlled is not fully understood, but in this species even in the absence of pregnancy, there is always a prolonged luteal phase.

The mechanisms whereby $PGF_{2\alpha}$ is transported to the ovary have not been conclusively shown in all species, but it is fairly well evaluated in the ewe and cow. In the former species, it appears that the close proximity of the ovarian artery and utero–ovarian vein is important, particularly because at their points of approximation the walls of the two vessels are thinnest and there is no anastomosis (Coudert et al. 1974). This allows leakage of $PGF_{2\alpha}$ from the uterine vein into the ovarian artery and thus to the ovary, by a form of countercurrent exchange through the walls of the vessels. It has been suggested that the variation in the response to partial or total hysterectomy in different species is probably due to differences in the relationships between the vasculature of the uterus and ovaries (Ginther 1974).

$PGF_{2\alpha}$ is a derivative of the unsaturated linolenic and arachidonic acids. It derived its name because it was first isolated from fresh semen and was assumed to be produced in the prostate gland. It is synthesised in the endometrium of a number of species (Horton & Poyser 1976), and in ruminants pulsatile secretion of $PGF_{2\alpha}$ is increased at and around the time of luteal regression (Mann et al. 1999). For complete luteal regression to occur, 5 to 8 episodic release of $PGF_{2\alpha}$ pulses at intervals of approximately 6 hours is required (Arosh et al. 2016). There is a positive feedback loop present whereby oxytocin secreted by the CL stimulates $PGF_{2\alpha}$ secretion. Thus each episode of $PGF_{2\alpha}$ release is accompanied by an episode of oxytocin release. Furthermore, $PGF_{2\alpha}$ stimulates further secretion of oxytocin from the ovary.

Luteal regression has two important components: (1) functional regression, in which the secretion of progesterone declines; this component is rapid, resulting in sharp decline in peripheral progesterone concentration; and (2) structural regression, in which there is physical involution of the CL and regression of luteal tissue; this process takes longer than the functional regression. The primary targets of $PGF_{2\alpha}$ in the initiation of luteal regression are the large luteal cells, which possess prostaglandin F receptors on their cell surface. Initially, it is the large luteal cells that decrease in size, followed by the reduction in the small luteal cell size. Simultaneously, there is a disruption to the luteal vasculature and infiltration of immune cells such as macrophages alongside the production of various cytokines such as tumour necrosis factor (Pate et al. 2012). There is a wealth of evidence indicating that luteal endothelial cells play an integral role in luteolysis, with $PGF_{2\alpha}$ acting on these cells. It appears that there is a transient increase in luteal blood flow following $PGF_{2\alpha}$ administration, which is mediated by nitric oxide-induced vasodilation. However, as luteolysis progresses, there is a gradual decline in blood flow as a consequence of vasoconstriction induced by elevated endothelin and angiotensin II levels (Meidan et al. 1999, Miyamoto et al. 2009).

The sensitivity of the uterus to oxytocin is determined by the upregulation of endometrial oxytocin receptors. In ruminants just prior to the time of luteal regression, they rise approximately 500-fold (Lamming & Mann 1995). Their concentrations are determined by the effects of progesterone and oestradiol, with high concentrations of progesterone after ovulation downregulating oxytocin receptor expression. Then, in the nonpregnant animal, oxytocin receptor expression in the luminal epithelium is upregulated on day 12 (sheep) and 16 (cow) (Mann et al. 1999). Although exogenous oestradiol can cause premature induction of oxytocin receptors, resulting in premature luteolysis (Hixon & Flint 1987), the exact role of oestradiol and the oestrogen receptor in the upregulation of oxytocin receptor remains controversial. In nonruminant species much less is known about the mechanisms by which luteolysis is upregulated.

The CL becomes more sensitive to the luteolytic effect of $PGF_{2\alpha}$ as it matures. The early (growing) CL is unresponsive to $PGF_{2\alpha}$. The refractoriness of the CL to $PGF_{2\alpha}$ is likely to be due to the lack of attenuated molecular and cellular infrastructure rather than the absence of the prostaglandin FP receptor expression, which is abundant through the oestrous cycle (Miyamoto et al. 2009).

Leptin

Leptin has an important role in not only regulating food intake in man and domestic animals, but also in controlling reproduction and in particular the time of onset of puberty and fertility. Leptin is a 16-kDa protein (of 140 amino acids) that is synthesised by the white fat cells of adipose tissue and acts not only primarily on the hypothalamus, but also the anterior pituitary and reproductive tract because leptin receptors have also been identified in these structures (Dyer et al. 1997, Lin et al. 2000). The production of leptin is influenced by body condition/weight and thus informs the brain of the level of the body's energy stores (Clarke & Arbabi 2016). The interaction between food intake and the hypothalamic–pituitary axis has been shown by examining the effect of acute fasting and chronic feed restriction on both serum leptin and LH levels. In the cow and ewe there was a marked decrease in serum LH release coinciding with reduced leptin levels (Amstalden et al. 2000, Henry et al. 2001). However, in the pig an acute 24 hours fast caused a decrease in leptin, with no effect on LH (Barb et al. 2001). This indicates species differences, and emphasises the dangers of extrapolating from one to the other. The current evidence indicates that leptin is likely to exert its effects on LH secretion by modulating kisspeptin (Hausman et al. 2012).

Insulin-Like Growth Factor System

It is clear that the 'insulin-like growth factor (IGF) system' plays a fundamental role in the growth and selection of follicles, as well as luteal development in most of the domestic species (Webb et al. 2002, Mazerbourg et al. 2003). It is likely that the IGF system integrates the metabolic status of the animal with reproductive performance (Lucy 2008, Hernandez-Medrano et al. 2012, Wathes 2012). The system comprises a number of different, but related, elements. They are: (1) two ligands, IGF1 and IGF2; (2) type 1 and type 2 IGF receptors; and (3) six principal IGF-binding proteins (IGFBPs), which have high but varying affinities for binding both IGF1 and IGF2. The predominant source of IGF1 is from the circulation, with its production by the liver increased by growth hormone (GH), whereas IGF2 is more locally produced in the follicle and CL (Lucy 2008). The circulatory levels of IGF1 parallel the energy status of that animal in several species; for example, plasma IGF1 levels decline during the period of negative energy balance postpartum in dairy cows (Lucy 2008,

VetBooks.ir

Wathes 2012). The principal signalling receptor is the IGF type 1 receptor, which is abundantly expressed throughout the ovary and uterus. The IGFBPs are ubiquitous in all biological fluids, including follicular fluid; however, in blood the most abundant is IGFBP3. The bioavailability of IGF1 and IGF2 is reduced when they are bound to their binding proteins, and classically, it was believed that IGFBP inhibited the action of IGFs. However, there is good evidence that the IGFBPs can potentiate IGF activity by increasing their half-life and maintaining the local tissue IGF level (Mazerbourg et al. 2003). In addition, there is also a protease that degrades IGFBPs in the follicle, called pregnancy-associated plasma protein (PAPP)-A. The action of PAPP-A on IGFBPs is to release and enable IGF1 and IGF2 to be biologically active. How does the insulin-like growth factor system function? IGFs stimulate follicular growth by stimulating granulosa cell proliferation, as well as the emergence of a dominant follicle, by sensitising follicular granulosa cells to the effects of FSH and LH. In the latter stages of follicular development, IGF1 is more involved with follicular maturation and differentiation (Mazerbourg et al. 2003). Both IGF1 and IGF2 increase oestradiol production by the granulosa cells (Mazerbourg et al. 2003). The intrafollicular levels of several IGFBPs increase during follicular atresia, and they have been proposed as markers of atretic follicles. PAPP-A has been identified in bovine, equine, ovine and porcine preovulatory follicles, concomitant with decreased IGFBP levels in preovulatory follicles (Mazerbourg et al. 2003). In the CL, IGF1 is known to stimulate progesterone by upregulating key steroidogenic proteins and has been proposed to stimulate the intense neovascularisation after ovulation (Webb et al. 2002).

Prolactin

The exact role of prolactin in controlling reproduction in many domestic species is still largely speculative, and in many cases it is only possible to extrapolate from studies in the traditional laboratory species. Unlike other anterior pituitary hormones, which require hypothalamic stimulation, it appears that prolactin secretion from lactotrophic cells of the anterior pituitary gland is spontaneous. The predominant regulatory signal is inhibitory, which is mediated by the hypothalamus-derived neurotransmitter dopamine (Bouilly et al. 2012). There is some evidence to suggest that dopamine may have a dual role as a stimulant of prolactin secretion, rather like a prolactin-releasing factor. The best characterised role for prolactin is its activity on the CL, particularly in rodents and dogs. In these species, prolactin is essential for CL function and the inhibition of prolactin secretion leads to luteal regression (Concannon 2011).

Role of Opioids

There has been interest directed towards the role of certain endogenous opioid peptides such as *beta*-endorphin and *met*-enkephalin, which are involved in regulating food intake. These substances are found in high concentrations in hypothalamic–hypophyseal portal blood, and the administration of exogenous opioid peptides inhibits FSH and LH secretion while stimulating the secretion of prolactin. If an opiate antagonist such as naloxone is infused, there is an increase in gonadotrophin concentrations in the plasma and the frequency of episodic gonadotrophin secretion. It is feasible that opioid peptides are a potential mechanism by which nutritional restriction, possibly via neuropeptide Y, suppresses the GnRH pulse generator (Diskin et al. 2003). The effect of opioids appears to be influenced by the background steroid environment. For example, in ewes naloxone increased the mean plasma concentration of LH and the episodic frequency in a high progesterone environment. However, in ovariectomised ewes or those with oestradiol implants, naloxone had no effect (Brooks et al. 1986). It is possible that the negative feedback of progesterone on LH release may be mediated via opioids (Brooks et al. 1986).

Stress

There are numerous stressors that can impact on domestic animals such as poor body condition, adverse temperature and certain management procedure. All these events elicit a coordinated endocrine response that can suppress normal oestrous behaviour and cyclicity. Often the disruption is temporary and, when stress is eliminated, normal cyclical activity resumes (Dobson et al. 2012). The exact mechanism whereby stress influences reproduction is poorly understood, but stress has an impact on the hypothalamus by reducing GnRH secretion and on the anterior pituitary gland by decreasing FSH and LH secretion. It is most likely that stress mediates its effect, at least in part, by elevating plasma cortisol (or corticosterone) levels, which is known to suppress LH pulse frequency. Indeed, it has been shown that the imposition of experimental stress during the follicular phase leads to a delay or complete suppression of the LH surge (Dobson & Smith 1998).

Ovarian Reserve and Ageing

Female mammals are born with a variable, but finite, number of follicles and oocytes in their ovaries, and as the animal ages the number of these will gradually decline and are never replenished. Because the formation of follicles in the ovary is completed by the time of birth, it has been hypothesised that the maternal environment during gestation could impact on the offspring's reproductive capabilities. This hypothesis is supported experimentally, when the offspring of cows nutritionally restricted through the first trimester had lower antral follicle counts in adulthood (Mossa et al. 2013).

In humans, once this ovarian reserve is nearly exhausted, then the menopause will commence. Although this does not occur in domesticated mammals, there is evidence that fertility declines in cows with a low AFC (Mossa et al. 2012) and a reduced response to superovulation (Evans et al. 2012). The exact association between AFC and fertility remains to be established. It is likely that the AFC and anti-Müllerian hormone (AMH), which are produced by the granulosa cells of preantral and small antral follicles, reflect the level of ovarian reserve (Ireland et al. 2008). This has led to the prospect of measuring the plasma AMH level as an indicator of ovarian reserve and fertility (Mossa et al. 2017). This measurement is routinely performed in women undergoing artificial reproductive technology programmes and is an excellent indicator of ovarian ageing in women (Nelson et al. 2012). There is minimal variation in the plasma AMH level throughout the oestrous cycle; thus a single sample at any time could indicate the ovarian reserve level. Indeed, there is some evidence that AMH level is correlated with several measurements of fertility (Mossa et al. 2017). The commercial use of AMH measurements as predictors of fertility remains largely unexplored.

The Horse

Fillies are often seen in oestrus during their second spring and summer (when they are yearlings), but under natural conditions it is unusual for them to foal until they are over 3 years old (see

VetBooks.ir

also Chapter 31). The mare is normally a seasonal breeder, with cyclic activity occurring from spring to autumn, whereas during the winter she will normally become anoestrus. However, it has been observed that some mares, especially those of native pony breeds, can cycle regularly throughout the year. This tendency can be enhanced if the mares are housed and given supplementary food when the weather is cold and if additional lighting is provided when the hours of daylight are short.

Horse breeding is influenced by the demands of thoroughbred racing because in the Northern hemisphere foals are aged from 1 January, irrespective of their actual birth date. As a result, the breeding season for mares has been, for over a century, determined by the authorities as running from 15 February to 1 July. Because the natural breeding season does not commence until about the middle of April with maximal ovarian activity from July onwards, it is obvious that the thoroughbred mare is often bred at a time when their fertility is suboptimal.

During winter anoestrus, both ovaries are typically small and bean-shaped, with dimensions of approximately 6 cm from pole to pole, 4 cm from the hilus to the free border, and 3 cm from side to side. It is not uncommon, however, in early spring or late autumn, for the anoestrous ovary to be medium to large in size and irregular in outline, due to the presence of numerous follicles of 10 to 15 mm diameter. Winter anoestrus is followed by a period of transition to regular cyclic activity. During this transition, the duration of oestrus may be irregular or very long, sometimes more than a month. The signs of oestrus during the transitional phase are often atypical, making it difficult for the observer to be certain of the mare's reproductive status. Also, before the first ovulation there is poor correlation between sexual behaviour and ovarian activity. Namely, oestrus in the transition period is often accompanied by the absence of large follicles, and some long spring oestruses are anovulatory. However, once ovulation has occurred, regular cycles usually follow.

The average length of the equine oestrous cycle is 20 to 23 days, with the cycles being longest in spring and shortest from June to September. The duration of oestrus is highly variable, lasting between 4 and 7 days. Ovulation occurs on the penultimate or last day of oestrus, and this relationship to the end of oestrus is fairly constant and irrespective of the duration of the cycle or the length of oestrus. Indeed, the manual rupture of the preovulatory follicle resulted in termination of oestrus within 24 hours (Hammond 1938). This makes predicting the time of ovulation, which is critical for the management of breeding by natural service or artificial insemination, potentially challenging. However, on the last day before ovulation, the tension in the preovulatory follicle (30-65 mm) usually subsides, and the palpable presence of a large fluctuating follicle is a sure sign of imminent ovulation. Thus the careful monitoring of the developing preovulatory follicle by transrectal ultrasonography can be performed to predict when ovulation is going to occur.

Ovulation of the preovulatory follicle results in the release of a single oocyte with a preponderance of ovulations from the left ovary. For example, Arthur (1958) recorded an incidence of 52.2% of ovulations from the left ovary from 792 postmortem reproductive tracts. In mares multiple ovulations commonly occur with a reported incidence of 27% (Burkhardt 1948), 18.5% to 37.5% (Arthur 1958), 21.5% (Henry et al. 1982) and 20.7% to 35.6% (Morel et al. 2005). The incidence is influenced by season and age; the majority of these are twin bilateral ovulations. It is also reported that there is a strong breed influence on twin ovulation rates, with thoroughbreds being prone, whereas with pony mares it is rare. All equine ovulations occur from the ovulation fossa only at the ovarian hilus. There may be the occasional protrusion of a CL but, because of the curvature of the ovary and the presence of the adjacent substantial fimbriae, these protrusions cannot be identified by rectal palpation.

The onset of oestrus typically occurs on the fifth through tenth day after foaling. This 'foal heat' is sometimes rather short, 2 to 4 days. It is traditional to cover a mare on the ninth day after foaling; however, the first two postparturient cycles are a few days longer than subsequent ones.

Folliculogenesis

There are large variations in ovarian size during the oestrous cycle depending on the number and size of the follicles. For example, during oestrus the ovary of the thoroughbred mare may contain two or even three follicles, each of 40 to 55 mm in diameter, and these, with other subordinate follicles, combine to give it a huge size. However, during dioestrus, the presence of an active CL and only atretic follicles result in the ovary being only a little larger than in anoestrus.

In the mare, follicular waves have been classified into: *major waves*, in which recruited antral follicles diverge into a dominant follicle and subordinate follicles in a similar manner to other monovular species; and *minor waves*, in which there is no divergence (Ginther & Bergfelt 1992). Major waves are further subdivided into primary waves, in which the wave originates middioestrus yielding a dominant follicle that ovulates, and secondary waves, in which the wave originates in late oestrus and either the dominant follicle is anovulatory or ovulation is delayed to after the end of oestrus (Ginther 1993). Minor wave and secondary waves occur most frequently during the transitional phase at the beginning of the breeding season, and the largest follicle does not attain more than 28 mm in size.

Day (1939), one of the early students of equine reproduction, produced a series of drawings of mare's ovaries collected after slaughter that give a clear picture of the changes that occur during the oestrous cycle (Figs. 1.3–1.7; they are half actual size) with the stage of the cycle having been determined clinically beforehand. Figs. 1.8 through 1.13 show examples of whole ovaries, crosssections, and B-mode ultrasound images.

Just before the onset of oestrus, several follicles enlarge to a size of 10 to 30 mm, with follicle deviation occurring when follicles reach around 22 mm in diameter. By the first day of oestrus, one follicle (the dominant follicle) is generally considerably larger than the remainder, having a diameter of 30 to 45 mm. During oestrus, this follicle will continue to grow at approximately 3 mm per day, until 2 days before ovulation when its growth plateaus at a diameter of 40 to 55 mm (Ginther 1993). The preovulatory

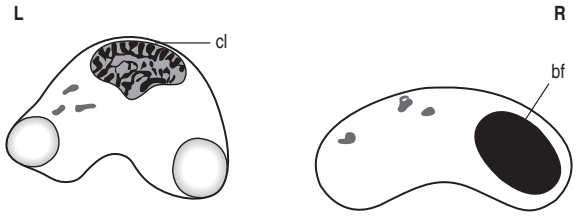
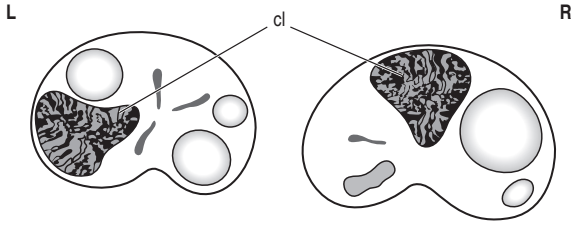
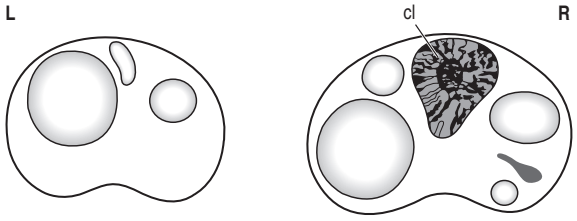
• **Fig. 1.4** Ovaries of a 9-year-old draft mare in dioestrus. Note presence of several sizeable follicles and corpus luteum *(cl)* in right ovary, which was orange in colour with the luteal tissue in loose pleats.



• **Fig. 1.5** Ovaries of a 4-year-old Shire mare in dioestrus. Corpus luteum *(cl)* in left ovary is brownish-red in colour with distinct pleats of luteal tissue. Right ovary contains a follicle filled with blood *(bf)*.



• **Fig. 1.6** Ovaries of a 6-year-old draught mare in dioestrus, with a corpus luteum *(cl)* in each ovary. Both are orange-yellow in colour with distinct pleats of luteal tissue.



• **Fig. 1.7** Ovaries of a 6-year-old hunter mare in dioestrus. Corpus luteum *(cl)* in right ovary is pale yellow in colour with distinct pleats of luteal tissue and a small central cavity.

follicle will continue to mature, and in the several hours before ovulation, it becomes much less tense and soft to touch. The horse is different from farm animal species in that it has not only much larger preovulatory follicles, but also that the follicles rupture from a specific indented region of the ovary termed the 'ovulation fossa'. The collapsed follicle is recognised by an indentation on the ovarian surface, and there is usually some haemorrhage into the follicle with the coagulum hardening within the next 24 hours. Quite frequently, the mare shows evidence of discomfort when the ovary is palpated soon after ovulation. Unless sequential transrectal palpation or ultrasonic examinations are performed, it is sometimes possible to confuse a mature follicle with the early corpus haemorrhagicum. This is because before ovulation, the follicular antrum is filled with follicular fluid, and then soon after ovulation it becomes filled with blood. For this reason, mares are sometimes incorrectly diagnosed as having failed to ovulate. For the next 3 days, the luteinising mass can be palpated as a resilient focus, but later it tends to have the same texture as the remainder of the ovary and is difficult to palpate. However, in pony mares Allen (1974) reported that it is possible to follow the growth of the CL by palpation because it forms a relatively large body within the small ovary of ponies. The CL enlarges within the ovary and attains maximum size after 4 to 5 days, but it does not protrude from the ovarian surface as in other species (Aurich 2011). After ovulation, the other follicles regress during the first 4 to 9 days of the ensuing dioestrus such that no follicles larger than 10 mm are likely to be present. On section of the ovary, it is brown and later yellow and of a triangular or conical shape, with the narrower end impinging on the ovulation fossa. Its centre is commonly occupied by a variable amount of dark brown fibrin. Plasma progesterone concentrations are maximal 8 days after ovulation, and the cyclical CL begins to regress on around day 14 of the cycle. Subsequently, there is a parallel fall in the blood progesterone concentration. From this day onwards, the events previously described recur. Ovulation with the subsequent formation of a CL does not always occur, and the follicle may regress or sometimes undergo luteinisation (Fig. 1.11B). These structures are termed haemorrhagic anovulatory follicles or luteinised unruptured follicles (Cuervo-Arango & Newcombe 2010).

Transrectal B-mode ultrasound imaging has been used to visualise follicles (Figs. 1.8–1.13). This is particularly useful in determining the timing of ovulation and also in detecting the possibility of twin ovulations. One particularly important observation is that in the preovulatory period there was a change in the shape of the follicle (from spherical to pear-shaped) and a thickening of the follicular wall, which, together with the assessment of the size of the follicle, could be used to predict the time of ovulation (Ginther et al. 2008). The examination of the CL after 5 days postovulation requires the use of ultrasonographic techniques. In approximately 50% of mares, there is persistence of the corpus haemorrhagicum as a central blood clot in the CL. Luteal activity strongly correlated with its vascularisation. Thus recent advances in the measurement of luteal blood flow using colour Doppler ultrasonography have enabled luteal functionality to be evaluated with reduced luteal blood flow indicating a regressing CL.

Reproductive Tract Changes During the Oestrous Cycle

The detection of the preovulatory period by visual examination of the vagina and the cervix using an illuminated speculum is possible. In dioestrus the vagina and cervix are pale pink in colour and the cervix is small, constricted and firm, while mucus is scanty and sticky. In contrast, during oestrus, there is a gradual increase in the vascularity of the genital tract and relaxation of the cervix with dilatation of the os. As oestrus progresses and ovulation approaches, the cervix becomes very relaxed and protrudes into the vagina; the folds are lying on the vaginal floor, with its folds oedematous. Additionally, the walls of the vagina glisten with clear, lubricant mucus. After ovulation there is a gradual reversion to the dioestrous appearance.

During anoestrus and pregnancy, both the vagina and cervix have a blanched colour; the cervix is narrow, constricted and generally turned away from the midline, the external os being filled with tenacious mucus.

• **Fig. 1.8** Ovary from an acyclic (anoestrous) mare. (A) The ovary was hard on palpation with no evidence of follicular activity. Note the ovulation fossa *(o)*. (B) Crosssection of the ovary. Note that there are a few small follicles *(f)* 1 cm in diameter, which are contained within the ovarian matrix. (C) B-mode ultrasound image of the same ovary showing small anechoic (black) areas 1 cm in diameter, which are follicles *(f)*.

Cyclic changes can be detected during the palpation of the uterus per rectum. In the luteal phase under the influence of progesterone, the uterus increases in tone and thickness, but these features diminish when the CL regresses. At oestrus, there is no increase of tone as observed in other species (e.g., cow). During anoestrus and for the first few days after ovulation, the uterus is flaccid (Hammond & Wodzicki 1941).

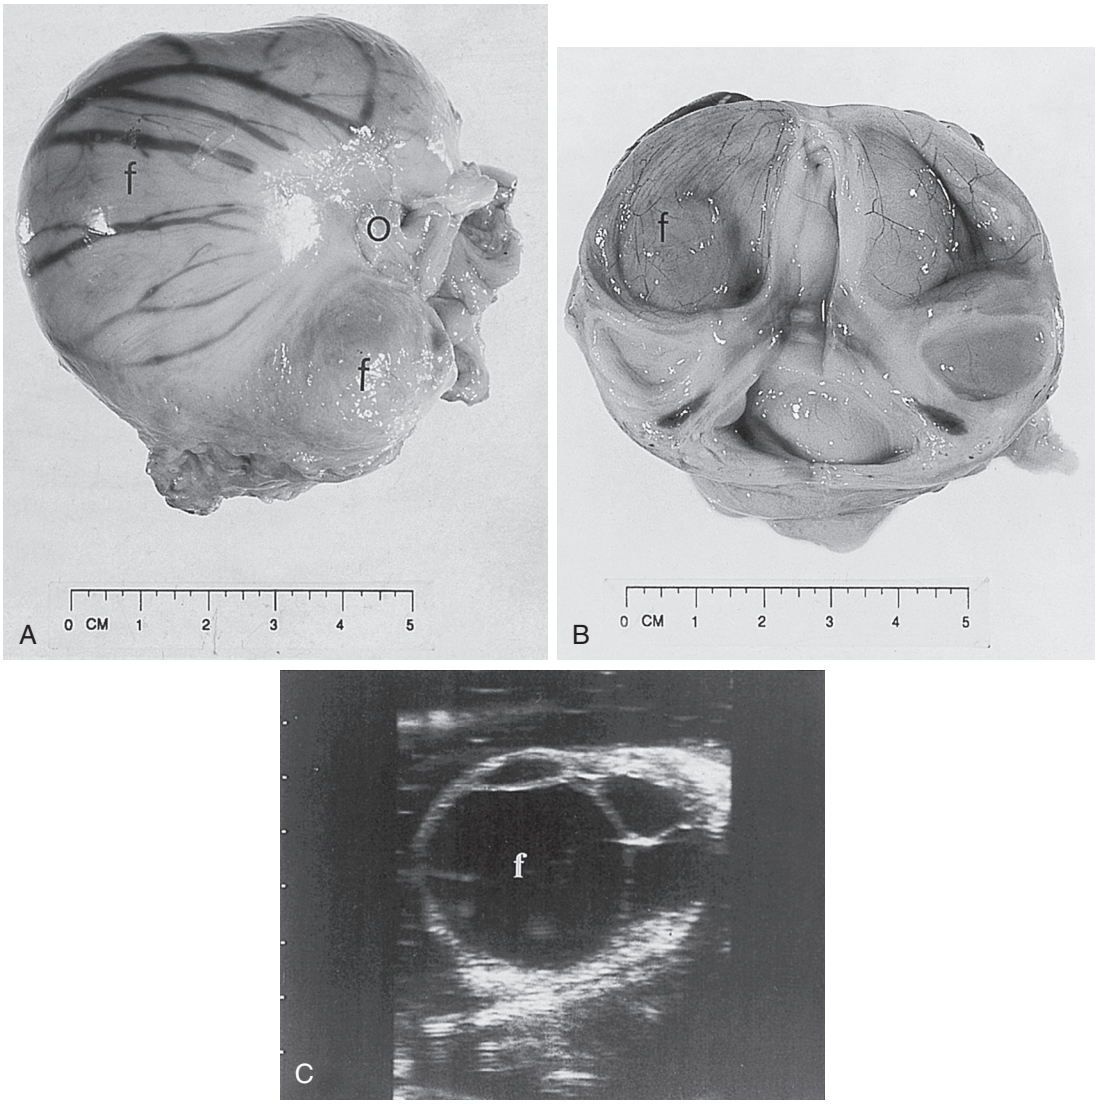
Signs of Oestrus

The mare becomes restless and irritable, and she frequently adopts the micturition posture and voids urine with repeated exposure of the clitoris (Fig. 1.14). When introduced to a stallion or teaser, these postures are accentuated with the frequent raising of her tail to one side and leaning her hindquarters. The vulva is slightly oedematous, and there is a variable amount of mucoid discharge. A mare that is not in oestrus will usually violently oppose the advances of a stallion, and for this reason 'trying' mares at stud should be done over a gate, box door or stout fence. If the mare is in oestrus the stallion usually exhibits flehmen. Good stud management requires that a mare is accustomed to the procedure and that, because of the interval between the end of the last oestrus and the start of the next, she is teased 15 to 16 days after the end of the last oestrus (see Chapter 31).

Endocrine Changes During the Oestrous Cycle

The trends in endocrine changes are shown in Fig. 1.15. The secretion of FSH is biphasic with surges at approximately 10- to 12-day intervals. One surge occurs just after ovulation, with a second prominent surge in mid to late dioestrus, approximately 10 days before the next ovulation. This second and robust FSH surge occurs in the absence of an increase in LH. It has been suggested that this increase in FSH secretion, which is unique to the mare,

VetBooks.ir



• **Fig. 1.9** Ovary from a mare in the early follicular phase. (A) The ovary was soft on palpation with evidence of large follicles near the surface of the ovary *(f)*. Note the ovulation fossa *(o)*. (B) Crosssection of the ovary. Note that three follicles are at least 2 cm in diameter. is responsible for priming the development of a new follicular wave from which a follicle will ovulate at the next oestrus (Evans & Irvine 1975). Indeed, the increase in FSH is paralleled by an increase in the size of the largest follicle; however, after follicle deviation, peripheral FSH levels will start to decline. The pattern of LH secretion is also unusual in this species because there is no sudden surge of this hormone, but a gradual increase and persistence of elevated levels for 5 to 6 days on either side of ovulation. Maximal LH bioactivity occurs shortly before ovulation, with LH pulse increasing from 0.5 to a peak of 2 pulses per hour (Aurich 2011). Oestrogens in the peripheral circulation increase during oestrus and peak around ovulation before declining to basal levels during dioestrus. In contrast, concentrations of progesterone and other progestogens follow closely the physical changes of the CL. Specifically, there is an immediate increase in progesterone after ovulation, before reaching maximal concentrations on day 8 after ovulation. Thereafter, progesterone concentrations gradually decline, before a pronounced fall at the onset of luteolysis on approximately day 15 of the oestrous cycle. Luteolysis is induced by the endometrial secretion of $PGF_{2\alpha}$, which is in turn stimulated by oxytocin. In the mare there is no significant production of luteal oxytocin; instead, the source of the oxytocin is believed to be the posterior pituitary gland and the endometrial itself (Bae & Watson 2003).

The Cow

Cyclic Periodicity

Under normal conditions cattle are polyoestrous throughout the year. After puberty, cyclical activity will continue, except during pregnancy, for 3 to 6 weeks after calving, during periods of severe negative energy balance (as can be observed during high milk yield) and with a number of pathological conditions (see Chapters 22, 25 and 26). Some cows and heifers also fail to show overt signs of oestrus yet have normal cyclical activity, a condition referred to as 'silent heat', or suboestrus. However, this can be due to the

herdsperson failing to observe the signs, rather than a failure of the cow to show signs.

The average length of the oestrous cycle is 20 days (range 18–22 days) in heifers and 21 days (range 18–24 days) in cows. Recent evidence indicates that the interservice interval is 22 days and that longer intervals are more widespread than originally thought (Remnant et al. 2015). For many years, the average duration of oestrus was recognised as being about 15 hours, with a wide range of 2 to 30 hours. However, there is good evidence that oestrus is much shorter in the modern Holstein cows, as compared to heifers, perhaps an average of 8 hours (Nebel et al. 2000, Dobson et al. 2008, Løvendahl & Chagunda 2010). This has been shown using radiofrequency data communication systems (e.g., 'HeatWatch') and is summarised in Table 1.1 (Nebel et al. 1997).

There are a number of factors that can influence the duration of oestrus: breed of animal, season of year, presence of a bull, nutrition, milk yield, lactation number, lameness, type of housing and the number of cows that are in oestrus at the same time (Wishart 1972, Esslemont & Bryant 1976, Roelofs et al. 2010). There is also good evidence that more signs of oestrus are observed during the hours of night, perhaps when the animals are least disturbed (Esslemont & Bryant 1976, Nebel et al. 2000). The optimal timing for artificial insemination (AI) is estimated to be 4 to 12 hours after of onset of oestrus (Roelofs et al. 2010), with spontaneous

ovulation occurring on approximately 28 to 30 hours after the onset of standing oestrus (or 12–18 hours after the end of oestrus) (Roelofs et al. 2005).

Signs of Oestrus

When AI is used, the accurate detection of oestrus by the herdsperson is paramount in ensuring optimum fertility. Poor detection is probably the most important reason affecting delayed breeding (Roelofs et al. 2010). Using traditional visual detection methods, the percentage of cows detected in oestrus varies from less than 50% to 90% of cows in oestrus (Roelofs et al. 2010). This can be further increased with the use of oestrus detection methods (e.g., pedometers, HeatWatch, physical methods) with rates of greater than 80% being reported using pedometers (Firk et al. 2002). However, on a number of commercial farms the detection of oestrus is a real challenge (see Chapters 22 and 25).

There are great variations among individual cattle in the intensity of oestrus signs, with the manifestations tending to be more marked in heifers than in cows. However, it is generally agreed that the most reliable criterion that a cow or heifer is in oestrus is that she will stand to be mounted by another (Williamson et al. 1972, Foote 1975).

The oestrous animal is restless and more active, and through the use of pedometer, there was an average increase in activity of two- to threefold at this time (Kiddy 1977, Lewis & Newman 1984). Furthermore, they showed that 75% of cows had peak pedometer readings on the day of onset of oestrus, whereas 25% peaked the day after oestrus. Equally, it has become clear that the use of pedometers requires them to be baselined for that individual

animal (Roelofs et al. 2010). Cattle in oestrus tend to group with other sexually active individuals and spend less time resting and ruminating, which frequently leads to a reduction in milk yield. Indeed, reduced milk yield reliably indicated the onset of oestrus with a compensatory rebound at the next milking (Horrell et al. 1984). In this study of 73 dairy cows, when a cow produced 25% less milk, there was a 50% chance of her being in oestrus. On the rare occasions, that her yield fell by 75%, then oestrus was always present.

As the cow approaches oestrus, she tends to search for other cows in oestrus, and there is licking and sniffing of the perineum. During this period, especially during oestrus and just afterwards, the cow will attempt to mount other cows. Before she does this she will usually assess the receptivity of the other cows by resting her chin on their rump or loins. If the cow to be mounted is responsive and stands, she will mount and sometimes show evidence of pelvic thrusting (Esslemont & Bryant 1976). If the cow that is mounted is not in oestrus, she will walk away and frequently turn and butt the mounting cow. A positive mounting response lasts about 5 seconds (Hurnik et al. 1975); however, if both cows are in oestrus, then this response increases to about 7 seconds. There is considerable variation in the number of standing events during oestrus between individuals and can vary from 1 to over 50 (Hurnik et al. 1975, Roelofs et al. 2005) (Table 1.1).

In some animals, during oestrus there is a vulvar discharge of transparent mucus with its elasticity causing it to hang in complete,

From Nebel et al. 1997.

clear strands from the vulva to the ground. It also can adhere to the tail and flanks. The vulva may be slightly swollen and congested, and the tail may be slightly raised. The hair of the tailhead is often ruffled, and the skin sometimes becomes excoriated through mounting by other cows. For the same reason, the rear of the animal may be soiled with mud. If at pasture, the oestrous cow may wander from the herd; if isolated, she will bellow. When she has access to a bull, the two animals lick each other, and the cow often mounts the bull before standing to be mounted by him. For a short time after mating, the cow will stand with a raised tail and arched back; if the actual service had been missed, then this posture would indicate that mating had occurred.

The body temperature of dairy cows falls by about 0.5°C on the day before oestrus; then it increases during oestrus and falls by about 0.4°C at ovulation. However, the vaginal temperature of 37.7°C was lowest on the day before oestrus, increased by 0.2°C on the day of oestrus and increased for the next 6 days until a plateau was reached. This was followed by a gradual decline from 7 days before the next oestrus (Lewis & Newman 1984). However, practical detection of this is tedious, but the use of temperature data logger attached to a vaginal implant device may enable such measurements to be made (Fisher et al. 2008, Sakatani et al. 2016). Automated methods of measuring the related increase in milk temperature in the milking parlour have also been described (Maatje & Rossing 1976); however, these milk-based methods often come with high false positive results.

The pH of the vagina also fluctuates throughout the oestrous cycle and is lowest, at approximately pH 7.3 on the day of oestrus (Lewis & Newman 1984).

Within 2 days of service, there is an occasional yellowish white vulvar discharge of mucus containing neutrophil leukocytes from the uterus. At about 48 hours after oestrus, irrespective of being served, heifers and many cows show a bright red sanguineous discharge, with the blood coming mainly from the uterine caruncles.

Cyclic Changes in the Vagina

The main variations are in the epithelial cells of the anterior vagina and in the secretory function of the cervical glands. During oestrus, the anterior vaginal epithelium becomes greatly thickened as a result of cell division and the growth of tall, columnar, mucus-secreting superficial cells. Leukocytic invasion of the vaginal mucosa is maximal 2 to 5 days after oestrus. During dioestrus the epithelial

VetBooks.ir

cells vary from flat to low columnar (Hammond 1927, Blazquez et al. 1989). Copious secretion of mucus by the cervix and anterior vagina begins a day or so before oestrus, which increases during oestrus and then gradually diminishes; it is absent by the fourth day after oestrus. The mucus is transparent and flows readily.

At the same time, the crystallisation pattern of the cervical mucus varies. These can be observed when dried smears of mucus are examined microscopically. During oestrus and for a few days afterwards, the crystals are disposed in a distinct arborisation pattern, whereas for the remainder of the cycle this pattern is absent. This phenomenon, together with the character and amount of cervical mucus, is dependent on the elevated peripheral oestrogen concentration. The postoestrous vaginal mucus shows floccules composed of leukocytes and, as previously mentioned, blood is frequently present.

The hyperaemia of the vaginal and cervical mucosae is progressive during prooestrus and oestrus; the vaginal protrusion of the cervix is tumefied and relaxed such that one or two fingers can be inserted into the cervical os. During metoestrus, there is a rapid reduction in vascularity, and from 3 to 5 days after oestrus the mucosa is pale and quiescent. At the same time, the external os is constricted, and its mucus becomes scanty, sticky and pale yellow or brown. There are also cyclic variations in vaginal thermal conductance and vaginal pH. Namely, there is an increase in vaginal thermal conductance just before oestrus (Abrams et al. 1975). When pH electrodes were placed in the cervical end of the vagina, the pH fell from 7.0 to 6.7 one day before the first signs of oestrus, before decreasing further to pH 6.5 at the start of oestrus (Schilling & Zust 1968). Similarly, vaginal electrical resistance increased during oestrus (Smith et al. 1989). This can be measured using commercially available devices such as Ovascan or Ovatec (Zuluaga et al. 2008, Hockey et al. 2010).

Cyclic Changes in the Uterus

During oestrus the uterus becomes congested, and the endometrium is suffused with oedematous fluid causing its surface to glisten. The muscularis layer is physiologically contractile such that when the uterus is palpated per rectum, this muscular irritability, coupled with the marked vascularity, conveys a highly characteristic tonic turgidity to the palpating fingers. Hence the horns will feel erect and coiled. This tonicity is present on the day before and through to the day after oestrus but is at its maximum during oestrus. With experience the veterinarian can detect oestrus on this sign alone. Between 24 and 48 hours after oestrus, the uterine caruncles show petechial haemorrhage, which gives rise to the postoestrous vaginal discharge of blood. In heifers there are often also associated perimetrial subserous petechiae. During dioestrus the endometrium is covered by a scanty secretion from the uterine glands. Quantification of the morphometric characteristics of the bovine endometrium during the oestrous cycle revealed that the total endometrial area increased during oestrous, whereas the density of the glands increased under the influence of progesterone during the luteal phase (Wang et al. 2007).

Cyclic Changes in the Ovaries

The size and contour of the ovaries will depend on the stage of the cycle. Postmortem sections and transrectal ultrasonography of such ovaries has revealed the most significant structures to be Graafian follicles and CLs. Usually one follicle ovulates, and hence one oocyte is liberated after each oestrus. Classically, the incidence of double ovulations in cows was considered to be 4% to 5% of cows, with triplet ovulations occurring more rarely. However, more recent evidence in the high-producing dairy cow indicates that the double ovulation incidence is more in the range of 13% to 20%. The incidence is greater in multiparous cows compared with primiparous cows. The influence of milk yield remains equivocal (López-Gatius et al. 2005, Lopez et al. 2005) with high incidence (>20%) reported in nonlactating cows (Mann et al. 2007). In dairy cattle about 60% of ovulations are from the right ovary, although in beef cattle the functional disparity between the ovaries is not great.

Follicular Growth and Development

For the purposes of clarity, this section will focus on the mature, unbred heifer. Follicular growth and atresia throughout the oestrous cycle of cattle has been extensively studied (Adams et al. 2008, Scaramuzzi et al. 2011, Ginther 2016). In the studies of Bane and Rajakoski (1961), two waves of growth were demonstrated, with the first wave beginning shortly after ovulation and the second starting in the midluteal phase. Consequently, a dominant follicle of 9 to 14 mm was present from day 5 to 11 of the cycle before becoming atretic. Then, in the second wave the ovulatory follicle developed between day 15 and 20 and was 9 to 16 mm in size. Thus this preovulatory follicle is selected 3 to 5 days before ovulation (Pierson and Ginther 1988). Subsequent studies have demonstrated that there are three, as well as two waves of follicular development (Sirois & Fortune 1988, Savio et al. 1990). In the case of three-wave follicular patterns, waves emerge on days 1, 8 and 16 of the cycle, whereas in two-wave patterns they emerge on day 1 and days 9 to 10 of the cycle. In each case the dominant follicle will undergo atresia if under the influence of progesterone. However, if there is an active dominant follicle present when luteolysis is induced, then this will become the ovulatory follicle. There are reports of majority of either two- or three-wave per cycle; however, others have reported a more equal distribution (Adams et al. 2008). In a small number of cows, four-wave cycles have been observed, although this is usually associated with delayed luteolysis and an extended interoestrous interval of more than 24 days. In contrast, four waves are common in *Bos indicus* cows (Bo et al. 2003) (Chapter 28).

The most notable feature is the regularity of the number of waves of follicular growth per oestrous cycle, which probably reflects genetic or environmental influences. Indeed, the proportion of cows with a repeatable number of waves per cycle within an individual (70%) was twofold greater than those individuals that had alternating patterns (30%) (Adams et al. 2008). Those individuals with two waves per cycle tend to have shorter interoestrous intervals (19.8 days) and larger preovulatory follicles than those animals with three waves (22.5 days). Interesting data (Tables 1.2 and 1.3) was obtained by Sartori et al. (2004) using sequential transrectal ultrasonography and shows some of the effects of parity and/or lactation on folliculogenesis, ovulation and CL formation, as well as serum oestrogen and progesterone concentrations. A noticeable feature is the high number of multiple ovulations in cows (17.9%) compared with heifers (1.9%). In addition, cows had larger ovulatory follicles and luteal tissue mass, but these structures were associated with lower oestrogen and progesterone concentrations, respectively.

The follicular waves are initiated by a small rise in circulatory FSH; if this does not occur or is delayed, the follicular wave also does not occur or is delayed. There is evidence that the follicle that is destined to become the dominant one may be slightly larger and

have a better blood supply than the rest (Zeleznik et al. 1981), such that it responds to the rise in FSH and produces more oestradiol and inhibin, which are critical for being selected for dominance (Scaramuzzi et al. 2011). There is also good evidence that the IGF system plays a critical role in the selection and growth of the dominant follicle in the cow. The IGFs stimulate granulosa cell growth and synergise with FSH to stimulate oestradiol production (see reviews by Fortune et al. (2001) and Mazerbourg et al. (2003)).

This means that during dioestrus several large follicles will be found ranging in size from 7 to 15 mm in diameter. These follicles do not alter the general oval contours of the ovaries, but do cause some overall variation in gross ovarian size. The ease of palpating them transrectally will depend upon the size, degree of protrusion and relationship with the CL. During prooestrus and oestrus, the dominant follicle destined to ovulate enlarges, and ovulation occurs when it has attained a size of 12 to 20 mm (Fortune 1994, Ginther et al. 1996, Adams et al. 2008). On transrectal palpation of the ovaries during oestrus, it is sometimes possible to detect the ovulatory follicle as a slightly bulging, smooth, soft area on the ovarian surface, although it is readily identified using transrectal ultrasonography. Ovulation may occur from any aspect of the ovarian surface, and the subsequent shape of the ovary when the CL develops will be influenced chiefly by this site. The point of ovulation is usually an avascular area of the follicular wall; consequently, haemorrhage is not a feature of bovine ovulation, although there is marked postovulatory congestion around the rupture point and sometimes a small blood clot is present in the centre of the new CL.

The Corpus Luteum of the Oestrous Cycle

After rupture the oocyte is expelled through a small breach in the surface of the follicle, and after the escape of the greater part of its fluid, the follicle collapses. If the opportunity arose for repeatedly carrying out rectal examinations during oestrus and for the subsequent 36 hours, this collapse would be detected. The ovary also frequently feels flattened and soft. However, on a single examination, the detection of the collapsed follicle is challenging, and the ovary can be classified as having no distinctive structure. If such an ovary is examined postmortem, the surface from which ovulation has occurred is wrinkled and distinctively bloodstained. The ovulatory point can also be observed (Ireland et al. 1980, Woad & Robinson 2016). The CL develops by hypertrophy and luteinisation of the granulosa and thecal cells that lined the follicle. Enlargement is extremely rapid, such that within 2 days it will be approximately 10 mm in diameter (Prokopiou et al. 2014). At this stage the developing CL is soft and yields on palpation; it is light brown in colour and the luteinised cells form loose pleats. The CL attains its maximum size by the day 7 or 8 of the cycle (Fig. 1.16). The luteinised pleats are now relatively compact, and the body comprises a more or less homogeneous mass that is orange-yellow in colour. Its shape varies; the majority are oval, but some are irregularly square or rectangular. The greatest dimension of the fully developed structure varies, but typically it is 20 to 25 mm. The changes in the CL dimensions are shown in Fig. 1.17. The weight of a fully developed CL also varies from 4.1 to 7.4 g; sometimes the centre of the CL is occupied by a cavity (Fig. 1.18, 1.28). Such cavities are seen in up to 50% of the CLs collected at abattoirs and are filled with yellow fluid. The size of the cavity varies, but it is small in the majority (approximately 4 mm in diameter). However, occasionally it is larger, up to 10 mm or more (Kastelic et al. 1990). In these cases there is evidence of ovulation as shown by the presence of a pinhead depression in the centre of the CL that projects from the ovarian surface. This serves to differentiate the CL from an abnormality of the cow's ovary in which the follicular wall is luteinised in the absence of ovulation to form a pathological structure, namely a luteal cyst (see Chapter 22). Nevertheless, it is probable that cavity-filled CL were described in the past as a cystic corpus luteum and regarded as pathological; the presence of a cavity in a CL is normal.

Projection of the Corpus Luteum From the Surface of the Ovary

As the CL enlarges, it tends to protrude from the ovary, thus stretching the serosa that covers the surface of the ovary, such that when it attains its maximum size, it often forms a distinct projection. The degree and appearance of this projection vary. In the majority it is a distinct bulge about 10 mm in diameter with a clear-cut constriction where it joins the general contour of the ovary. In other cases it is nipple-like (Fig. 1.16). In a third type, the projection is indistinct, and in this case the CL can occupy the greater part of the ovary. It has been suggested that the type of protrusion that develops depends on the extent of the

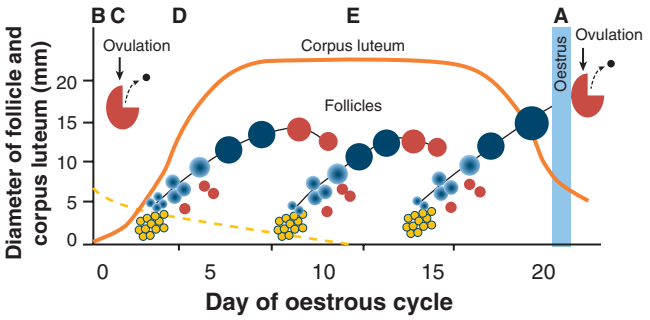
surface of the ovary occupied by the follicle just before ovulation. Figs. 1.19 through 1.27 show bovine ovaries during the oestrous cycle[1].

[1]Throughout the book, drawings of bovine ovaries are of a section from the attached to the free border through the poles. In those cases in which this section did not pass through the greatest dimension of the significant corpus luteum or the largest follicle, the drawing has been made as though it did so, but without materially altering the size of the ovary.



• **Fig. 1.17** The development of follicular waves *(dotted line)* and corpus luteum *(solid line)* during the oestrous cycle of the cow. (A–E refers to Fig. 1.19–1.27.)

Regressing Corpus Luteum

The CL maintains its maximum size and remains unaltered in appearance until luteolysis and the onset of prooestrus. From this point it undergoes a rapid reduction in size and changes in colour and appearance. By the middle of oestrus its diameter is reduced to 15 mm, and its protrusion is much smaller and less distinct. Its colour also changes to a very bright yellow (hence the name corpus luteum: the yellow body). This colour contrasts strikingly with the orange-yellow colour of the active structure. Its consistency becomes compact and dense; scar tissue invasion will commence. By the second day of next dioestrus, its size is reduced to about 10 mm, and its outline is becoming irregular. By this time its colour is changing to brown. By the middle of dioestrus, it has shrunk to about 5 mm, and its surface protrusion is a little larger than a pinhead. As it further regresses, its colour tends to change to red or scarlet; small red remnants of CLs tend to persist for several months.

Size of the Ovaries

From the foregoing account it will be appreciated that the size of an ovary will depend chiefly on the stage in the oestrous cycle at which it is examined and on whether or not it contains an active CL. The presence of follicles does not alter the size of an ovary to anything like the same extent. In the great majority of heifers and young cows examined at any time between day 6 and 18 of the cycle, one ovary will be distinctly larger than the other. In heifers the approximate dimensions of the larger one will be 3.5 cm from pole to pole, 3 cm from the attached to the free border and 2.8 cm from side to side. (All ovarian dimensions given in this book are in this order.) The CL will protrude from some part of its surface, although the degree of protrusion will vary between ovaries. The smaller ovary will have approximate dimensions of 2.5 × 1.5 × 1.2 cm, and it will be flat from side to side.

During the first 4 or 5 days after ovulation, there will be relatively little variation in size, for as yet the developing CL has not attained a sufficient mass to influence the size of the ovary, although the regressing CL will be smaller. During oestrus there will also be little difference in size unless the ovary which contains the developing preovulatory follicle also contains the regressing CL. In this case the ovary containing the two structures will be a little larger than the other, but not strikingly so.

Ovaries of the Multiparous Cow

The ovaries of the normal multiparous cow do not differ greatly from those of the heifer or first calver. However, they tend in

many cases to be larger. This increase in size is due in part to the progressive deposition of scar tissue resulting from prolonged functional activity and in some cases also to the presence of large numbers of small but visible follicles. Typically, the ovary that does not contain a CL measures 4 × 3 × 2 cm. Nevertheless, it is generally possible in middioestrus to detect the CL, which even without a distinct protrusion gives the ovary a plum-like shape, whereas the other is distinctly flattened from side to side. As well as normal follicles and CLs at various stages of development and regression, there are additional structures, namely old scarred CLs of previous pregnancies. They generally show as a white, pinhead-sized projection on the ovarian surface of the ovary and

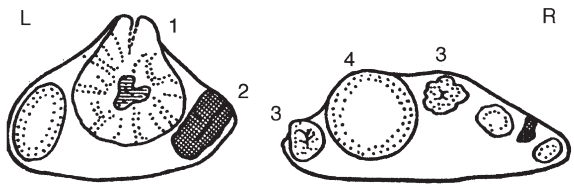
• **Fig. 1.24** Ovaries of a 4-year-old cow in early dioestrus. *(1)* Active corpus luteum, loose pleats, colour orange-yellow, central cavity; *(2)* regressing corpus luteum, dense, and brown colour; *(3)* corpus albicans. Stage C in Fig. 1.17.

are comprised mainly of scar tissue. They are irregular in outline, with a maximum dimension of 5 mm. They are brownish white or white in colour; hence they are called corpus albicans (white body). The CL of pregnancy does not atrophy after parturition as quickly as the CL from the oestrous cycle. It is an appreciable structure for several weeks after parturition, brown in colour and about 10 mm in diameter. It becomes progressively invaded by scar tissue, but remains throughout the cow's life. On postmortem examination the presence of the corpus albicans serves to distinguish the cow from the heifer; in the cow a count of the number of corpora albicantia gives the number of calves born.



• **Fig. 1.25** Ovaries of a 6-year-old cow in early dioestrus. *(1)* Active corpus luteum, orange-yellow, atypical protrusion; *(2)* regressing corpus luteum, small, shrunken, scarlet colour; *(3)* corpus albicans; *(4)* follicle. Stage D in Fig. 1.17.

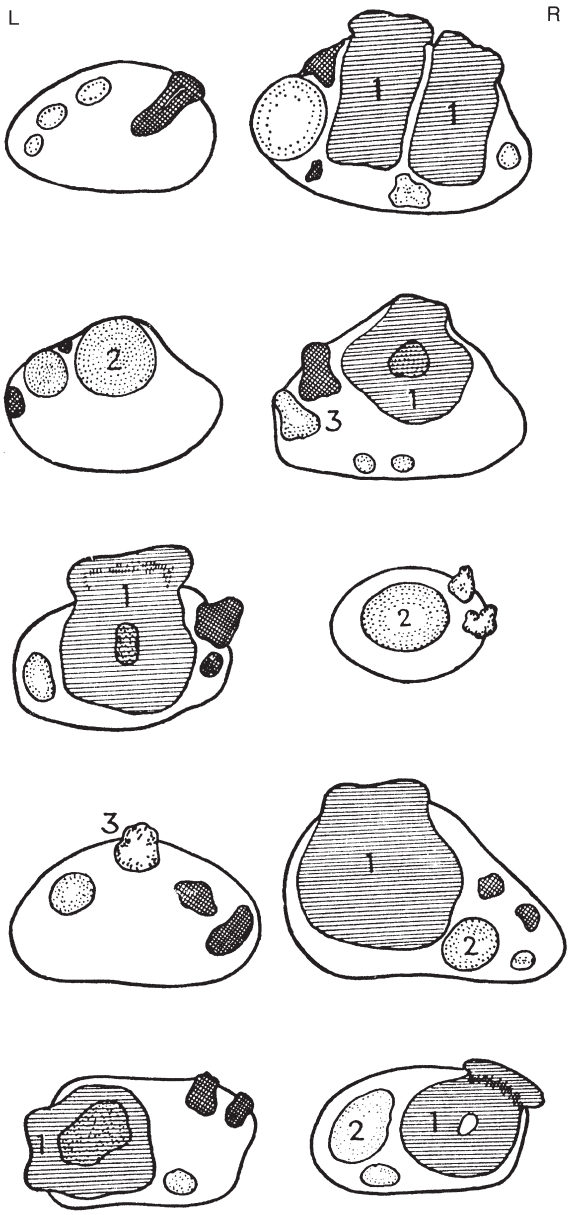
The fully developed corpus luteum is present by day 7 post ovulation and persists unchanged until the onset of prooestrus. Exceptional corpora lutea are shown in Fig. 1.28.

Ultrasonic Appearance of the Ovaries

In previous sections of this chapter, there are descriptions of the texture (as determined by palpation) and the appearance (as determined by sectioning after slaughter) of the ovaries and their contents. The advent of transrectal B-mode, real-time, grey scale ultrasound imaging, particularly using a 7.5 to 10 MHz transducer, has enabled detailed, accurate, sequential examination of the ovaries to be made without adversely affecting the cow's health or fertility. For a detailed description of the echogenic appearance of the ovaries, readers are advised to consult Pierson and Ginther (1984) and DesCôteaux et al. (2009).

The following normal structures can be identified (see Figs. 1.16 and 1.18): the ovarian stroma, antral follicles, CLs and ovarian blood vessels. In addition, pathological structures such as ovarian

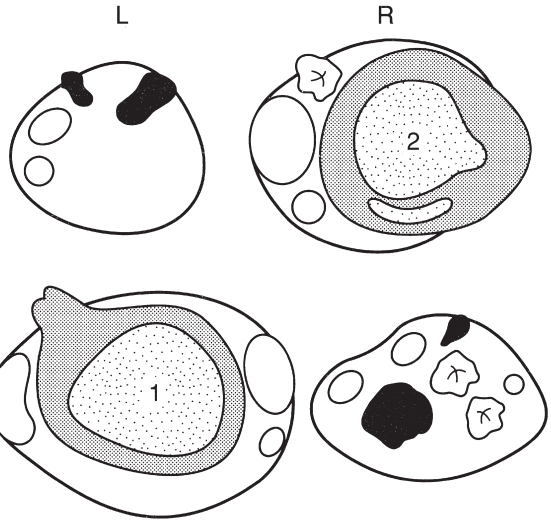
VetBooks.ir



• **Fig. 1.27** Ovaries of parous cows in dioestrus. *(1)* Corpus luteum; *(2)* largest follicle; *(3)* corpus albicans. Stage E in Fig. 1.17.

cysts can be seen; the ovarian stroma has a mottled echotexture. The antral follicles are readily identifiable as anechoic (black) structures of variable size, with a clearly defined line of demarcation between the follicular wall and antrum. Follicles will not always be regular and spherical in shape; typically, follicles with an irregular shape will be atretic. CLs have a well-defined border and a mottled echogenic appearance that is less echogenic than the ovarian stroma. The presence of a fluid-filled lacuna can be readily identified as a dark, nonechogenic area in the centre. Differentiation between developing CLs and CLs that have started to regress can be difficult. As the CL further regresses, it will become isoechogenic with the ovarian stroma (DesCôteaux et al. 2009). Ovarian blood vessels, which can be confused with antral follicles, are black, nonechogenic structures; movement of the transducer will usually demonstrate their elongated appearance.

Over recent years there have been major advances in the use of colour Doppler ultrasound techniques to show haemodynamic



• **Fig. 1.28** Examples of vacuolated bovine corpora lutea, showing single *(1)* and sometimes multiple *(2)* cavities.

changes in the local circulation of the follicle and/or CL. To date, its use has principally been limited to researchers, but the technology offers exciting opportunities. For example, it can be used to measure follicular blood flow enabling identification of normal developing follicle. It can also provide an enhanced imaging modality to distinguish between functional and nonfunctional corpora lutea, i.e., whether the CL is developing or regressing (Bollwein et al. 2016).

Endocrine Changes During the Oestrous Cycle

The trends in concentrations of reproductive hormones in the peripheral circulation are illustrated schematically in Fig. 1.29. It is important to stress that many hormones are secreted in a pulsatile manner and fluctuate considerably day by day; readers are invited to read the descriptions by Peters (1985) and Forde et al. (2011).

Just before the onset of behavioural oestrus, there is a sudden rise in plasma oestrogen, particularly oestradiol. The maturing preovulatory follicle is the source of this oestradiol. Peak values occur at the beginning of oestrus, with a subsequent decline to basal concentrations by the time of ovulation. The prooestrus rise in oestradiol stimulates the LH surge that is necessary for final follicular maturation, ovulation and CL formation; a secondary, less discrete, peak has been demonstrated 24 hours after the ovulatory surge of gonadotrophin (Dobson 1978). During the rest of the cycle, there are fluctuations in plasma oestradiol concentrations along the baseline, although there is a discrete peak around day 6 of the cycle (Glencross et al. 1973). It is hypothesised that this is related to the first wave of follicular growth (Ireland & Roche 1983).

The changes in progesterone concentrations mimic closely the physical changes of the CL. In a number of cows there is evidence of a delay in progesterone production or secretion by the CL (Lamming et al. 1979), which appears to affect the fertility of the individual adversely. Peak values are reached by days 7 and 8 after ovulation and decline fairly quickly from day 18. When progesterone values fall to fairly low basal levels, the removal of the anterior pituitary block allows the sudden release of gonadotrophins. Meaningful prolactin values are frequently difficult to obtain because stress induced by restraint for venepuncture is sufficient to cause a significant rise.

The Sheep

The reproductive season of most breeds of sheep in the UK and Northern Europe is from October to February (it will be the reverse in the southern hemisphere), during which time there are 8 to 10 recurrent oestrous cycles. The stimulus for the annual onset of sexual activity is declining length of daylight. The extent of the breeding season diminishes with increase in latitude; thus at the equator ewes may breed at any time of year, whereas in regions of high latitude – in both northern and southern hemispheres – the breeding season is restricted and distinct, with a prolonged phase of anoestrus after parturition.

The average duration of oestrus in mature ewes of British breeds is about 30 hours and is at least 10 hours less in immature ewes. In Merinos, oestrus may last 48 hours. Ovulation occurs towards the end of oestrus, and the length of the oestrous cycle averages 17 days; it is remarkably consistent between cycles (Bartlewski et al. 2011).

Signs of Oestrus and Mating Behaviour

Oestrous ewes are restless, will seek the ram and together form a following harem. The ram 'tries' members of this group for receptivity, by pawing with a forefoot, rubbing his head along the ewe's side and nipping her wool. A nonreceptive ewe moves away, but when in full oestrus she stands, waggles her tail and moves it laterally. The vulva is slightly swollen and congested, and there is often a slight discharge of clear mucus. The ram mounts and makes a series of probing pelvic thrusts and then dismounts. After variable intervals further mounts occur before intromission is achieved, characterised by a deep pelvic thrust. An essential feature of successful coitus in the Najdi and Awassi breeds of the Middle East is the lateral displacement by the ram of the fat tail of the ewe. Rams of other breeds are unable to move the tail sufficiently to perform intromission.

More ovine matings occur during early morning and evening. When several rams run with a flock, a hierarchy is established, and the dominant male attracts the largest harem. Despite this, a majority of ewes will mate with more than one ram. In addition, ewes show a preference for rams of their own breed or for a ram of their particular group if that group is mixed with other groups of different origin (Lees & Weatherhead 1970). The number of services received by an oestrous ewe averages a little above four. Rams may serve between 8 and 38 ewes in a day.

Changes in the Ovaries

The ovaries of the ewe are smaller than those of the cow, and their shape is nearer the spherical. During anoestrus their size is approximately $1.3 \times 1.1 \times 0.8$ cm, and the largest follicles present vary from 2 to 6 mm. The time period from the primordial to preovulatory follicular stage exceeds 6 months in ewes. Studies of follicular waves are more difficult in ewes than in the cow or mare because transrectal, ultrasonic, sequential access to the ovaries is much more difficult. Although there is some conflicting evidence, most studies indicate that there are two to four follicular waves per oestrous cycle in ewes (Evans 2003). If there are three waves, then there are two during the luteal phase, with the final and ovulatory wave occurring during the follicular phase (Noel et al. 1993, Bartlewski et al. 2011). There is less certainty about the exact endocrine mechanisms involved in folliculogenesis. However, it appears that the stimulus for the emergence of the follicular wave is the transient increase in FSH and that subsequent growth and demise are independent of FSH (Bartlewski et al. 2011). It is also likely that the IGF system, described in the cow, is involved in the selection of the dominant follicles (Scaramuzzi et al. 2011). Because ewes frequently have double ovulations, or more in prolific breeds, the follicles that ovulate can arise from either the same follicular wave or from the subsequent one. This suggests that the follicular dominance is weaker in sheep than in monoovular species (Bartlewski et al. 1999a, Gibbons et al. 1999). Even during anoestrus, folliculogenesis occurs with follicles reaching the size of those frequently present during cyclical activity (Ravindra & Rawlings 1997, Bartlewski et al. 1998).

Follicles destined for ovulation are 6 to 7 mm in diameter, with smaller subordinate anovulatory follicles (5–7 mm). The follicle walls are thin and transparent, and the follicular fluid when viewed externally appears purple in colour. Ovulation of the follicle is preceded by the elevation of a small papilla that develops above the ovarian surface; then ovulation occurs through rupture of this papilla about 36 hours after the onset of oestrus (Cardwell et al. 1998). The development of the CL is rapid, being linear from day 2 to 12 after ovulation (Jablonka-Shariff et al. 1993, Duggavathi et al. 2003). By day 5 of cycle, it is 6 to 8 mm in diameter and attains its maximum size of 11 to 14 mm (Bartlewski et al. 2011). The prolific breeds tend to have smaller ovulatory follicles, and the resulting CLs tend to be smaller (Bartlewski et al. 2011). As the CL develops, its colour changes from blood red to pale pink. Its size remains constant once it has reached its maximal size until the onset of the next oestrus (Bartlewski et al. 1999b). Then luteal regression is rapid and the colour changes, first to yellow and later to brownish yellow.

VetBooks.ir

The luteolytic mechanism is similar to that in the cow: at the end of the luteal phase, there is an increase in the number of uterine oxytocin receptors, and, at the same time, luteal oxytocin stimulates uterine $PGF_{2\alpha}$ secretion and vice versa. The upregulation of the oxytocin receptors is principally regulated by oestradiol and progesterone (Mann et al. 1999). The first CLs formed after the first ovulations at the beginning of the breeding season have a shorter life span than subsequent ones. In twin ovulations, the CLs may occupy the same or opposite ovaries. During pregnancy the CL is a similar size (10–14 mm in diameter) as the cyclic CL (Schrick & Inskeep 1993). Its colour is pale pink, but the central cavity has disappeared, having become filled by white, fibrous tissue.

Ovulation with CL formation, but without signs of oestrus, may occur towards the end of anoestrus and certainly at the first ovulation of the new breeding season. As to the number of oocytes shed at oestrus, genetic and nutritional factors play a part. Hill sheep in the UK generally have one lamb, but if they are transferred to lowland pastures where pasture is rich (before the onset of the breeding season) twins become common. With lowland breeds, the general expectancy is an average of 1.5 lambs per ewe. Age is also a factor in the incidence of twinning, with primiparous ewes very much less likely to have twins than multiparous ones. The maximum prolificacy occurs when ewes are 5 to 6 years old, after which it remains constant. Ewes of the Border Leicester and Lleyn breeds are the most prolific of British sheep and commonly bear triplets. The Finnish Landrace and Cambridge breeds normally produce 2 to 4 lambs per pregnancy. Precise genetic mutations have been identified that affect ovulation rates in high prolificacy breeds such as Inverdale, Hanna, and Booroola (McNatty et al. 2002).

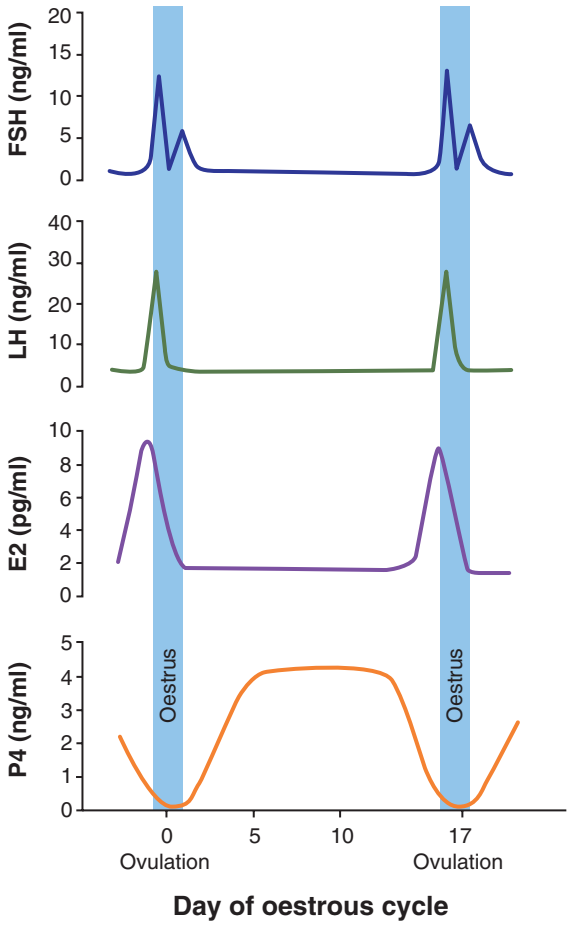
Endocrine Changes During the Oestrous Cycle

The endocrine changes are shown in Fig. 1.30. Just before the onset of oestrus, there is an increase in oestrogens in the peripheral circulation, particularly 17β-oestradiol. This is followed by a sudden surge of LH, which reaches a peak about 14 hours before ovulation and, coincidental with this peak, is a rise in FSH. There is also a second FSH peak 2 days after ovulation (Baird 1978, Rawlings & Cook 1993).

Progesterone concentrations follow closely the physical changes of the corpora lutea, but maximum values are lower than those of the cow, i.e., 2.5 to 4 ng/ml (Bartlewski et al. 2011). Prolactin fluctuates throughout the oestrous cycle; however, concentrations rise during oestrus and ovulation, presumably reflecting the role of this hormone in the formation of the CLs (Campbell et al. 1990).

The Goat

The breeding season in the Northern hemisphere is from August to February, with the greatest activity in the months of October, November, and December. Near the equator there is no evidence of seasonality but continuous cyclic activity. The doe (nanny) goat is polyoestrous, with an average interoestrous interval of 21 days, although this is highly variable particularly at the beginning of the breeding season. The duration of oestrus is 24 to 48 hours (mean 36 hours) and is dependent on age, breed and presence of the male. For example, Angora goats have short oestrus (about 24 hours), whereas Boer goats have relatively long oestrus (about 37 hours). The time from onset to LH surge varies between breeds and individuals, but is typically in the first part of oestrus (approximately 12 hours after oestrus onset) with ovulation occurring 20 to 26 hours later. This means that ovulation relative to oestrus occurs 2 to 36 hours after the onset (Fatet et al. 2011) and generally to the later stages of oestrus.



• **Fig. 1.30** Trends in hormone concentrations in the peripheral circulation of the ewe during the oestrous cycle.

Oestrous behaviour has two phases: (1) proreceptivity in which the doe seeks out and stimulates the male; and (2) receptivity in which the doe will express an immobilisation reflex to the male that involves nudges and standing for mating (Fatet et al. 2011). The detection of oestrus in a doe is difficult in the absence of a male goat. The vulva shows some evidence of oedema and hyperaemia and the tail will wag from side to side and up and down (the most reliable sign according to Llewelyn et al. (1993)). The doe is also restless and more vocal, has a reduced appetite and milk yield and shows mounting behaviour. The presence of the pheromones from the male goat, which can be transferred from the scent gland on to a cloth, will often intensify the signs.

The ovaries are of variable shape, depending upon the structures that are present; the longest dimension is about 2.2 cm. Ultrasonographic studies revealed each cycle has two to six follicular waves, although three to four are most prevalent (see review by Evans (2003)). The preovulatory follicles are 6 to 9 mm in diameter and, when they protrude from the surface, often have a bluish tinge. When multiple ovulations occur, the follicles involved usually arise from the same wave; however, in some cases they arise from consecutive waves. The CLs can be detected 3 days after ovulation and reach 12 mm in diameter by day 8 (Medan et al. 2003). They are pink in colour.

VetBooks.ir

The endocrine changes measured in the peripheral circulation are very similar to those of the ewe (Medan et al. 2003, Fatet et al. 2011).

The Pig

The domestic sow is generally considered to be polyoestrous, but in the wild she is a seasonal breeder, with the main period of activity being late autumn, and a second peak in April (Claus & Weiler 1985). There is some evidence of a photoperiodic influence on reproduction in the domestic sow, with anoestrus more prevalent in summer and less so in February and March. Equally, the ovulation rate is lower in the summer. For the most part the recurrent reproductive cycles of 21 days are interrupted by pregnancy and lactation. Oestrus is typically 40 to 60 hours in duration (mean 53 hours), with spontaneous ovulation occurring between 38 and 42 hours from the beginning (Signoret 1971); oestrus tend to be shorter in gilts. During lactation the physical stimuli of suckling suppresses cyclical activity, but many sows show an anovulatory oestrus 2 days after farrowing. When weaning occurs at 5 or 6 weeks, oestrus can be expected in 4 to 6 days; earlier weaning results in a slightly longer time interval (Soede et al. 2011).

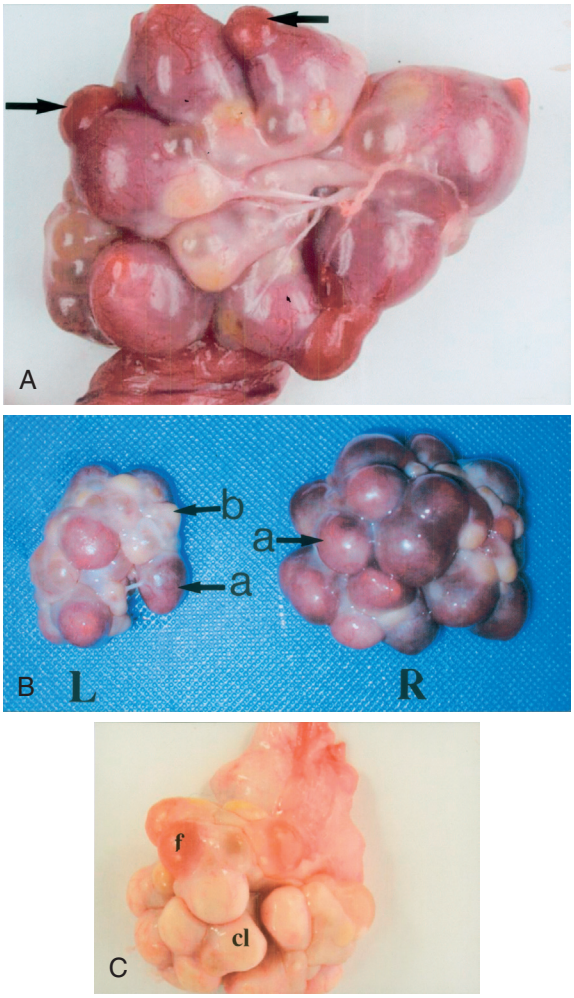
Signs of Oestrus

Beginning 3 days before oestrus, the vulva becomes progressively swollen and congested; these features persist throughout oestrus and then gradually subside during the 3 days afterwards. Restlessness is an unfailing sign of the approach of oestrus, and a peculiar repetitive grunt is emitted. With other sows, the prooestrous animal sniffs their vulvae and may try to ride them or will be the recipient of such attentions. The boar is sought, and in his presence the prooestrous female noses his testes and flanks and may mount him, but will refuse to be mounted. At the height of oestrus, the sow assumes a stationary, rigid attitude with her ears cocked, and she appears to be quite oblivious to her environment. The olfactory and tactile stimuli from the boar are important to observe a standing response. The sow generally remains still during coitus, which lasts an average of 5 to 7 minutes; however, when mating with heavy boars, gilts may become fidgety. Oestrus can be readily detected by firmly pressing the sow's loins with the palms of both hands, such that the oestrous sow will stand motionless with cocked ears. This is known as the back pressure test; the sow not in oestrus will object to this approach (Signoret 1971).

The same immobilisation response can be elicited if the attendant sits astride the sow, and it can also be obtained in the absence of a boar by reproducing the voice or odour of the boar. The substance responsible for boar odour has been identified as 5α-androst-16-ene-3-one and is secreted by the salivary glands (Patterson 1968). In the form of an aerosol, it can be sprayed in the vicinity of sows to promote the standing reaction of oestrus. Silent heat occurs in about 2% of porcine cycles.

Cyclic Changes in the Ovaries

The ovaries of the mature cyclical sow are relatively large and mulberry-like (Fig. 1.31); the lobulated appearance is due to the presence of many large follicles and CLs. The mature, preovulatory follicles attain diameters of 7 to 9 mm. It is much more difficult to study follicular dynamics in the sow than in the cow and mare. First, there are the problems of identifying an individual follicle among large numbers of similarly sized follicles; and second, until the development of small transrectal B-mode ultrasound transducer probes, it has been almost impossible to study changes sequentially in the same animal.



• **Fig. 1.31** Ovaries of sows. (A) Ovary of a sow a few days after ovulation showing a large number of reddish purple corpora lutea (CLs), in some of which the ovulation papilla can be seen *(arrow),* giving them a conical shape. (B) Left *(L)* and right *(R)* ovaries of a sow in middioestrus on the left ovary 5 and on the right 14 CLs of the current oestrous cycle can be seen *(arrow a),* and on the left ovary 4 and on the right 5 CLs of the previous cycle can be seen, which are a white/cream colour *(arrow b)*. (C) Ovary from a sow at 15 to 18 days of the oestrous cycle showing the typical, creamy yellow coloured CLs *(cl)* several follicles *(f)* can be seen. (Courtesy Dr. M. Nevel.)

Unlike other domestic species, there are no clear follicular waves whereby follicles develop up to a dominant stage and then regress if not ovulated. It has been shown that, except during the follicular phase of the cycle, there is continuous proliferation and atresia of follicles, so that there is generally a pool of about 30 to 50 between 2 and 7 mm in diameter (Guthrie & Cooper 1996). In the sow any change in plasma FSH concentration is more subtle than in other species; however, more recent evidence indicates that, during the oestrous cycle, there are FSH surges lasting 2 to 3 days that coincide with changes in inhibin and follicle diameter (Noguchi et al. 2010). The absence of a follicular wave pattern may be due to the different hormones produced by the CLs such as oestradiol and inhibin, which exert a negative feedback effect on FSH

VetBooks.ir

secretion (Driancourt 2001). Between about day 14 and 16 of the cycle, there is a coordinated recruitment of follicles, probably under the influence of gonadotrophin stimulation induced by the decline in progesterone and the withdrawal of its negative feedback effect (Soede et al. 2011). FSH increases the number of recruited follicles, whereas LH is required for growth to preovulatory size. A substantial number of these follicles are destined for ovulation, although it is not possible to identify the preovulatory population until day 21 to 22 of the oestrous cycle. The growth of selected preovulatory follicles during the follicular phase is associated with rapid atresia of small follicles and a block to their replacement in the proliferating pool. This indicates some intraovarian control mechanism (Foxcroft & Hunter 1985). The precise nature of the substances is not fully understood, although various substances have been proposed: steroids, growth factors (epidermal/transforming, fibroblast, and insulin-like), and their related binding proteins (Hunter & Picton 1999).

During lactation LH concentrations and pulsatility are suppressed due to suckling, which inhibits the GnRH pulse generator. As lactation progresses, the suppression of LH wanes, and by the end of lactation sows appear to have synchronised follicular development with follicles reaching approximately 4 to 5 mm in size and then regressing (Soede et al. 2011). At weaning the largest antral follicles will be recruited, and the sow will enter the follicular phase, which lasts 4 to 6 days. Primiparous sows tend to have smaller follicles at weaning than multiparous one. This is likely to result from primiparous sows having a greater negative energy balance during the preceding lactation. As a consequence, primiparous sows have a slightly longer weaning to ovulation interval (WOI) (Soede et al. 2011).

The preovulatory follicle is pale pink in colour with a fine network of surface blood vessels and a very transparent focus that indicates the site of imminent ovulation. The pool of preovulatory follicles is not homogenous, with both larger and smaller follicles present. The LH surge will trigger ovulation and luteinisation of the preovulatory follicle, with ovulation occurring approximately 30 hours after the LH peak. Ovulation itself is likely to occur over a 1- to 3-hour time period; haemorrhagic follicles are common. After ovulation there remain a considerable number of follicles of about 4 mm, which will regress thereafter.

Typically between 15 and 30 follicles will be ovulated each oestrous cycle. Ovulation rate is influenced by breed and factors that affect the growth and development of antral follicles (e.g., nutrition). Thus sows with a more severe negative energy balance are likely to have a reduced ovulation rate.

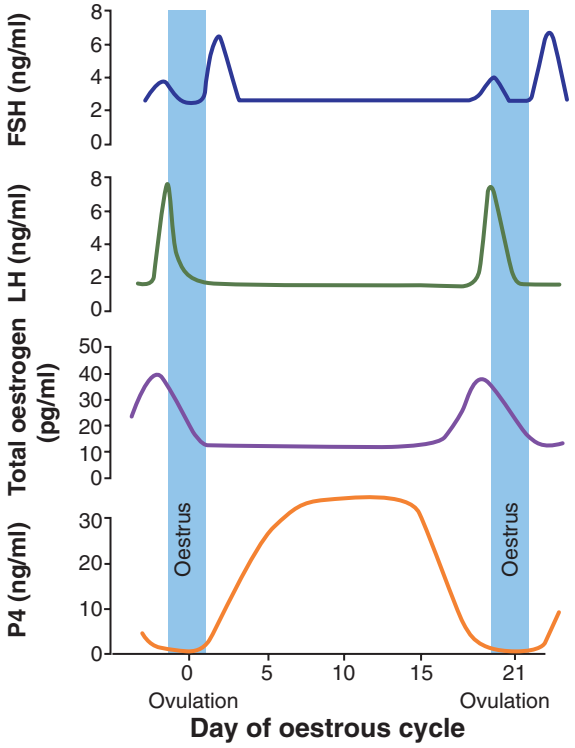
Immediately after ovulation, the ruptured follicle is represented by a congested depression, but the accumulation of a blood clot soon gives it a conical shape (Fig. 1.31A). By day 3, its cavity is filled with a dark red blood clot, which by day 6 is replaced by a connective tissue plug, or yellow fluid (probably serum); this may persist up to day 12. The CLs attain their maximum size at 7 to 9 days, after which they gradually regress to the next oestrus. They are a dark red colour up to day 3, but then change to and remain a red wine colour until day 15 (Fig. 1.31B). As the CLs regress between days 15 and 18, the colour changes rapidly from red wine to yellow, creamy yellow or buff (Fig. 1.31C).

The mechanism of luteolysis is not fully understood in the sow. Although $PGF_{2\alpha}$ is secreted by the uterus as early as days 12 to 16 of the cycle, which is earlier than in other species (Weems et al. 2006), the role of oxytocin in stimulating $PGF_{2\alpha}$ release remains unresolved. The CLs are unresponsive to exogenous $PGF_{2\alpha}$ until about 12 days after ovulation; thus prostaglandins cannot be used to synchronise oestrus in pigs. During the process of luteolysis, the CLs are invaded by macrophages that produce tumour necrosis factor (TNF), and this, in combinations with $PGF_{2\alpha}$, probably causes luteolysis (Weems et al. 2006). In addition, there is also a suggestion that TNF inhibits oestradiol production, thereby removing a luteotrophic source.

There is further rapid luteal regression at the next oestrus, but throughout the succeeding dioestrus, the CLs will remain as distinct entities after which they regress rapidly to grey, pinhead foci. Therefore when a cyclic sow is slaughtered in the first half of the luteal phase, the ovaries may show the red wine–coloured CLs of the current cycle along with the smaller, pale CLs of the previous cycle and the grey specks of the third generation CLs (Fig. 1.31B). During the luteal phases of the cycle, oestrogens are luteotrophic; as a result, it is possible to prolong the life span of the CLs for several weeks, resulting in a pseudopregnancy (Conley & Ford 1989).

Endocrine Changes During the Oestrous Cycle

The endocrine changes are shown in Fig. 1.32. Oestrogens in the peripheral circulation start to rise rapidly when the CLs begin to regress, reaching a peak at the onset of oestrus, approximately 36 hours before ovulation (Noguchi et al. 2010). The ovulatory LH peak occurs 8 to 15 hours after the oestrogen peak. For the remainder of the cycle, LH concentrations fluctuate at low levels, whereas FSH concentrations vary throughout the cycle and appear to have some pattern of secretion; thus there are two surges, one concurrent with the LH peak and a larger one on day 2 or 3 of the cycle (Noguchi et al. 2010). The latter peak coincided with the minimum value of oestradiol (Van de Wiel et al. 1981), and as with other species, the progesterone concentrations closely follow



• **Fig. 1.32** Trends in hormone concentrations in the peripheral circulation of the sow during the oestrous cycle.

VetBooks.ir

the physical changes of the CLs. Peripheral progesterone concentrations reach a maximum of 20 ng/ml, and for the first 8 days after ovulation, there is a good correlation between progesterone levels and the number of CLs; however, by 12 days it is less obvious.

There is a sharp decline in prolactin concentrations within hours of weaning (Shaw & Foxcroft 1985). During the follicular phase two prolactin surges have been identified: the first one is concomitant with the preovulatory LH and oestrogen surges, and a second is just before ovulation (Van de Wiel et al. 1981).

The Dog

Reproductive activity in the bitch differs from the polyoestrous pattern of other species, in that there are no frequent, recurring periods of oestrus, either repeatedly throughout the year as in cattle and pigs or seasonal as in horses, sheep, goats and cats. All bitches have a prolonged period of anoestrus or sexual quiescence between successive oestruses irrespective of whether they have been pregnant or not; this pattern has been described as mono-oestrus (Jochle & Andersen 1977). There is no luteolytic mechanism, and in the nonpregnant bitch the prolonged luteal phase will lasts for 55 to 75 days. It is only comparatively recently that the mechanisms involved in determining the duration of anoestrus and when bitches come into oestrus have started to unfold. In addition, it must be stressed that this, as with much of the work on canine reproduction, has been done on experimental Beagle colonies, which may or may not be representative of the species in general. Anoestrus is 'obligate' enabling time for the endometrium to repair and lasts a minimum of 7 weeks, but averages 18 to 20 weeks (Concannon 2011). Towards the end of anoestrus GnRH pulse frequency and amplitude increases; consequently, FSH concentrations increase in the latter stages of anoestrus. There is strong evidence that dopaminergic substances are involved in initiating folliculogenesis, thus causing the transition from anoestrus to prooestrus and oestrus. When treating bitches with dopamine agonists such as bromocriptine and cabergoline that can shorten the duration of anoestrus, it is possibly acting by inhibiting prolactin secretion; however, metergoline, which lowers prolactin levels via the serotonin pathway, did not shorten the duration of anoestrus. There is evidence that endogenous dopaminergic substances have a direct effect on regulating GnRH secretion, thereby stimulating basal FSH secretion and initiating antral follicle development (see review by Okkens & Kooistra (2006)). Just prior to prooestrus, there is increased LH pulsatility.

The average interval between successive oestrous periods is 7 months, but it is variable (typically 6–10 months), and there is some evidence that the breed of the bitch can have an effect. For example, in the Rough Collie it is 8.5 months (37 weeks) compared to 6 months (26 weeks) in the German Shepherd (Christie & Bell 1971); the other breeds that were studied had mean intervals between these two figures. Mating does not appear to influence the interval, although pregnancy caused a slight increase (Christie & Bell 1971). There does not appear to be any seasonal effect on reproductive function because there is a fairly even distribution of the occurrence of oestrus throughout the year (Sokolowski et al. 1977).

The oestrous cycle is traditionally divided into four phases (Heape 1900).

Prooestrus

The bitch has a true prooestrus characterised by the presence of vulvar oedema, swelling and a sanguineous discharge. Some fastidious bitches show no evidence of discharge, as they are continually cleaning the perineum. The bitch is attractive to males but will not accept the male.

Oestrus

The bitch will accept the male and adopts the breeding stance. The vulva becomes less oedematous, and the vulvar discharge becomes clearer, less sanguineous and less copious.

The duration of prooestrus and oestrus combined is about 18 days, i.e., 9 days each. However, this can be very variable; some bitches showing very little sign of prooestrus before they will accept and stand for the dog, whereas others produce a copious sanguineous discharge during true oestrus. Some bitches also show evidence of sire preference, which can affect the timing. Ovulation usually occurs 1 to 2 days after the onset of oestrus, although, using laparoscopy, it has been observed that some follicles continue to ovulate up to 14 days later.

Metoestrus

This stage starts when the bitch ceases to accept the dog; however, there is dispute about its duration. Some consider that it ends when the CLs have regressed at 70 to 80 days, whereas others measure it in relation to the time taken for repair of the endometrium, namely 130 to 140 days.

Anoestrus

At the end of metoestrus the bitch passes into a period of anoestrus without any external signs; the same is also true after parturition following a normal pregnancy. This phase lasts 2 to 10 months before the bitch returns to prooestrus.

Signs of Oestrus

The first indication that prooestrus is approaching is the onset of slight swelling of the vulvar lips; this generally precedes the commencement of bleeding by several days. Labial swelling is progressive during the prooestrus period. Bleeding attains its maximum early in prooestrus and continues at this level into the early part of true oestrus. During the greater part of prooestrus the bitch, although attractive to the dog, takes no interest in his attentions. She will not stand for him and generally attacks him if he attempts to mount her. A day or so before the end of prooestrus, her attitude changes, and she shows signs of courtship towards the male. These comprise sudden darting movements, which end in a crouching attitude with her limbs tense and her face alert. She barks invitingly, but as the dog approaches she moves suddenly again; she will not yet allow him to mount. With the onset of oestrus, the invitation to coitus is obvious. She stands in the mating position with her tail slightly raised or held to one side, and remains still while the male mounts and copulates. In the later stages of the copulatory tie, which occupies 15 to 25 minutes, she becomes restless and irritable, and her attempt to free herself may cause the male considerable physical embarrassment. After the first 2 days of oestrus, sexual desire gradually recedes but, with the continued persuasion of the male, she will accept coitus until the end of the period. Bleeding, although reduced in amount, generally continues well into oestrus; more often, however, the discharge becomes yellow as oestrus proceeds. Vulvar swelling and tumefaction are greatest at the onset of the stage of acceptance. During the course of oestrus the enlarged labia become softer in consistency; some labial swelling continues into the first part of the metoestrous phase.

Changes in the Vagina and Uterus

Vaginal Smear

The cyclical changes that occur in vaginal cytology have been described in detail (Griffiths & Amoroso 1939, Schutte 1967, Hewitt & England 2000). Vaginal smears stained with either a simple stain such as Leishman's or a Trichrome stain such as Shorra's can, with practice, be used to determine the stage of the oestrous cycle; the advent of the Diff-Quik staining method has greatly simplified the procedure. At the onset of prooestrus large numbers of erythrocytes are present; however, when true oestrus occurs, the number of erythrocytes is reduced, and the smear consists of superficial cell types from the stratified squamous epithelium such as anuclear cells, cells with pyknotic nuclei, and large intermediate cells. Towards the end of oestrus, numbers of polymorphonuclear neutrophil leukocytes appear in the smear. These, together with small intermediate cells, are the dominant cell types during metoestrus. In anoestrus nucleated basal and intermediate cells of the stratified squamous epithelium, together with a few neutrophils, form the characteristic smear.

Fig. 1.33 shows the cyclical changes of the cell types, and Fig. 1.34 shows examples of stained smears.

Vaginal Epithelium

The vaginal epithelium during anoestrus is of the low, columnar, cuboidal type and comprises two or three layers only. During prooestrus the epithelial cells change to the high, squamous, stratified type and persist in this form until the later stages of oestrus. The stratum corneum and the layers immediately beneath it are lost by desquamation during the prooestrous and oestrous periods, leaving a low, squamous structure that becomes converted to columnar epithelium in 1 to 3 weeks after the end of oestrus. During metoestrus (and pregnancy) the epithelium is of a higher columnar type than during anoestrus.

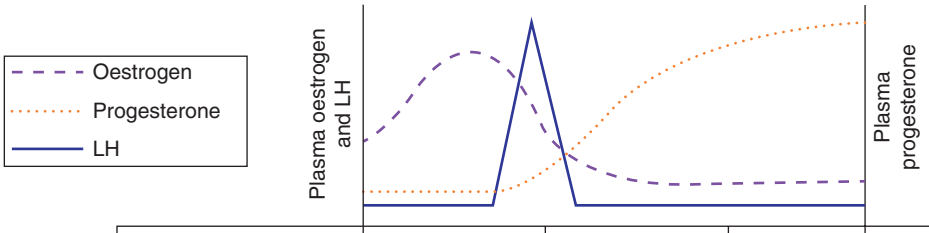
During prooestrus, oestrus and early metoestrus, the epithelium and lamina propria are infiltrated with large numbers of neutrophils, which eventually escape into the vaginal lumen.

Endometrium

The endometrium shows considerable change during the oestrous cycle. The endometrial glands in prooestrus and oestrus are loosely coiled with very obvious lumina and deep epithelial lining. During metoestrus the glands become larger, the lumina smaller, and the coiled parts in the basal layer of the endometrium more tortuous. As the bitch passes into anoestrus, there is a reduction in the amount and degree of coiling of the glands. At about 98 days after the onset of oestrus, i.e., in metoestrus, there is evidence of desquamation of the endometrial epithelium; however, by about 120 to 130 days the epithelium has been restored by proliferation of cells from the crypts of the endometrial glands.

Changes in the Ovaries

During anoestrus the ovaries are oval and slightly flattened. In a bitch of medium size, they measure approximately 1.4 cm from pole to pole and 0.8 cm from the attached to the free border. No



Cell type		Prooestrus Early	Prooestrus Late	Oestrus Early	Oestrus Late	Early metoestrus	Anoestrus	Vaginitis pyometra

(A) Anoestrus: parabasal epithelial cells and small intermediate epithelial cells. (B) Prooestrus: small intermediate epithelial cells, large intermediate epithelial cells and erythrocytes. Polymorphonuclear leucocytes are also found in low numbers during this stage of the cycle but are not demonstrated here. (C) Early oestrus: large intermediate epithelial cells, anuclear epithelial cells and erythrocytes. Polymorphonuclear leucocytes are generally absent during this stage of the cycle. (D) Oestrus: anuclear epithelial cells, large intermediate epithelial cells and erythrocytes. The percentage of anuclear cells is high. (E) Metoestrus (higher magnification than A = D): small intermediate epithelial cells and large numbers of polymorphonuclear leucocytes. During early metoestrus large intermediate epithelial cells may be present; later numbers of parabasal epithelial cells increase. There is often a large amount of background debris. (F) Late metoestrus (higher magnification than A = D): parabasal epithelial cells and small vacuolated intermediate epithelial cells are typical of this stage of the cycle but may also be found during anoestrus and more rarely during prooestrus.

appreciable follicles can be seen, although on section the minute remnants of the CLs of the previous cycle may be seen as yellow or brown spots. In the young bitch, the surface of the ovaries is smooth and regular, but in the aged animal it is irregular and scarred. At the commencement of prooestrus, developing follicles have already attained a diameter of 4 mm (England & Allen 1989). They progressively enlarge until, at the time of ovulation, their size varies from 7 to 11 mm (England & Allen 1989, Hayer et al. 1993). By this time the ovary is considerably enlarged, its size depending on the number of ovulatory follicles present; its shape is irregular because of the projection of the follicles from its surface. Because of the thickness of the follicle wall, it may be difficult to distinguish between follicles and CLs. Prior to ovulation, the surface of the follicle shows a slightly raised papule, pinhead-sized, and the epithelium covering it is brown, which contrasts with the flesh colour of the remainder of the follicle. A remarkable feature of the ovulatory follicle of the bitch is the thickness of its wall. This is due to hypertrophy and folding of the granulosa cells, which can be seen on section with the naked eye as evidence of preovulatory luteinisation.

VetBooks.ir

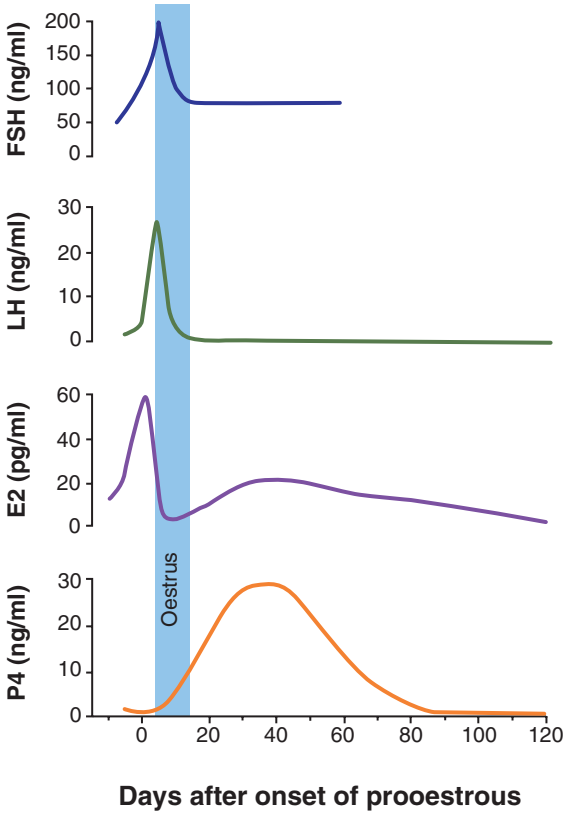
Ovulation is spontaneous, and normally occurs 48 to 60 hours after the LH surge (Concannon 2011). Ovulation is nearly always synchronous among the ovulatory follicles (Concannon 2011). Unlike other domestic species in which a secondary oocyte is ovulated, the oocyte in the bitch is ovulated at the primary stage. The oocyte will then mature and become a secondary oocyte and is capable of being fertilised after 96 to 108 hours. The secondary oocyte remains viable for 24 to 48 hours (day 5 or 6 after LH surge), but occasionally up to 144 hours (day 10) after ovulation (Tsutsui et al. 2009). The CL at first contains a central cavity, but becomes filled by compact luteinised cells within 10 days of ovulation, by which time the body has attained its full size (6–10 mm); CLs now comprise the greater mass of the ovary. As a rule, an approximately equal number of CLs are found in each ovary, although occasionally there are wide differences. In this connection it is interesting to note that the numbers of fetuses in the respective uterine horns during pregnancy frequently differ from those of the CLs in the ovaries on the respective sides. Thus it appears that embryonic migration into the uterine horn on the contralateral would appear to be common. On section the CL is yellowish pink in colour, and it remains unchanged in the nonpregnant bitch until about the 30 days after ovulation, after which it slowly undergoes atrophy. Visible vestiges may be present throughout anoestrus. During pregnancy the CLs persist at their maximum size throughout, but regress fairly rapidly after parturition.

Ultrasound Appearance of the Ovaries

Using a transabdominal approach via the flank with the bitch standing and a 7.5 MHz real-time linear array transducer, England and Allen (1989) were able to identify ovarian structures at the onset of prooestrus that were circular and anechoic and were obviously developing antral follicles. When the bitch was in oestrus, they had increased in size, reaching a maximum of 4 to 10 mm in diameter on day 13 (day 0 being onset of prooestrus) (Hayer et al. 1993). The walls of the follicles became thickened from day 10 onwards, presumably because of preovulatory luteinisation. Ovulation was characterised by decreased number of fluid-filled follicles with similarly-sized hypoechoic structures. There is further gradual thickening of the wall as the CLs develop, with the eventual obliteration of the central anechoic cavity (England & Yeager 1993); there was no evidence of follicular collapse associated with ovulation. At 25 to 30 days after the onset of prooestrus, the ovaries were difficult to identify.

Endocrine Changes During the Oestrous Cycle

The trends in endocrine changes are shown in Fig. 1.35. The main feature that distinguishes them from other domestic species is the prolonged luteal phase, illustrated by the persistence of high progesterone levels in the peripheral blood. It is noticeable that progesterone levels start to rise before ovulation has occurred, which confirms the morphological evidence of preovulatory luteinisation of the mature follicles 60 to 70 hours before ovulation (Concannon 2011). This preovulatory rise in progesterone may provide the stimulus for the bitch to accept the male (Concannon et al. 1975). In addition, it is used as a method to determine the optimal timing of artificial insemination. In that peripheral plasma progesterone concentrations should have increased above the baseline (less than 1 ng/ml), with mating or insemination planned for 4 to 6 days after the progesterone rise is first detected



• **Fig. 1.35** Trends in hormone concentration in the peripheral circulation of the bitch during the oestrous cycle. (From Jeffcoate 1998; de Gier et al. 2006.)

or, ideally, the day after values exceeded a threshold as determined by the assay kit (Hewitt & England 2000).

Oestradiol rises rapidly during prooestrus and peaks just before the onset of standing oestrus; this is accompanied by an increase in androstenedione and testosterone concentrations. An oestradiol peak occurs on average one day before the LH peak (de Gier et al. 2006), which lasts much longer than that of other species (36 ± 55 hours; de Gier et al. (2006)), with ovulation occurring 48 to 60 hours after this (Phemister et al. 1973, Concannon 2011). The preovulatory LH surge is generally accompanied by the FSH surge, with FSH concentrations reaching a peak at oestrus and coinciding with that of LH, but lasting much longer (110 ± 8 hours; de Gier et al. (2006)). Peripheral progesterone concentrations continue to increase after ovulation and peak around 25 days after ovulation. Thereafter, progesterone concentrations will gradually decline and remain above 1.5 ng/ml until day 70 (Concannon 2011).

Prolactin is required in addition to LH to support luteal function in the bitch. Prolactin appears to have a negative correlation with progesterone from about 25 days after ovulation; thus as progesterone levels fall towards the end of metoestrus or pregnancy, prolactin concentrations increase and therefore maintains the CLs. It is the major luteotrophic hormone in this species. During pregnancy there is enhanced secretion of prolactin from the placenta, which is responsible for elevated progesterone concentrations in the pregnant bitch compared with nonpregnant counterparts.

Progesterone and oestradiol concentrations are low during anoestrus. LH is also generally low, but there will sporadic spikes of LH. Conversely, FSH concentrations will be high (presumably due to lack of negative feedback of progesterone and oestradiol on the hypothalamus) with sporadic spikes of FSH that are concomitant

VetBooks.ir

with the LH spikes. FSH will gradually increase towards prooestrus (Concannon 2011); during prooestrus, FSH concentrations will decrease as the oestradiol concentrations rise.

Pseudopregnancy

Most, if not all, bitches show some evidence of pseudopregnancy during metoestrus, with intensity and signs being very variable. For this reason it is preferable to refer to *covert* pseudopregnancy, in which the bitch will be in metoestrus but will show little or no signs, and *overt* pseudopregnancy. In the latter, the clinical signs will range from slight mammary development and lactogenesis, while at the opposite extreme the bitch will show all the external signs of pregnancy and will ultimately undergo a mock parturition, with nesting, loss of appetite, straining, emotional attachment to inanimate objects and heavy lactation.

Pseudopregnancy was originally believed to be due to an intensification and prolongation of metoestrus; however, a number of studies have demonstrated that there is no difference in the progesterone concentrations in the peripheral blood of bitches with or without signs of pseudopregnancy. It is likely that prolactin is responsible for initiating the changes, with the decline in progesterone appearing to coincide with the rise in prolactin. If bitches undergo ovariohysterectomy when they are pseudopregnant, then the condition can be intensified and prolonged. Furthermore, prolactin inhibitors such as bromocriptine and cabergoline have been successfully used to cause remission of the signs of pseudopregnancy and are now widely used in veterinary clinical practice.

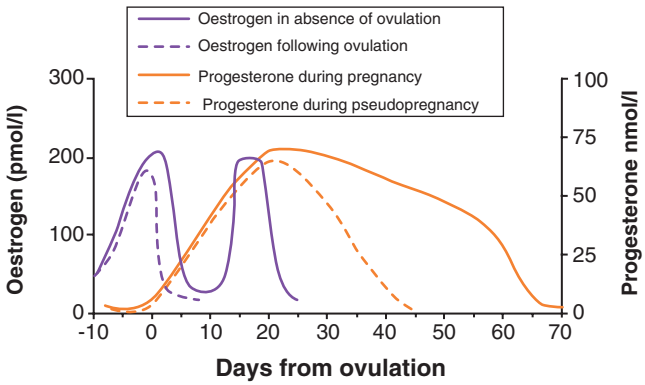
The Cat

In most breeds, females will usually show their first oestrus once a body weight of 2.3 to 2.5 kg has been attained, at an approximate age of 7 months. Puberty is also influenced by the season of birth; females born very early in the year may mature in the autumn of that year, whereas those born later will not normally show oestrus until the following spring (Gruffydd-Jones 1982). The time of onset of puberty is much more variable in pedigree cats (Jemmett & Evans 1977).

Free-living nonpedigree and feral cats are seasonally polyoestrous, with a period of anoestrus beginning in the late autumn. Increasing daylight length is the most important factor inducing the resumption of reproductive activity, and the first oestrus usually occurs after the shortest day of the year. There may be a period of apparent lack of oestrous activity in the early summer, but this corresponds with the pregnancy or lactation following mating earlier in the year rather than true anoestrus. Essentially, there are four possible outcomes following oestrus in the queen:

1. A mating occurs that induces ovulation (24–36 hours later), CL formation and if there is a fertile mating, then pregnancy is likely to occur.
2. A mating occurs; there is likely to be ovulation, CL formation, but no fertilisation and a pseudopregnancy will ensue.
3. Mating may or may not occur; there may be no ovulation, which will be followed by follicular regression and atresia and, after a short interoestrous interval of a few days, a return to oestrus. In some cases, the interoestrous interval is so short that some individuals may appear to be continuously oestrus.
4. At the end of the breeding season, in which there is no ovulation, the queen cat may become anoestrus.

Some nonpedigree cats have regular oestrous cycles lasting approximately 3 weeks, but others may show no regular pattern



• **Fig. 1.36** Changes in the mean peripheral plasma concentrations in the queen cat of progesterone (during pregnancy and pseudopregnancy) and oestrogen (in the absence of ovulation and following ovulation).

(Shille et al. 1979). The duration of oestrus is 5 to 8 days and is not significantly shortened by mating (Shille et al. 1979, Wildt et al. 1981). Oestrous cycle patterns show considerably more variation in pedigree cats. Long-haired cats may have only one or two oestrous cycles each year, whereas the period of oestrus may be longer in Oriental queens with a reduced interoestrous interval. Oestrogen concentrations increase dramatically at the time of oestrus from the baseline of 60 pmol/l and may double within 24 hours, reaching a peak of up to 300 pmol/l (Shille et al. 1979) (Fig. 1.36). The principal oestrogen produced by the ovary is 17β-oestradiol. The rapid rise in oestrogen concentrations corresponds to an abrupt appearance of behavioural changes indicative of oestrus, and queens do not usually show a distinctive prooestrous phase.

The oestrual display is characterised by increased vocalisation, rubbing and rolling. The queen becomes generally more active and will solicit the attention of a tom; she may adopt the mating posture either in response to the tom or, occasionally, spontaneously. She lowers her front quarters with the hind legs extended, resulting in lordosis. The tail is held erect and slightly to one side. There may occasionally be a slight serous vaginal discharge, but there are usually no changes in the appearance of the external genitalia. The extent of the oestrual display varies considerably between queens, but is generally more prominent in the Oriental breeds.

Mating and Ovulation

During mating the tom mounts the queen and grasps her neck with his teeth. The queen's hind legs paddle as he adjusts his position, and this becomes more rapid during coitus, which lasts up to 10 seconds. The queen cries out during copulation, and as the tom dismounts, she may strike out at him, displaying the typical rage reaction. This is followed by a period of frantic rolling and licking at the vulva. As soon as this postcoital reaction has ceased, the tom will usually attempt to mate the queen again, and there may be several matings within the first 30 to 60 minutes.

At oestrus, there are 5 to 8 follicles present in both ovaries, and they are 3 to 4 cm in diameter at the time of ovulation (Wildt et al. 1980, Shille et al. 1983); the cat is an induced ovulator, and thus mating is important in triggering ovulation. Receptors are present within the queen's vulva that are stimulated during copulation, ultimately triggering the release of LH from the anterior pituitary. Only about 50% of queens will ovulate after a single mating, and multiple matings may be required to ensure adequate release of LH to induce ovulation (Concannon et al. 1980). The

VetBooks.ir

ovulatory surge of LH begins within minutes of coitus, peaks within 2 hours and returns to basal values within about 8 hours; peak LH concentrations of greater than 100 ng/ml have been reported (Shille et al. 1983, Tsutsui & Stabenfeldt 1993). Further matings before the peak of LH concentrations has been reached will lead to additional increments. However, after multiple matings over a period of 4 hours or more, further matings may fail to induce any additional increase in LH concentrations. This is thought to result from depletion of the pituitary pool of the hormone or development of refractoriness to GnRH (Johnson & Gay 1981).

Ovulation is an all or nothing phenomenon, and once significant concentrations of LH have been achieved all ovulatory follicles will rupture (Wildt et al. 1980). It has been estimated that ovulation occurs 30 to 40 hours after coitus (Wildt et al. 1980, Shille et al. 1983). The mean ovulatory rate for nonpedigree cats is approximately four, but is more variable in pedigree animals.

Occasionally, ovulation will occur in the absence of any contact with entire toms. Receptors similar to those found in the vulva are also located in the lumbar area (Rose 1978), and these may be stimulated if the queen is mounted by other females or castrated male cats, or even by stroking over this area. Neutered toms may mate queens in oestrus, even if they have been castrated prepubertally. However, in a study involving a colony of American shorthaired cats in which the queens were housed individually and in which tactile stimulation of the hindquarters and perineal regions by handlers was avoided, ovulation was detected as defined by progesterone concentrations great than 4.8 nmol/l in the peripheral circulation. The queens had sight and sound of other cats, including males. It is noteworthy that six of the seven cats that ovulated were older than 7 years of age (Lawler et al. 1993).

Pseudopregnancy

Sterile matings that successfully induce ovulation will lead to pseudopregnancy. Concentrations of progesterone are very similar to those of pregnancy for the first 3 weeks (Fig. 1.36), after which levels gradually fall, reaching baseline by approximately 7 weeks (Paape et al. 1975, Shille et al. 1979) (Fig. 1.36). Oestrus will usually occur shortly afterwards.

Nesting behaviour and milk production are rarely seen in pseudopregnant queens, but hyperaemia of the nipples will usually be evident as in pregnancy. The queen's appetite may increase, with some redistribution of fat leading to an increase in abdominal size.

Reproductive Physiology of Male Animals

TIMOTHY J. PARKINSON

The reproductive organs (Fig. 2.1) of the male animal have three major functions: production of spermatozoa in the testis, maturation, storage and transport of spermatozoa within the duct system, and deposition of semen within the female genital tract via the penis. The functions of the male hormones are also threefold: maintenance of spermatogenesis, production of masculine behaviour (primarily libido and aggression), and development of the masculine body form.

Anatomy of the Male Reproductive System

Testis, Spermatic Cord, and Scrotum

The testes of all domestic male animals are located at the inguinal region within a scrotum. In the bull and the ram this structure is pendulous and has an elongated neck**,** but in most other domestic species the scrotum is closely applied to the inguinal region. The scrotum consists of a skin pouch overlying various fibroelastic and muscular layers, of which the most prominent is the tunica dartos (Fig. 2.2). The dartos layers are confluent between the testes, where they form the intertesticular septum. In the boar the external spermatic fascia is also prominent. The testis itself is surrounded by two layers of peritoneum, which are formed during its descent into the scrotum, as a single outpouching of the parietal peritoneum, through the inguinal canal. The outer layer of peritoneum, the processus vaginalis (tunica vaginalis reflexa), is reflected on to the testis to form the serous outer layer of that organ, the tunica vaginalis propria. Accompanying this outpouching of peritoneum through the inguinal canal is a diverticulum of the internal abdominal oblique muscle, which inserts on to the cremasteric fascia and the vaginal tunics. This muscle, the cremaster, raises or lowers the testis in response to the immediate environmental temperature or noxious stimuli.

The capsule, or tunica albuginea, of the testis is composed principally of fibrous tissue but has a smooth muscle component whose function is largely unknown. Overlying the capsule is the tunica vaginalis propria. The main blood vessels of the testis are distributed over the surface of the tunica albuginea, before penetrating the capsule to supply the testicular parenchyma; the innervation of the testis is mainly confined to the periphery, and little nervous tissue is found in its substance. The substance of the testis (Fig. 2.3) is composed of two main tissues: seminiferous tubules and interstitial tissue. Each seminiferous tubule is a highly convoluted, unbranched tube that opens at both ends into collecting tubules and then into the rete testis. The seminiferous tubules are limited by a basement membrane, which is partially surrounded by contractile myoid cells. Within the tubule the seminiferous epithelium is composed of two main cell lines: somatic Sertoli cells and the sperm-producing germinal cell lines. Interstitial tissue, which consists of steroid-producing Leydig cells, blood vessels, and lymphatics, exhibits much variation in its quantity and morphology between species. For example, Leydig cells in the ram occur in small clusters around blood vessels, interspersed in relatively large lymphatics, whereas the interstitial tissue of the boar has densely packed Leydig cells and small lymphatics (Fawcett 1973).

At the ends of each seminiferous tubule, there is a transitional zone between spermatogenic tissue and the rete testis. In ungulates and carnivores the rete testis is in the centre of the testis within the fibrous matrix of the mediastinum, although its position differs in rodents and primates. The number of seminiferous tubules opening into each of the transitional zones varies between species, as does the number of channels comprising the rete (Setchell & Breed, 2006). The rete testis consists of a network of interconnecting channels with a simple epithelial lining that moves the sperm into the epididymis. The rete opens into the epididymis via 13 to 20 efferent ducts (Hemeida et al. 1978). These tubules are initially relatively straight but have a long convoluted section before opening into the epididymal duct. Fluid resorption occurs in both rete testis and efferent ducts.

The epididymis is a single, highly convoluted tube into which the vasa efferentia drain the seminiferous tubules. Grossly, the epididymis appears as an approximately cylindrical organ, which is divided into a prominent head that is situated close to the suspension of the testis from the spermatic cord, a smaller, medially situated body, and a distended tail that is continuous with the ductus deferens (vas deferens). The muscular wall of the epididymal duct moves sperm through its lumen by peristalsis so that, during their passage through the epididymis, sperm, which are immature on release from the testis, undergo final maturation. The tail of the epididymis also acts as a reservoir for fully mature sperm, which becomes turgid with the accumulation of stored sperm in sexually active animals. In domestic animals the epididymis is closely applied to the exterior of the testis, whereas in rodents and primates the connection is much looser.

The vas deferens is a relatively thick-walled, muscular tube that acts as both a reservoir for sperm and the means of their conduction between the epididymis and the penis. It is situated mediocaudally within the spermatic cord, in a small diverticulum of peritoneum. In addition to the vas deferens the spermatic cord also contains the arteries, veins, and nerves supplying the testis,

All the layers are closely apposed to their adjacent structures so that the only (potential) space is the cavity of the vaginal tunic. (Redrawn with permission from Cox 1982.)

all of which are contained within the peritoneal vaginal tunics. Together, these structures form the spermatic cord. The spermatic sac includes the spermatic cord, the internal spermatic fascia, cremaster muscle, and cremasteric fascia. The cremaster muscle is situated on the opposite side of the sac to the vas deferens (i.e., on the cranio–lateral surface). The vasa deferentia enter the abdomen through the inguinal canals, from where they run in a caudal direction to join the pelvic urethra where the latter organ joins the neck of the bladder.

A number of short ligaments exist between the various structures within the scrotum, as shown in Fig. 2.4. The proper ligament of the testis joins the ventral pole of the testis to the tail of epididymis, which is also joined to the vaginal tunic by the caudal ligament of the epididymis. These ligaments are derived from the gubernaculum. Finally, on the external surface of the vaginal tunic, the scrotal ligament joins the tunic to the scrotal fascia.

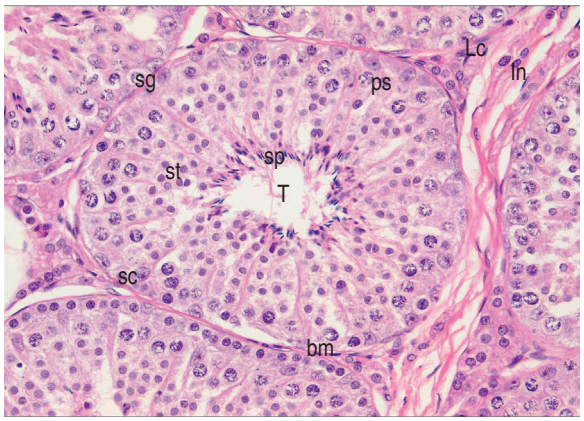
Blood and Nervous Supply to the Testis

The testes are supplied with blood through the spermatic arteries, which arise from the caudal aorta close to the renal arteries. In the domestic species these arteries pass through the inguinal canal, enclosed in peritoneum, forming a major component of the spermatic cord. In animals with scrotal testes the spermatic artery becomes highly convoluted from the point at which it passes through the inguinal canal, although the degree of convolution is less if the scrotum is inguinal than if pendulous. In the bull the spermatic artery in the spermatic cord is approximately 5 m in length (Setchell & Breed 2006). The artery does not divide until it reaches the testis (Setchell & Breed 2006), at which point it divides into major distributing arteries that run over the surface of the testis before descending into its parenchyma.

The testis is drained by an anastomosing plexus of veins (the pampiniform plexus) that arise in the tunica albuginea and return to the spermatic cord through the inguinal canal and thence to the caudal vena cava. Initially, many veins are identifiable in the plexus, but as the plexus ascends the spermatic cord, fewer and fewer collateral branches are apparent until a few main veins penetrate the inguinal canal. These finally join, as a single vein, with either the caudal vena cava or renal vein (Setchell & Breed 2006). In the bull, veins of different sizes are present in the plexus: large veins running parallel to each other and surrounding the spermatic artery, smaller veins with a less organised architecture, and tiny veins in or closely applied to the walls of the spermatic artery. All these veins communicate with one another (Hees et al. 1984), and there is also evidence of arteriovenous anastomoses within the spermatic cord.

The spermatic artery is therefore in very intimate contact with the pampiniform plexus. This complex vascular anatomy fulfils several functions. The extension of the length of the spermatic artery results in the arterial pulse being almost completely eliminated by the time the artery reaches the testis (Waites & Moule 1960). In the rat (Maddocks & Setchell 1988) the pulse is reduced from 34 mm Hg at the proximal end of the spermatic cord to 6 mm Hg at the testicular end. It appears that a pulsatile arterial blood supply to the testis is incompatible with normal spermatogenesis. Second, spermatogenesis is more efficient at temperatures lower than the mammalian core body temperature. The close apposition of artery and veins allows heat exchange to occur between spermatic artery and vein such that the temperature in the testis is several degrees lower than the core body temperature. Third, it is possible that some countercurrent exchange of small molecules such as testosterone may occur between spermatic vein and artery, although the importance of such transfers remains to be established.

The nervous supply of the testis is derived from the thoracolumbar sympathetic outflow, whose visceral motor fibres innervate the smooth muscle of the testicular arterioles and of the testicular and epididymal capsules. These fibres and their accompanying visceral sensory fibres run in the spermatic cord. The scrotum has both visceral and somatic innervation, which is derived from nerves that pass through the inguinal canal, and arise as branches of the pudendal nerve. A further prominent feature of the innervation of the scrotum is the motor supply to the cremaster muscle and dartos. However, as might be expected from the interspecies variation in anatomy of the scrotum, there is also considerable variation in the detail of its nervous supply.



• **Fig. 2.3** Histology of the testis. TABLE 2.1 Accessory sex glands of the main domestic species

Species	Ampulla	Prostate	Vesicular Gland	Bulbourethral Gland
Cat		++		++
Dog	(+)	+++		
Horse	++	++	++	+
Cattle	(+)	++	+++	+
Sheep	(+)	++	+++	+
Pig		+	++	+++

The relative size and importance is indicated by the number of + symbols. Ampullary glands are present in species marked (+) but are not anatomically prominent.

Accessory Glands

The accessory glands include the ampullae, prostate, vesicular glands, and bulbourethral (or Cowper's) glands. There is much variation between the anatomy of the accessory glands in the different species, which is summarised in Table 2.1.

Structure and Function of Spermatozoa

Spermatozoa are divided into three main segments: the head, midpiece, and tail (Fig. 2.5). The head consists of little other than the condensed nucleus and the overlying acrosome. Of the other enzymes contained within the acrosome, the main two are acrosin and hyaluronidase. During the acrosome reaction the outer acrosomal membrane fuses with the sperm membrane, under the control of intra- and extracellular calcium, whereupon exocytosis of the contents of the acrosome occurs (Harrison & Roldan 1990). The main functions ascribed to the acrosomal enzymes are dispersal of the cumulus oophorus and local lysis of the zona pellucida. The inner membrane of the acrosome is relatively stable and remains intact after the acrosome reaction has occurred; some of the acrosomal enzymes are probably bound to the inner acrosomal membrane (Ferrer et al. 2012). Penetration of the zona pellucida and fusion with the oolemma are both receptor-mediated events, with specific areas of the sperm head binding to target components of the oocyte (Wassarman 1990). The classical proposed sequence of acrosome reaction and fertilisation is that the acrosome reaction is initiated in the cumulus oophorus and that the action of the acrosomal enzymes plus the hypermotility of the capacitated sperm propels the sperm through the cumulus until it binds with the zona pellucida (Jin et al. 2011). However, there is evidence for zona-induced acrosome reaction in some species, whereas in others, induction of the acrosome reaction by the cumulus, rather than by the zona, may be required for successful fertilisation (Gadella 2013). Moreover, there is now evidence that acrosin, apart from any role it has in dispersal of the cumulus or zona, is also involved in the binding between the sperm head and the oolemma (Mao & Wang 2013).

The midpiece and tail of the sperm may be considered to form a single functional entity. The tail itself consists of a central axoneme, which, in the region of the midpiece, is sheathed in a helix of mitochondria (Bedford & Hoskins 1990, Amaral et al. 2013). Sperm metabolise simple molecules, principally sugars and their derivatives (e.g., fructose, glucose, mannose, and pyruvate), by both aerobic and anaerobic pathways to provide energy for motility and the maintenance of ionic gradients across membranes (Florman & Sulcibella 2006). Forward motility of sperm results from coordinated waves of flagellar bending progressing from the neck along the length of the tail. Bending of the tail occurs as the result of forces generated between adjacent peripheral doublets of the axoneme (Satir et al. 1981). The dynein arms of the doublet, which in the resting state are bound to the adjacent doublet, unbind, elongate, and then bind to a new site further along the filament. The unbinding process, which is the adenosine triphosphate (ATP)-using step, is then repeated, resulting in a progressive bending of the flagellum. The doublets on one side of the axoneme work in opposition to each other, providing the alternating beat of the tail. After capacitation the rate and amplitude of the flagellar beat greatly increases, and the rate of energy usage by the sperm is correspondingly elevated (Florman & Dulcibella 2006). The motility of the cell itself probably has little role in the movement of spermatozoa through the cervix and uterus, for this is accomplished mainly through contractions of the female genital tract (Hunter 1980). However, passage through the uterotubal junction and within the oviduct does require sperm motility, whereas the enhanced, whiplash motility of the capacitated sperm is necessary for penetration of the cumulus and zona pellucida.

Development of the Male Reproductive System

Very early in embryonic development, primordial germ cells start to develop in the yolk sac, under the control of growth factors from the bone morphogenic protein (BMP) series (Itman et al. 2006). Invagination of the hindgut during embryonic differentiation brings the cells passively into the body cavity of the embryo, but thereafter they start to actively migrate. Primordial germ cells enter the endoderm of the prospective hindgut, after which they enter into its surrounding mesentery. They then enter the dorsal mesentery, before moving into the developing gonads (Cantu & Laird 2017). Quite small numbers of primordial germ cells enter the genital ridge, where they cease migration, aggregate together, and enter a period of mitotic replication (Wilhelm et al. 2007). In rodents replication of these gonocytes is arrested during the latter stages of fetal development (Yao et al. 2003), resuming after birth, whereas in the fetal ram there appears to be continuous replication of gonocytes from Day 42 until birth (Hochereau-de-Reviers et al. 1995). Resumption of gonocyte replication in the rodent testis is accompanied by differentiation of gonocytes into spermatogonia (Itman et al. 2006). Meiosis does not commence until the onset of puberty (McLaren 1995). The somatic cells that will form the future Sertoli cells also migrate into the gonadal ridge from the coelomic epithelium, whereas the precursors of the interstitial and Leydig cells are derived from the underlying mesonephros (O'Shaughnessy et al. 2006). At this stage the gonad is bipotential, with its somatic components being capable of differentiating into the support and steroidogenic cells of either the male or female gonad (Merchant-Larios et al. 1993).

In male embryos, development of the presumptive gonad into a testis is stimulated by the activation of the sex-determining gene of the Y chromosome (*Sry*) in pre-Sertoli cells (Sinclair et al. 1990). Activation of *Sry* is dependent on the prior expression of several promotor genes in the undifferentiated gonad. *Sry,* once activated, through an interaction between steroidogenic factor 1

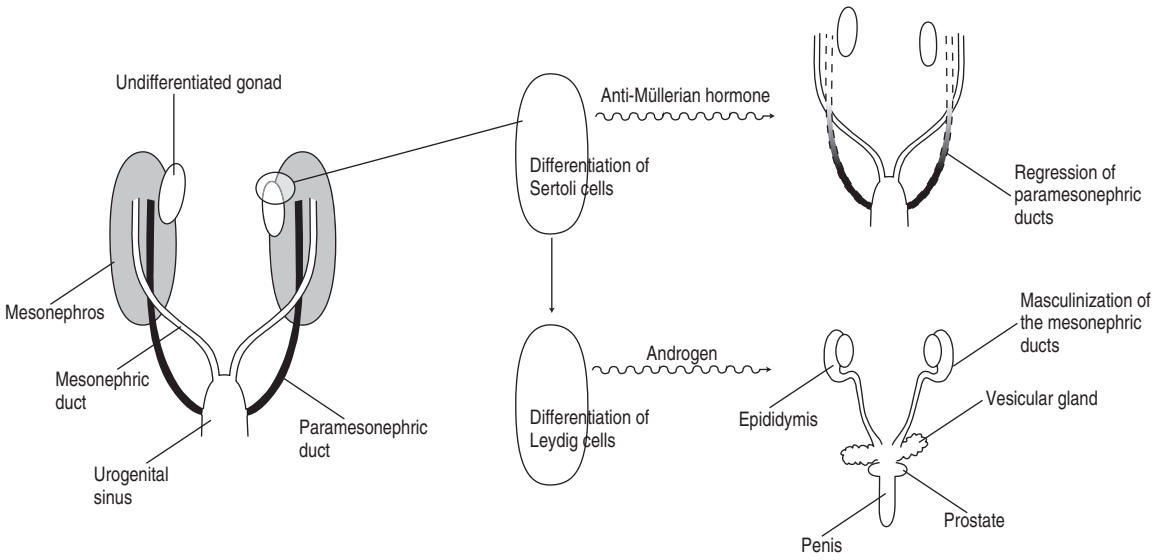
(*SF1*), provides for the upregulation of the autosomal gene, *Sox9* (Gunes et al. 2016), within the prospective Sertoli cells. *Sry* transcription ceases soon after the onset of *Sox9* production in mice, although it continues for a little longer in ruminants (Parma & Radi 2012); as its expression declines, *Sox9* becomes the dominant hormone of sex determination. *Sox9* stimulates transcription of *Fgf9* (fibroblast growth factor 9), which in turn stimulates the proliferation of future Sertoli cells (Schmahl et al. 2004). Sertoli cells are therefore the first cell type to differentiate from bipotential supporting cell precursors within the gonad, and their presence is therefore the first indicator that the gonad has passed from the indifferent stage into testis development (Wilhelm et al. 2007). Thus the level of *Sox9* expression and the number of Sertoli cells appear to be critical for normal male differentiation (She & Wang

VetBooks.ir



• **Fig. 2.6** Development of the male reproductive tract.

2017), at least partly due to the need to maintain expression of *Sox9* through a positive feedback mechanism. *Sox9* also stimulates the expression of prostaglandin D synthetase; prostaglandin D promotes the uptake of *Sox9* into the nucleus, where it binds to its own promotor to maintain its expression (Windley & Wilhelm 2015).

The onset of *Sry* expression is associated with migration of further cells from the mesonephros that will become the myoid cells of the seminiferous tubules (Capel et al. 1999). Differentiation of Sertoli cells and migration of myoid cells results in the development of testis cords, which initially appear as groups of germ cells surrounded by Sertoli cells, which are further surrounded by peritubular myoid cells. It appears that both Sertoli cells and myoid cells are needed for the normal development of testis cords (Buehr et al. 1993). These cords will eventually become the seminiferous tubules of the mature testis (Tilmann & Capel 1999).

Products of the Sertoli cells and Leydig cells are thereafter responsible for the differentiation of the remainder of the male reproductive tract. *Sox9,* derived from the Sertoli cell, initiates the expression of a series of genes that regulate the differentiation of the male reproductive system. *Sox9* and *SF1* act synergistically to initiate expression of *Amh* (anti-Müllerian hormone, also known as Müllerian inhibiting substance), which is responsible for the regression of the paramesonephric ducts (Swain 2006). *Amh* is a large (~140 kDa), dimeric protein (Swain 2006) that belongs to the TGFβ superfamily (Wilhelm et al. 2007). Its actions are primarily paracrine, acting through receptors in the mesenchymal cells that surround the paramesonephric duct, resulting in apoptosis of the epithelial cells of the paramesonephric ducts (Roberts et al. 2002). *Fgf9* and *Sox9* also act to suppress the expression of female-specific genes (Eggers & Sinclair 2012). *Amh* also has a positive role in male development inasmuch as it is required for normal development of the efferent ducts (Behringer et al. 1994).

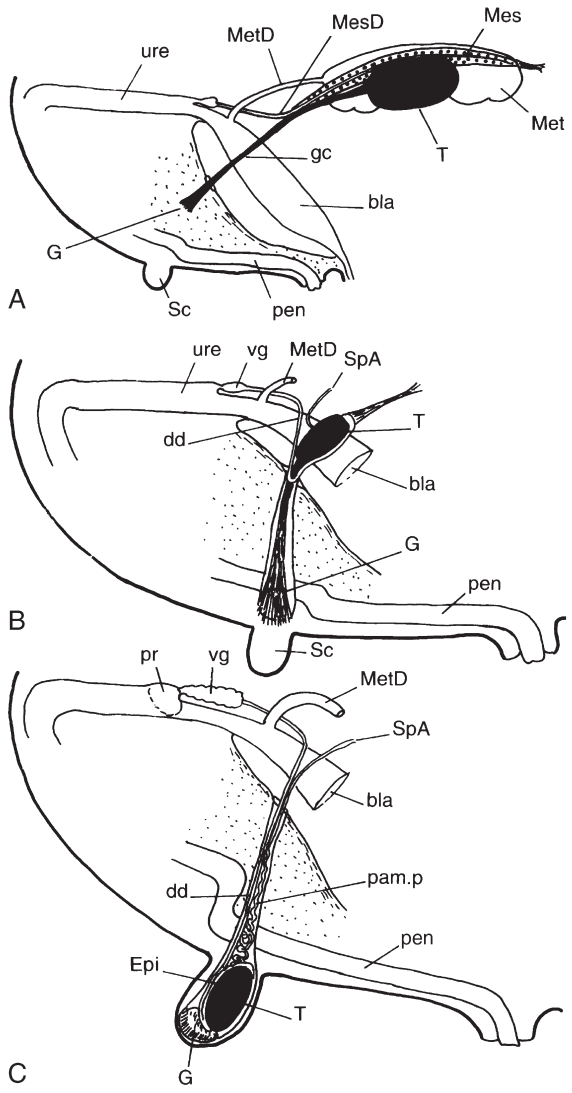
Desert hedgehog (*Dhh*), which is secreted by the Sertoli cells, has many morphogeneic effects, acting through its receptor PTCH1 to induce differentiation of peritubular myoid cells and Leydig cells (Clark et al. 2000). Myoid and endothelial cells also play a role in directing the differentiation of Leydig cells (Kitamura et al. 2002). Different populations of Leydig cells are present in the fetus and adult, which are dissimilar to each other in terms of the steroids that they produce and the regulation of their steroidogenesis. Precursors of fetal Leydig cells appear to comigrate from the mesonephros with the cells that will become the steroidogenic cells of the adrenal (O'Shaughnessy et al. 2006). Multiplication and differentiation of these precursor cells are under the control of the Sertoli cells, through signalling molecules such as *Dhh* (Yao et al. 2002) and platelet-derived growth factor (Brennan et al. 2003). Fetal Leydig cells differ from those of the adult, inasmuch as their primary steroid secretion is androstenedione rather than testosterone, which has to be converted into testosterone in the seminiferous tubules (O'Shaughnessy et al. 2000). In the mouse, fetal Leydig cell steroid secretion occurs without a requirement for trophic hormones, although it can be stimulated by both luteinising hormone (LH) and adrenocorticotrophic hormone (ACTH) (O'Shaughnessy et al. 2005).

Furthermore, Leydig cells produce androgens, which stimulate the development of the mesonephric (Wolffian) ducts (Fig. 2.6) to form the tubular parts (including epididymis, ductus deferens, ampulla, vesicular gland, and prostate) of the male genital tract. Androgens are also responsible for the differentiation of the penis from the genital tubercle (Swain 2004). Exposure of the female fetus to androgens results in masculinisation of the internal genitalia, with development of the mesonephric ducts and atrophy of the paramesonephric ducts, and a greater or lesser degree of masculinisation of the genital tubercle (Jost 1953). It also causes masculinisation of the hypothalamopituitary endocrine axis (Robinson et al. 2003). Evidence of this masculinisation can be seen in genotypic female animals that have been exposed to androgens *in utero* (e.g., the freemartin ewe: Parkinson et al. 2001 and see Chapter 9).

Descent of the Testis

As the testis develops in the mesonephros, differentiation of the definitive kidney (the metanephros) begins, and as it grows, the metanephros replaces the mesonephros as the organ of osmoregulation. The testis then migrates from its position within the abdomen towards its definitive position in the scrotum in a process referred to as the descent of the testis. The testis traverses the abdomen (Gier & Marion 1970; Fig. 2.7 A, B) partly (i) as a result of differential growth between the pelvis, abdomen, kidney, and testis; (ii) by

VetBooks.ir



• **Fig. 2.7** Descent of the testis in the bull. (A) 65-day fetus, (B) 96-day fetus, and (C) 140-day fetus. the action of the gubernaculum; and (iii) as a result of regression of the cranial suspensory ligament of the gonad, which holds the urogenital tract near the developing diaphragm (Mamoulakis et al. 2015).The transabdominal phase of testicular descent does not appear to be under androgen control, except that regression of the cranial suspensory ligament is androgen-dependent, whereas the inguinal–scrotal phase (Fig. 2.7C) requires androgen. Insulin 3 (*syn:* insulin-like hormone 3), derived from Leydig cells, appears to be the key regulator of testicular descent; the transabdominal phase of descent and the development of the gubernaculum appear to be critically dependent on it (Verma-Kurvari et al. 2005), and there is good evidence that it is also involved in the inguinal–scrotal (Kaftanovskaya et al. 2011) phase of descent. Genetic deficiencies of insulin 3 production at the time of the descent of the testis appear to be a major component of the inherited basis of cryptorchidism,

TABLE 2.2 Age at which testes descend into the scrotum

Species	Time of Testicular Descent
Cat	2–5 days after birth
Dog	Between the last few days of gestation and the first few days after birth
Horse	Between 9 months of gestation and a few days after birth
Cattle	3.5–4 months of gestation
Sheep	Midgestation (≈80 days)
Pig	After 85 days of gestation

whereas oestrogen-induced impairment of insulin 3 may be of significance as an environmental cause.

Before the testis itself passes through the inguinal canal, the canal itself is distended by a thickening of the gubernaculums and by the passage of the tail of the epididymis. Thus the gubernaculum, tail of epididymis and tip of the vaginal process precede the testis through the inguinal canal. Final passage of the testis, in the inguinal–scrotal phase of the descent, requires androgen; however, the target of this androgen is not the gubernaculum but, rather, appears to be the nucleus of the genitofemoral nerve within the CNS (Hutson & Beasley 1987). This nucleus releases CGRP (calcitonin gene-related peptide) that, in rodents, acts on the muscular component of the developing gubernaculum/cremaster muscle to produce contraction upon the descending testis (Momose et al. 1992). In the latter stages of the descent of the testis, the gubernaculum shrinks concurrently with the testicular descent. It remains controversial as to whether this shrinkage 'pulls' the testis into the scrotum, although the changes of structure of the gubernaculum over the period of testicular descent (i.e., increase in connective tissue and a marked increase in collaged and elastic tissue) strongly suggest that its role in testicular descent is an active one (Favorito et al. 2014). Thus the mechanisms of the descent of the testis are complex, involving: differential growth of the pelvis, abdomen, and kidney; pressure from the abdominal viscera upon the testis; and a role of the gubernaculum. The latter, although clearly critical, still has to be fully elucidated. The times at which the testis is first present within the scrotum are given for the main domestic species in Table 2.2.

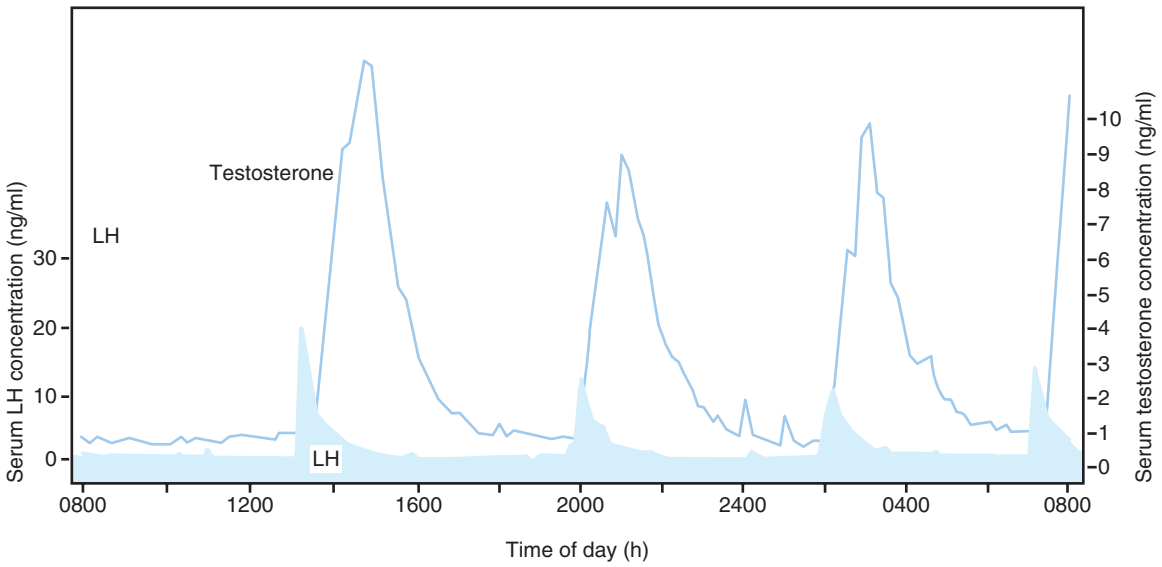
Physiology of the Testis

Endocrinology

Male reproductive physiology is under the primary endocrine control of the pituitary gonadotrophins, luteinising hormone (LH), and follicle-stimulating hormone (FSH), both of which are synthesised and secreted in response to gonadotrophin-releasing hormone (GnRH). At a local level, many of the functions of the testes are also regulated by intratesticular paracrine and autocrine factors, as well as being influenced by a number of endocrine metabolic regulators.

The secretion of LH is pulsatile in response to episodic stimulation of the pituitary by GnRH, resulting in irregular episodes of LH secretion occurring every 2 to 4 hours. The primary action of LH is upon the Leydig cells, in which it controls testosterone synthesis.

VetBooks.ir



• **Fig. 2.8** Typical profile of the patterns of LH and testosterone secretion in the ram. (Redrawn from D'Occhio et al. 1982a.)

In fact, it appears that regulation of testosterone synthesis is the only indispensable function of LH within the testis (Holdcraft & Braun 2004). Peak testosterone concentrations follow those of LH by about 40 minutes and decline to prestimulation values over a further 40 to 80 minutes (D'Occhio et al. 1982a; Fig. 2.8).

LH receptors are primarily present on Leydig cells, although there is also evidence of their presence in germ cells (Lei et al. 2001). Experiments upon hypophysectomised rams suggest that the role of these receptors may be to control the rate of division of stem spermatogonia (Courot & Ortavant 1981). The actions of LH upon the Leydig cell are mediated through adenylate cyclase, guanylate cyclase, and calcium channels (Tremblay 2015) that, through a series of intermediate steps, regulate steroidogenesis by controlling the conversion of cholesterol into pregnenolone (Stocco & McPhaul 2006). This conversion is the rate-determining step of testosterone synthesis. It, in turn, is regulated by the activity of steroidogenic acute regulatory protein (*StAR*), which controls the rate of cholesterol uptake into mitochondria (i.e., into the site of steroid synthesis). Activation and expression of *StAR* requires both chronic and acute stimulation by LH (Shiraishi & Matsuyama 2017): hence, the necessity for continuous pulsatile secretion of LH. A number of other growth factors and cytokines have been demonstrated to have positive**,** and negative**,** modulatory effects upon the action of LH upon Leydig cells (Bornstein et al. 2004). Among these the effects of growth hormone (Colon et al. 2005), insulin-like growth factor-1 (IGF-I) (Abo-Elmaksoud & Sinowatz 2005), insulin (Ballester et al. 2004), and fibroblast growth factor 9 (*FGF9:* Lin et al. 2010) appear to be of importance in stimulating testosterone synthesis; others (e.g., *Amh* and tumour necrosis factor–α) have inhibitory effects.

Negative-feedback regulation of LH secretion is mediated by the effects of testosterone upon hypothalamic GnRH and by pituitary synthesis and secretion, both directly and after conversion to dihydrotestosterone or aromatisation to oestradiol (O'Donnell et al. 2006). Curiously, in long-term castrated ruminants neither negative feedback nor libido can be restored by testosterone administration, for brain aromatase activity is eventually lost and oestrogen itself has to be given for the restoration of these effects (D'Occhio et al. 1982b).

Testosterone is required for the production of spermatozoa and their subsequent maturation in the epididymis, as well as for the function of the accessory sex glands and for the development of masculine secondary sexual characteristics. Within the testis, androgen receptors are present in Leydig, Sertoli, and myoid cells (Holdcraft & Braun 2004) but not in germ cells. Testosterone is converted by 5α–reduction into 5α–dihydrotestosterone (DHT) in Sertoli cells and accessory sex glands. DHT, which is not susceptible to aromatisation and is a more potent androgen than testosterone itself, appears to be the primary androgen controlling accessory sex gland activity, whereas testosterone is the primary androgen involved in spermatogenesis (Walker & Cheng 2005). Both testosterone and DHT are bound within the tubule lumen by androgen-binding protein (ABP), which is secreted by the Sertoli cells. The role of ABP therefore appears to be to maintain high androgen concentrations in the lumina of the seminiferous tubule and epididymis.

The main target of FSH is the Sertoli cell, in which it also acts through adenylate–cyclase-linked enzyme systems. Under the influence of FSH, Sertoli cells secrete ABP (Gunsalus et al. 1981) and aromatise testosterone into oestrogens (Setchell et al. 1983); FSH is also responsible for switching on a great many genes in the Sertoli cell that regulate or support spermatogenesis (Walker & Cheng 2005). Most aspects of spermatogenesis require support by FSH and/or testosterone. However, it appears from genetic and pharmacological studies in rodents that the primary role of FSH in spermatogenesis is stimulation of Sertoli cell proliferation during prepubertal development (Heckert & Griswold 2002), and, because the number of Sertoli cells largely determines the number of germ cells (O'Donnell et al. 2006), this action is an important determinant of postpubertal spermatogenic yield (Holdcraft & Braun 2004).

It is generally considered that the secretion of FSH lacks the episodic pattern that is characteristic of LH, exhibiting longer term fluctuations instead. However, there are some reports of a more clearly pulsatile pattern of FSH secretion. Negative feedback is by both gonadal steroids and inhibin. Inhibin is produced by Sertoli cells (Baird et al. 1991) and causes negative feedback on FSH secretion, directly at the level of the pituitary (Tilbrook et al.

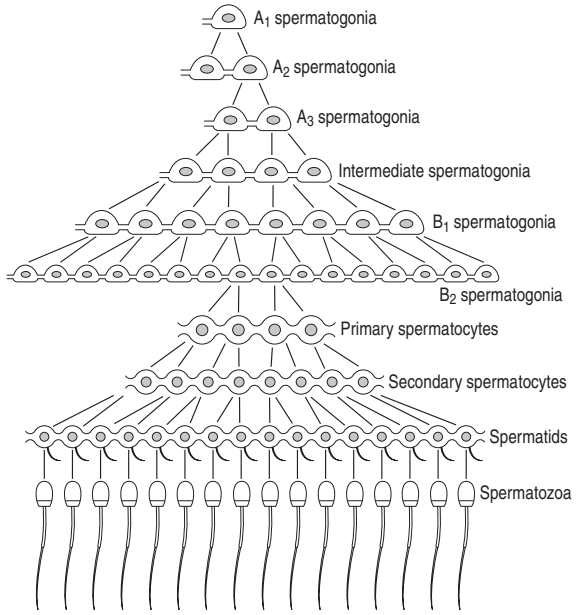
• **Fig. 2.9** Diagram of the endocrine relationships controlling the testis. *abp,* Androgen-binding protein; *E,* oestrogen; *GnRH,* gonadotrophin-releasing hormone; *I,* inhibin; *T,* testosterone. (Redrawn and adapted from Amann & Schanbacher 1983.)



• **Fig. 2.10** Multiplication of cells during spermatogenesis in the bull. A_1 spermatogonia undergo a series of mitotic divisions to produce A_2, A_3, intermediate, B_1, and B_2 spermatogonia. The final mitotic division produces primary spermatogonia, which enter meiosis, producing secondary spermatocytes after the first meiotic division and spermatids after the second. Spermatids then differentiate into spermatozoa without further cellular division.

1993); it has little effect on LH (Tilbrook et al. 1995). Inhibin B is the predominant form (Phillips 2005) in the males of most domestic species, although in the ram it is inhibin A (McNeilly et al. 2002). Activin, which is also produced by the Sertoli cell, stimulates FSH production in the pituitary, although most of its functions actually seem to be as a paracrine agent within the testis (de Kretser et al. 2004). A schematic summary of the main endocrine relationships of the testis is given in Fig. 2.9 (Amann & Schanbacher 1983).

Spermatogenesis

Spermatogenesis is the basic process of male reproduction, resulting in the production of spermatozoa. It occurs in the seminiferous tubule of the adult testis and comprises three main processes: mitotic replication of spermatogonia, meiosis, and postmeiotic differentiation into spermatozoa (Fig. 2.10).

These processes of spermatogenesis are reflected in the functional morphology of the seminiferous tubule (Courot et al. 1970). The seminiferous epithelium appears as concentric layers of spermatogonia, spermatocytes and spermatids, with characteristic associations between generations of cells throughout the depth of the seminiferous epithelium (Fig. 2.11). Cellular associations are generally classified into Type I, in which two generations of primary spermatocytes and one of spermatids are present, and Type II, in which there is only one generation of primary spermatocytes but two of spermatids. Transition between Type I and Type II occurs after the maturation divisions, whereas Type II changes into Type I with the release of spermatozoa and the arrival of a new generation of spermatocytes from the last spermatogonial division. Each generation of seminiferous cells is linked by cytoplasmic bridges, so that developmental stages are synchronous within each generation, and substantial areas of seminiferous epithelium exhibit cells at a similar stage of development. Fibroblasts and myoid cells surround the basement membrane of the seminiferous tubule externally. The blood supply is limited by the basement membrane and does not pass into the tubule itself.

Within the tubule, there are somatic Sertoli cells and the various stages of the seminiferous cell line, which together form the seminiferous epithelium. Sertoli cells, which rest upon the basement membrane, are irregularly cylindrical in shape and have large, variably shaped nuclei situated close to the basement membrane. They multiply during fetal and prepubertal life (Wilhelm et al. 2007) in a process that is dependent on FSH and activin (Boitani et al. 1995) but is independent of testosterone. It is generally accepted that the full complement of Sertoli cells is present at the time of puberty, although there is some evidence for an annual cycle of loss and replication of Sertoli cells in at least some seasonally breeding species (Johnson & Thompson 1983, Hochereau-de-Reviers et al. 1987). Sertoli cells extend through the entire thickness of the seminiferous epithelium, so that the germinal cells in all stages of spermatogenesis are in close contact with them. As Sertoli cells are the only somatic cells that are in direct contact with differentiating germ cells, they have to provide both physical

• **Fig. 2.11** Spermatogenesis in the bovine testis. Stem cells undergo mitotic *(m)* divisions producing successive generations of diploid spermatogonia (A_1, A_2, A_3, intermediate (In), B_1, and B_2), before entering the first meiotic division *(me1).* Preleptotene primary spermatocytes *(PL)* pass through the successive stages of the long first meiotic prophase (*L,* leptotene; *Z,* zygotene; *P,* pachytene; *D,* diakinesis), becoming short-lived secondary spermatocytes. These proceed through the second meiotic division *(me2),* producing early round spermatids *(R).* These differentiate into spermatozoa without further division, after nuclear condensation *(C)* and elongation *(El).* The solid horizontal line indicates the position of tight junctions between Sertoli cells: the site of the blood–testis barrier. Four major groupings of cells can be determined, based upon the morphology of the spermatids/spermatozoa: *E,* elongation; *G,* grouping; *M,* maturation; *R,* release. These recur every 13.5 days. (Adapted from an original drawing by Brian Setchell.)

and nutritional support for spermatogenesis (Griswold 1998). The seminiferous tubules are divided into basal and luminal compartments by junctional complexes (tight cell junctions: TCJ) between adjacent Sertoli cells (Setchell & Breed 2006). These junctions form the blood–testis barrier (Stocco & McPhaul 2006), which maintains the specialised environment of the lumen of the seminiferous tubules and separates meiotic and postmeiotic (haploid) cells from the immune system. The blood–testis barrier is not only a physical barrier, but also a functional barrier: Stanton (2016) described its functions as being a physical barrier, a physiological barrier of cell transporters that control movement of substances to and from the lumen, and an immunological barrier comprising immuno–regulatory factors and tolerance mechanisms. The formation of the blood–testis barrier is androgen-dependent, as is the adhesion between germ cells and Sertoli cells (Holdcraft & Braun 2004), and first forms at around the time of puberty.

FSH and testosterone are essential for the normal activity of Sertoli cells. Although many aspects of the Sertoli cell support of spermatogenesis can be maintained by either hormone (Walker & Cheng 2005) (probably though activation of similar intracellular pathways), normal spermatogenesis cannot be completed in the absence of androgen. Some aspects of Sertoli cell function appear to have an absolute requirement for FSH because, in the sheep, some spermatogonial divisions can only be supported by FSH (Kilgour et al. 1998). However, the main hormone responsible for maintenance of spermatogenesis in the postpubertal animal is testosterone (O'Donnell et al. 2006). Many other substances contribute to the regulation of Sertoli cell activity, particularly IGFI, IGFII, insulin, activins, follistatin and inhibin, and BMPs (Itman et al. 2006, Dimitriadis et al. 2015). In response to stimulation by these agents, Sertoli cells secrete oestrogens, inhibin, a GnRH-like peptide, proteins (including ABP), lactate, pyruvate, and tubule fluid. Significant changes to the morphology and activity of Sertoli cells occur in the peripubertal period, associated with the onset of spermatogenesis, although there are also annual changes in their morphology in seasonally breeding species according to the activity of the gonadotrophic axis (Hochereau-de-Reviers et al. 1985).

After the migration of the primordial germ cells into the genital ridge, they replicate and differentiate into spermatogonia. In the mature animal, spermatogonia are divided into A, intermediate, and B classes, with each class further subdivided according to morphology and degree of differentiation (Fig. 2.11). Thus in the bull and ram, A_0, A_1, A_2, A_3, intermediate, B_1, and B_2 spermatogonia are present (Hochereau-de-Reviers 1976). A-series spermatogonia are the least differentiated and form the reservoir of stem cells within the seminiferous tubule. It is likely that stem cells are regenerated by asymmetrical divisions of early A-series spermatogonia, with one progeny cell remaining as an uncommitted stem cell and the other being committed to undergo further mitotic and meiotic divisions. In mice (see Chen & Liu 2015), these A-series spermatogonial stem cells are divided into A_{single} and A_{paired} or $A_{aligned}$, such that the former are true stem cells and the latter two are committed to enter the cascade of mitotic divisions. Various transcription factors are present in A_{single} that are not present in more committed/differentiated spermatogonia, and which disappear as spermatogonia progress from the progenitor pool into the differentiating pool. Griswold (2015) considered that retinoic acid is the key extrinsic factor that controls the entry of A spermatogonia stem cells into the developing pool of the mouse testis. The onset of meiosis in prespermatocyte germ cells is similarly signalled by Sertoli cell-controlled paracrine mechanisms. Two of these mechanisms are worthy of mention: the copromotion of meiosis by retinoic acid (the active form of Vitamin A) and FSH (Zhang et al. 2011); and the promotion of meiosis by androgen–androgen receptor interactions, both within the Sertoli cell. Mutations in the androgen receptor

VetBooks.ir

are commonly associated with XY-sex reversal or nonspecific male infertility (Gottlieb et al. 2012).

All spermatogonia remain in contact with the basement membrane, but the area of contact is significantly reduced in B spermatogonia (de Kretser & Kerr 1994). As the final meiotic division of spermatogonia give rise to the primary spermatocytes, the cytoplasm of the Sertoli cells intervenes between the basement membrane and the primary spermatocytes. DNA synthesis occurs during mitotic divisions and then, to its greatest extent, during the formation of tetraploid nuclei during meiosis (Stocco & McPhaul 2006). RNA synthesis occurs during preleptotene and late pachytene (Kierszenbaum & Tres 1974). The first meiotic division then proceeds through the highly sensitive zygotene and pachytene stages. The pachytene stage is particularly sensitive to noxious damage such as by high testicular temperature or inadequate hormonal support. During the first meiotic division, the cells move deeper into the seminiferous epithelium, and the tight cell junctions of the Sertoli cells form beneath the spermatocytes and degenerate above them (Russell 1977, 1978), so that the cells effectively pass through the blood–testis barrier. The mechanism by which leptotene spermatocytes 'move through' the blood–testis barrier appears to involve a number of phases. These include: transient formation of an intermediate compartment enclosing the early leptotene spermatocytes; the progressive opening of tight junctions above migrating germ cells that then close below them once migration is completed; and the proliferation of tight junction components for assembly by an endocytic pathway (Stanton 2016). The TCJs themselves appear to be regulated by the stimulatory effects of androgen and retinoic acid and by the inhibitory effects of activin and TGFβ3, which, in turn, relates to the assembly of the 'new' TCJ below the spermatocyte and the disassembly of the 'old' TCJ above it (Nicholls et al. 2013). The role of FSH in barrier development is less well understood, with evidence for and against its direct involvement.

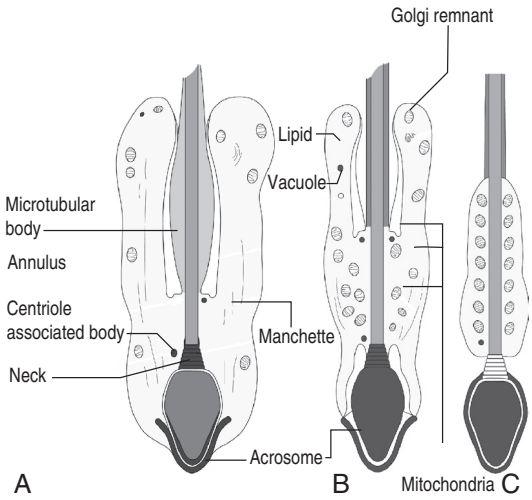
The consequence of this activity is that the progeny of the first meiotic division – the secondary spermatocytes – have moved from the basal to the luminal compartment of the seminiferous epithelium, and are thereafter separated from the general tissue fluid compartment. The second meiotic division produces spermatids, which do not divide further. At the end of meiosis, spermatids are round cells with round nuclei. Thereafter, they undergo marked changes in cell function and morphology that are associated with differentiation into spermatozoa (spermiogenesis).

Spermiogenesis

Immediately after completion of meiosis, the spermatids undergo a period of RNA synthesis, which is then followed by the beginnings of nuclear chromatin condensation (Monesi 1971). During the compaction of the nuclear chromatin, there is an abrupt change from a histone-based structure to a protamine-based structure (Rathke et al. 2014); the protamine-based structure is essential for normal fertility in mice. Acrosomal contents are concurrently synthesised in the Golgi complex. Vesicles derived from the Golgi fuse over the nuclear membrane overlying the basal pole of the nucleus (Courtens 1979), with further material subsequently being transported into the developing acrosome (Eddy 1994). The nucleus moves from a central position towards the margin of the cell, at the point at which the acrosome is developing. As the nucleus condenses and elongates, it shrinks significantly in size, resulting in redundancy of nuclear membrane.

The transient microtubular structure, the manchette, which appears in the postnuclear cytoplasm of the elongating spermatid during nuclear condensation, plays a key role in the shaping of the nucleus and in the formation of the tail. The manchette consists of microtubules and actin filaments which are connected and stabilised by the perinuclear ring (Lehti & Sironen 2016). Abnormal manchette formation is associated with abnormal development and shape of the sperm head (Calvi et al. 2015); the manchette has a key role in the development of the tail, particularly by the transport of proteins required for tail elongation (Kierszenbaum 2001). The tail is formed from the centrioles, one of which forms the connecting piece of the neck of the sperm, the other the axial filament of the tail (Eddy 2006). The structure of the axial filament (see later in this chapter) is common to flagella and cilia. The outer dense fibres are not derived from the centriole, although they are attached to the outer microtubules of the axial filament (Fawcett & Phillips 1969). The development of the midpiece occurs late in the process of spermatogenesis, as a helix of mitochondria condenses around the proximal part of the flagellum (Fig. 2.12). This process cannot take place until the manchette has disappeared. During formation of the acrosome and flagellum, the cytoplasm of the spermatid is deeply invaded by a process of the Sertoli cell, which extends between the forming flagellum and the residual cytoplasm. Finally, most remaining cytoplasm is engulfed by the Sertoli cell (Fouquet 1974) as the formed spermatozoon, with its remnant cytoplasmic droplet, is expelled from the crypt of the Sertoli cell into the lumen of the seminiferous tubule (spermiation). The mechanism of spermiation is not fully resolved; however, there is evidence that remodelling of the actin in and around the cell junctions between the Sertoli cell and the spermatid is at least one element in the process (Cheng & Mruk 2011).

The duration of spermatogenesis, i.e., the time between spermatogonial divisions and the release of the spermatozoon, is approximately 60 days in most domestic animals. Epididymal transit takes a further 8 to 14 days. Thus the interval between the most sensitive stage of spermatogenesis, meiotic prophase, and ejaculation is approximately 30 days (Amann & Schanbacher 1983). Hence the interval between damage to the testis and the appearance of abnormal spermatozoa in the ejaculate is generally between 30 and 60 days, depending on the site of damage.



• **Fig. 2.12** Formation of spermatozoa within the luminal crypts of the Sertoli cells. After formation of the acrosome and condensation of the nucleus at the basal pole of the developing sperm (A), there is a progressive alignment of the mitochondria around the flagellum (B) until, in the fully formed sperm (C), the helical sheath of mitochondria that makes up the midpiece is fully developed.

Physiology of the Epididymis

When sperm are released from the seminiferous epithelium, they are immature, lacking normal motility and being incapable of fertilising. They acquire these abilities in their transit through the epididymis (Amann 1987, Eddy 2006); because the genome of the spermatozoon is almost completely inactivated, these changes are dependent on posttranslational modifications of the cell (Baker 2016). The epididymis is highly androgen-dependent; thus if androgen production is suppressed, epididymal function is immediately impaired. Likewise, the embryonic and postnatal development of the epididymis is highly dependent on androgen, mediated through androgen receptors and paracrine growth factors to induce differentiation and proliferation of the epididymal epithelium (Murishima et al. 2014). Dihydrotestosterone appears to be of greater importance than testosterone in the adult epididymis; high levels of 5α–reductase are present in the epididymis, especially in its initial segment. Interestingly, however, the activity of the efferent ducts, in which resorption of seminiferous tubule fluid takes place, is coregulated by oestradiol (Lee et al. 2000).

Anatomically, the epididymis can be considered to consist of four regions: the initial segment, head (caput), body (corpus), and tail (cauda). Functionally, it is divided into two major regions: a proximal region, which is involved in sperm maturation, and a distal region, which is concerned with storage and transport (Jones 1998a). The proximal segment has a relatively narrow lumen, an actively secretory epithelium and relatively sparse sperm population. The distal segment has a larger lumen, a much more prominent muscle layer surrounding the tubule, and a dense population of sperm. Studies in rodents suggest that each segment is further divided into several physiological compartments (Domeniconi et al. 2016), which differ widely from each other in terms of protein secretion and in their roles in the eventual development of functionality of the sperm. At the cellular level, the pseudostratified epithelium that lines the epididymal tubule includes**:** principal, narrow, clear, and basal cells. Principal and basal cells are present throughout the epididymis; narrow cells are located exclusively in the initial segment; and clear cells are present in the caput, corpus, and cauda of the epididymis (Breton et al. 2016).

Spermatozoa take between 8 and 14 days to traverse the epididymis, according to species. In the bull, sperm take 5 days to pass through the initial segment, head (caput), and body (corpus) of the epididymis and a further 5 to 9 days to traverse the epididymal tail (cauda). The transit time of the proximal segment is fixed, but it is variable in the distal segment of the epididymis because of its dual functions of maturation and storage. Hence, in periods of high ejaculation frequency, the passage time of the tail may be reduced**,** and relatively immature sperm may be ejaculated (Robaire et al. 2006). Movement of sperm through the epididymis is a passive process, which relies on the activity of the epididymal tubule rather than on the motility of the sperm (Robaire et al. 2006).

The protoplasmic remnant, which is initially sited close behind the sperm head, migrates distally to the end of the midpiece, before being finally shed in the tail of the epididymis. Sperm are immotile in the head of the epididymis but acquire the capacity for motility as they pass through its body. Actually, the environment within the lumen of the epididymal duct is maintained at a low pH and low bicarbonate concentrations by the actions of the clear cells as a means of maintaining sperm in a dormant state during their passage of the epididymis (Breton et al. 2016); thus the acquisition of motility is due in part to the epididymal environment. Indeed, a rise in pH and bicarbonate concentrations may occur in the preejaculatory phase, as a 'priming' of the sperm for activity after ejaculation. In the head of epididymis, sperm do not have the ability to fertilise, but this is acquired during passage through the epididymal body.

Less obvious, but of equal or greater importance to the morphological changes exhibited by sperm during their passage through the epididymis, are the changes in their plasma membrane, to which surface glycoproteins are added or modified by epididymal secretions and luminal cells. It is likely that these act to stabilise the acrosome when the sperm is within the female genital tract to reduce the surface immunogenicity of the sperm and to enhance the ability of the sperm membrane to bind to the zona pellucida (Amann 1987, Hammerstedt & Parkes 1987). During transit through the epididymis, sperm undergo changes in morphology, metabolic processes, activity of the flagellum, and the ability to bind to the zona pellucida (Eddy 2006). These changes are largely brought about by changes to the surface membrane of the sperm in response to substances, especially proteins, which are produced by the epididymis. The most active segment of the epididymis for protein secretion is the initial segment (Dacheux et al. 2003), whereas little protein is secreted in its distal segment. Some proteins are transferred to sperm by secretion into the lumen; others appear to be transferred via the apocrine secretion of membrane vesicles (Cooper 1998), whereas other proteins are lost from, or modified within, the sperm membrane. Likewise, there are changes of the phosphorylation state of proteins within the sperm head (Lewis & Aitken 2001) that are correlated with the ability of the sperm to undergo acrosome reaction. Similarly, there is also a reorganisation of the acrosome with, for example, redistribution and modification of the activity of some of its contents (Yoshinaga & Toshimori 2003). There is considerable remodelling of the lipids of the sperm membrane (Jones 1998b), with a net loss of cholesterol and a considerable, but selective, loss of phospholipids (Hammerstedt & Parkes 1987), mainly from the inner leaflet of the membrane bilayer. There is also uptake of secreted glycoproteins (Tulsiani et al. 1998) and remodelling of these and endogenous glycoproteins within the sperm membrane. It appears that the addition of glycoproteins to the cell surface results in an increase in negative charge, which has, in turn, been suggested to contribute to the capacitation and egg-binding processes. Furthermore, glycosylation has been suggested as a means by which the sperm avoids immune detection in the female tract (Baker 2016). These changes in the membrane are associated with the acquisition of motility and fertilising ability (Jones 1998b).The acquisition of motility and fertilising ability are, however, not synonymous, although motility is required for fertility (Robaire et al. 2006). Acquisition of motility may also require modification to the dynein ATPase, together with the uptake of motility proteins and modifications to the intracellular compartmentalisation of calcium (Dorman & Dulcibella 2006).

Gervasi and Visconti (2017) summarised the changes that occur in the epididymis as follows: (i) in the caput epididymis, sperm are immotile, unable to fertilise, and the cytoplasmic droplet is close to the sperm head; (ii) there are low levels of sialic acid residues, few disulphide bonds, a high cholesterol to phospholipid ratio, and low membrane fluidity; (iii) the egg-binding protein, IZUMO1, which must be phosphorylated for fusion with the egg to occur, is not phosphorylated; (iv) in the cauda epididymis, the sperm are motile, able to fertilise and have either lost the cytoplasmic droplet or it has translocated to the distal end of the midpiece; (v) the

VetBooks.ir

sperm have high levels of sialic acid and disulphide bonds, a low cholesterol to phospholipid ratio, and high membrane fluidity. IZUMO1 in the equatorial segment of the sperm head is highly phosphorylated.

Physiology of the Accessory Glands

The accessory sex glands (vesicular gland, prostate, ampulla, and bulbourethral gland; Table 2.1) all have a critical requirement for androgens for their function. Testosterone is the prohormone for the more active androgen, dihydrotestosterone, which is produced by 5α–reductase in the accessory glands.

Ampullae are present as dilations of the terminal portion of the ductus deferens, just before they enter the pelvic urethra, where their main function is to act as reservoirs of sperm. In the bull, ram, and dog the ampullary glands, which are present, contribute slightly to the seminal plasma, whereas their contribution to the ejaculate is relatively more important in the stallion. The main constituent of ampullary secretion in the stallion is ergothioneine (Mann et al. 1956).

Vesicular glands are prominent in ruminants, the stallion, and the boar. They are sac-like in the stallion and boar and are firm, lobulated structures in the ram and bull. The glands are adjacent to the neck of the bladder and lateral to the ampullae. They open into the urethra just distally to the ductus deferens. Their secretion, which is generally watery, contributes substantially to the volume of the semen. In all species its secretion contains large quantities of citrate, although in the ruminants it also contains fructose and in the boar inositol (Marley et al. 1977).

The prostate is intimately related to the pelvic urethra and, in most species, is in two parts: its body surrounds the neck of the bladder, and its disseminated part spreads around the pelvic urethra, into which it has several openings. In the dog the prostate is the main accessory gland and is relatively large, forming a discrete organ around the urethra. The prostatic secretion is watery and contains large quantities of chloride ions, but neither citrate nor fructose nor inositol is present in high concentration (Huggins 1945).

In the stallion, bull, and ram the bulbourethral (or Cowper's) glands are small, rounded structures lying between the anus and urethra. Their watery secretion is discharged before coitus and is considered to cleanse the urethra of urine. In the boar the bulbourethral glands are large, cylindrical structures lying along each side of the intrapelvic urethra. In this species their secretion is very viscid because of its high sialomucin concentration (Boursnell et al. 1970) and combines with the secretion of the vesicular glands to produce a gelatinous phase of the seminal plasma (Boursnell & Butler 1973).

The physiological functions of the various constituents of seminal plasma remain a matter of debate (for a review, see Poiani 2006). There is much interspecies variation in the composition of seminal plasma, so it has been difficult to ascribe absolute functions to many of its constituents. Provision of energy, maintenance of osmotic pressure, chelation of free calcium ions, and buffering are some of the suggested functions; other possibilities include immunosuppression in the female genital tract and regulation of spermatozoan motility. Seminal plasma is also responsible for the coagulation of semen, which occurs shortly after ejaculation in many species. On the other hand, it has been argued that the wide variety in composition of seminal plasma between species indicates that it has no critical role, an argument that is emphasised by the ability of sperm to survive in relatively simple media that bear little resemblance to seminal plasma. Paradoxically, the seminal plasma of many species appears to contain spermicidal factors, especially in the postsperm-rich fraction of the species that produce a fractionated ejaculate.

The Penis

Erection

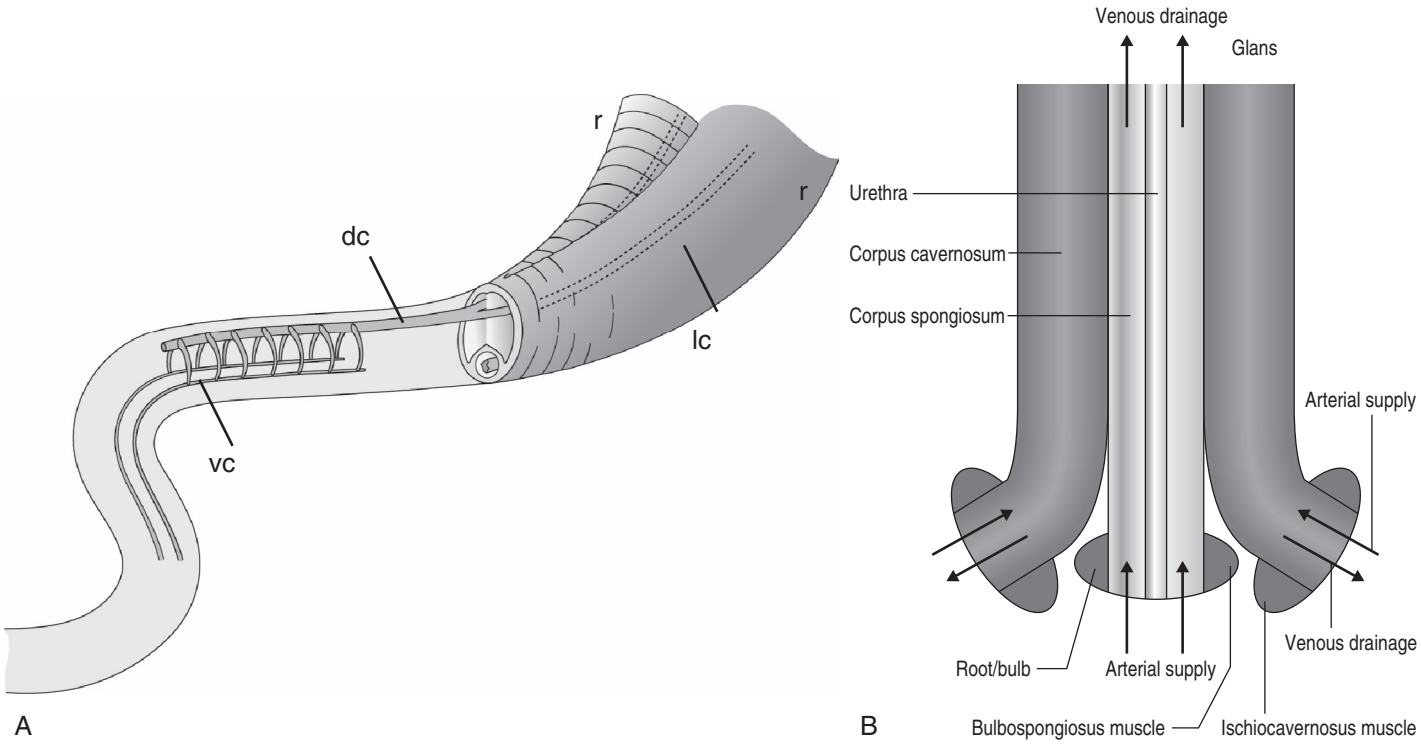
The penis comprises three tracts of erectile tissue and the penile urethra. The urethra is surrounded by the corpus spongiosum penis (CSP), which arises at the bulb of the penis and terminates in the glans penis. The erectile tissue of the glans penis is contiguous with the CSP, although the structure of the CSP glandis differs from that of the shaft of the penis. The dorsum of the penis is made up of the paired corpora cavernosa penis (CCP; Fig. 2.13), which arises in the two crura (roots) of the penis**,** and terminates behind the glans. The blood supply of all three tracts is via branches of the pudendal artery, but the venous drainage of the CCP is markedly different from that of the CSP. The CCP is drained via the root of the penis into the pudendal vein, whereas the CSP drains into the dorsal vein of the penis from its distal extremity (Ashdown & Gilanpour 1974). Thus both the supply and drainage of blood to the CCP is via the root of the penis, whereas the supply of the CSP is through the bulb and its drainage from its distal part.

Erection is achieved by raising the haemostatic pressure within the erectile tissues of the penis. It is mediated via a reflex that is predominantly coordinated at the spinal level (Andersson 2003) but is initiated and modulated centrally (Andersson & Wagner 1995). Most studies on the physiology of erection have been undertaken on the human, laboratory rodents, the dog, and, as it responds similarly to human penile smooth muscle, the bovine retractor penis muscle. In these species, erection is initiated by relaxation of smooth muscle within the CCP, leading to reduced vascular resistance and increased blood flow (Andersson & Wagner 1995). The penis is normally maintained in a flaccid state through tonic noradrenaline (norepinephrine) release from its sympathetic innervation, which causes contraction of the smooth muscle of the penile artery and CCP (Simonsen et al. 2002) through α_1–adrenoceptors and calcium-mediated pathways (de Tejada et al. 2004). The sympathetic stimulus also has antivasodilatory effects.

Erection is initiated via the parasympathetic system derived from the sacral plexus. Nitric oxide, produced from the action of parasympathetic–neural nitric oxide synthetase (nNOS) on L-arginine (Andersson & Wagner 1995), raises concentrations of cyclic guanosine monophosphate (GMP) in smooth muscle cells, leading to a reduced responsiveness to calcium and hence relaxation (Andersson 2003, de Tejada et al. 2004). Cyclic AMP-mediated pathways are also involved in vasodilation, in response to vasoactive intestinal peptide (VIP), prostaglandins E_1 and E_2, and noradrenaline (norepinephrine) acting through α_2–adrenoceptors (Simonsen et al. 2002). Increased flow through the penile arteries stimulates the endothelium to further release of these vasoactive substances, leading to further increases in blood flow (Kunelius et al. 1997). The role of each of these agents in other domestic species is not fully established. For example, although the bovine retractor penis muscle expresses both nNOS and VIP, their distribution is different from that in the penile smooth muscle of rodents (Vanhatalo et al. 2000).

Central nervous control of erection in primates and rodents is primarily derived from the hypothalamus and limbic system, with

VetBooks.ir



• **Fig. 2.13** Functional vascular anatomy of the bovine penis: (A) representational and (B) diagrammatic. Blood enters and leaves the corpus cavernosum via the arteries and veins of the crura (roots) of the penis, so that contraction of the overlying ischiocavernosus muscles occludes the venous drainage and forces blood into the penis under pressure. The blood passes through the penis in longitudinal canals *(lc).* Two canals arise in the roots *(r)* of the penis and unite to form a single dorsal longitudinal canal *(dc).* This gives off a series of lateral branches in the region of the sigmoid flexure, which unite to form paired ventral canals *(vc).* The corpus spongiosum is drained from its distal end, so contraction of the bulbospongiosus muscle only produces a transient increase in hydrostatic pressure. This is of sufficient magnitude to temporarily occlude the urethra, so that a bolus of semen can be propelled along its length. During detumescence vascular pressure is lost, and the penis is returned to the preputial cavity by the retractor penis muscle. (Redrawn and adapted with permission from Laing et al. 1988.)

the medial preoptic hypothalamic centre having a key integrating role (O'Donnell et al. 2006). Coordination of erection with other components of sexual responses appears to be an important role of the paraventricular nucleus (Swanson & Sawhenko 1983). The primary stimulatory pathways are mediated by oxytocin, with upstream regulation by the excitatory amino acids (Melis et al. 2004), glutamic and aspartic acids (and their agonists), and dopaminergic pathways (Andersson & Wagner 1995). Nitric oxide also stimulates the activity of central oxytocic stimulatory pathways. Inhibitory pathways include those producing gamma-amino butyric acid (GABA), serotonin, and opioids (Argiolas & Melis 2005).

Control of the processes of erection and ejaculation at the spinal level are dependent on a number of tracts of neural tissues within the spinal cord. First, there is the spinal nucleus of the bulbocavernosus (SNB: 'nucleus of Onuf'), a group of neurons in the low lumbar or sacral spine which regulate micturition, defecation, and the muscular contraction of ejaculation (Sakamoto 2011). In dogs, cats, and rodents (and humans) it is in the ventral horn, but in the pig it is dorsolateral from the central canal (Blok & Holstege 1998). It is sexually dimorphic, containing more neurons in males than females, a differentiation which occurs late in gestation under the control of androgens. Secondly, there is a group of lumbar spinothalamic neurons in the midlumbar spinal cord, which has been proposed (at least in the rat) as a 'spinal ejaculation generator', as it is activated during ejaculation – but not during other components of male behaviour (Truitt et al. 2003). Finally, there are projections of spinal gastrin-releasing peptide neurons from the midlumbar region to the sacral parasympathetic nucleus and the SNB, which are androgen controlled and which appear to regulate the erection and ejaculation reflexes.

Testosterone has a key role in the central and peripheral modulation of erectile function (Foresta et al. 2004), with a mode of action that is permissive rather than critical. In humans, testosterone may directly affect erection by acting directly as a vasodilator of the penile arterioles and cavernous sinusoid (Mikhail 2006), by inhibiting the breakdown of cyclic GMP or by regulating the synthesis of nitric oxide (Morelli et al. 2005). Testosterone is also responsible for the centrally mediated sexual behavioural responses.

Contraction of the ischiocavernosus muscles at the roots of the penis increases blood flow in the penile vasculature and occludes the veins that drain the CCP. In the dog the levator ani, the coccygeus, and the internal obturator muscles also participate in venous occlusion (Ninomiya et al. 1989). Small venules that drain the CCP of the human penis are occluded as a result of the lengthening that occurs during erection (Udelson et al. 2000). Despite these various mechanisms, venous occlusion is not complete as, when the dorsal vein of the penis is occluded, some drainage continues through smaller channels (Carati et al. 1988, Ninomiya et al. 1989). In humans venous drainage also continues during erection and, if excessive, can lead to erection failure (Hsieh et al. 2005). As blood

VetBooks.ir

flow in the penile arteries and CCP increases and as the venous drainage is interrupted, the cavernous spaces of the erectile tissue in the blind-ending CCP become engorged with blood, causing stiffening and lengthening of the penis (Beckett et al. 1974). At the peak of erection in the stallion, blood ceases to be able to enter the CCP from the pudendal artery because of the occlusion of the penile arteries by the action of the ischiocavernosus muscles (Bartels et al. 1984).

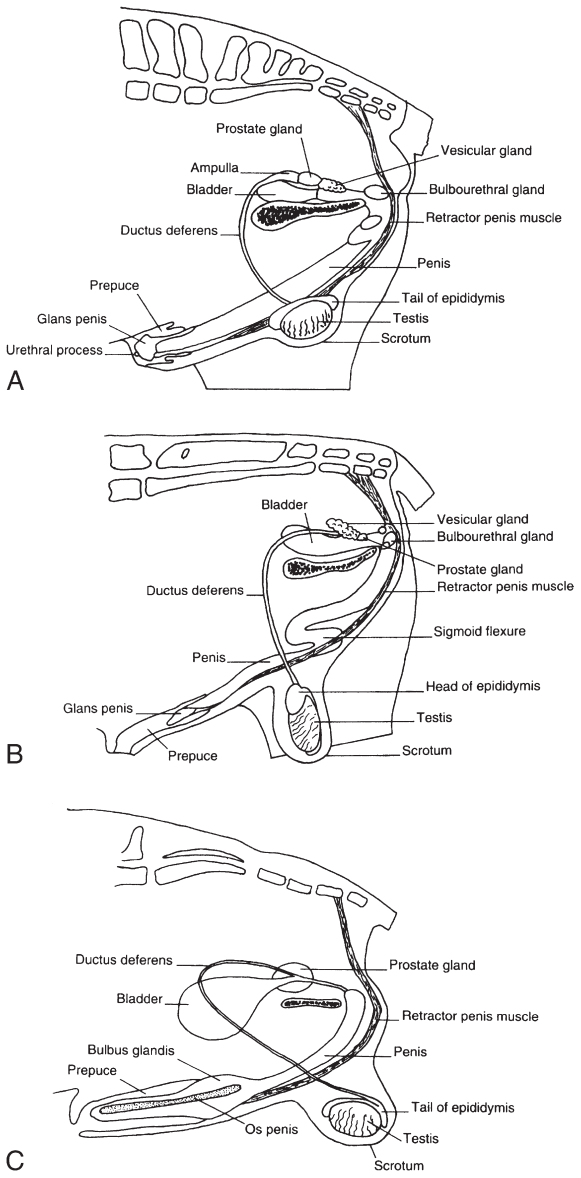
Ejaculation

The ejaculation reflex is stimulated by sensory nerves within the glans penis, which transmit to the spinal cord through the dorsal nerve of the penis, a branch of the pudendal nerve (Johnson & Halata 1991). The integrity of this nerve is essential for the ejaculation reflex to take place, and if it becomes damaged, ejaculation, though not erection, becomes impossible (Beckett et al. 1978). Pressure, tactile sensation, and, in the bull, temperature are the main stimulants to ejaculation. Afferent fibres also pass along the hypogastric nerve into the spinal cord via the sympathetic chain (Baron & Janig 1991). Efferent fibres are derived from the sympathetic and parasympathetic outflows, whereas somatic motor fibres innervate the bulbospongiosus muscle (Giuliano & Clement 2005). Ejaculation is primarily coordinated as a spinal reflex in the lower lumbar and sacral segments of the spinal cord, although with central regulation via the medial preoptic area of the hypothalamus and connecting nuclei. Central control of ejaculation is facilitated by dopamine and inhibited by serotonin (Hull et al. 1995, Waldinger & Olivier 2004). There are two components to ejaculation: (1) emission and accessory gland secretion, which are primarily controlled by the autonomic nervous system; and (2) propulsion, which is controlled via somatic nerves. Emission is under the primary control of sympathetic noradrenaline (norepinephrine). Propulsion of semen out of the urethra is caused by rhythmic contractions of the bulbospongiosus muscle, which overlies the CSP in the bulb of the penis, and of smooth muscles of the urethra (Giuliano & Clement 2005). This is accompanied by proximal closure of the bladder neck and intermittent relaxation of the external urethral sphincter and urogenital diaphragm.

Contraction of the bulbospongiosus muscle causes increased haemostatic pressure in the CSP. However, because the CSP drains from its distal end, the high pressures achieved in the CCP cannot be attained. Thus each contraction of the bulbospongiosus muscle causes a transient wave of increased pressure in the CSP, which progresses from the bulb to the glans, where it dissipates by dorsal venous drainage of the blood. Because the CCP is turgid, the increased pressure within the CSP causes a wave of occlusion of the urethra. This progressive wave of urethral occlusion, assisted by the contraction of the muscle that surrounds the extrapelvic urethra, causes conduction of boluses of semen along the urethra.

Species Differences

Details of the anatomy of the penis vary greatly between species, and, as a result, details of the functional anatomy of erection are similarly variable. In Artiodactyla (Fig. 2.14), the penis has a thick, fibrous tunica albuginea overlying the CCP and surrounding the urethra, and the individual cavernous spaces within the CCP are relatively small. The penis also has a sigmoid flexure, which is either caudal (postscrotal), as in the ruminants, or cranial (prescrotal) to the scrotum, as in the boar. In these species, relatively little blood enters the penis during erection, although the blood pressures achieved



• **Fig. 2.14** Comparative anatomy of the penis of (A) the stallion, (B) bull, and (C) dog. (Redrawn and adapted with permission from Laing et al. 1988.)

are considerable, exceeding 40,000 mm Hg during ejaculation. In order that the increased pressure induced by ischiocavernosus muscle activity can be transmitted throughout the length of the penis, specialised artery-like vascular canals and the longitudinal canals run the length of the penis. Paired canals arise in the crura of the penis, which fuse shortly afterwards to produce a single dorsal canal. Thereafter, either side of the dorsal canal gives rise to a series of branches, which join together to form paired ventral canals. The dorsal canal runs for the proximal third of the penis and the ventral canals for the remaining distance, with a short distance of overlap with the dorsal canal. Lengthening of the penis is achieved partly by longitudinal expansion of the cavernous spaces between the trabeculae of the CCP, but mainly by straightening of the sigmoid flexure of the penis (Ashdown 1970). As a result, the penis, which is normally carried high in the preputial cavity, is fully exteriorised from the narrow preputial orifice. Obliteration of the sigmoid flexure and forward movement of the penis

VetBooks.ir

is made possible by the very loose arrangement of the connective tissue that surrounds the penis and prepuce. In the ruminants full erection is only briefly attained during the single ejaculatory thrust, but copulation is more prolonged in the boar. Erection is terminated by cessation of ischiocavernosus muscular contraction, and the penis is returned to the preputial cavity by contraction of the retractor penis muscles, which restores the sigmoid flexure.

The other domestic species have a musculocavernous penis, in which the tunica albuginea is less pronounced and the cavernous spaces of the erectile tissue are larger than in the artiodactyls. In the stallion (Nickel et al. 1973, Amann 1993) tracts of longitudinally oriented smooth muscle fibres are associated with the trabeculae of the CCP. These are normally in a state of tonic contraction, holding the penis in the prepuce. The tone in these muscles falls during erection and micturition, leading to prolapse of the penis from the prepuce. In the stallion and dog (Evans & deLahunta 1988) erection produces increases in both length and girth of the penis and, as there is no sigmoid flexure, the lengthening of the penis is caused entirely by vascular engorgement.

During ejaculation, the glans of the penis of the bull and goat becomes coiled (Ashdown & Smith 1969), whereas the vermiform appendage of the penis of the ram shows a vigorous flicking movement. It is probable that these conformational changes are to assist with deposition of semen in and around the external os of the cervix. The glans penis of the stallion and boar engages in the cervical canal, with ejaculation occurring through the cervix into the uterine lumen. Thus the penis of the boar adopts a spiral conformation during copulation, which mirrors that of the cervix of the sow, but the stallion shows only a very pronounced enlargement of the glans penis during ejaculation. The dog is unique among the domestic animals in having a bone in the penis (os penis), in whose grooved ventral floor the urethra lies. During copulation the penis of the dog is gripped by the levator vestibuli of the vagina of the bitch, whereupon engorgement of the bulbus glandis occurs. Ejaculation occurs over a prolonged period of time, with the brief production of the preejaculatory and sperm-rich fractions, followed by a very protracted deposition of prostatic fluid during the copulatory tie.

Development of the Penis

The development of the external genitalia of the male was summarised by Pansky (1982). In brief, initial development of the genital organs is similar in both sexes, beginning with the development of the cloacal folds, which fuse together in front of the cloacal membrane to form the cloacal eminence. Thereafter, the cloacal membrane ruptures to form the urogenital and anal openings, the cloacal folds form the genital folds, and the cloacal eminence elongates to form the genital tubercle. Concurrently, a second pair of folds, the labioscrotal folds, develop laterally to the genital folds. At this stage the sexes are similar, but thereafter there is androgen-dependent development of the genital tubercle of the male to form the phallus. The phallus pulls the urogenital folds forward, such that the folds elongate along its ventral side to form the lateral walls of the urethral groove. The urethral groove progressively fuses along its length to form the definitive urethra, while the opening of the urethra moves distally towards the glans. The erectile tissue of the CCP and CSP differentiate at the same time. Finally, the labioscrotal folds grow towards each other and fuse in the midline to form the scrotum. Androgens are required for the differentiation of the male external genitalia; mutations of any step in the androgen synthesis pathway or in the activity of androgen receptors result in abnormalities or failure of the male genitalia to develop.

At birth the penis is fused with the prepuce throughout its length, with small lateral veins draining the erectile tissue. During prepubertal development the connective tissue joining penis and prepuce breaks down and the veins become occluded. The frenulum is the most substantial of the connections between the penis and prepuce, frequently containing quite large blood vessels. It is often the last part to break down and may not infrequently persist into postpubertal life.

Libido and Mating Behaviour

Libido is primarily dependent on androgenic steroid hormones, which allow mating and aggressive behaviour to occur, as well as maintaining the function of all parts of the male reproductive system. Libido is seldom expressed in animals that are castrated before puberty, although if a mature animal that has learnt to copulate is castrated, erection and copulation may persist for long periods or, occasionally, indefinitely. Despite the dependency of male behaviour upon androgen, there has been much debate over the relationship between absolute concentrations of androgen and libido (Foote et al. 1976, Wodzicka-Tomaszewska et al. 1981). Some have argued a permissive role for androgen, whereas others have demonstrated positive correlations between testosterone concentrations and measures of libido. Breeds of bull that are aggressive and respond quickly to the presence of an oestrous female tend to have higher testosterone concentrations than the more phlegmatic breeds, but whether this is a causal relationship remains unclear.

The males of those domestic species that are naturally herd animals spend a great deal of time detecting oestrus (Chenoweth 1981). Oestrous females of many species secrete pheromones to attract males, whereas others, notably the cow and some breeds of pig exhibit homosexual behaviour as a signal to the male of the presence of oestrus. All males smell the perineal region of the female, and the odour of the oestrous female induces the so-called 'flehmen' reaction in the bull, ram, camel, and stallion – a characteristic raised posture of the head and elevation of the upper lip. Females that are not in oestrus signal their objection to the advances of the male and, at the least, will respond by moving away or perhaps by attacking the male in the offensive manner peculiar to the species. During prooestrus the interest of the male in the female is increased, but, whereas she associates with the male, she will not permit mounting. Oestrous females signal receptivity by squatting, urinating, moving the tail to one side, and remaining stationary (Fig. 2.15). During this foreplay, the male becomes progressively aroused; there are frequent erections of the penis, with emission of accessory fluid, and many unsuccessful attempts to mount the female. Finally, mounting and copulation occur.

Stallion

After intromission the stallion performs a succession of copulatory movements of the hindquarters, which, within a minute, culminate in ejaculation. During ejaculation, successive waves of urethral peristalsis can be palpated on the lower surface of the penis, while the stallion exhibits a characteristic 'flagging' movement of the tail (Fig. 2.16). The stallion then dismounts.

Ruminants

Copulation in all the domestic species of ruminants is brief. After detecting an oestrous female, mounting is followed quickly by the single ejaculatory thrust. The male then immediately dismounts

VetBooks.ir

• **Fig. 2.15** Signs of oestrus in the mare include (A) protrusion of the clitoris and (B) squatting, urination and moving the tail to one side. (Photographs courtesy Dr. Jonathan Pycock.)

• **Fig. 2.16** The main external sign of ejaculation in the stallion is tail flagging. Peristaltic waves can also be palpated in the penile urethra.

but frequent repeated matings occur. Farm management of rams and bulls should take this high mating frequency into account. Thus whereas individual sires can service quite large groups of spontaneously cyclic females, the groups of females have to be much reduced if these have undergone oestrous synchronisation (see Chapters 8, 25 and 26). Furthermore, care has to be exercised in the use of young sires. The testis does not reach its full size and sperm-producing capacity until 1 to 2 years after puberty, nor does the epididymis reach its full length until the same time (reviewed by Salisbury et al. 1978). Until maturity has been reached, groups of females should be smaller than for adult animals. If overused, both the numbers of sperm produced are too few for adequate conception rates to be achieved and sperm from the tail of the epididymis are ejaculated before their functional maturation is complete. Thus sperm numbers and sperm maturity are both adversely affected, causing severe limitation of the chances of conception.

Boar

Copulation is relatively prolonged in pigs, lasting for between 5 and 15 minutes. After intromission the first phase is occupied by a series of vigorous thrusting movements of the hindquarters of the boar. During this phase the first part of the fractionated ejaculate is produced, which comprises only accessory fluid. The second phase is quieter and accompanied by production of the sperm-rich fraction of the ejaculate. This is followed by a final, more vigorous phase, in which the third, jelly-like accessory secretion is discharged. Ejaculation occurs directly into the uterus, which is distended with semen immediately after copulation, whereas the cervix is often sealed with a gelatinous plug. The large volume of semen produced by the boar is necessary to assist the transport of its spermatozoa along the extensive length of the uterus of the sow.

• **Fig. 2.17** The copulatory tie in the dog.

Dog

The dog achieves intromission by vigorous thrusting of the hindquarters. Once intromission has been achieved, the bulbus glandis swells considerably, while the constrictor vulvae muscles of the bitch contract behind it, thus forming the 'copulatory tie'. The sperm-rich fraction of canine semen is ejaculated within as little as 80 seconds of intromission, so that conception may occur even if copulation does not proceed through to its second stage. In this second stage the dog dismounts but remains 'connected' to, but faces away from, the bitch (Fig. 2.17). This change of position causes the penis to become bent through an angle of 180 degrees; the efferent veins of the penis are thereby occluded and the penis remains turgid. The function of the tie may be to prevent penile detumescence throughout the prolonged second stage of copulation, during which some 30 mL of sperm-free accessory fluid is pumped into the vagina and then to the uterus, where it flushes the sperm-rich fraction through the uterus. The sexes remain locked until the vulval muscles relax and penile erection wanes.

VetBooks.ir

Cat

During mating, the tom mounts the queen and grasps her neck with his teeth. As the tom adjusts his position the queen paddles her hind legs, continuing to do so at an increasing frequency during the 10 seconds, or so, for which coitus lasts. The queen cries out during copulation, and, as the tom dismounts, she may strike out at him, displaying the typical 'rage' reaction. This is followed by a period of frantic rolling and licking at the vulva. As soon as the postcoital reaction has ceased, the tom will attempt to mount again. Several matings may therefore occur within the first 30 to 60 minutes. The cat is an induced ovulator (see Ch. 1; Shille et al. 1983), so the number and frequency of matings are important in ensuring that the LH surge is of sufficient magnitude to cause ovulation (Tsutsui & Stabenfeldt 1993).

Puberty and Seasonality

RICHARD LEA AND GARY C. W. ENGLAND

In nature it is the general rule that animals breed once annually, and parturition occurs in the spring, the time most favourable to the progeny because the early neonatal period of their life will occur during the period of increasing light and warmth and at the time when food for the mother is most abundant to ensure adequate lactation. Under the conditions of feeding and housing provided by domestication, the breeding season tends to be lengthened, and some of our species, particularly cattle, may breed at any time during the year; all domesticated animals, however, show a constant tendency to revert to the natural breeding season, as evidenced by reduced fertility during summer and early autumn in sows.

Puberty and the Onset of Cyclic Activity

The young female animal shows no evidence of recurring or cyclic periods of sexual receptivity. The onset of such changes, when the female becomes sexually mature and able to reproduce**,** is referred to as puberty. Among females of the domestic species, puberty precedes the development of physical maturity and, although they become capable of reproducing, their efficiency, particularly with respect to their fecundity (number of offspring), has not reached its maximum. For example, juvenile ewes mated just after puberty produce on average 0.6 lambs to weaning compared with 1.2 lambs produced from ewes 1 year older (Kenyon et al. 2004). This is reported to be caused by a lower ovulation rate, increased fertilisation failure, embryo loss and failure to be mated by the ram (Edwards et al. 2016).

The initiation of puberty is largely a function of the animal's age and maturity because the female is born with a genetic potential for cyclic reproductive activity. Provided the environmental influences are favourable at this time, then once the 'biological clock' is started, it will continue for as long as the environment remains promising. In none of our domestic species is there a physiological change comparable with the menopause of women. However, reproductive senescence is reported in killer whales and pilot whales, and in these species, this is thought to be a strategy to boost the ecological fitness. Postreproduction aged females take a leadership role in the group and are thus central to the maturity of the younger members of the pod (Brent et al. 2015).

Among nonseasonal polycyclic animals such as the cow and sow, the recurring cyclic activity is interrupted by pregnancy, lactation and pathological conditions. In those species that are seasonally polycyclic (i.e., the mare, ewe, doe (or nanny) goat and cat) or monocyclic (i.e., the bitch) there are periods of sexual quiescence or anoestrus.

When the female reaches puberty, the genital organs increase in size. During the prepubertal period the growth of the genital organs is very similar to that of other organ systems. At puberty their growth rate is accelerated, a point well illustrated in the gilt in which the mean length of the uterine horns is increased by 58%, the mean weight of the uterus by 72% and the mean weight of the ovaries by 32% between 169 and 186 days of age (Lasley 1968). Females of domestic species reach the age of puberty at the following times:

- Mare: 1 to 2 years
- Cow: 7 to 18 months
- Ewe: 6 to 15 months
- Doe or nanny goat: 4 to 8 months
- Sow: 6 to 8 months
- Bitch: 6 to 20 months
- Queen cat: 7 to 12 months

The changes that occur at puberty depend directly upon the activity of the ovaries, which have two functions: the production of the female gametes and the synthesis of hormones. Consider the changes that occur in the ovary of the heifer calf. At birth the ovaries may contain up to 150,000 primary or primordial follicles apiece, and each follicle consists of an oocyte surrounded by a single layer of granulosa cells but no thecal cells. Soon after birth, the ovaries start to produce growing follicles, which consist of an oocyte with two or more layers of granulosa cells and a basement membrane. The stimulus for the development of these follicles is intraovarian; until the heifer reaches the age of puberty, they will develop only to the stage in which they have a theca interna and then start to undergo atresia. Further development of these follicles to produce mature Graafian or antral follicles, of which there are about 200 growing follicles at puberty, is dependent upon the stimulus of gonadotrophic hormones. Despite the absence of oestrous cycles, there is follicular growth, as has been shown using transrectal ultrasonography in calves from 2 weeks of age. It was noted that there were follicular waves in response to follicle-stimulating hormone (FSH) secretion that were similar to those of the adult and that individual follicular development was characterised by growing, static and regressing phases (Adams et al. 1994).

The sheep has been used extensively for studying many of the mechanisms involved in the initiation of puberty; however, it must be stressed that seasonality exerts an overriding influence in this species. The onset of puberty is signalled either by the occurrence of the first oestrus or the first ovulation; in the ewe lamb these do not occur simultaneously because the first ovulation is not preceded by behavioural oestrus. A similar response is

VetBooks.ir

seen in sexually mature ewes at the onset of the normal breeding season.

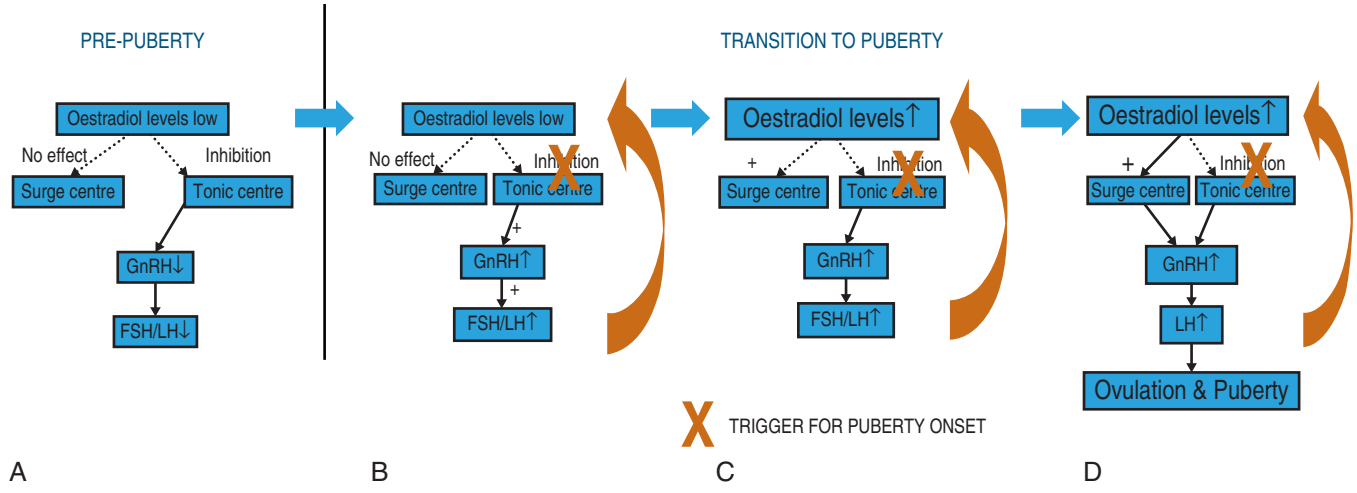
The hormone that is primarily associated with the onset of ovarian activity, and hence puberty, is luteinising hormone (LH). In adult ewes during the normal breeding season, basal LH concentrations increase together with the LH pulse frequency to one per hour during the period of maximum follicular growth. This results in the development of follicles to the preovulatory stage and to their secretion of oestradiol, which activates the LH surge causing ovulation and corpus luteum formation. In the prepubertal ewe lamb, LH pulses occur at similar amplitudes but much lower frequencies (one every 2–3 hours). As a consequence, follicular growth is insufficient to activate the LH surge necessary for final follicular maturation and ovulation.

Experimental evidence in prepubertal ewe lambs has shown that ovarian follicles are capable of responding to exogenous gonadotrophin stimulation, and the pituitary is capable of secreting LH at a frequency to stimulate ovulation. The failure of the prepubertal ewe lamb to undergo ovulation and exhibit oestrus is caused by the high threshold for the positive feedback effect of oestradiol, and thus there is no LH surge. Indeed, the endocrine trigger for puberty is based on sex steroid feedback regulatory mechanisms, which operate at the level of the tonic or surge centres of the hypothalamus (Day et al. 1984, Ebling et al. 1990). The sequence of events that results in the onset of puberty is depicted in Fig. 3.1. Puberty onset relies on the secretion of ovarian oestradiol so that the circulating concentration is sufficient to stimulate a preovulatory gonadotrophin-releasing hormone (GnRH) and LH surge. Before puberty, when the concentration of oestrogen is too low to exceed the necessary threshold required for ovulation, the oestrogen that is present has an inhibitory effect on the tonic centre of the hypothalamus (Fig. 3.1A). As puberty approaches, the inhibitory effect of oestrogen on the tonic centre is reduced (Fig. 3.1B). Consequently, the hypothalamic-pituitary-gonadal axis (HPG) axis starts to become more active so that the pulsatile frequency of GnRH increases as do FSH and LH. The increased FSH thus stimulates more follicle development, which then starts secreting oestrogen. This process continues until oestrogen concentrations are high enough to stimulate the surge centre of the hypothalamus, thus causing a preovulatory GnRH and LH surge (Fig. 3.1 C, D). The endocrine trigger for puberty is therefore considered to be the loss of feedback inhibition of oestrogen on the tonic centre of the hypothalamus (Ebling et al. 1990).

Male Puberty Onset

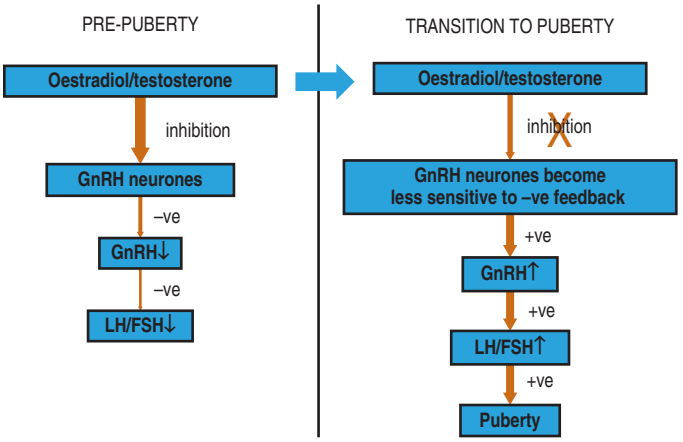
Different parameters can be used to define puberty onset in the male. These may be behavioural or relate to the age of first ejaculation, both of which occur before sperm numbers are high enough to achieve fertilisation. Indeed, younger males will have smaller testes and relatively short epididymides, and therefore daily sperm production will be lower than in more mature animals. Consequently, males that are within a few months of puberty will have a reduced capacity to establish high pregnancy rates. The quality of the ejaculate may therefore also be considered as an index of puberty, in terms of sperm production and the generation of sufficient numbers, to reliably establish a pregnancy.

Similar to the female, puberty in the male occurs as a result of a decrease in hypothalamic sensitivity to oestradiol and testosterone. Because the male testosterone crosses the blood–brain barrier and is then converted to oestradiol by the enzyme aromatase, the inhibitory effect is primarily caused by oestradiol. As puberty onset occurs in the male, the inhibitory effects of oestradiol and testosterone on hypothalamic GnRH secreting neurons are reduced (Fig. 3.2). The increased pulsatile release of GnRH then stimulates more LH and FSH, which stimulate the testis to undergo spermatogenesis, thus initiating the onset of puberty. In the male the rise in LH begins earlier than in the females. Consequently, the rise in testosterone is gradual, and in the sheep this includes the 2-month period required for spermatogenesis. It is thought that the earlier initiation of puberty in the male allows sperm development to occur before the females develop the capacity to ovulate (Foster et al. 2006).



• **Fig. 3.1** Puberty onset in the female. Before puberty: (A) The ovary does not secrete enough oestradiol to stimulate the surge centre of the hypothalamus to produce high amplitude episodes of GnRH. Low concentrations of oestradiol also have a negative feedback effect on the hypothalamic tonic centre. (B) As the transition to puberty begins, the sensitivity of the tonic centre to oestradiol inhibition reduces, enabling hypothalamic neurons to secrete GnRH. (C) Consequently, the frequency of LH and FSH episodes increase, which stimulates the ovary to produce more oestradiol. (D) When the concentration of oestradiol reaches a threshold, it stimulates the surge centre to secrete a preovulatory surge in GnRH, which results in a preovulatory surge in LH, ovulation and the initiation of puberty.

VetBooks.ir



• **Fig. 3.2** Puberty onset in the male. Before puberty, low concentration testosterone crosses the blood–brain barrier and is converted to oestradiol by aromatase. Both oestradiol and testosterone have a negative feedback effect on hypothalamic GnRH neurons. As the transition to puberty begins, the sensitivity of the hypothalamic neurons to oestradiol reduces. Increased GnRH release stimulates LH and FSH secretion, which act on the testis to initiate puberty.

Seasonal Breeding as a Recurring Model of Puberty

In those species that are seasonal breeders such as the ewe, mare and queen, the age at which puberty occurs will be influenced by the effect of season of the year. For instance, a filly born early in the year (i.e., January or February) may have her first oestrus in the May or June of the following year (i.e., when she is 16 or 17 months old). A filly foal born late in the year, July or August, may not have her first oestrus until she is 21 or 22 months old.

By definition, seasonal breeders undergo a period of anoestrus (nonbreeding season), and the annual transition to the breeding season has many similarities to puberty. In both cases, the fundamental endocrine mechanisms that enable a sexually quiescent animal to become sexually active are very similar. For example, the anoestrous and prepubertal animal is characterised by the lack of an LH surge necessary for ovulation to occur, and yet in both cases the ability to produce an LH surge in response to a stimulus (GnRH) is present. In both cases, LH secretion is pulsatile but low frequency, and thus the stimulus for an adequate rise in oestrogen is missing. Finally, the trigger for puberty described previously also applies to animals transitioning between anoestrus and the breeding season.

Other factors are also involved. The frequency of LH secretion is dependent upon GnRH from the hypothalamus, which is controlled by an area in the hypothalamus referred to as the neural GnRH pulse generator. Age-related changes in brain morphology and neuronal cytoarchitecture may also be important because extrapolation from studies performed in rats, for example, has shown an increase in the number of GnRH cells with spine-like processes on the soma and dendrites. In addition, the inhibitory effect of opioid peptides on LH secretion is reduced with age, which may provide a neurochemical explanation for the changes in pituitary sensitivity to oestradiol feedback that occur at puberty (Bhanot and Wilkinson 1983, Wray and Hoffman 1986).

The reason for the 'silent' first oestrus of the pubertal animal is believed to be because the central nervous system requires priming with progesterone before it will respond and the animal will show behavioural signs of heat. The first ovulatory cycle has been shown to be short in pubertal heifers (7.7 ± 0.2 days), and the first corpus luteum (CL) not only has a shorter than normal life span but is also smaller in size. One explanation for this is that the dominant follicle, from which the first ovulation arises, has already entered the static phase of growth. The subsequent interovulatory interval is normal (Adams 1999). Once puberty has occurred, in most domestic species, there are waves of follicular growth and regression. However, even in the prepubertal animals, follicular waves have been identified; these have been recorded in heifers (Evans et al. 1994a, b) and fillies (Nogueira and Ginther 2000).

Melatonin, Puberty and Seasonality

Melatonin and Other Pineal Peptides

The pineal gland appears to have an important role in controlling reproduction in seasonal breeding species and in the timing of puberty by influencing the release of FSH, LH and prolactin. Although much of the interest has been in the action of the indoleamine melatonin, there is increasing interest in the other pineal peptide hormones, namely arginine vasotocin, gonadotrophin and prolactin-releasing and inhibitory hormones. There is some suggestion that melatonin may not act directly upon the hypothalamus/anterior pituitary, but indirectly via the other pineal peptide hormones.

Melatonin drives the reproductive response of the ewe to inductive photoperiods (Bittman et al. 1983). Rhythmic administration of melatonin to adult ewes exerts a similar effect to increased hours of darkness by inducing the onset of the breeding season (Arendt et al. 1983) and causes changes in prolactin concentrations in the plasma that are similar to those after exposure to short days (Kennaway et al. 1982). In sheep an intact pineal gland is required for a normal photoperiodic response to altered daylight patterns; however, other seasonal environmental cues are important because pinealectomised ewes still show seasonal breeding (Lincoln et al. 1989).

The mare is a seasonal breeder but is 'switched on' by increasing day length. The pineal gland is involved because if it is removed, the mare does not show a normal response to changes in photoperiod. In intact mares, melatonin concentrations increase during hours of darkness (Grubaugh et al. 1982). There is some evidence that foals are conditioned at an early age and develop a pattern of melatonin secretion from about 7 weeks of age (Kilmer et al. 1982).

The Role of Kisspeptin in the Onset of Puberty and Seasonality

For many years it was thought that an increase in the frequency and amplitude of GnRH secretion was the main marker of puberty. However, puberty and seasonality are influenced by a number of environmental factors, including nutrition and degree of fatness (discussed later in this chapter), and this is indicative of a higher level of control. This control is mediated by presynaptic neurons that are sensitive to environmental influences and, in turn, stimulate neuronal GnRH secretion. One of the key proteins released by presynaptic neurons is the hormone kisspeptin, which when released, binds to its receptor (KISS1R or GPR54: galanin-like G protein-coupled receptor 54), which is expressed on GnRH secreting neurons. There is now considerable evidence that an intact kisspeptin signalling pathway is a prerequisite for the onset of puberty in mammals, which has led to the expression that 'puberty begins with a Kiss' (Dungan et al. 2006, Terasawa et al. 2013).

VetBooks.ir

An addendum to the mechanism describing the onset of puberty (Figs 3.1 and 3.2) must therefore also include kisspeptin-secreting neurons that are found in the arcuate nucleus and the periventricular nucleus of the hypothalamus. The rising oestrogen concentrations that eventually activate the HPG axis do so by a positive feedback effect on kisspeptin signalling. Indeed, kisspeptin-secreting cells express the oestrogen receptor subtype alpha (ERα) necessary for the feedback effects of oestrogen, whereas the receptor is not present on GnRH secreting cells (Clarke et al. 2009). Similarly, it is thought that the negative feedback effect of oestrogen before puberty works through reduced kisspeptin levels. This goes beyond puberty because the effects of oestradiol on kisspeptinergic nuclei require integration into the mechanism of ovulation described in Chapter 1.

Kisspeptin also plays a key role in seasonality. Studies in sheep have shown that the expression of the kisspeptin gene increases with reduced photoperiod, and these seasonal changes occur in the arcuate nucleus of the hypothalamus. Furthermore, kisspeptin treatment of anoestrous sheep has been shown to restore reproductive function (Clarke et al. 2009). This raises the possibility of a future clinical use of kisspeptin in the manipulation of seasonality in this species.

Although the primary translation product of the kisspeptin gene is a 145 amino acid polypeptide, various isoforms are produced and a decapeptide (kisspeptin 10) has full biological activity central to the control of seasonality in both short- and long-day breeders (Revel et al., 2007). The most investigated long-day breeder is the Syrian hamster, and studies have shown that kisspeptin 10 administration can restore reproductive function under photoinhibitory conditions (Ansel et al. 2011). Similarly, in sheep, as short-day breeders, kisspeptin 10 can induce ovulation in anoestrous ewes (Caraty et al. 2007).

Despite these advancements, the mechanism by which reduced melatonin has opposite effects on seasonality in short- and long-day breeders and how this relates to kisspeptin function is not fully understood. However, some insight has come from the study of another family of peptides called RFamide-related peptides (RFRP) that are also expressed by hypothalamic neurons and have been shown to inhibit gonadotrophin release (Henningsen et al. 2016). RFRP3 appears to be the main inhibitory peptide in mammals and is thought to act on the same GnRH neurons that are regulated by kisspeptin 10. Therefore it has been postulated that seasonality is regulated through the relative activities of kisspeptin 10 and RFRP3 secreting neurons in the hypothalamus. Further research is required to truly clarify the precise mechanisms involved.

Other External Factors Influencing the Time of Onset of Puberty and Seasonality

The time of onset of puberty is determined by the individual's genotype, with smaller breeds of animal tending to be slightly more precocious. However, this inherent timing is influenced by a number of external factors.

Nutrition

There is good evidence that, in most domestic species, the onset of puberty is closely linked to the attainment of a critical body weight, as well as a minimum percentage body fat, or metabolic mass (Frisch 1984). Thus nutrition is an important factor. Animals that are well fed with good growth rates reach puberty before those that are poorly fed with slow growth rates. However, unless the animal is severely malnourished, cyclical activity will eventually occur. Although the cellular mechanisms which underlie metabolic influences on hypothalamic GnRH neurons are not fully characterised, dietary changes clearly alter GnRH secretion. For example, dietary restriction in sheep delays puberty by an effect on both frequency and amplitude of GnRH secretion (I'Anson et al. 2000).

The protein leptin (see later in this chapter), secreted by white fat cells in adipose tissue, is an important link between metabolic status and the neuroendocrine axis. Although several studies have shown that leptin treatment can advance the onset of puberty in both restricted and ad lib fed animals (Barash et al. 1996, Ahima et al. 1997) and that serum leptin concentrations increased in pigs (Qian et al. 1999) and heifers (Garcia et al. 2002) at puberty, it is generally accepted that leptin is not the triggering signal for puberty, but a permissive signal that enables puberty to occur (Barb and Kraeling 2004). Leptin acts as a metabolic 'gate' as circulating concentrations increase over the course of pubertal development; serum leptin levels reach a putative stimulatory threshold that permits activation of the hypothalamic–pituitary–gonadal axis. This is associated with a decrease in the negative feedback action of oestradiol on the hypothalamic–pituitary axis, and stimulation of adipose leptin gene expression (Barb and Kraeling 2004). Because GnRH neurons do not express leptin receptors, the effects of leptin on puberty must be indirect and are thought to be mediated by presynaptic hypothalamic neurons. Specifically, leptin is thought to act not only through kisspeptin neurons, but also through POMC (proopiomelanocortin) and neuropeptide Y (NPY) neural networks. In other words, these neurons are thought to transmit leptin signals to the neural networks that regulate GnRH secretion (Amsteldam and Williams 2014). Other metabolic factors, including glucose and fatty acids, may also act indirectly on GnRH through activities on 'metabolic sensitive' neurons, which then influence kisspeptin and ultimately GnRH secretion.

Proximity of the Male

Studies in sheep and pigs have shown that exposure to the male of the species will advance the timing of the onset of puberty. This so-called 'ram or boar effect' is probably mediated by pheromonal and other sensory cues influencing hypothalamic GnRH secretion.

Climate

Anthropomorphic extrapolation has assumed that animals living in the tropics reach puberty at an earlier age than those in temperate climates. Studies carried out in Zambia have shown that in cattle this is not true.

Disease

Any disease that can influence the growth rate, either directly or because of interference with feeding and utilisation of nutrients, will delay the onset of puberty.

Puberty and Seasonality: A Species Overview

Horse

Puberty

Fillies are often seen in oestrus during their second spring and summer (when they are yearlings); however, under natural

VetBooks.ir

conditions, it is unusual for them to foal until they are over 3 years old. As outlined previously, the timing of puberty will be affected by season, with fillies born earlier in the year having their first oestrus 5 months earlier than those born later in the year.

Seasonality

The mare is normally a seasonal breeder, with cyclic activity occurring from spring to autumn; during the winter she will normally become anoestrus. However, it has been observed that some mares, especially those of native pony breeds, cycle regularly throughout the year. This tendency can be enhanced if the mares are housed and given supplementary food when the weather is cold and inclement and if additional lighting is provided when the hours of daylight are short.

Horse breeding has been influenced by the demands of thoroughbred racing because, in the northern hemisphere, foals are aged from 1 January, irrespective of their actual birth date. As a result, the breeding season for mares has been, for over a century, determined by the authorities as running from 15 February to 1 July. Because the natural breeding season does not commence until about the middle of April and maximum ovarian activity is not reached until July, it is obvious that a large number of thoroughbred mares are bred at a time when their fertility is suboptimal.

Winter anoestrus is followed by a period of transition to regular cyclic activity. During this transition the duration of oestrus may be irregular or very long, sometimes more than a month. The manifestations of heat during the transitional phase are often atypical and make it difficult for the observer to be certain of the mare's reproductive status. Also, before the first ovulation, there is poor correlation between sexual behaviour and ovarian activity because it is common for the early heats to be unaccompanied by the presence of large follicles and some long spring heats are anovulatory. However, once ovulation has occurred, regular cycles usually follow with oestrus typically lasting 6 days of the 20 to 23 day equine cycle.

Cow

Puberty

Under conditions of domestication, normal and well-cared-for cattle are polyoestrous throughout the year. The age at first oestrus, or puberty, is affected by nutrition and season of birth and ranges from 7 to 18 months, with an average of 10 months. A small proportion of heifers do not ovulate at the first heat, and in a majority of young cattle, the oestrus associated with the first ovulation is 'silent' (Morrow et al. 1969). Poor feeding and calfhood disease delay puberty.

Seasonality

By definition, cows are polyoestrous and therefore not seasonal breeders. However, melatonin levels are influenced by photoperiod, and effects have been reported on milk yield, which is increased with long photoperiod; thus there may be more subtle effects on reproduction/reproductive performance (Dahl et al. 2000). Interestingly, once puberty has been reached, cyclical activity should persist, except during pregnancy, for 3 to 6 weeks after calving, during high milk yield (especially if there is some evidence of dietary insufficiency) and with a number of pathological conditions. Some cows and heifers also fail to show overt signs of oestrus yet have normal cyclical activity, a condition referred to as 'silent heat' or suboestrus. This may, however, be caused by failure of the herdsperson to observe the signs rather than a failure of the cow to show signs. The typically reported length of oestrus in heifers is 15 hours but with a wide range of 2 to 30 hours; the oestrous cycle is 20 days.

Sheep

Puberty

The onset of puberty in the ewe is typically around 8 to 9 months, but there is variation with breed and a strong influence of the time of birth as a result of photoperiod. For example, lambs born in the spring when natural food sources are good may reach puberty as early as 6 months. By contrast, those born later in the year may not reach puberty for 12 to 15 months.

Seasonality

The sexual season of most breeds of sheep in Britain is from October to February, during which time there are 8 to 10 recurrent oestrous cycles. The stimulus for the annual onset of sexual activity is declining length of daylight. The extent of the breeding season diminishes with increase in latitude; thus at the equator ewes may breed at any time of year, whereas in regions of high latitude – in both northern and southern hemispheres – the breeding season is restricted and distinct, with a prolonged phase of anoestrus after parturition. The breed of ewe also influences the duration of the breeding season; for example, in Dorset Horns it is distinctly longer than in other breeds – in which three crops of lambs can be obtained in 2 years – but in hill breeds, such as the Welsh Mountain and Scottish Blackface, it is shorter. Local breeds of central Europe and the Merino in Australia may not show an annual anoestrus. Also, in 'ordinary' breeds in Britain, such as the Clun Forest that normally shows a distinct seasonal activity, isolated instances of successful mating may occur in every month of the year. Ewe lambs and yearling ewes have shorter breeding seasons than older ewes. The seasonal onset of sexual activity can be advanced by artificial manipulation of the photoperiod and by the use of hormonal agents (described later in this chapter). Once cyclicity has been initiated, the interovulatory interval in British breeds is around 17 days and oestrus lasts about 30 hours.

Goat

Puberty

The onset of puberty in the doe goat varies from 4 to 8 months and is influenced by breed, the month of birth and the presence of a male. Similar to sheep, puberty usually occurs with reduced photoperiod in the autumn. However, does born in the spring will achieve puberty in autumn of the same year, whereas those born in autumn will not reach puberty until late the following year.

Seasonality

The breeding season in the UK is from August to February, with the greatest activity in the months of October, November and December. Near the equator, there is no evidence of seasonality but continuous cyclic activity. The doe (nanny) goat is polyoestrous, with an interoestrous interval of 20 to 21 days, although it is rather irregular at the beginning of the breeding season. The average length of oestrus is 36 hours, ranging from 24 to 28 hours.

Pig

Puberty

Puberty in gilts occurs at about 7 months, but diet, breed (including the degree of inbreeding) and season of birth influence the time of

VetBooks.ir

onset. At the first oestrus the number of ovulations is low, but it increases thereafter so that, if mating is delayed until the third heat, a larger litter will result. The crossbreeding of inbred lines increases the ovulation rate, as does the provision of a high energy diet for 11 to 14 days before the expected oestrus; however, continuing such a diet after mating increases embryonic loss. Fecundity is best from the fourth to seventh gestations.

Seasonality

Although the domestic sow is generally considered to be polyoestrous, the wild pig is a seasonal breeder, with the main period being late autumn and a second peak of activity in April (Claus and Weiler 1985). There is some evidence of the influence of photoperiod on reproduction in the domestic sow. For example, anoestrus is more prevalent in summer and to a lesser extent in February and March, whereas the ovulation rate is lower in summer. For the most part, the recurrent reproductive cycles of 21 days are interrupted by pregnancy and lactation. The average length of oestrus is 53 hours, with spontaneous ovulation occurring between 38 and 42 hours from the beginning (Signoret 1971).

Dog

Puberty

Puberty onset in the bitch ranges between 5 and 24 months and is influenced by breed, body weight and environmental factors. The smaller breeds of dog reach puberty earlier (5–6 months) than larger breeds, with little evidence of an effect of photoperiod on puberty onset in the domestic dog because it has lost the seasonality effects seen in wild canids (Gobello 2014).

Seasonality

Reproductive activity in the bitch differs from the polycyclic pattern of other species in that there are no frequent, recurring periods of oestrus, either repeatedly throughout the year as in cattle and pigs, or seasonally driven as in horses, sheep, goats and cats. In the domestic bitch, there is little evidence of a seasonal effect on reproductive function because there is a fairly even distribution of the occurrence of oestrus throughout the year (Sokolowski et al. 1977). In contrast, wild canids do exhibit seasonal influences on reproduction. For example, a study of captive African wild dogs has shown that there is evidence of seasonality, with the females exhibiting a biphasic pattern of receptivity manifest in the winter and summer (Newell-Fugate et al. 2012).

All bitches have a prolonged period of anoestrous or sexual quiescence between successive heats irrespective of whether they have been pregnant or not; this pattern has been described as monocyclic (Jochle and Andersen 1977). Despite extensive research, it is only comparatively recently that the mechanisms involved in determining the duration of anoestrus, and when bitches come into oestrus, have started to unfold. In addition, it must be stressed that this, as with much of the work on canine reproduction, has been done on experimental Beagle colonies, which may or may not be representative of the species in general. Recent evidence suggests that endogenous dopaminergic substances have a direct effect on regulating GnRH secretion, thereby stimulating basal FSH secretion and initiating folliculogenesis (Okkens and Kooistra 2006). The average interval between successive oestrous periods is 7 months, but it is variable. There is some evidence that the breed of the bitch can have an effect. For example, for the Rough Collie it is 37 weeks, but for the German Shepherd it is 26 weeks (Christie and Bell 1971); other breeds that were studied had mean intervals between these two figures. Mating does not appear to influence the interval, although pregnancy caused a slight increase (Christie and Bell 1971).

Cat

Puberty

Body weight is the most important factor in determining puberty in nonpedigree cats (Feldman and Nelson 1996). Females will usually show their first oestrus once a weight of 2.3 to 2.5 kg has been attained, at an approximate age of 7 months. Puberty occurs a month or two later in males, at a weight of approximately 3.5 kg. Puberty is also influenced by the season of birth; females born very early in the year may mature in the autumn of the same year, whereas those born later will not normally show oestrus until the following spring. Puberty is much more variable in pedigree cats (Jemmett and Evans 1977). Oriental queens (Siamese and Burmese) may show their first oestrus before 5 months of age, whereas pedigree long-hair cats may not mature until over 1 year of age.

Seasonality

Free-living nonpedigree and feral cats are seasonally polyoestrous, with a period of anoestrus that begins in the late autumn. Increasing daylight length is the most important factor in inducing the resumption of reproductive activity, and the first oestrus will usually be seen soon after the shortest day of the year. If a constant 14 hours of lighting is provided daily during the breeding season, sexual activity will continue throughout the year; this manipulation of photoperiod will alter the circadian rhythm of melatonin production (Leyva et al. 1984). If the lighting regimen is changed from 14 to 8 hours, then cyclic activity will cease immediately (Leyva et al. 1984). There may be a period of apparent lack of oestrous activity in the early summer, but this corresponds with the pregnancy or lactation after mating earlier in the year, rather than true anoestrus. In the cat, the duration of oestrus is 7 to 10 days and the interoestrous interval is about 17 days.

Artificial Induction of Puberty and Seasonality

In seasonal breeders, the ability to produce offspring out of season or to advance the time of onset of cyclic activity has advantages. In these and in other species, the ability to ensure that an individual or group of animals does not come into oestrus, or is in oestrus at the same time, has attractions. The methods that are available can be divided into two main groups: those that do not involve the use of hormones and those that do.

Nonhormonal Methods

Light

The onset of cyclical activity in the mare, ewe, goat and cat is dependent upon changes in the hours of daylight. The mare and queen are stimulated to activity by a lengthening photoperiod, whereas in the ewe and goat, it is the effect of a decreasing photoperiod that is the stimulus.

In ewes and doe goats, it is likely that it is the preceding long day length that controls the timing of the breeding season, with the decreasing day length actually synchronising the rhythm of the endocrine events that trigger the onset of cyclical ovarian activity. The provision of housing with controlled lighting enables the timing of the breeding season to be advanced or changed, even to the extent of providing an equatorial lighting regimen so that breeding

VetBooks.ir

can occur throughout the year. There are two approaches: (1) the gradual and (2) the abrupt. In the former, day length is reduced incrementally until the final fixed day length is reached. In the latter, the ewes and does are subject to a lighting regimen that on day 1 is the natural one, with a sudden decrease on day 2, and are then kept on reduced lighting until breeding has taken place. One method that obviates the need for special daylight-proof housing is if in late pregnancy or at parturition, ewes are exposed to 22 hours of daylight using an artificial source and then a reduction to natural day length. Alternatively, in late pregnancy ewes are exposed to 18 hours of daylight for 1 month, followed by a sudden return to 8 hours. This results in ewes having a fertile oestrus 3 months after lambing. Modifying photoperiod has not been used much commercially because it is not without problems, not least of which is the fact that there is a wide range in the response of the ewes as measured by the time of onset of cyclical ovarian activity. In the sow, an artificial reduction in day length from May to August has been shown to decrease the interval from weaning to oestrus from 23.6 to 5.7 days (Claus and Weiler 1985).

If mares are stabled in late autumn in the northern hemisphere and are subjected to artificial light, preferably of increasing duration, then it is possible to advance the onset of normal cyclical activity so that there is oestrus and ovulation. This effectively shortens the transition phase between anoestrus and the breeding season, a process that naturally takes place over several weeks or months. The recommendation for artificial lighting is to initiate it from 1 December at the latest. An economic, reliable and relatively easy way to manage artificial lighting is to expose mares to 2.5 to 3 hours of light at sunset. Day length itself does not appear to be the absolute factor in determining seasonality because mares naturally exposed to different periods of photostimulatory light have been shown to enter the breeding season at about the same time. Some studies not only suggest that 2.5 hours of additional light in the evening was sufficient to advance the breeding season, but also that additional lighting in the morning did not further advance the season (Sharp 2011). Of interest is that a 1-hour pulse of light after the onset of darkness appears only to be effective when applied 9.5 to 10.5 hours into the dark phase (Palmer et al. 1982). The mechanisms that underlie these effects are uncertain, although data is beginning to emerge on clock genes that appear to be regulated by the suprachiasmatic nucleus of the hypothalamus and coordinated throughout the body (Lowrey and Takahashi 2004). In a recent study, equine circadian clock genes (e.g., *PER1*: period homolog 1) were detected in hair follicles and shown to demonstrate 24 hour oscillations, thus providing a way of monitoring peripheral clock changes in the horse (Watts et al. 2012).

Nutrition

Because both photoperiod and nutrition influence reproduction at the level of the hypothalamus, altered nutrition is likely to have the capacity to influence reproductive parameters such as seasonality. For example, a study carried out over a 3-year period demonstrated that the well-fed mare has a longer period of cyclicity than those on a more restricted diet (Scaramuzzi and Martin 2008). Furthermore, the stabling of mares and the provision of good feeding are believed to assist in stimulating the onset of cyclic activity in early spring. There is also evidence for the converse because it has been reported that when yarded mares are turned out to fresh spring grass, about 80% of them come into oestrus and ovulate within 14 days (Allen 1978). Furthermore, barren and maiden mares maintained in yards on adequate, but mainly dried, feedstuffs during the winter and spring remain in anoestrus longer than those that are kept out at grass. An explanation for this is difficult to find, although it may be related to the beta-carotene content of the diet as fresh spring grass contains large amounts of this substance. Nutrition has also been reported to affect the seasonal pattern of activity in a number of other species, including goats and sheep, and can also influence the resumption of ovarian activity in postpartum cows (Scaramuzzi and Martin 2008).

Other Nonhormonal Methods

The presence of a male animal can exert its effect upon the cyclical activity of the female. This is well demonstrated in sheep, in which the introduction of a vasectomised tup at the start of the breeding season will stimulate the onset of oestrous cycles in the majority of ewes, as well as bringing about some degree of synchronisation of cyclical patterns.

Hormonal Methods

Kisspeptin

There has been considerable interest in kisspeptin as a stimulator of GnRH release. This has been investigated in a variety of species, including the rat, mouse, sheep, monkey and human. In the anoestrous ewe, a low dose infusion of kisspeptin stimulates gonadotrophin secretion and induces ovulation. Furthermore, kisspeptin is able to synchronise LH surges in progesterone-primed ewes (Caraty et al. 2007). This raises the possibility that kisspeptin or kisspeptin analogues may have a future use as pharmacological agents in the manipulation of the ovine reproductive axis.

In the anoestrous mare, equine kisspeptin-10 (eKp10) is able to induce LH and FSH secretion, but in contrast to the ewe, it is not able to induce ovulation. A similar response was observed when given to mares at different stages of the cycle (Decourt et al. 2014). Consequently, the role of kisspeptin in equine ovulation is less clear than in the sheep, which provides limitations on the kisspeptin system as a means of manipulating the equine reproductive axis. A novel kisspeptin-10 has also been identified in the dog, which is able to stimulate LH secretion when administered in vivo to the anoestrous bitch (Albers-Wolthers et al. 2014). Although dopamine–kisspeptin interaction has not been investigated in the bitch, this is a possibility because, in sheep, inhibitory dopaminergic neurons have been shown to block kisspeptin stimulation of GnRH during anoestrous (Goodman et al. 2012).

Although these experimental studies are promising in terms of future strategies to manipulate kisspeptin neurons to control puberty onset and seasonality, further research is required to fully understand the hypothalamic mechanisms involved.

GnRH

It seems sensible that repeated dosing with GnRH should induce oestrus in prepubertal females. However, there is little clinical justification for early induction of puberty, and efficacy is poor unless the female is close to puberty (i.e., is physiologically mature).

The reason for pubertal animals being acyclical may be a result of seasonality (e.g., mare, ewe, queen), monooestrous cyclicity (e.g., bitch) or postpartum anoestrus (e.g., cow).

For females in seasonal anoestrus, the repeated administration of GnRH or its analogues may induce a return to cyclical activity; however, efficacy is poor unless the female is close to a spontaneous cycle. For example, a study in the southern hemisphere (Williams et al. 2007) reported that low dose GnRH-releasing pumps advanced the onset of breeding activity in anovulatory mares. However, the greatest efficacy for oestrus induction in the mare is observed

VetBooks.ir

when treatment begins after the vernal transition (waves of follicle growth without ovulation) has already commenced. In clinical practice, exposure to artificial lighting regimes is required before implementation of GnRH regimes for termination of anoestrus.

For bitches in anoestrus, it is possible to induce oestrus using a GnRH superagonist (deslorelin) implant (Kutzler et al. 2009). The initial response to inserting a deslorelin implant is the release of FSH and LH, which causes follicle growth and results in a return to oestrus. At this point, the implant needs to be removed to prevent later receptor down-regulation (the deslorelin implant is marketed as a contraceptive). Fertility with deslorelin-induced cycles in bitches appears good.

Anoestrus, common in postpartum animals, can be a particular concern in the cow, in which the principle causes are negative energy balance and stress, which adversely affect systemic concentration of metabolic hormones, insulin and insulin-like growth factor. In these cases there is follicle growth but a lack of ovulation. Single doses of GnRH have limited success at terminating postpartum anoestrus in dairy cows; rather, regimes using GnRH to cause luteinisation of the anovulatory follicles are followed by prostaglandin administration to cause luteolysis of the luteinised follicle (see Chapter 25).

Gonadotrophins

For induction of oestrous cyclicity in pubertal animals, the repeated administration of crude pituitary extracts or of equine chorionic gonadotrophin (which is mainly FSH-like in activity) has moderate success, notwithstanding the underlying causes of anoestrus noted previously (seasonal breeders, nonoestrous breeders, postpartum nutrition and stress). In these circumstances, modification of the underlying situation is the most important aspect of clinical management. Furthermore, notice should be paid to the important role of progesterone in the establishment of normal cyclicity in many species (see species overviews earlier in the chapter). For example, the use of eCG alone to induce oestrus in seasonally anoestrous ewes is not very successful. However, if progesterone is administered to the ewes before the injection of eCG, then there is synchronised oestrus and ovulation. Perhaps surprisingly, eCG does not appear to stimulate ovarian activity when given to mares in winter anoestrus. The reasons for this are probably twofold. First, it may be that the dose required to stimulate follicular development is large, and second, eCG has both FSH and LH activity in the mare and so may cause follicle luteinisation rather than ovulation.

Melatonin

The pineal gland controls reproductive activity in seasonal breeding species such as sheep, goats, horses and cats by the secretion of melatonin. The administration of melatonin cannot be used to induce seasonal activity in the long-day breeders because it would be necessary to inhibit the secretion of melatonin or neutralise its effect (in fact in the queen melatonin implants can be used to suppress oestrous cyclicity). Termination of melatonin secretion can be most easily affected by exposure to appropriate artificial lighting regimes (see earlier mention). However, in the ewe and doe, which are short-day breeders, melatonin has been used commercially to advance the timing of the onset of the breeding season. The hormone is administered as an implant containing 18 mg of melatonin that is inserted subcutaneously at the base of the ear. It is critical that rams (and bucks) should be separated from the ewes so that they are out of sight, sound and smell at least 7 days before the insertion of the implant. They must remain separated for at least 30 days, but not more than 40 days, when rams (or bucks) should then be reintroduced. Peak mating activity occurs 25 to 35 days later. The breeding season can be successfully advanced by 2 to 3 months with good fertility. Melatonin should not be used in ewe lambs because its use can significantly delay the onset of puberty.

Progesterone

The physiological role of endogenous progesterone in initiating normal ovulatory cycles has been described previously. Exogenous progesterone may be used in anoestrous females to induce oestrus, as long as the species is polyoestrous. Consideration should always be given to the underlying causes of the anoestrus as described previously. Although detailed regimes are described in the species-specific chapters of this book, the broad principles are that progesterone is given continually over a period of time similar to the normal luteal phase, thus mimicking the luteal phase such that, when progesterone is withdrawn, the events of a normal follicular phase will be stimulated. Progesterone or progestogens are marketed as oral preparations given daily (e.g., for mares and sows), vaginal sponges (e.g., for ewes) or as vaginal devices (e.g., for cows). Progesterone alone is not highly efficacious in treating anoestrus because some individual animals: (1) have insufficient follicular activity at the beginning of treatment; (2) ovulate spontaneously during treatment; and (3) have follicle growth but fail to ovulate after withdrawal of the progesterone. A variety of species-specific regimes have therefore been developed to overcome these problems. These include: (1) before progesterone treatment starts, ensuring follicle activity by adequate lighting (e.g., mare) or administration of GnRH preparations (e.g., cow); (2) causing lysis of any spontaneous luteal tissue by administration of prostaglandin at the time of progesterone withdrawal (e.g., cow); and (3) ensuring that induced follicle growth results in ovulation by administration of GnRH or hCG shortly after progesterone withdrawal (e.g., mare, cow, ewe).

Oestrogens

Administration of exogenous oestrogens can cause signs of behavioural oestrus in many species. In cows, oestrogens have been used in combination with progesterone in the belief that they augment the signs of oestrus when progesterone is withdrawn (see previous mention); however, they have no role in inducing follicular activity.

A number of anecdotal reports suggested that low dose oestrogen could induce oestrus in anoestrous bitches. This was confirmed by Bouchard et al. (1993), who found that diethylstilboestrol administered orally at 5 mg/day/dog induced oestrus within 6 to 9 days and that pregnancy rates and litter size were normal (Bouchard et al. 1993). This work has not been progressed further because of the risk of adverse effects of oestrogen and the relative safety of using prolactin inhibitors (see next section).

Prolactin Inhibitors

In bitches, prolactin is the principle luteotrophic factor during the luteal phase. Daily administration of prolactin inhibitors, such as cabergoline and bromocriptine during the luteal phase, causes a rapid decline in progesterone concentrations, and the bitch enters anoestrus. Surprisingly, if administration continues during anoestrus, there is a significant shortening of anoestrus, and the bitch returns to oestrus. If treatment begins in the luteal phase, administration may be required for 8 to 10 weeks, and pregnancy rates are approximately 60%. However, when treatment begins in anoestrus, administration may only be required for 6 weeks, and pregnancy rates are greater than 80% (Spattini et al. 2007). The exact mode of action is unknown, but prolactin inhibitors appear to be the most useful method of oestrus induction for clinical practice.

Fertilisation and Development of the Conceptus

MARCEL TAVERNE

Development of the Conceptus

Within the Uterine Tube

As the ripe follicle is about to rupture, the fimbriated end of the uterine tube partially envelopes the ovary at ovulation when the follicular fluid and egg are discharged. In many domestic species those sperm that traverse the female tubular genital tract are sequestered in the isthmus of the uterine tubes and are only released and migrate to the ampullae of the tubes (where fertilisation occurs) at the start of ovulation. Thus sperm's ascent and oocyte's descent to the ampulla are synchronised. Fertilisation requires that there is fusion of nuclear material from only one spermatozoon and one oocyte, although many thousands of spermatozoa will be released from sequestration in the isthmus at the same time; thus there will be many present in the ampullae at the time of fertilisation. The oocyte has mechanisms to prevent fertilisation by more than one spermatozoon (polyspermy) because if this occurs, it will result in the abnormal development of the embryo (see Chapter 9). This mechanism is called the 'polyspermic block'.

After fertilisation, cleavage of the zygote begins, and as a result of peristaltic contractions and ciliary currents in the uterine tube, it is propelled toward the uterus. When it reaches the uterus, at 3 to 4 days in cattle and at 5 to 8 days in the dog and cat, the zygote consists of 16 to 32 cells in the form of a morula. With further cell division and cell orientation, the morula becomes 'hollowed out' to form a blastocyst, and its wall becomes two layered; the inner is the endoderm and the outer is the ectoderm, and the cavity is known as the blastocoele (Fig. 4.1 and 4.2A). The embryo will form from a thicker portion of the ectoderm, referred to as the embryonic knot or disc (see Fig. 4.1 and 4.2A and B). The remaining part of the ectoderm is referred to as the trophoblast (from the Greek meaning nourishing layer) and will have an important subsequent role in the formation of the placenta (Perry 1981).

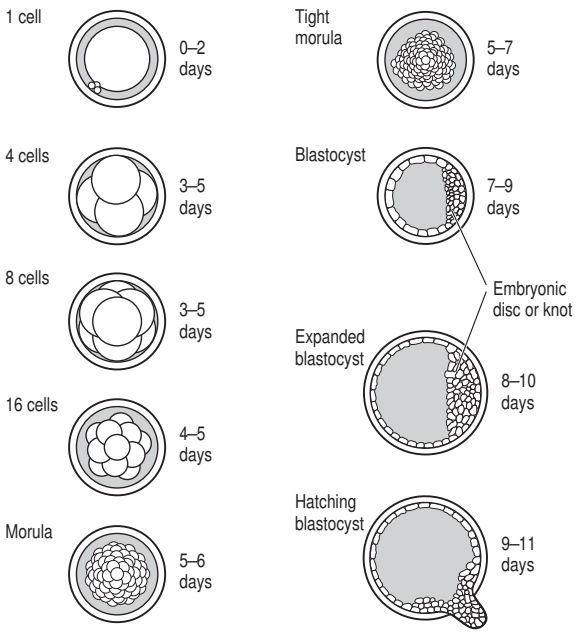
Up to the time of shedding of the zona pellucida at the ninth day (often called 'hatching') (see Fig. 4.1), there is little absolute growth of the mammalian egg from its original dimension of 0.14 mm. The fertilised eggs of the ewe enter the uterus at the eight-cell stage on day 3, whereas in the sow they progress down the uterine tube within 2 days of ovulation, arriving in the uterus at the four- to eight-cell stage (see Fig. 4.1). Tubal transport of the fertilised eggs of the mare probably takes 5 to 6 days, by which time they are at the blastocyst stage; van Niekerk and Gernaeke (1966) showed that unfertilised equine eggs remain in the tubes for several months, where they slowly degenerate. The variable duration of travel by the fertilised egg in the uterine tube of the domestic species appears to be determined positively by the degrees of activity of the tubal muscle and cilia and negatively by the muscular constriction, either at the tubal isthmus or at the uterotubal junction. Both positive and negative factors are probably influenced by variable concentration of ovarian steroid hormones and possibly by locally produced prostaglandins.

Within the Uterus

From the time of its arrival in the uterus until attachment, the zygote is propelled or aspirated into the uterine lumen, where it is nourished by the exocrine secretions of the uterine glands referred to as 'uterine milk'. In the polytocous species the blastocysts are distributed throughout the uterus so as to utilise the uterine space effectively; thus there occurs free migration of embryos between the cornua, regardless of the side of ovulation. In the monotocous cow such migration rarely occurs, and in the ewe it is not uncommon, whereas in the mare extensive migration always occurs (see later in this chapter). After the ninth day, the blastocyst elongates rapidly in ruminants and pigs. For example, the sheep blastocyst is 1 cm long at 12 days, 3 cm at 13 days, and 10 cm at 14 days, whereas in the sow at 10 days just after hatching it is a flaccid sphere 8 to 10 mm in diameter, by day 13 the apparent length of each blastocyst is 20 to 30 cm, but because of the folding of the mucosal surface, it may be a metre or more in length; the diameter is very small in comparison. A characteristic feature of the elongated porcine blastocyst is that it is always aligned with the uterine attachment of the broad ligament. By day 21 in the mare, the blastocyst measures 7 x 6.5 cm, but in the cow it extends almost throughout the entire pregnant horn. Embryonic attachment to the uterus occurs at approximately these times: 12 days, cow; 18 days, sow; 15 days, ewe; 13 to 17 days, dog and cat; and 35 to 40 days, mare.

A tough, elastic glycoprotein capsule surrounds the equine blastocyst between 6 and 23 days after ovulation, which provides physical support for the embryo as it traverses the uterus; it also accumulates the constituents of the 'uterine milk' (Allen & Stewart 2001). The unique intrauterine mobility of the equine embryo has been demonstrated by means of B- mode real time transrectal ultrasonography by Leith and Ginther (1984). The location of the vesicle was observed in seven mares over a 2-hour period daily from days 9 to 17. There was increasing mobility from day 9 to day 12, and a plateau of high mobility persisted until day 14,

VetBooks.ir

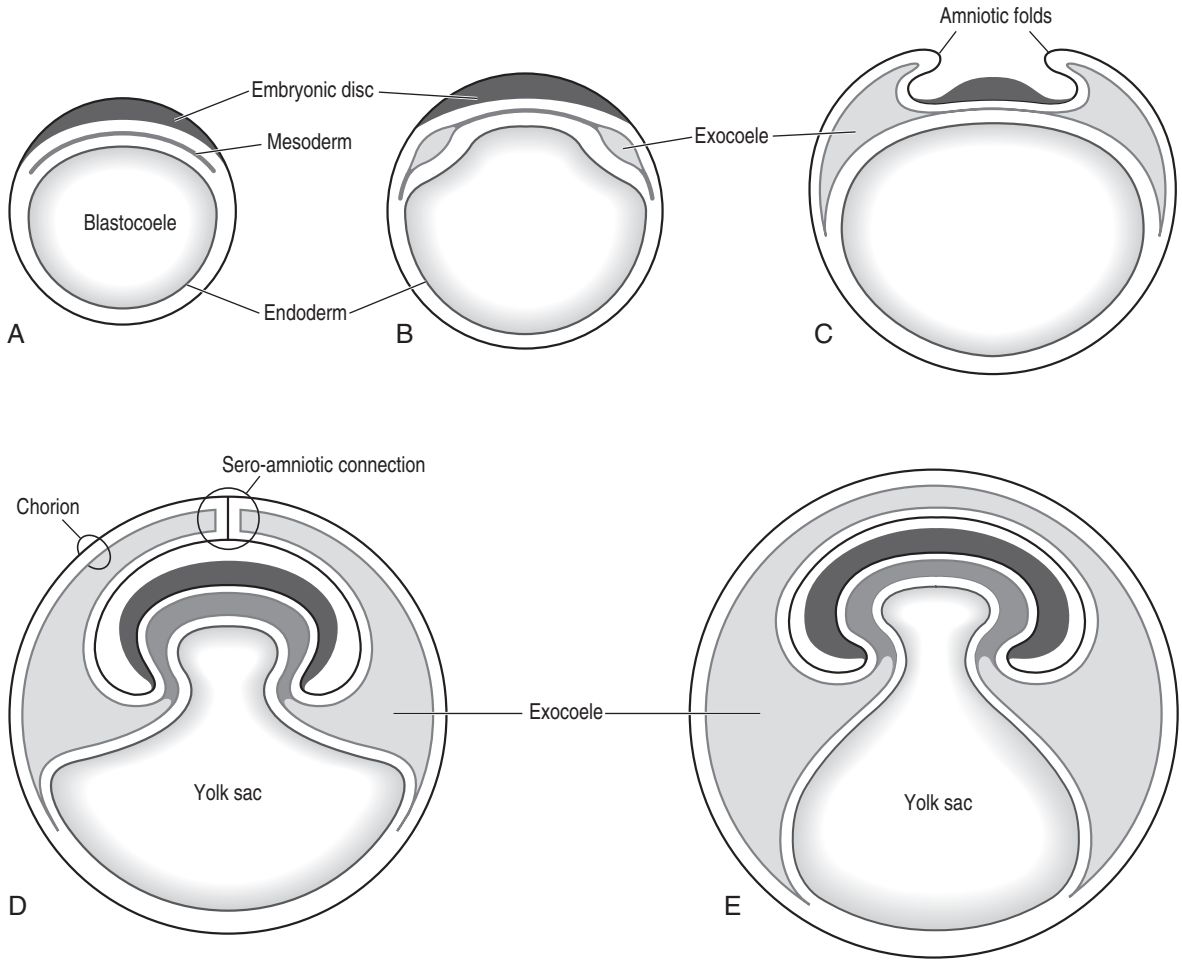


• **Fig. 4.1** Stages of early embryonic development in domestic species and their approximate timings.

after which there were few location changes on day 15 and none on days 16 and 17, indicating that fixation has occurred at the base of one of the uterine horns and is due to increased uterine tonicity. On days 9 and 10 the vesicle was at least twice as likely to be in the uterine body as in a uterine horn; on days 11 to 14 this proportion was reversed, and beyond day 15 the embryo was always cornually disposed.

Formation of the Fetal Membranes

A detailed knowledge of the formation and structure of the fetal membranes is crucial for a correct interpretation by manual palpation and for visual interpretation of ultrasound images of early pregnancy (see Chapter 5). In addition, early embryonic structures are involved in the dialogue between the embryo and the uterus, thus enabling the maternal recognition of pregnancy (see Chapter 5), implantation, placentation, and growth of the conceptus. At around the time of the blastocyst 'hatching' the embryonic (subsequently fetal) membranes develop, some of which will have a major role in the formation of the placenta. These are: yolk sac, amnion, chorion, and allantois. Soon after 'hatching', the inner (endodermal) layer of cells of the bilaminar blastocyst (see Fig. 4.2C), usually formed by the tangential division of a few cells of the embryonic disc, migrate around the inner surface of the ectoderm



• **Fig. 4.2** Development of the amnion and chorion, and the extension of the exocoele around the yolk sac shown in transverse section in the pig. In (D) the amniotic folds have met, but not yet fused, so that the amnion and chorion are joined by a 'sero-amniotic' connection. (From Perry 1981.)

and the blastocoele to form the yolk sac (see Fig. 4.2D). In eutherian mammals, and thus in all of the common domesticated species, it contains no obvious yolk. In mares the yolk sac will have been formed completely by day 11, and its spherical dimensions rapidly increase until day 20. The yolk sac fluid of the equine embryo is the first recognisable structure that can be identified during early ultrasonographic pregnancy diagnosis (see Chapter 5). The equine yolk sac fluid is hypertonic and contains high levels of fructose, proteins, and prostaglandins. The wall of the yolk sac produces IGF-1 and synthesises and metabolises steroids and prostaglandins (Betteridge 2007, Stout & Allen 2002). In the pig the yolk sac reaches its maximum size at about 18 days, but by 20 days, probably associated with its separation from the trophoblast, it has shrunk (Fig.4.2D and 4.3A and B; Perry 1981). In the mare, dog, and cat the yolk sac persists for a much longer time and can be easily recognised during ultrasonic scanning. The amnion develops as an enveloping fold of ectoderm and mesoderm, ultimately fusing and completely surrounding the embryonic disc, embryo, and fetus (see Fig. 4.2E and 4.3A and B); it is complete, for example, in the pig by day 17 and in mares it can be recognised during scanning from about day 30 onwards. Although the amnion has some involvement in the intramembranous absorption of amniotic fluid and solute into the fetal circulation (Brace et al. 2004), its main role is protective, containing the amniotic fluid in which the fetus 'floats' and/or moves.

At around the same time the chorion is formed by the outer layer of mesoderm and trophoblast (see Fig. 4.2D). The last of the embryonic/fetal membranes to form is the allantois, which develops as a thin walled, sac-like outgrowth of endoderm surrounded by mesoderm, from the embryonic gut close to the opening connecting the gut with the yolk sac; in the pig it starts to develop at about 14 days (see Fig. 4.3A and B). The allantois grows very rapidly, passing through the umbilical cord and appearing as a crescent-shaped sac filling the exocoele, except for the region around the embryo where the amnion is in contact with the chorion (see Fig. 4.3A and B). The mesoderm covering the allantois fuses with the mesoderm lining the chorion to form the allantochorion (chorioallantois), the structure which is involved in the formation of the placenta (Figs 4.3B, see also 4.5A; Perry 1981). The allantois also fuses with the amnion, to form the allantoamnion. In mares the early development of the allantois can be visualised with transrectal ultrasonic scanning; around day 29 the allantois occupies about 50% of the oval-shaped conceptus, with the embryo in the middle of a tissue line consisting of the apposed walls of allantoic and yolk sacs (see Fig. 5.2D; Ginther 1995, Allen & Wilsher 2009). Detailed overviews of the development and final state of the yolk sac, amnion, allantois, and chorion in different mammals have recently been published (Carter & Enders 2016, Chavatte-Palmer & Tarrade 2016).

Ruminants

After hatching of the blastocyst the bovine embryo, although differentiating fast, elongates slowly compared with the chorion, and at 1 month after mating it is only just over 1 cm long. The chorionic vesicle, which is at first string-like with a central distended sphere of amnion containing the embryo, is progressively filled by allantoic fluid to form an extensive allantochorionic sac; this already occupies the nonpregnant horn at the end of the fourth week of gestation. Recognition of this allantoic fluid enables early ultrasonographic pregnancy diagnosis between days 20 and 25 to be made (see Chapter 5). Because of its expansion, the allantoic sac begins to distend the gravid uterine horn from about day 35 onwards (Fig. 4.4A). At this stage, it can also be palpated manually, together with the amniotic vesicle. At this time the chorion already extends into the nongravid horn; its length is about 40 cm, and at its widest part in the dependent portion of the gravid horn, it is 4 to 5 cm in diameter.

The early development in sheep is very similar to that of the cow. The allantochorion, which eventually surrounds the allanto–amnion, is separated from it by allantoic fluid. When the vascularisation of the chorion by the allantois is complete (at 40–60 days in the cow), the allantochorion is ready to participate in placental function (see Figs.4.4A–C, and 4.5). Before this time the embryo has been nourished through its chorion and amnion by diffusion from the uterine milk. For a detailed description of the early development of the bovine fetal membranes and placenta see Assis-Neto et al. (2010) and Peter (2013).

In the ruminant uterus, where the allantochorion contacts the uterine caruncles, finger-like processes or villi containing capillary tufts grow out from the allantochorion into the crypts of the maternal caruncles, which are also surrounded by capillary plexuses. Thus is formed the characteristic ruminant placentome, through which nutrient and gaseous exchange between the mother and fetus takes place (Fig. 4.6). There can be up to 120 functioning cotyledons in the cow (Figs 4.4, 4.5, 4.7, and 4.8) and about 80 in the sheep, which are arranged in four rows along each of the uterine horns. As already mentioned previously, the chorion and, preceding it, the allantois, both extend into the nongravid horn,

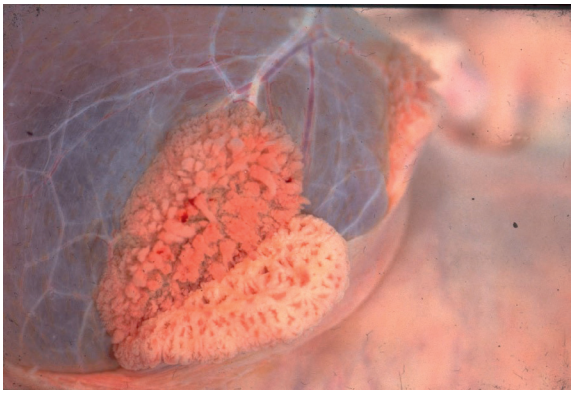
Note the fetus contained within the discrete – almost spherical – amniotic sac, with an elongated allantochorion, and evidence of the formation of cotyledons.

• **Fig. 4.5** Bovine conceptus at 90 to 100 days. Note the relatively larger amniotic sac compared with Fig. 4.4 A, B and C, and obvious cotyledons which are larger towards the centre of the allantochorion.



• **Fig. 4.6** A cotyledon, consisting of finger-like processes (villi) of the vascularised allantochorion *(blue in colour)*, is manually separated from crypts in a caruncle of the uterine wall *(lower part of the picture)*.

and thus it is normal in the ruminant for there to be numerous functioning placentomes in the nonpregnant horn.

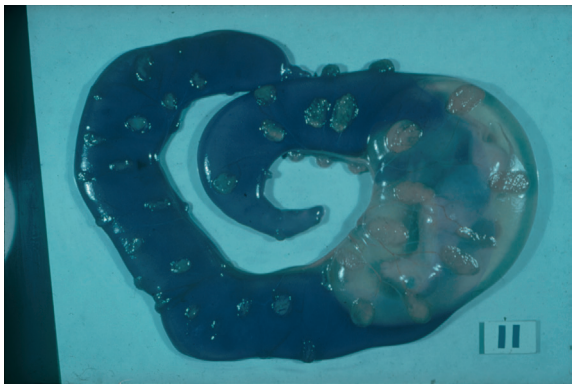
During early development of the ruminant embryo, there occurs an extensive fusion between the allanto–amnion and the allantochorion (forming the so-called 'amnio-chorion'), thus largely obliterating the cavity of the allantois. As a result of where it lies over the amnion, the allantois is reduced to a narrow channel. Here its shape resembles the letter 'T', with the stem coming out of the urachus along the umbilical cord and then diverging as the two crosspieces over the lateral face of the amnion. Consequently, there is little allantoic fluid over the amniotic area; most of it lies in the extremities of the allantois, one of which lies in the nongravid horn (see Figs 4.7 and 4.8). However, studies of bovine uteri in late gestation (Arthur 1959) have shown that, with the increasing pressure of accumulating allantoic fluid, the allantochorion tends to become separated again from the allanto–amnion, so that at term, the allantois may almost surround the amnion.

Horse

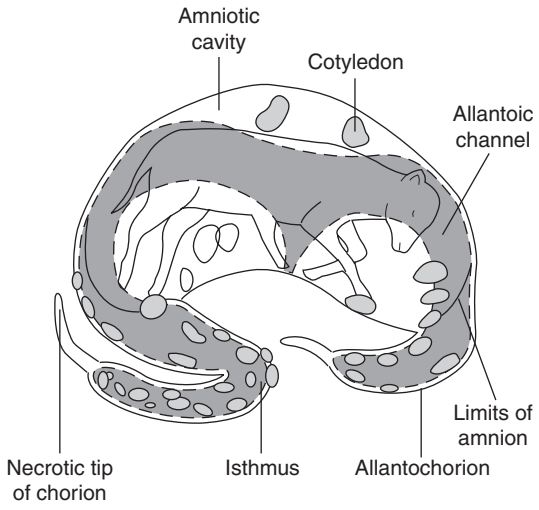
The equine conceptus does not show the initial rapid elongation of the blastocyst–chorion, as occurs in ruminants and pigs. For example, at 35 days the equine chorion is oval rather than cylindrical and is more distended by the allantoic fluid. This causes an earlier, more discrete uterine enlargement than in the cow, and

VetBooks.ir

this is helpful in early clinical pregnancy diagnosis (Fig. 4.9). In the mare, unlike the cow, the amniotic and allantoic sacs do not fuse as in ruminants, so that the amnion floats freely, contained within the allantoic sac except for its attachment at the umbilicus, throughout gestation (Figs 4.10A and B). The relationships of the fetal sacs at birth will be referred to again in Chapter 6 on parturition.



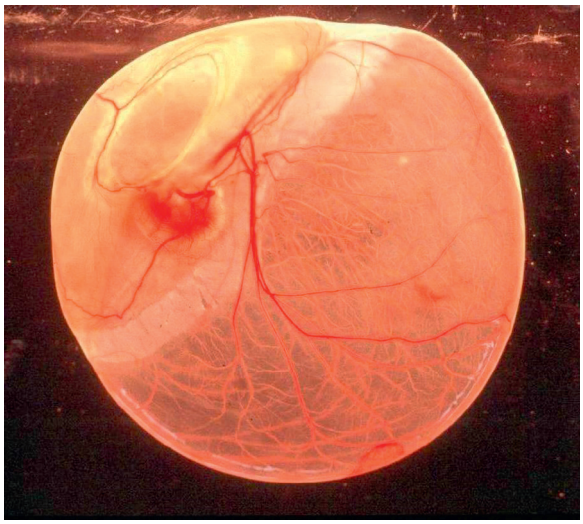
• **Fig. 4.7** Bovine conceptus at about 100 days, in which methylene blue dye has been injected in to the allantochorionic sac post mortem.



• **Fig. 4.8** Bovine conceptus showing the allantochorion of early pregnancy. (From Zeitzschmann 1924.)

In the mare, after the establishment of a stable microvillus contact between the allantochorion and endometrium at about day 40, there develops over the next 100 days a complex of multibranched interdigitations with the endometrium to form what are referred to as microcotyledons (Samuel et al. 1975, Steven 1975). Although more or less fully differentiated by day 150, there is continued lengthening and branching during the second half of gestation (McDonald et al. 2000). The microcotyledons are distributed over the whole surface of the allantochorion and can be seen with the naked eye, giving the allantochorion a stippled, velvety appearance (Figs 4.11A–C and 4.12). Between the microcotyledons are areas of pseudostratified trophoblast cells that overlie the ducts of the endometrial glands, absorbing their secretions (Steven 1982).

At day 35 the trophoblast of the spherical conceptus has separated into its invasive and noninvasive components. Cells from the former, distinguished as the thickened annulated chorionic girdle (see Fig. 4.9), invade the endometrium to form the endometrial cups, structures unique to equines (Allen & Stewart 2001). These appear as crateriform structures, which are disposed in a concentric manner at the base of the pregnant horn. They are present from



• **Fig. 4.9** Equine conceptus at 5 weeks. Between the vascularised allantochorion (on the right) and yolk sac (upper left), the embryo can be recognised. The white band between the two sacs is the chorionic girdle from which cells will migrate into the endometrium to form the endometrial cups. (Courtesy of Professor W.R. Allen.)

the 6th to the 20th week of gestation, and in them the equine chorionic gonadotrophin (eCG) is produced. The cups express foreign fetal antigens (they are fetal trophoblast cells), stimulating strong maternal humoral and cell-mediated immune responses, which ultimately curtail their lifespan; they regress and disappear at about day 140, although the timing of this varies (Allen & Wilsher 2009).

The immunological importance of the endometrial cups in protecting the 'foreign' conceptus has been demonstrated by Allen (1982). In interspecies transfers of fertilised eggs between horses and donkeys, no endometrial cups were formed, and the donkey fetuses died at 80 to 90 days. A final stage of the regression of the endometrial cups can also be recognised by the formation of so-called allantochorionic pouches (Ginther 1992). Projecting into the allantoic fluid, these are peculiar invaginations of the allantochorion, which are first found at a fetal body length (FBL) of about 11 cm, and occur in juxtaposition with the endometrial cups. Their size corresponds with the secretory activity of the endometrial cups, being largest at FBL 15 to 20 cm, and regressing after FBL 30 cm. They are few in number and are not pathological structures.

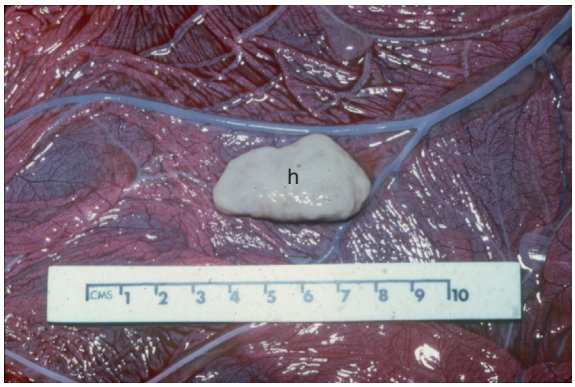
The surface of the allantochorion, adherent to the endometrium, is red in colour with a 'velvety' appearance and texture. The area adjacent to the internal opening of the cervix is devoid of placental villi, giving rise to the so-called called 'star' (see Fig. 4.12). The inner surface of the allantochorion, which is outermost when the placenta is shed, has a smooth surface (see Fig. 4.11). Sometimes attached to the allantochorion or floating freely in the allantoic fluid, there are soft calculi of cellular and inorganic debris called

VetBooks.ir

hippomanes (Fig. 4.13); they consist of concentric layers of cellular debris and appear to have no physiological function (Whitwell & Jeffcott 1975).

Pig

The development of the fetal membranes has been extensively studied in the pig and very clearly described by Perry (1981) as well as in a textbook on comparative placentation (Steven 1975). After the blastocysts have hatched at day 7, they enlarge so that on day 10 they are flaccid spheres, 8 to 10 mm in diameter. These are then distributed and spaced along both horns (Dziuk 1985) before becoming 'fixed' on day 12 by 'adhering' to the endometrium near the attachment of the broad ligament. Over the next 1 to 2 days, there is a huge transformation of the conceptus in that it undergoes rapid elongation, forming a very long narrow cylinder. Although occupying 20 to 30 cm of horn length, because of the extensive folding of the endometrium, the blastocyst may actually be over a meter in length. The amnion forms from 10 days, and the allantois first appears at about 14 days, expanding into a voluminous crescentic vesicle by 18 days; by 19 days it has fused with the chorion to form the allantochorion. By 22 days the allantochorion has developed intricate corrugations, which interlock with the folds and crevices of the endometrium to establish the placenta (Marrable 1969, Dantzer & Leiser 1994). There is a rapid accumulation of fluid within the allantoic cavity between day 20 and 30 (Figs 4.14A–C and see Fig. 4.18). The presence of this fluid in the allantochorionic sacs of the multiple fetuses allows the early pregnancy diagnosis with ultrasonic scanning (see Chapter 5).



• **Fig. 4.13** Allantochorionic membrane of the mare with hippomane *(h)* attached.

Dog and Cat

After intrauterine and transcornual migration between days 12 and 17 after the LH surge, fixation and implantation begins by days 17 to 19 in dogs (Pretzer 2008).

Until 20 days of gestation, there is a choriovitelline placenta in which the vascular yolk sac is involved. Even at 24 days, the yolk sac is 3 times the length of the embryo and can easily be recognised during ultrasonic scanning (see Chapter 5). The embryo is completely surrounded by the avascular amnion, which contains translucent fluid, and is in contact with the yolk sac via the vitelline duct. From 20 days the allantois develops, and by day 22 it is twice the size of the yolk sac and contains a clear yellow fluid; it completely envelopes the amnion and thus the embryo and fetus. The central part of the allantoic sac, having fused with the

chorion and which is in contact with the endometrium, forms the epithelial chorial zonary placenta. In the dog it completely encircles the embryo (Fig. 4.15A), but in the cat it is incomplete.

Types of Placentation

Placentae may be classified according to the way the villi are distributed on the fetal chorion. Thus when they are uniformly dispersed, as in the mare and sow, the placenta is said to be diffuse. When they are grouped into multiple circumscribed areas, as in the ruminant, the placental arrangement is called cotyledonary, whereas in the bitch and cat the villi are disposed in the form of a broad encircling belt forming a zonary placenta. Formerly, the placentae were differentiated according to whether or not maternal tissue separated from the fetal tissue at birth. Thus of the domestic mammals the placentae of the bitch and cat were said to be deciduae and those of the remainder nondeciduae. More commonly, embryologists favour Grosser's (1909) division of placental types, in which the degree of proximity of the maternal and fetal blood circulations is the criterion of classification. Such a concept recognises the phagocytic property of the trophoblast, or chorionic epithelium that may be exerted on tissues with which it comes into contact. In the simplest, or epitheliochorial type of placenta, seen in the horse and pig, the chorion is everywhere in contact with the endometrium, and there is no loss of maternal tissue during the formation of the placenta. In the cow the placenta is described as being synepithelialchorial (Wooding 1992, Leiser & Kaufmann 1994). Soon after embryonic attachment a syncytium is formed on the maternal side of the placentomes by the fusion of binucleate cells, derived from the trophectoderm, with uterine epithelial cells. Unlike the sheep and goat, the syncytium in bovine placentomes is only temporary, as fairly soon the syncytial plaques are overgrown by the rapid division of the remaining maternal epithelium (King et al. 1979). In the third endotheliochorial type, there is further invasion of the endometrium by the trophoblast, which is now apposed to the maternal capillaries. Such a type is typical of the carnivora. In the haemochorial placenta, only the tissues of the chorionic villi separate the fetal and maternal blood. According to the number of trophoblast layers, these structures were further subdivided (Enders 1965) into haemotrichorial (rat, mouse, and hamster), haemodichorial (lagomorphs and early human placenta), and haemomonochorial (cavia, higher apes, and human placenta at term). The placenta of the dog and cat is partly haemochorial in that the main zonary placenta, which is of endotheliochorial type, is flanked by marginal haematomata. At about 22 to 25 days, they are visible at the margins of the of the placental girdle. In the dog they are green in colour due to the presence of the blood pigment uteroverdin and are 1 mm width at this stage but reach 8 mm at term (see Fig. 4.15B). In the cat they are less obvious, although they can be seen microscopically; the pigment is brown in colour. The role of these haematomata is believed to be the transfer of iron to the fetus. In the majority of cat placentas, there is a well developed fissure similar to that seen in mink; its function is not known (Miglino et al. 2006). When separation of the canine placenta begins at parturition, it is the escape of this altered blood from the marginal haematoma that gives the characteristic green colour to the normal parturient discharges.

A simple diagrammatic representation of the types of placenta, based on Grosser's classification, is shown in Fig. 4.16. The degree of intimacy of the maternal and fetal placental blood vessels is the basis for the variable function of the 'placental barrier' of different species. This is of interest in certain diseases of the fetus and newborn. For example, in the haemolytic disease of foals, antigens from the fetus pass across the placenta to the mother, but the resultant antibodies can return to the foal only via the colostrum, whereas in women similar antibodies may traverse the placenta and cause an antigen–antibody reaction in the unborn fetus.

There is good evidence that both the microscopic and macroscopic structure of the placenta may be influenced by factors such as the nutritional status of the dam during pregnancy and breed. The consequences that such factors may have for impaired fetal and postnatal growth of large domestic animals have been extensively reviewed by Wu et al. (2006). The following examples may illustrate this: A comparison of the gross morphology of the placentomes of ewes subjected to modest undernutrition during the first 70 days of pregnancy with those on a normal control diet has shown a change in the distribution of the types of placentomes based on the classification of Vatnick et al. (1991). Undernutrition of the dam results in a decrease in the type A placentome (the 'classical' shape) and an increase in the type D, in which the fetal component of the placenta is increased (Steyn et al. 2001). This shows that the placenta is a dynamic organ and may respond to the demands of the fetus – in this case the provision of sufficient nutrition to maintain normal intrauterine growth. However, there is also evidence in sheep that the response of the placentomes

VetBooks.ir

to undernutrition in midgestation can be influenced by previous nutritional conditioning (Vonnahme et al. 2006). On the other hand, 'overnutrition' of pregnant adolescent sheep (in order to promote rapid growth of these young ewes) also impaired vascular development in the fetal portion of the placentomes during early to midpregnancy and resulted in reduced fetal weight (Redmer et al. 2009). Apparently, nutritional benefits in this model were directed to the mother at the expense of placental and fetal development.

During the past two decades an overwhelming amount of evidence, obtained from studies in humans, laboratory animals, and farm animals, has shown that the intrauterine environment of the conceptus (i.e., fetus and placenta) may alter the expression of the fetal genome during prenatal development. This so-called 'fetal programming' may result in permanent changes in the morphology, physiology, and metabolism of the offspring and may thus have consequences for health, production parameters, and diseases during later life. For further reading on this topic, one is referred to the pioneering book by Gluckman and Hanson (2005) and to selected reviews (Fowden & Forhead 2004, Wu et al. 2006, Evans et al. 2016, Fowden et al. 2016, Gonzalez-Bulnes et al. 2016, Symonds et al. 2016).

Fetal Fluids

Cattle

The total quantity of fetal fluid of cattle increases progressively throughout pregnancy; early ultrasonographic pregnancy diagnosis is based on the recognition of allantoic fluid within the uterine horns (see Chapter 5). Its volume averages about 5 litres at 5 months, and 20 litres at term. Sharp rises in the total quantity occur between 40 and 65 days, between 3 and 4 months, and again between 6.5 and 7.5 months. The first and last of these are due to an increase in allantoic fluid, and the second to an increase in amniotic fluid. For nearly the whole of the first third of pregnancy, when the conceptus consists of an elongated allantochorion with a central spheroidal amnion closely investing the relatively small embryo, there is more allantoic fluid; during most of the second third of pregnancy, amniotic fluid predominates, but for the greater part of the final third, allantoic fluid is again clearly in excess (Fig. 4.17).

Throughout gestation the allantoic fluid is watery or urine-like. In the first two-thirds of pregnancy the amniotic fluid is similar, but for the remainder of gestation it is a mucoid fluid. The latter change gives it the lubricant property that is so helpful at parturition. At birth the allantoic sac forms the first and the amnion the second 'water bag'. The allantochorion is thicker and tougher than the transparent amnion.

Sheep

The studies of Malan and Curson (1937) and Cloete (1939) have revealed that the total volume of fetal fluid increases with advancing age of the conceptus but that the separate fetal fluid volumes show different tendencies. As in the cow, the visualisation of allantoic fluid at the end of the first month can be used as a tool for early pregnancy diagnosis (see Chapter 5). During the first 3 months, apart from an initial preponderance, the allantoic fluid accumulates

VetBooks.ir

3	604	131	735
4	686	485	1171
5	369	834	1203

(Data from Malan & Curson 1937 and Cloete 1939.)

slowly, e.g., 131 mL at 3 months, whereas the increase in amniotic fluid occurs largely during this time, so that at 3 months it reaches 604 mL. In the fourth month the rate of increase in allantoic fluid greatly accelerates to 485 mL whereas the amniotic fluid increases only slightly. During the last (fifth) month of gestation, the allantoic fluid almost doubles its volume to 834 mL, but the volume of amniotic fluid diminishes to 369 mL (Table 4.1). When twins are present, the totals of fluids are approximately doubled (Arthur 1956), and the decrease of amniotic fluid apparently starts already during the third month (Naaktgeboren & Stegeman 1969).

Horse

It is recalled that the first fluid to be recognised during early ultrasonographic pregnancy diagnosis (from about day 10 onwards) is the fluid within the yolk sac. The allantoic fluid becomes visible after about day 24 (Ginther 1995). Ranges of weights of the total fetal fluid for each month of pregnancy in the mare as given by Rűsse and Grunert (1993) are shown in Table 4.2.

TABLE 4.2 Weight of fetal fluids in the horse

Month of Gestation	Weight of Total Fluid (kg)
1	0.03–0.04
2	0.3–0.5
3	1.2–3.0
4	3.0–4.0
5	5.0–8.0
6	6.0–10.0
7	6.0–10.0
8	6.0–12.0
9	8.0–12.0
10	10.0–20.0
11	10.0–20.0

	81.5	1670	5210

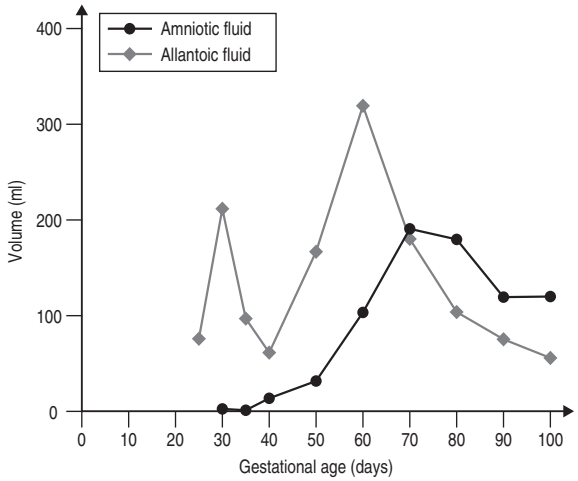
[a]Estimated volume in a preserved specimen
[b]Some allantoic fluid lost in transit

Serial values for the separate amounts of amniotic and allantoic fluids are only available for a limited number of pony mares during the first 200 days of gestation (Ginther 1992). The data showed that amniotic fluid volume remains smaller than allantoic fluid volume but increased rapidly between days 100 and 160 to equal the volume of allantoic fluid at midpregnancy. The observations of Arthur (1956) in mares (Table 4.3), together with data provided by Amoroso (1952), Zietzschmann (1924), and Ginther (1992), suggest that the trends are similar to those of cattle. Thus allantoic fluid predominates in early as well as late pregnancy and measures 8 to 15 litres at term. The amniotic fluid volume differs from that of cattle. It is low during the first 3 months; thereafter it increases more rapidly and at midpregnancy equals the volume of allantoic fluid, whereas at term it is 3 to 5 litres.

Pig

The volume of allantoic fluid shows an early rise to about 200 mL at 30 days and enables an easy recognition during early ultrasonographic pregnancy detection (see Chapter 5). Thereafter, it

VetBooks.ir



• **Fig. 4.18** Mean changes in the volume of amniotic and allantoic fluid in porcine conceptuses. (From Knight et al. 1977.)

declines and then increases to reach a maximum of 320 mL at 60 days, before gradually declining to term. Amniotic fluid gradually increases, reaching a maximum of about 200 mL on day 70, before declining slightly until term (Fig. 4.18).

Dog and Cat

Published serial values for the separate amounts of amniotic and allantoic fluids are not available for the dog and cat. In kittens of fetal body length up to 9 cm, the amniotic fluid increases gradually to 10 to 15 mL, after which there is some decrease, followed by a slight rise just before term. The allantoic fluid starts with a more rapid rise and at midterm is higher than the amniotic (20 mL), but towards the end of gestation declines to about 6 mL.

Form and Disposition of the Fetal Sacs

Ruminant Species

Throughout gestation the amnion enclosing the fetus, together with the larger portion of the allantochorion, remains in the uterine horn adjacent to the ovary with the corpus luteum of pregnancy; a smaller 'limb' of allantochorion projects across the uterine body into the other horn. Most of the allantoic fluid gravitates to the poles of the allantochorion, which lie in the dependent parts of the uterine horns, and the uterine distension thus caused in cattle is the chief clinical sign of early pregnancy. By the third month, considerable fluid (up to 0.75 litres) accumulates in the spherical amnion, and it now gives rise to the main palpable mass in the pregnant horn (see Figs 4.5–4.8).

On the inner face of the amnion of ruminants, particularly near and on the umbilicus, are numerous raised, rough, discrete, round foci called amniotic plaques or pearls. They are rich in glycogen but of unknown function and usually disappear after 6 months of gestation. Towards the end of pregnancy, smooth, discoid, rubber-like masses may float in the allantoic fluid. They originate from invaginations of the allantochorion around accumulations of compacted histiotroph between the chorion and endometrium. Initially, they can be found still attached by a stalk to the allantochorion. They are called 'hippomanes' (in cows more rarely 'boomanes') and have no functional significance (Rűsse & Grunert 1993).

Horse

Much of the allantochorion and the greater part of the amnion are contained within the gravid horn, with a direct continuation of similar width into the uterine body. The part of the allantochorion that projects into the nongravid horn is much narrower and is about two-thirds of the length of the gravid horn segment (see Fig. 4.11A). In the rare case of a bicornual pregnancy, the allantochorion occupies both cornua to a similar extent. A hippomanes on the inside of the chorioallantoic membrane of a mare is illustrated in Fig. 4.13.

Pig

After the distribution and spacing of blastocysts at about 10 days of gestation, the rapid elongation of the blastocysts (see later in this chapter) results in their distribution along the length of both uterine horns – from one ovary to the other – and with the one nearest the body of the uterus often extending into both horns. The uterine surface of the sow's allantochorion is studded with small, round, grey foci called 'areolae' in which the placental villi are absent. They occur opposite focal aggregations of uterine glands (Dantzer & Winther 2001).

Relationship Between Fetal Membranes of Twins and Multiple Fetuses

The relationship of the membranes of contiguous fetuses is simplest in carnivora, and although the extremities of the allantochorionic sacs impinge on each other, they remain separate. The next gradation is in the mare pregnant with twins; here, apparently owing to the lack of uterine length, the distal pole of one allantochorion invaginates the proximal extremity of the other. According to Williams (1939), this results in an unequal sharing of the uterine space and thus competition for the reduced area of endometrium available with which the trophoblast can become attached to form the placenta. Thus usually one fetus suffers severe growth retardation, resulting in: death in utero resulting in the birth of the survivor as a singleton; complete failure of the pregnancy with abortion; or the birth of live twins of very disparate size (Figs 4.19A and B).

Two noticeable features of the allantochorionic sacs of the pig are that from about 27 days of gestation, the tips of the elongated allantochorion become ischaemic and then necrotic (Crombie 1971, Flood 1973; see Fig. 4.14A and B). It has been suggested that this might be a mechanism to prevent vascular anastomosis, which might result in the development of freemartins (see Chapter 9). Frequently, the ends of adjacent allantoic sacs become 'glued' together by a gelatinous substance, although the attachment is not a strong one. Furthermore, in some cases there is complete fusion of the allantochorion of adjacent sacs as early as 22 days, although there appears to be no vascular anastomosis thus eliminating the development of freemartins (Crombie 1971). The intervening 'wall' between adjacent conceptuses often disappears, most likely close to term or during farrowing because of propagated uterine contractions. As a result, there develops a continuous allantochorionic 'tube' through which fetuses are seen to pass during parturition (see Chapter 6). These have been called 'synchorial tubes' by Marrable (1969). Interesting breed differences have been identified in pigs with respect to early and late placental development (Ford 1997, Wilson & Ford 2001). In the Yorkshire breed the placentae increase in size and surface area in the last third of gestation, whereas in the Meishan, placental size remains constant in late gestation, although the density of blood vessels at the allantochorionic/endometrial interface increases markedly (Wilson et al. 1998). In addition, it has also been shown that whereas in the Yorkshire if a conceptus dies as late as 40 days, there is acceleration of the growth rate of

• **Fig. 4.19** (A) Mare with her newborn twins. (B) The collected afterbirths have been inverted so that the chorionic sides of the allantochorionic membranes are exposed. Those parts that were contained within the two uterine horns are at the lower end of the figure *(see arrows)*. Where the two allantochorionic sacs apposed each other, no contact could have been made with the endometrium, and the chorion remained villous (white portions; *double arrow*).

the placentae of the adjacent live ones, in the Meishan this does not occur (Vonnahme et al. 2002). In the rare case of anastomosis of allantoic blood vessels of porcine fetuses of unlike sex, a basis for the 'freemartin' condition exists as in cattle (see Chapter 9).

In the majority of twin or triplet pregnancies of sheep and cattle, contiguous chorionic sacs coalesce (Figs 4.4D, 4.20, and 4.21), and in many cases the allantoic cavities are confluent, whereas in cattle – but only in about 0.8% of sheep – allantoic vascular intercommunication is the rule (see Fig. 4.4D). Such anastomosis, according to Lillie (1917), is present between bovine fetuses from the 40th day, and it forms the main premise of his theory of the origin of the bovine freemartin (see Chapter 9). It is now thought that the passage from male to female fetuses of the anti-Műllerian hormone (rather than androgens) is a crucial factor in causing masculinisation of the female fetus (Padula 2005).

Of 25 sets of equine twins, 11 were found by Vandeplassche et al. (1970) to have blood chimerism, thus indicating vascular anastomosis between the twin placentae. However, on dissection the genital organs of the female members of four heterosexual chimerical pairs were found to be normal, whereas five other mares of heterosexual chimerical pairs were found clinically to have normal genitalia; they had normal oestrous cycles and became pregnant. The fact that blood chimerism has been found in adjacent fetuses of horse, sheep, and pig, as well as cattle gestations, indicates that there is also a basis for the freemartinism in these species. However the observed incidence of freemartinism is very low in pigs and sheep (see Chapter 9) and is nil in horses; this may be due, according to Vandeplassche et al. (1970), to late allantoic vascular anastomosis in these three species compared with the early (30-day) fusion in cattle.

Fetal Movements During Pregnancy

When discussing placental relationships, it is instructive to consider the subject of fetal mobility within the uterus. With the introduction of real-time ultrasonography, direct observations and quantification of (early) fetal movements could be made in domestic animals (Ginther 1995 & 1998, Cohen 1999). The earliest fetal movements in cattle have been observed around day 40, and their frequency rapidly increases thereafter, coinciding with a rapid increase of amniotic fluid. Obviously, in all species, within the amnion, fetal movement about both the longitudinal and transverse axes is possible. Rotation about the former is limited by the length of amniotic sac and the umbilical cord, and about the latter by the length of the fetus and the width of the amnion. In cattle not more than a three-fourths revolution around the long axis is possible and, although several rotations about the transverse axis may occur, a complete rotation of the bovine umbilical cord is not normal; coincidently, it has been seen only in mummified fetuses. In equine fetuses, however, complete rotation of the (amniotic portion) of the umbilical cord is possible. Another possibility for intrauterine fetal movement is the mobility of the entire amniotic sac (with contained fetus) within the allantochorion sac. Owing to

the extensive fusion of the allantochorion to the allanto–amnion in the cow, ewe, and sow, such mobility would be impossible. However, in the mare, such movements do take place and lead to twisting of the allantoic portion of the umbilical cord.

Active fetal movements are responsible for changes in intrauterine presentation, position, and posture during pregnancy and at birth (see Chapter 11). Data collected from pregnant bovine uteri by Naaktgeboren (1963) and Ginther (1998) and from equine specimens by Vandeplassche (1957) (Table 4.4) indicates that, initially, anterior and posterior presentations occur in about equal numbers. At between 5 and 6 months of pregnancy, the body length of the fetal calf exceeds the width of the amnion, and thus at this stage the final polarity of 95% of fetuses in anterior presentation is adopted. Based on weekly examinations in a group of 10 mares, some 40% to 60% of fetuses were still in posterior presentation up to the end of the fifth month. The final gestational presentation of nearly 99% of foals, anteriorly disposed, occurred from the seventh month onwards, with few changes thereafter (Ginther 1993). It would seem likely that changes of the longitudinal presentation that occur during gestation in the mare are due to movements of the amnion within the allantochorion, initiated and supported by active fetal movements. An explanation for the final overwhelming proportion of anterior presentations in the cow was given by Naaktgeboren (1963). By submerging and measuring of fetuses of different gestational ages in a water bath, it was concluded that the point of gravity of their body shifted caudally. Together with the expansion of the amniotic cavity towards the tip of the pregnant horn, this enables the fetus to descend with its hindquarters in the horn and assume an anterior presentation. In addition, the hindlimbs may become trapped behind the sharp kink of the pregnant horn at the curvatura minor, which contributes to stabilising the fetus in anterior presentation (Naaktgeboren & Slijper 1970). Similar mechanisms appear to play a role in other domestic ruminants and in mares. Both in the pig (Taverne et al. 1977) and dog (Van der Weyden et al. 1981), some 20% (pig) and 7% (dog) of the fetuses were born in a presentation that differed from the one observed during laparotomy a few weeks earlier. Yet there is still no explanation for the slight preponderance of anterior presentations observed during late pregnancy and parturition in species such as the pig, dog, and cat.

Fetal Growth and Size

Fetal growth depends on many genetic and environmental factors. Given the variety of (neonatal) body sizes found in different breeds of the same domestic species, fetal growth curves have to be judged with caution. Yet it is sometimes necessary to estimate the age of aborted fetuses; for example, when details of their origin are unknown. For this purpose, growth curves, based on measurements of embryos/fetuses obtained at the slaughterhouse (Table 5.3) or from laparotomies at different stages of gestation (bovine fetus: Figs 4.22 and porcine fetus: 4.23) may be useful. Richardson et al. (1976) have shown that long bone length (conveniently radius and tibia) is a reliable indicator of fetal age from 50 days of gestation to term in the sheep and may be obtained radiographically in the living fetus or by postmortem measurement. Mean values for the respective ages of sheep fetuses are shown in Table 4.5. The occurrence and implications of fetal growth retardation in domestic ruminants, pigs, and horses have been reviewed by Wu et al. (2006).

During the past few decades, many studies using B-Mode real time ultrasonography have demonstrated that it is possible to measure a variety of fetal dimensions, thereby enabling ageing of fetus(es). Published data are available for horses (Ginther 1995, Hendriks et al. 2009), cows (Kähn 1989, Ginther 1998, Breukelman et al. 2004, Chavatte-Palmer et al. 2006), sheep (Russell 1989, Aiumlamai et al. 1992), and goats (Medan et al. 2004, Karen et al. 2009). In dogs (Moriyoshi et al. 1996, Groppetti et al. 2015, Socha et al. 2015) and cats (Zambelli et al. 2002, 2004) such data have also been used for the prediction of the parturition date.

Pregnancy and Its Diagnosis

MARCEL TAVERNE AND DAVID E. NOAKES

Maternal Recognition of Pregnancy

In most domestic species, the establishment and maintenance of pregnancy require that the luteal phase of the oestrous cycle is prolonged by the persistence of a single corpus luteum (CL) or a number of corpora lutea (CLs). As a result of the persistence of the luteal tissue, progesterone concentrations remain elevated. This results in a negative feedback on the hypothalamus and anterior pituitary with a resultant inhibition of follicular development and ovulation and, in polyoestrous species, a prevention of return to oestrus. In many species the placenta subsequently replaces or supplements the luteal source of progesterone.

In Chapter 1 the importance of the CL in regulating the periodicity of the oestrous cycle was discussed, and the role of prostaglandin (PG)$F_{2\alpha}$, produced by the endometrium, in causing regression of the CL and the consequent return to oestrus was described. The presence of a viable, developing embryo(s), however, prevents the CL from regressing and thus in polyoestrous species inhibits the return to oestrus. This phenomenon was described by Short (1969) as the 'maternal recognition of pregnancy'. It is particularly interesting because this maternal endocrine response is detectable before the blastocyst is attached to the endometrium by microvilli. In five of the domestic species the time of maternal recognition of pregnancy has been determined (Table 5.1). Mechanisms involved in the maternal recognition of pregnancy in domestic species have been thoroughly reviewed (Spencer & Bazer 2004, Weems et al. 2006, Bazer 2013) and clearly illustrated (Senger 2005, Bazer 2013). Knowledge of this topic is essential for understanding the possible background of pregnancy failures that are based on disruption of these early communication mechanisms between embryo and dam. In addition, these mechanisms might provide a means for the development of tests for the early diagnosis of pregnancy.

Sheep

In sheep early work by Moor (1968) and Martal et al. (1979) demonstrated that the conceptus produces a protein. In recent years it has been characterised as existing in three or four isoforms of molecular weight of 19 to 24 kDa, depending on glycosylation. Originally, it was named ovine trophoblast protein or oTP-1. This substance has been shown to be a type 1 interferon, classified as an ovine tau interferon (oIFN-tau), and is nonglycosylated. A similar but N-glycosylated protein, bovine tau interferon (bIFN-tau) has been found in cows (see later in this chapter). It is produced by the trophectoderm from about day 10, at the time that the blastocyst starts to elongate (Chapter 4).

Details of the mechanism of luteolysis have been described in Chapter 1. The effect of IFN-tau in the maternal recognition of pregnancy is to alter the dynamics of $PGF_{2\alpha}$ secretion at this early stage of pregnancy, compared with the same stage of the oestrous cycle. The number of luteolytic pulses is reduced between days 15 and 17, yet surprisingly the basal secretion of $PGF_{2\alpha}$ is increased at this time (Zarco et al. 1988). A similar phenomenon was observed during spontaneous prolongation of the luteal phase in unmated cyclic ewes (Zarco et al. 1984). IFN-tau secreted by the embryo silences the transcription of the oestrogen receptor alpha gene in uterine luminal and superficial glandular epithelial cells that precedes the oestrogen-induced expression of oxytocin receptors in these cells. The consequence is that IFN-tau indirectly suppresses the expression of oxytocin receptors in endometrial epithelial cells. Oxytocin of luteal and pituitary origin can thus no longer bind to the uterus, and this results in a reduction in the pulsatile secretion of $PGF_{2\alpha}$ (Spencer & Bazer 2004; Bazer 2013). Because basal production of $PGF_{2\alpha}$ is even greater in pregnant than in cyclic sheep, and because IFN-tau does not affect expression of cyclo-oxygenase 2 in the endometrium of early pregnant sheep, other researchers have emphasised a reduced luteal sensitivity to $PGF_{2\alpha}$ and enhanced production of luteotrophic PGE_2 as the dominant mechanisms in the maternal recognition of pregnancy in this species (Costine et al. 2007). There is indeed recent evidence that oIFN-tau may protect the ovine CL from luteolytic actions of PGF by an endocrine route (Antoniazzi et al. 2013; Romero et al. 2015).

Cattle

In the cow the importance of the blastocyst in prolonging the life span of the CL was shown by the studies of Northey and French (1980). They found that, if the blastocyst was removed at day 17 or day 19, the interoestrous intervals were extended to 25 and 26 days respectively, compared with those in which the embryo was removed at day 13, or that were not mated in the latter cases the intervals were 20 to 21 days. The antiluteolytic signal produced by the bovine conceptus is a protein with a molecular weight of 24,000. Originally called bovine trophoblast protein (bTP-1), it was found to cross-react immunologically with oTP-1. As well as having a high amino acid sequence homology with both oTP-1 and IFN-alpha, it also possesses antiviral activity (Bazer et al. 1991). As in sheep, it is now classified as tau interferon (bIFN-tau), with maximum secretion occurring between days 16 and 19 of gestation. It is first secreted at the time of elongation of the blastocyst and, unlike oIFN-tau, continues to be secreted until day 38 of gestation

TABLE 5.1 Time of maternal recognition of pregnancy

Species	Day of Maternal Recognition of Pregnancy	Day of Definite Attachment
Sow	12	18
Ewe	12–13	16
Cow	16–17	18–22
Mare	12–16	36–38
Goat	17	

(After Findlay 1981.)

(Bartol et al. 1985, Godkin et al. 1988). When it is infused into the uterine lumen of nonpregnant cyclical cows between days 14 and 17, the life span of the CL is extended. Similar results have been obtained following the administration of recombinant bovine INF-alpha$_1$ using the same route of administration and also intramuscularly (Plante et al. 1989).

As in the ewe, the luteolytic patterns of $PGF_{2\alpha}$ are attenuated in the cow in early pregnancy; however, the luteolytic pulses are abolished without major increases in basal secretion (Thatcher et al. 1995). Similar to the effect of oIFN-tau in sheep, bIFN-tau exerts this antiluteolytic effect by silencing the expression of the oestrogen receptor in uterine epithelial cells, thereby preventing an oestrogen-induced expression of oxytocin-receptors in these cells. It is important to realise that, besides the production of bIFN-tau, the preimplantation embryo produces a large number of unique proteins that were found in the uterine luminal fluid during the pregnancy recognition period (day 16–18; Forde et al. 2015). Together with bIFN-tau and certainly also due to the actions of bIFN-tau, these proteins play a crucial role in the interactions between preimplantation embryo and endometrium to facilitate conceptus growth and development.

Goat

In the goat, the removal of conceptuses from the uterine lumen between days 13 and 15 does not prolong the life span of the CL, but removal on day 17 increases the interoestrous interval by 7 to 10 days. The caprine conceptus secretes a protein originally designated cTP-1, which, as in other ruminants, is cIFN-tau (Gnatek et al. 1989). Caprine IFN-tau is mixture of nonglycosylated and N-glycolylated forms and is secreted between days 16 and 21 of gestation. As has been shown in sheep and cattle, this protein suppresses pulsatile prostaglandin secretion from the endometrium and extends the lifespan of the CL (Newton et al. 1996). This prolongation of luteal function apparently also occurs spontaneously in pseudopregnancy in this species, when in unmated does the CL persists and fluid (hydrometra) accumulates in the uterine lumen (Pieterse & Taverne 1986). Active immunisation of cyclic goats against $PGF_{2\alpha}$ results in luteal persistence and development of hydrometra (Kornalijnslijper et al. 1997).

Pig

Although in the sow the maternal recognition of pregnancy also involves the prevention of luteolysis by uterine-derived prostaglandins, the mechanisms are quite different from those described previously for the domestic ruminant species. After their entry into the uterus on day 4, some 2 days after ovulation, embryos start migrating throughout both uterine horns so that by day 12 they have more or less become evenly distributed, a process called 'spacing'. The early porcine conceptus has been shown to convert progesterone to oestrone and oestradiol-17beta, as well as another isomer of 16alpha, 17-oestradiol (Fischer et al. 1985). The production of oestrogens increases with the rapid elongation of the blastocyst, which may reach a length of 80 to 100 cm each between days 12 and 15. As a result of the spacing and elongation, the conceptuses are able to influence locally a large surface of the endometrium. The oestrogen production by the conceptus plays a vital role in the maternal recognition of pregnancy and the extension of the life span of the CLs. The administration of exogenous oestrogens parenterally from day 12 in nonpregnant gilts has been long known to be luteotrophic, thus prolonging the life span of the CLs and extending the interoestrous interval (Kidder et al. 1955). In addition, a wide range of maternal (endometrial) and conceptus-derived products, such as proteases, calcium, growth factors, adhesion molecules and cytokines, are involved in a complex signalling cascade to establish pregnancy, as well as attachment and implantation (Jaeger et al. 2001). After the initial secretion of oestrogens at day 11, a second sustained release of oestrogens by the conceptus is necessary between days 14 and 18 for luteal persistence beyond day 25 (Geisert et al. 1990). Several mechanisms have been proposed by which the conceptus-secreted oestrogens may prevent luteal regression (Ziecik 2002). These include a direct luteotrophic effect, a reduction in the endometrial synthesis and a release of $PGF_{2\alpha}$. The luteotrophic effects include maintenance of LH receptors in the CLs and secretion of prostaglandin E_2 to protect the CLs against the luteolytic action of $PGF_{2\alpha}$. However, there is convincing evidence that they exert their effect by altering the transport of $PGF_{2\alpha}$ from an endocrine (towards the uterine vasculature) to an exocrine (into the uterine lumen) direction, thereby preventing $PGF_{2\alpha}$ from reaching the CLs (Bazer et al. 1984; Bazer, 2013). Oestrogen-induced prolactin receptors in the endometrium might facilitate this redirecting. The fate of the intrauterine $PGF_{2\alpha}$ is not known; however, fetal membranes readily metabolise it to PGFM (15-keto-13, 14-dihydro-$PGF_{2\alpha}$), which is inactive. The oestrogen stimulation of calcium secretion into the uterine lumen also appears to be involved in the process.

As in ruminant species, the pig conceptus produces interferons at the time of elongation (11–17 days of gestation) (Cross & Roberts 1989); to date, two interferons have been identified, a type I (IFN-delta) and a type II (IFN-gamma). The infusion of total conceptus-derived secretory proteins into the uterine lumen failed to prolong the life span of the CLs in cyclic sows (Harney & Bazer 1989). Their precise functions are not known, but it has been postulated that they may have a specific protective antiviral role or that they may act in conjunction with conceptus-derived oestrogens in prolonging the life span of the CLs (La Bonnardiegravere 1993, Cencic & La Bonnadiegravere 2002).

Horse

In the mare the mechanisms responsible for the recognition of pregnancy are less completely understood (Allen 2005, Stout 2016). Evidence of the importance of the developing conceptus in this process has been shown by the effects of its removal at varying stages of gestation: if it was removed at 10, 15 and 20 days, then the return to oestrus was 22.3, 38.0 and 47 days respectively (Hershman & Douglas 1979). However, it is not clear yet how the

VetBooks.ir

early embryo prevents luteolysis in the mare (Stout 2016). A low molecular-weight protein has been identified in the uterine flushings of mares in dioestrus, which persists during pregnancy (McDowell et al. 1982). The equine conceptus also produces oestradiol and oestrone (Berg & Ginther 1978, Zavy et al. 1979), which enhance the production of a glycoprotein, uteroferrin, by the uterus. PGF secretion from the pregnant uterus is apparently blocked because lower concentrations of PGF have been identified in the uterine venous blood of pregnant mares compared with nonpregnant mares (Douglas & Ginther 1976) and similarly lower concentrations of PGFM in the peripheral circulation (Kindahl et al. 1982). There does not appear to be any sequestration of PGF in the uterine lumen during early pregnancy, but when endometrial tissue was incubated in vitro with material of conceptus origin, there was a reduction in PGF synthesis or secretion (Berglund et al. 1982). It has been demonstrated that this suppression of uterine PGF production is caused by a temporary (until about day 16) conceptus-directed downregulation of endometrial prostaglandin synthase 2 activity, accompanied by a posttranscriptional inhibition of endometrial oxytocin-receptor expression. As a result, the endometrium becomes nonresponsive to oxytocin of endometrial and hypothalamic origin (see review by Stout 2016). An important feature of the mechanism of maternal recognition of pregnancy in the horse is the migration of the spherical conceptus within the uterine lumen until it becomes 'fixed' at 16 to 18 days of gestation at the base of the uterine horn. This has been demonstrated in some elegant experiments by McDowell et al. (1988). By restricting the mobility of the conceptus using ligatures at various parts of the uterus, the maternal recognition was compromised so that the CL regressed spontaneously. Migration of the conceptus appears to be caused by uterine contractions induced by prostaglandins either from a conceptus or uterine origin (Stout & Allen 2001). Unlike in ruminants, the equine conceptus does not secrete interferon, and although it produces oestrogens in high amounts from day 10 onwards, oestrogens appeared unable to extend the luteal lifespan when applied in physiological doses (see review by Aurich & Budik 2015). However, as already mentioned, it does produce a variety of other hormones and growth factors that may indirectly be involved in maternal recognition of pregnancy. Yet the exact nature of the antiluteolytic factor(s) secreted by the conceptus remains to be elucidated.

Dog

The bitch is atypical in that the length of the luteal phase (metoestrus/dioestrus) is not shorter, but frequently exceeds that of pregnancy. No increases in PGFM concentrations have been found during the demise of the CLs in nonpregnant dogs (Luz et al. 2006; Concannon 2009), and surgical removal of the nonpregnant uterus in metoestrus/dioestrus does not prevent the demise of the CLs (Okkens et al. 1985). So there appears to be no need for maternal recognition of pregnancy to maintain the life span of the CLs and the continuation of progesterone production. However, it may seem a contradiction that CLs of both the pregnant and nonpregnant bitch require luteotrophic support by LH and, predominantly, prolactin, especially during the second half of their life span (Onclin et al. 2000; Kowalewski 2014).

Cat

The length of the luteal phase in the mated but nonpregnant (pseudopregnant) queen is about 40 days, whereas in pregnant females luteal progesterone production continues for another 20 days. Little is known about the mechanisms underlying the maternal recognition of pregnancy in the queen. In cats with hormonally induced corpora lutea, neither hysterectomy nor surgical diversion of uterine venous blood away from the ovarian vasculature had any effect on the duration of the luteal phase (Wheeler et al. 1988). This suggests that, as in dogs, maternal recognition of pregnancy in cats does not involve prevention of luteolysis caused by a uterine luteolysin.

Pregnancy Diagnosis

The detection of pregnancy, or its absence, in domestic species is important in a number of respects, but particularly in relation to their husbandry. In polyoestrous species (cattle, horse, pigs, sheep, goats) early and accurate detection of the nonpregnant individual is important because it enables early rebreeding. In recent years many new biochemical markers of pregnancy have been identified, and although they can be very accurate, often they can only be detected in a laboratory using expensive equipment and by skilled scientists. Particularly in farm animal production systems, it is important that a positive or negative diagnosis is made at the time the animal is being examined.

The sensitivity of a diagnostic method refers to the correctness of identifying pregnant animals, whereas the specificity refers to the correctness of identifying nonpregnant animals. However, it is important that inexperienced veterinarians should select a time when they are confident of their accuracy in making the diagnosis, irrespective of the method used.

In the mid-1970s it was observed that lymphocytes retrieved from mice shortly after mating displayed altered reactivity during rosette inhibition testing (Morton et al. 1974). During rosette inhibition testing, lymphocytes are incubated with heterologous erythrocytes and form 'rosettes', which describes the arrangement of erythrocytes around a central lymphocyte. The inhibition of rosette formation observed in females during early pregnancy is attributed to the presence of an immunosuppressive protein, the 'early pregnancy factor' (EPF), now identified as chaperonin 10 or heat-shock protein10. Early pregnancy factor is undoubtedly the earliest sign of the developing embryo affecting the maternal environment; in the horse it can be identified as early as 48 hours after mating. In addition to the rat its presence has also been detected in pig and cow. Thus it enabled the very early identification of individual animals in which fertilisation had not occurred and thus could be prepared for early rebreeding. Kits were available commercially to perform the rosette inhibition test on the farm or breeding establishment, but unfortunately they were not reliable.

From a practical perspective, in a nonpolyoestrous species such as the dog, early detection is not as critical. Early identification of nonpregnant individuals enables decisions to be made on the future of individual animals. In the case of nonpregnant individuals this could be the choice between rebreeding and culling; for pregnant individuals it would enable selecting the time of weaning or applying nutritional management.

A variety of methods can be used to detect pregnancy; many are common to all species whereas others are species-specific. They can be considered under four broad categories: management, clinical, ultrasonographic, and laboratory-based. Of these the first two are generally well tried and tested, whereas the latter two are generally more specific, and in most cases have been improved and refined extensively in recent years. Because ultrasonography is now used

VetBooks.ir

in all domestic species, the broad principles behind the technology ultrasonography will be reviewed before the methods applicable to the various species are described.

Ultrasonography

Three types of ultrasound technique have been used for pregnancy diagnosis. The ultrasonic fetal pulse detector was the first type used. This is based upon the Doppler phenomenon, in which high-frequency (ultrasonic) sound waves emitted from a probe placed on the exterior of an animal, or in the rectum, are reflected at an altered frequency when they strike a moving object or particles, e.g., the fetal heart, fetal body parts or blood flowing in fetal or uterine arteries. The reflected waves are received by the same probe, and the differences in frequencies are converted into amplified audible sound or converted into a colour image; this is particularly useful in measuring blood flow in both arteries and veins.

The ultrasonic amplitude depth analyser (A-mode) relies upon a transducer head that emits high frequency sound waves and receives the sound reflected at interfaces of tissues of different acoustic impedance. The echoes are shown as a one-dimensional display of echo amplitudes for various depths, usually on an oscilloscope, but also on the newer light-emitting diodes or by 'squeak-producing' devices. This has been used successfully in many species, notably the sow.

A more advanced ultrasound technology is the one that uses the B (brightness) mode image display of the acoustic impedance, providing a two-dimensional (cross) section of the tissues. The technique is frequently referred to as real-time ultrasound or imaging. This just implies that there are live or moving displays in which the echoes are recorded continuously. It has become a very versatile tool in studying a wide range of reproductive events in many species. The transducer probe can be inserted into the rectum or vagina or placed on the surface of the body. The transducer contains numbers of piezoelectric crystals, which, when subjected to an electric current, expand or contract and produce high frequency sound waves. When these sound waves are transmitted through tissues, a proportion, depending upon the characteristics of the tissue, will be reflected back to the transducer. The returning echoes will compress the same piezo crystals, resulting in the production of electric impulses, which are displayed in B-mode as a two-dimensional display of dots on a screen. The brightness of the dots will be proportional to the amplitude of the returning echoes and hence will provide an image ranging from black through various shades of grey to white. In the linear transducers the piezo crystals are arranged in a number of parallel elements, whereas in the sector the ultrasound beam is produced by a single crystal, which oscillates or rotates to produce a fan-shaped beam. The piezo crystals rotate through an angle, producing wedge-shaped image. An intermediate form is the so-called curved array transducer, which in fact is a modified linear array with a curved surface. Liquids, if clear, do not reflect ultrasound and thus are depicted as black on the screen, i.e., nonechogenic, whereas at interfaces of solid tissues such as bone or cartilage, a high proportion of the sound waves is reflected, i.e., they are echogenic and appear white on the screen. Each transducer produces ultrasonic waves at frequencies between 1 and 18 MHz. The most commonly used frequencies are 3.5, 5 and, more recently, 7.5 MHz. The lower frequency transducers give better tissue penetration but poorer resolution. Because when using the transrectal approach the structures requiring imaging are within a few centimetres of the transducer head, high frequency equipment is the most effective. So the choice of the shape and frequency of the transducer mainly depends on the type of investigation to be performed.

Because a tissue/gas interface can result in up to 99% of the sound waves being reflected, it is important that air should not be trapped between the transducer face and the tissues to be examined. For this reason a coupling medium or gel (usually methyl cellulose) is applied to the transducer face before it is placed on the skin or rectal mucosa so that air is eliminated. It is also important to select an area that is relatively hairless, or alternatively, it may be necessary to clip the hair. Curved-array and sector transducers allow ready access to most of the thoracic and abdominal viscera, although very superficial structures may not be readily identified because of the shape of the beam. Sector and curved-array transducers require less skin surface contact, which can reduce the time required to examine each animal; hence they are used for the transabdominal approach, especially in sheep. Linear transducers are usually cheaper to buy and more robust, and they produce a rectangular image, which is easier to interpret. The transducer should be small enough to be cupped in the hand, smooth in contour, waterproof, and easy to clean (Boyd & Omran 1991). For good biosecurity the transducer should be thoroughly cleaned, especially when the same equipment is used on different farms.

Readers who wish to extend their knowledge of these techniques are recommended to consult Ginther (1995; 2014), Taverne and Willemse (1989) and the textbooks by Kähn et al. (1994) and Goddard (1995), covering the major applications in reproduction of domestic species.

Pregnancy and Its Detection in the Horse

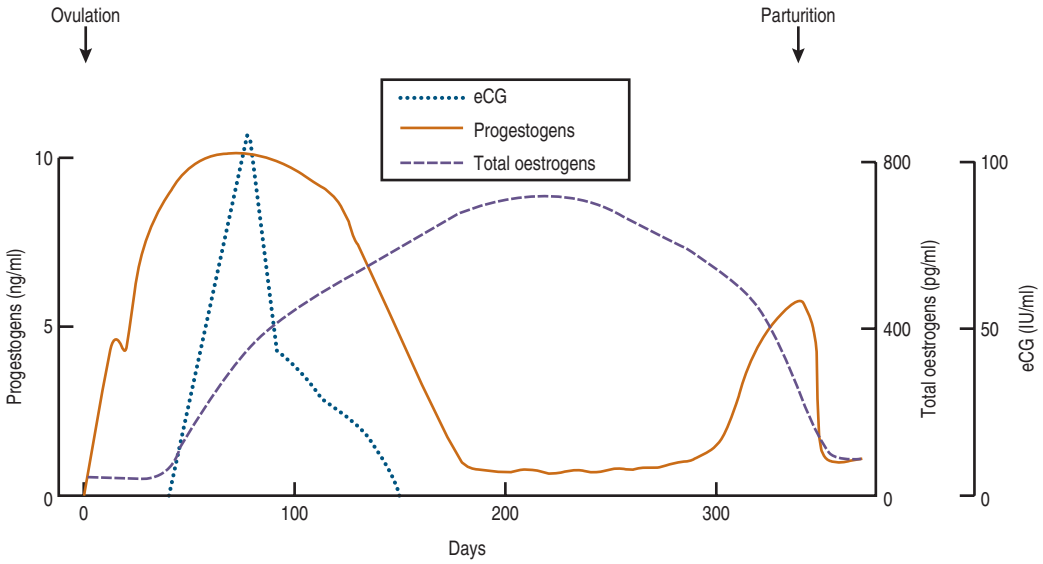
Endocrinology

The endocrine changes in the mare during pregnancy are particularly unusual when compared with other domestic species because of the development of temporary hormone-producing structures, the endometrial cups (see Chapter 4).

After ovulation and the formation of the corpus haemorrhagicum and the CL, plasma progesterone concentrations in the peripheral plasma rise to 7 to 8 ng/ml by 6 days. They persist at about these levels for the first 4 weeks of gestation, but there is frequently a transient fall at about 28 days after ovulation to 5 ng/ml (Holtan et al. 1975), followed by a later rise. Published values for progesterone in the blood and plasma vary considerably between laboratories. This is because there are other progesterone-like substances (progestogens) that crossreact with the antisera during the assay; for this reason, several authors refer to this as 'total progestogens'.

In the early part of the second month of pregnancy, the endometrial cups are formed. These are discrete outgrowths of densely packed tissue within the gravid horn, derived as a result of the invasion of fetal trophoblast cells into endometrium, in which they subsequently give rise to the endometrial cup cells (Moor et al. 1975). Usually, there are about 12 cups present at the junction of the gravid horn and body as a circumferential band. The endometrial cups produce pregnant mare serum gonadotrophin (PMSG), which is now referred to as equine chorionic gonadotrophin or equine chorionic gonadotrophin (eCG). It is first demonstrable in the blood 38 to 42 days after ovulation, reaches a maximum at 60 to 65 days, declines thereafter and disappears by 150 days of gestation (Fig. 5.1). The eCG has both follicle-stimulating hormone (FSH)-like and luteinising hormone (LH)-like activity; it is generally assumed that, in association with pituitary gonadotrophins, it

VetBooks.ir



• **Fig. 5.1** Schematic representation of the trends in hormone concentrations in the peripheral circulation of the mare during pregnancy and at parturition. *eCG,* Equine chorionic gonadotrophin.

provides the stimulus for the formation of accessory CLs (Allen 1975) and regulates luteal steroidogenesis (Daels et al. 1998). These structures start to form between 40 and 60 days of gestation, either as a result of ovulation, in the same way that the CL of dioestrus is formed (32%), or as a result of luteinisation of anovulatory follicles (68%) (Squire et al. 1974). Because of the presence of the accessory CLs, the progestogen concentrations in the peripheral circulation increase, to reach and maintain a plateau from about 50 to 140 days and then decline (see Fig. 5.1). By 180 to 200 days the concentrations are below 1 ng/ml; they remain so until about 300 days of gestation, when they increase rapidly to reach a peak just before foaling and subsequently decline rapidly to very low levels immediately after parturition.

Concentrations of total oestrogens in the peripheral circulation during the first 35 days of pregnancy are similar to those of dioestrus, although there is a temporary production of oestrogen by the embryo at 12 to 20 days (Mayer et al. 1977). After this time they increase to reach a plateau between 40 and 60 days at values slightly above those that occur before ovulation, about 3 ng/ml; the rise is probably due to the increased follicular development associated with eCG production. After day 60 it is likely that the increase is due to the activity of the fetus or placenta (Terqui & Palmer 1979). Maximum values are observed at about 210 days, the main source being the fetal gonads (Cox 1975), with a gradual decline towards the time of foaling and a precipitous fall postpartum. The main oestrogens in the mare are oestrone and a ketonic steroid, equilin, as well as oestradiol-17beta, oestradiol-17alpha and equilenin.

Prolactin levels show no distinct pattern, there being considerable variation within and between mares, but there is some evidence of a slight increase towards the end of gestation (Nett et al. 1975).

The main source of progesterone in early pregnancy is the 'true' CL or CL verum (formed from the follicle that ovulated and generated the oocyte that was fertilised) and the accessory CLs. The true CL is active for the first 3 months of gestation and regresses at the same time as the accessory CLs (Squire & Ginther 1975). The placenta must take over the production of progesterone after the regression of the accessory corpora lutea, and, although concentrations fall in the peripheral circulation, they remain high in the placental tissue and must maintain pregnancy by virtue of a localised effect (Short 1957). When ovariectomy is performed at 25 to 45 days of gestation, mares will abort or resorb the fetus; when it is performed after 50 days the response is variable between 140 and 210 days the pregnancy or it continues uninterrupted to term. Thus after 50 days there is evidence of a nonovarian source of progesterone and by 140 days the ovaries are no longer necessary for the maintenance of pregnancy (Holtan et al. 1979).

Changes in the Genital Organs

Conception to 40 Days

Ovaries. The CL *verum* can only be palpated per rectum for 2 to 3 days after its formation. Thereafter, although it persists for 5 or 6 months, it cannot be identified. In pony mares there is some palpable follicular development at about 15 days, whereas during the next 14 days there is quite a marked increase in folliculogenesis with a large number of follicles less than 3 cm diameter, giving the ovaries a 'bunch of grapes' appearance. Ovulations during this period are rare (Allen 1975).

Uterus. During late dioestrus and oestrus, the uterus is soft and the endometrium is oedematous. After ovulation, tone increases and the uterus becomes more tubular. These textural changes are not marked in the nonpregnant animal, in which they subside after the CL begins to regress at 10 to 14 days. However, in the pregnant mare the CL persists, and the tone of the uterus increases to a maximum at 19 to 21 days, when the conceptus causes a soft, thin-walled ventral cornual swelling close to the uterine body. The horn involved is not necessarily on the same side as the ovary which produced the ovum because there is extensive mobility of the conceptus within the horns and uterine body before fixation, which occurs between days 16 and 18. Most clinicians have reported more equine pregnancies in the right horn; for example, Vandeplassche (1957) noted 64%, although in ponies there is only a small majority of right-horn pregnancies. The excess of right-side pregnancies, coupled with the slightly greater incidence of left-side ovulations, indicates a major embryonic migration from left

VetBooks.ir

to right in horses generally. There is, however, good evidence that other factors can influence the horn in which pregnancy occurs. In a survey of 937 thoroughbred mares, Butterfield and Mathews (1979) found that there was no significant difference between the numbers of right- or left-horn pregnancies: 469 left and 468 right. However, when they examined the results for mares that conceived when they were not lactating, there were a significantly greater number of right-horn pregnancies. There is also good evidence that implantation usually occurs on the opposite side to that of the previous pregnancy. Feo (1980) found that 19 of 22 mares that conceived at the foal heat were pregnant in the opposite horn to that of the previous gestation. Allen and Newcombe (1981) found that in 82.5% of cases the conceptus was present in the opposite horn. Nearly similar percentages were reported by Davies Morel et al. (2009), and these authors also found that the number of pregnancies in the previously gravid horn increased with maternal age and the foaling to conception interval.

The conceptual swelling of the uterine horn protrudes ventrally and craniocaudally but not dorsally and grows slowly during the phase of organogenesis, i.e., until about 30 days. Thereafter, growth is faster, and the swelling progressively extends to the tip of the pregnant horn. Twins are usually disposed at the base of each horn, and in this situation there will be two groups of endometrial cups. If both twins are present in the same horn, only one set of cups will be present.

Vagina and Cervix. During early pregnancy, the vagina becomes progressively paler and dryer and is covered by thin, tacky mucus. The cervix is small and tightly closed and the external os uteri is gradually filled by a plug of mucus and points eccentrically.

40 to 120 Days

Ovaries. This period is characterised by marked ovarian activity, with multiple follicular development causing one or both ovaries to become temporarily larger than during oestrus – in some cases very much larger. Ovulations, forming accessory CLs, and luteinisation of anovular follicles occur. Follicular activity has usually subsided by 100 days, and the CLs begin to regress. In pony mares Allen (1971) found ovulations in pregnancy between 21 and 112 days, with the highest incidences between days 40 to 42, 54 to 56 and 63 to 66.

Uterus. The conceptus completely occupies the pregnant horn by about 60 days, after which the body and then the nonpregnant horn are invaded by the allantochorionic membrane. The pregnant horn now changes from a transverse to a longitudinal disposition in the mare's abdomen. By 100 days the fluid-filled uterus is a somewhat tense swelling on the pelvic brim. At this time the small fetus, closely enveloped in the amnion, floats in a relatively large volume of allantoic fluid.

120 Days to Term

Ovaries. With the gradual regression of all luteal elements and follicles, the ovaries become progressively smaller and harder and are drawn forwards and downwards by the gravid uterus. Except in very large mares, they can usually be palpated throughout pregnancy.

Uterus. Gradual distension of the uterus by the fetus and fluids causes increased tension on the utero–ovarian ligament, and the anterior border of the uterus sinks downwards and forwards. After the eighth month the fetus normally assumes an anterior longitudinal presentation and ventral position (see Chapter 14 for definitions of these terms). Except in very large mares, the fetus can be palpated throughout this period. Fremitus can be detected in the uterine arteries, although it is less obvious than in the cow.

Methods of Pregnancy Diagnosis

Management Methods

Failure to return to oestrus is a good sign that a mare is pregnant. The demonstration of the signs of oestrus (see Chapter 1) usually requires the presence of a teaser stallion, although some mares will respond to geldings and to androgenised geldings. It is preferable that mares should be accustomed to the teasing routine, which should commence 16 days after service and continue for a further 6 days.

False positives will occur for the following reasons:

- The mare has a 'silent heat', a common problem when the foal is at foot.
- The mare becomes anoestrus as a result of lactation or environmental factors.
- The mare has a prolonged luteal phase, yet has not conceived (see Chapter 32).
- The mare has a prolonged luteal phase associated with embryonic death; this is referred to as pseudopregnancy (see Chapter 32).

False negatives will occur in a few mares, which will show oestrus at this time although they are pregnant.

Clinical Methods

Before the availability of ultrasonic methods to detect pregnancy (see later in this chapter), the only clinical methods available were visual inspection of the vagina using a speculum or palpation transrectally using the hand and arm. For experienced clinicians, such methods of pregnancy diagnosis were quick and accurate and, in the absence of the necessary ultrasonographic equipment, still applicable today.

Vaginal Examination

This is best done using a speculum; however, manual exploration can be used. The vaginal mucosa is pale pink, the mucus is scant and sticky, and the cervix small and tightly closed; although the external os is gradually filled with thick, tacky mucus, it is not really apparent as a plug, and points eccentrically.

False positives can occur in early pregnancy because the vagina is indistinguishable from that seen in dioestrus. Errors can also be made as a result of prolonged luteal phase and pseudopregnancy (see Chapter 31).

Rectal Palpation

The presence of follicles during the third week after service does not necessarily indicate that the mare is returning to oestrus. Follicles are normally present during the first 3 months of gestation and give considerable size to the ovaries.

Uterine tone is marked at 17 to 21 days of pregnancy, when the uterine cornua can be palpated as resilient tubular organs. If no conceptual swelling is palpable, then this tone should only be interpreted as suggestive of pregnancy. The uterine body and the nonpregnant horn remain tonic until at least day 50 of gestation. Marked uterine tone may also be found in the puerperal mare mated at the foal heat, when there is acute endometritis and during pseudopregnancy (when early embryonic death is followed by autolysis or expulsion of the conceptus but the uterus retains the texture of pregnancy because of the persistence of the CL).

Palpation of the conceptus is first possible at 17 to 21 days, when it is a small soft swelling of 2.4 to 2.8 cm in diameter or is an apparent 'gap' in the otherwise tonic horn. It is more easily felt between 21 and 30 days, but still only the cranioventral portion of the distension can be appreciated. At 25 days, the conceptual

VetBooks.ir

swelling is 3 to 3.4 cm. At 30 days, its dorsoventral diameter is 3 to 4 cm. At 35 days, it is 4.5 to 6 cm, and at 40 days it is 6 to 7 cm in diameter, which is about the size of a tennis ball. Thereafter, it is not possible for the conceptual swelling to be completely cupped within the palm of the hand. By 60 days it is becoming oval in shape and measures approximately 13 × 9 cm, whereas by 90 days it has increased to approximately 23 × 14 cm.

There is a natural variation in the size of the conceptual swelling in mares of similar size and ovulation dates because of the variation in the volumes of fetal fluids present. However, swellings that appear small for the given stage of pregnancy should be reexamined later to exclude the possibility of impending resorption (hence the clinician should keep written records of the findings for later comparisons). Twin conceptuses can be identified up to 60 days. After this, a single conceptus is likely to involve both horns and the swelling becomes more diffuse. Care must be taken not to confuse a partially filled urinary bladder with the pregnant uterus during the 70- to 100-day period or with an inflated large colon during days 90 to 120; when in doubt, a search should be made for the ovaries in order to establish an anatomical link between them and the uterus via the utero–ovarian ligament.

At about 100 days it is often possible to ballotte the fetus as it floats in the fetal fluid of the uterine body. Growth of the fetus and reduction in tension of the fetal sacs enable the examiner to palpate parts of the fetus in the uterine body from the end of the fourth month onwards. It may be difficult to locate between the fifth and seventh months in large pluriparous mares and very occasionally in mares near term. The palpable absence of a nonpregnant uterus and tension in the mesovarium are reassuring features.

False-positive results by rectal palpation can be obtained either when, in rare instances, pregnancy is confused with pyometra (see Chapter 32), or when, in the very early stages, the uterine tone due to incomplete involution might be assumed to be due to pregnancy in mares that have been served at the foal heat and in those that have developed a pseudopregnancy. It should also be remembered that mares may suffer embryonic or fetal death with resorption or abortion after they have been confirmed pregnant.

False-negative results can be obtained if there is confusion over the service date, i.e., later than the one recorded, or if the uterus is not palpated completely.

Ultrasonographic Methods

The Doppler and A-mode ultrasonographic methods are of little or no value in the mare; however, B-mode is now commonly used in this species (Fig. 5.2). With this imaging mode and a 5.0 MHz transducer, the earliest gestational age that pregnancy has been confirmed in the mare is 9 days, when the conceptual vesicle appears as a black sphere of about 3 mm in diameter. By 11 days the vesicle has been identified in 98% of ponies and horses examined (Ginther 1986). The conceptus at this stage moves freely within the uterus and has been identified in all parts of the uterine horns and in the uterine body just cranial to the cervix; in fact, it is found more frequently in the body at this stage. Rapid growth of the conceptual vesicle occurs from 9 to 16 days, with evidence of some reduction in growth rate from 16 to 28 days, before it increases. This plateau in growth may be an artefact because, with a reduced turgidity of the vesicle, it is capable of being compressed by the uterine walls. This is also associated with an apparent change in the shape of the vesicle from spherical to oval to triangular, after which it then becomes irregular in outline. Fixation at the base of the horn occurs between 16 and 18 days, when the diameter of the conceptual vesicle is about 19 to 24 mm (Ginther 1986).

Twin ovulations are very common, especially in thoroughbred and draught mares, in which they can occur in up to 30% of ovulations (Davies Morel et al. 2012), although the birth of live twins is relatively uncommon, ranging between 0.8% and 3%, depending upon the breed. The reasons for the discrepancy are:

- Fertilisation failure,
- Death of one or both embryos before or after fixation,
- Death of one fetus, which is relatively uncommon, and
- Abortion of both fetuses; this is the most common sequel and is obviously the most costly one.

Although the detection of double ovulations by B-mode ultrasound has enabled better management and hence prevention of the problem, it is still possible for double ovulations to go undetected. Thus early identification of twin embryos, preferably between days 12 and 14 before fixation occurs, can enable more effective management of the problem (see Chapter 31). For this reason it is important to scan the whole of the uterine body and uterine horns.

In addition to the detection of pregnancy, it is also possible to determine the sex of the foal. However, this requires that the person has good-quality equipment, as well as considerable experience of transrectal ultrasonography and interpretation of ultrasonic images. The method is based on determining the relationship of the genital tubercle to surrounding structures. The genital tubercle is the embryonic precursor of the penis in the male and clitoris in the female. As the fetus develops, the tubercle moves from a position between the hind legs to near the tail in the female, and near the umbilicus in the male. The optimum gestational age is between 59 and 68 days (Curran & Ginther 1989); although accurate results were obtained up to 99 days (Curran 1992), it becomes more difficult after this stage.

Laboratory Methods

Milk or Blood Progestogens. As can be seen in Fig. 5.1, plasma progestogens concentrations in the pregnant mare remain elevated just before or during the time when the mare would have returned to oestrus. Blood or milk samples collected 16 to 22 days after service should have elevated progestogen concentrations in pregnant mares, whereas in nonpregnant mares the levels would be low and typical of those obtained at oestrus. Although Hunt et al. (1978) have quoted 100% accuracy in diagnosing pregnancy using this method, false-positive results occur due to a prolonged luteal phase or activity, which occurs in 20% of mares (Pycock 2007) and is indistinguishable from pregnant values. For this reason the method is not reliable.

Identification of Equine Chorionic Gonadotrophin. Blood samples should be collected, preferably between 50 and 90 days after service, although it is possible to identify the hormone between 40 and 120 days. The test is performed on serum.

Originally, biological methods were used to identify the presence of the gonadotrophin. The most frequently used method was the injection of serum into 3.5-week-old, immature mice, a positive result being the production of ripe follicles in the ovaries and the presence of a swollen enlarged uterus.

Immunological methods are now used – either gel diffusion or the haemagglutination inhibition technique. The latter method is available commercially in simple solid phase ELISA kit with all of the reagents provided, and it is possible for the procedure to be carried out in any veterinary practice laboratory.

VetBooks.ir

• **Fig. 5.2, cont'd**

False-negative results are obtained if the blood sample is taken either too early or too late, and for this reason it is important to sample at the optimum times stated previously. Some mares produce low levels of eCG that are briefly sustained and cannot be detected using the method.

False-positive results are obtained as a result of embryonic or fetal death, either after the blood sample was collected or in some cases before. Once the endometrial cups have formed, they will persist and still secrete eCG even if the fetus dies. They regress at the time that they would have done if the pregnancy had continued normally. For this reason owners should always be warned of the problems to save subsequent disappointment, and certificates should indicate that a positive result has been obtained with an explanation of the significance of such a result.

Blood Oestrogens. A method of detecting pregnancy by determining the concentration of total oestrogens in the peripheral blood has been suggested by Terqui and Palmer (1979). By 85 days of gestation the concentration should exceed the maximum values obtained in nonpregnant mares.

Urinary Oestrogens. Oestrogens (oestrone and oestradiol-17beta) are present in the urine of pregnant mares in sufficient amounts for accurate detection by a chemical method (Cuboni 1937) between 150 and 300 days of gestation. A modification of this test (Cox & Galina 1970) can be carried out easily.

Because the presence of blood oestrogens depends on a functional placenta, false positives, as seen with the eCG test, do not arise. This chemical test is not sensitive enough to identify the urinary oestrogens of oestrus. It is nearly 100% accurate between 150 and 300 days.

Optimum Time for Diagnosing Pregnancy

The optimum time, as with all species, is as early and as accurately as possible. In thoroughbred mares in particular, in which twin ovulations are common, the early identification of the resultant twin conceptuses, should they be present, is important (see Chapter 31). The use of transrectal B-mode ultrasonic imaging has enabled early identification, which is important because termination of pregnancy in the case of twins must be carried out before the endometrial cups develop. It is important to stress that good results depend upon good equipment and knowledgeable interpretation of the images. Similarly, many of the earlier changes in uterine tone can be identified only by an expert using sequential palpation.

If the mare is not pregnant and has not been observed in oestrus, or if she is in a prolonged luteal phase or anoestrus, the necessary action can be taken (see Chapter 31).

Hazards of Pregnancy Diagnosis

There is no evidence that careful palpation of the genital tract will cause failure of the pregnancy. In those mares in which fetal death occurs after a normal rectal examination has been performed, the pregnancy would have failed in the absence of the examination.

Pregnancy and Its Detection in Cattle

Endocrinology

The main source of progesterone for the maintenance of pregnancy in the cow is the CL, the placenta producing only small amounts. The results of ovariectomy and removal of the CL are controversial. Up to about 200 days of gestation, removal of the ovary containing the CL, or ablation of the CL, either surgically or with the use of $PGF_{2\alpha}$, usually results in abortion. However, after this stage until just before term, pregnancy very often continues. Placental cells produce progesterone in vitro, and a positive venous/arterial difference of the plasma progesterone concentration was maintained after ovariectomy on day 250 but not on day 270 of gestation (Pimentel et al. 1986). Therefore the placenta may only secrete significant amounts of progesterone during a limited period of gestation (from about days 150 to 265), when it can easily substitute for luteal progesterone after induced luteolysis.

The hormonal changes during pregnancy are illustrated in Fig. 5.3. Progesterone concentrations in the peripheral circulation during the first 14 days of gestation are similar to those of dioestrus; thereafter, those of the nonpregnant cow decline sharply from about the 18th day after ovulation (see Fig 1.29). In the pregnant cow there is normally only a slight decline at this stage, with a rapid recovery. Thereafter, the concentration increases slightly during pregnancy until it starts to decline at about 20 to 30 days prepartum. Oestrogen concentrations during early gestation and midgestation are low, less than 100 pg/ml; however, towards the end of gestation, in particular after day 250, oestrogen concentrations increase to reach peak values 2 to 5 days prepartum of 7 ng/ml estrone sulphate and 1.2 ng/ml estrone (Thatcher et al. 1980). These rapidly decline from about 8 hours prepartum to low levels immediately postpartum.

Both FSH and LH concentrations remain low during gestation and show no significant fluctuations. So there is no evidence to suggest that the prepartum decline of maternal plasma progesterone concentrations, which starts already several weeks before calving, with a more precipitous fall at about 30 to 40 hours before delivery, is due to withdrawal of maternal gonadotrophic support. Prolactin is low during pregnancy until just before calving, when it increases from basal concentrations of 50 to 60 ng/ml to peak values of 320 ng/ml 20 hours prepartum, until a subsequent decline to basal concentrations by 30 hours postpartum. Bovine placental lactogen (bPL) can be detected in the peripheral circulation of the dam after the first month of gestation, increasing dramatically to maximum concentrations between 200 days and term (Bolander et al. 1976, Forsyth 1986). However, other authors reported that maternal levels remain low throughout pregnancy, whereas fetal plasma levels were 7 to 10 times higher at day 90 and gradually declined towards term (Beckers et al. 1982). The physiological role of this placental hormone is still unclear, but it appears to have prolactin and growth hormone-like activities.

Changes in the Genital Organs

Ovaries. In the cow the CL of pregnancy remains at its maximum size throughout the whole of the period of gestation, and a significant decrease is only seen after calving (Ginther 1998). Fundamentally it is indistinguishable from the fully developed CL of dioestrus, but there are certain features by which its persistence can be recognised when examined postmortem. More recently, Scully et al. (2014) performed sequential transrectal ultrasonography of the uterine horns, ovaries and blood flow to and within the ovaries from days 18 to 21 after AI. The best logistic regression model to predict pregnancy included scores for CL blood flow, CL size, and uterine echotexture on day 21 following AI. Accuracy of pregnancy diagnosis was highest on day 21, with sensitivity and specificity being 97.6 and 97.5%, respectively. However, this type of sequential examination would not be practicable in routine veterinary practice.

The chief feature of the CL of pregnancy is that the protrusion of the structure from the surface of the ovary is less marked and the epithelium over it is white and scarred. The CL of dioestrus often contains a central lacuna, whereas during pregnancy this becomes filled. It is considered by some that the CL of pregnancy is larger than that of dioestrus. If this is the case, it is too slight to be of significance; moreover, there are considerable variations in the weights of pregnancy CLs in individuals (3.9–7.5 g), which bear no relationship to the stage of pregnancy. The colour of the CL of pregnancy, however, differs somewhat from that of dioestrus. There is a wider range from yellow through orange to light brown, and the appearance of the luteal tissue is duller. Figs 5.4 to 5.9 show examples of bovine ovaries (natural size) obtained from gravid genital tracts recovered after slaughter. Note the variations in the

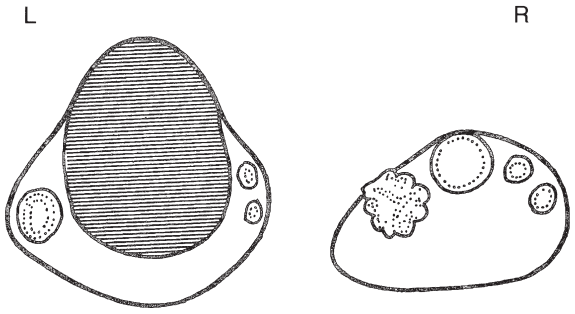
shape of the ovaries and the position of the CL of pregnancy. In addition, these sagittal sections also show that folliculogenesis and regression continue throughout pregnancy (Ginther et al. 1996).

As pregnancy advances, the relative position of the ovaries within the pelvic and abdominal cavities changes. Their location, however,



• **Fig. 5.9** Ovaries of the cow at 190 days of pregnancy. Corpus luteum verum orange.

in nongravid animals is not constant. In heifers and young cows they are generally situated on each side of and slightly below the conjoined horns at the level of the pelvic brim. They may lie in the pelvic cavity. In multiparous animals they are often situated in the abdominal cavity 5 to 8 cm in front of the pelvis, where their detection is more difficult. Consequent on the increase in the weight of the uterus and hypertrophy of the ovarian and uterine ligaments, the ovaries pass deeper and deeper into the abdominal cavity as pregnancy advances. From the fifth month onwards the weight and size of the uterus is such that it sinks down into the abdomen to rest on the abdominal floor. Hammond (1927) found the weight of the uterus and its contents in primigravidae at 5 months to be some 48 kg. Provided that the animal is comparatively easy to examine, it is generally possible to palpate the ovaries with reasonable certainty up to day 100, by which time, in heifers, the one on the gravid side is about 8 to 10 cm in front of and slightly below the pelvic brim and that on the nongravid side is a little nearer the pelvis. In occasional cases both ovaries may be detected as late as day 150, although by this time there is a risk that they will be confused with cotyledons. In the later stages of pregnancy it is not so much that they are beyond the reach of the hand as that one is unable to depress the rectum sufficiently deeply into the abdomen to locate them.

Uterus. During the early stages, detection of an increase in size of the uterus affords strong evidence of pregnancy, but the recognition of these changes necessitates an appreciation of the size of the quiescent uterus in subjects of varying ages and parity (Fig. 5.10, Table 5.2), the quantities of fluid present in the respective fetal sacs and the disposition of those sacs in the uterus. Uterine echotexture scores were similar for pregnant and nonpregnant cows from day 18 to 20.

At 28 days of pregnancy the amniotic sac is spherical in outline and about 2 cm in diameter. It occupies the free portion of the gravid horn. The allantoic sac is about 18 cm long, but the amount of contained fluid is insufficient to cause a noticeable (i.e., externally visible) distension and its width is negligible. It occupies almost the whole of the gravid horn. At this stage the embryo is 0.8 cm long, a quite inappreciable size.

At 35 days fetal body length is 1.8 cm, and the diameter of the spherical amniotic sac 3 cm. They still occupy the free part of the horn. The conjoined portions of the horns and the free portion of the nongravid horn are not appreciably changed. It is possible, particularly in a heifer easy of examination, that the distension in the free part of the gravid horn will be detected.

At 60 days the fetal crown–rump length is approximately 6 cm. The amniotic sac is oval and tense, having a transverse measurement of about 5 cm. This causes the free part of the gravid horn to be distended to a width of about 6.5 cm, compared with 2 to

TABLE 5.2 Dimensions of nongravid genital tract from a nulliparous heifer and pluriparous cow

	Unbred Nulliparous Heifer (cm)	Pluriparous Cow (cm)
Width of conjoined cornua immediately anterior to cervix	2.5	4.0
Width of each cornu at external bifurcation	2.0	3.5
Length of externally connected parts of cornua	9.0	14.0
Length of free portions of cornua	0.5	1.2
Length of cervix	5.0	10.0
Width of cervix	3.0	5.0

3 cm in the quiescent stage in the heifer and young cow. In such subjects this distension may be recognised.

At 80 days the fetus measures 12 cm and the total quantity of fluid is about 1 litre. Distension of the free part of the gravid horn varies from 7 to 10 cm, while that of the conjoined part is but little greater than normal. The greater length of the gravid horn can often be detected.

By 90 days uterine distension is such that it can be detected with accuracy in the great majority of cases. The conjoined horns are tense, the gravid one having a width of about 9 cm and the nongravid one about 4.5 cm. In most individuals the organ is still high up at the pelvic brim; it is generally possible to pass the hand well over the curvature of the distended horn, but in some multigravid cows the uterus lies in the abdomen and to palpate it effectively it is necessary to retract the organ. Sometimes it is possible to detect the fetus at this stage. Tapping the distended horn with the fingers may reveal the fetus rather similar to a piece of wood floating in the fluid beneath. By gently squeezing the uterus one may be able to pick up the fetus; its body length is about 15 cm.

By the fourth month, the uterus sinks below the pelvic brim and distension is less easy to recognise as the fluid gravitates towards the extremities of the horns. The cervix lies on the pelvic brim.

Changes in the size and shape of the gravid uterus during the first 4 months of gestation are shown in Fig. 5.11. A detailed description of the morphology and growth of the bovine conceptus (embryo/fetus, fetal membranes, and placenta) between days 20 and 70 of gestation has been provided by Neto et al. (2010).

Fetus. Several workers (Hammond 1927, Winters et al. 1942) have recorded fetal body lengths (crown–rump) during the various stages of pregnancy. Data have been collected chiefly from pregnant heifers, and thus allowance must be made for the greater size of the fetus in cows, particularly in the later periods of pregnancy (Table 5.3). The fetal bulk in relation to these body lengths will be greater. Changes in several fetal body measures have also been measured repeatedly in the same animals by means of ultrasonography (Kähn 1989, Ginther 1998, Breukelman et al. 2004).

During the period 120 to 160 days it will be possible to palpate the fetus in more than 50% of cases. The presented extremity will lie within reach in front of and below the pelvic brim. In some cases the fetus may be touched transiently at the commencement of examination before it sinks into the depths of the uterus and is beyond reach. Similarly, if a series of examinations of an individual is made during this period, the fetus may be detected on some occasions and not others.

Between 5.5 and 7.5 months the fetus is detected less frequently than during the previous period – perhaps about 50% of the time. In some individuals the fetal head and/or flexed limbs can be palpated just anterior to the pelvic brim. Touching the fetus often provokes reflex movements.

From 7.5 months to the end of gestation the fetus will, in the majority of cases, be palpated readily. However, in some individuals, especially if they are deep bellied, multiparous cows, it may

not be possible to palpate the fetus on a single examination even at term. Several authors (Ruumlsse 1968, Dufty 1973, Taverne et al. 2002) have shown variations in myometrial tone and activity during late pregnancy. Dufty (1973) found that, in a large number of Hereford heifers examined daily by rectal palpation near term, it was frequently impossible to palpate the fetal calf. The reason for this finding was the considerable relaxation of the myometrium, which allowed the calf to descend into the abdomen.

Nongravid Horn. The extent to which the allantochorionic sac occupies the nongravid horn varies greatly. In the great majority of bovine pregnancies the sac occupies some part of it, in some extending to the apex. In others the caudal two-thirds or one-half only is occupied, whereas in exceptional cases the nongravid horn is entirely unoccupied by fetal membranes. In the majority of cases the nongravid horn also plays its part in placentation and its caruncles hypertrophy, although the degree of caruncular enlargement is not as great as that of the pregnant horn. Occasionally, the nongravid horn, although occupied by the allantochorion, plays no part in placentation, and its caruncles remain undeveloped. In such cases, and also in those in which the nongravid horn is unoccupied, the placentomes in the gravid horn, particularly those in the region of the fetal trunk, become grossly hypertrophied and may at the time of parturition be as large as 8 to 12 cm.

Placentomes. Detection of placentomes is evidence of pregnancy, but variations occur in their size at the various stages of pregnancy in different individuals; this is probably due to differences in numbers, although there is substantial variation throughout the same gravid uterus. Those situated about the middle of the gravid horn are larger than those of the extremities, whereas those in the nongravid horn are smaller than those in the gravid one. Occasionally, there is no placentation in the nongravid horn. As pregnancy continues, they become progressively larger, until in the terminal stages they may be 5 to 6 cm in diameter; however, because the pregnant uterus sinks into the abdomen, it may not be possible to palpate placentomes from the fifth to the seventh month. Development (their number, size, and weight) of placentomes was found to be disturbed in cows carrying fetuses derived from in vitro–produced embryos (Farin et al. 2000, Bertolini & Anderson 2002, Miles et al. 2004).

Uterine Arteries. Evidence of pregnancy is afforded by hypertrophy of the middle uterine arteries and a characteristic change in their pulse wave, which is referred to as fremitus. Blood flow through this enlarged uterine artery has been quantified by means of transrectal Doppler sonography (Bollwein et al. 2002).

Pregnant Side. It is generally accepted that dairy cows are more often pregnant in the right horn and that the CL is in the ovary on the side of the pregnant horn. In a large series of pregnant bovine uteri examined by one of us, the proportion has been 60% right-side pregnancies to 40% left-side. In only one case was the fetus present in the horn opposite to the ovary containing the CL; another case showed a CL of normal size in each ovary with a single fetus in the right horn. In a series of 1506 uteri of dairy cattle examined in the US, Erdheim (1942) found the fetus in the right horn in 1015 (67.4%) and in the left in 474 (31.4%). In a series of 2318 uteri of beef cattle, however, the side incidence of pregnancy was approximately equal: right, 1178 (50.8%) and left, 1121 (48.3%). Among all Erdheim's (1942) specimens there was one exceptional single pregnancy in which he found the CL in the left ovary and fetus in the right horn. Of 133 pregnant uteri from Swedish Highland cattle, Settergren and Galloway (1965) found 59.4% pregnant on the right side and 40.6% on the left. This series also included one specimen in which the CL was in the left ovary and the fetus in the right horn. So transuterine migration of the embryo before implantation appears to be really exceptional in cows. Unequal distribution of sexes within the left and right uterine horns has recently been reported: the sex ratio (% males) of fetuses in the left horn was significantly lower than the sex ratio in the right horn (Giraldo et al. 2010). The mechanism underlying this disparity remains to be elucidated.

Twinning. In the past, the incidence of twinning was about 1% in dairy cattle and 0.5% in beef cattle. Individual breed records showed higher figures: 2.7% to 8.85% for Brown Swiss; 3.08% to 3.3% for Holsteins; 2.8% for Ayrshires; 1.95% for Guernseys; and 13% for Jerseys (Meadows & Lush 1957, Johansson 1968). The rate increases with age, with figures for Holsteins showing 1.3% for heifers rising to 7% in 10-year-old cows. In dairy cattle, twinning rates have significantly increased over the past decades, alongside the increase in milk production (Nielen et al. 1989), with double ovulations reaching more than 20% and twin birth rates exceeding 9% in very high-producing animals. In an 11-year study involving 12,589 calvings in Friesian-Holsteins, the average twinning rate was 5% to 6%, with yearly values ranging from 3.9% to 7.7% (Andreu-Vazquez et al. 2012).

In the majority of cases, one CL is present in each ovary and a fetus in each horn. Not infrequently, however, two CLs are found in a single ovary but with a pregnancy in each horn. In a study of 211 cases within a large dairy farm (Lopez-Gatius & Hunter 2005), 41% were found to be bilateral and 59% unilateral twin pregnancies, with at least two CLs present in each of the animals. This observed natural preponderance of unilaterally disposed twins does not conform to the experimental results of Rowson et al. (1971), which showed that induced twin pregnancies were more stable when an embryo was transplanted into each horn than when two embryos were placed in one horn. Arthur (1956) and Erdheim (1942) each encountered only one case of identical twinning in which there was a single CL associated with two developing fetuses. The aggregate recorded statistics for identical twinning is 4% to 6% of all twins. The incidence of bovine triplets is about 1 in 7500 single births.

Methods of Pregnancy Diagnosis

A variety of different methods have been used to detect the presence or absence of pregnancy in the cow. These range from the

TABLE 5.4 Methods of pregnancy diagnosis in cattle and the times in gestation when they can be first used

Diagnostic method	Day of Gestation
Real-time ultrasound (direct imaging)	13–21
Failure to return to oestrus and persistence of CL	21
Progesterone concentration in plasma or milk	21–24
Assay of pregnancy specific protein B (PSPB) or pregnancy-associated glycoprotein (bPAG)	24
Palpation of the allantochorion ('membrane slip')	33
Unilateral enlargement of horn and disparity in size, thinning of the uterine wall, fluid-filled fluctuation of enlarged horns	35
Palpation of the early fetus when amnion loses its turgidity	45–60
Palpation of placentomes	80
Hypertrophy of the middle uterine artery until presence of fremitus	85
Oestrone sulphate in blood and milk	105
Palpation of fetus	120

identification of substances that are present in body fluids using laboratory assays and from different ultrasound modes to simple clinical methods such as transrectal palpation; the latter has been the most ubiquitously used method for the last 70 years (Figs 5.12–5.15). Table 5.4 lists the methods of pregnancy diagnosis and the earliest times that they can be used. In terms of efficient livestock production, it is the early identification of the nonpregnant cow that is important because immediate measures can be taken to attempt to induce pregnancy again as soon as possible.

Management Methods

Failure to Return to Oestrus and Persistence of the CL. Failure of regression of the CL at about 21 days, as determined by transrectal palpation or ultrasonography, provides a method of anticipating that the cow is probably pregnant. It is seldom used as a practical procedure, and there are reasons for the CL persisting in the absence of pregnancy (see Chapters 22 and 23). Rectal examination at about this time in an individual that was close to or in oestrus would demonstrate the presence of a turgid, coiled uterus and a mucoid vaginal discharge.

How reliable is failure to return to oestrus as a method of diagnosing pregnancy? This depends on the efficiency and accuracy of oestrus detection. In a large group of dairy cows it can be expected that about 50%, or fewer in many cases, will become pregnant after artificial insemination and thus 50% will not. Those that are pregnant will not return to oestrus, whereas those that are

VetBooks.ir

not pregnant will return. However, a substantial number returning to oestrus will not be detected (see Chapter 22) and thus will incorrectly be assumed to be pregnant, although there will be an opportunity for detection at subsequent oestruses. Assuming an oestrus detection rate of 60% (see Chapter 22), 30% of cows will be incorrectly assumed to be in calf. This constitutes a large error and fully justifies the use of other diagnostic procedures. In addition, following early pregnancy diagnosis, there is always a chance that the pregnancy will fail, and if the cow is not seen to return to oestrus, she will incorrectly be assumed to be pregnant.

Mammary Glands. Mammary changes during pregnancy are best observed in primigravida. The teats of the pregnant heifer begin to enlarge about the fourth month, and, with a little experience, it is an easy matter to distinguish them from those of the nonpregnant or early pregnant animal. From the sixth month the mammary glands become more firm to the touch, and their enlargement can be seen. Hypertrophy is progressive and is particularly marked during the terminal month. As parturition approaches, the glands become grossly enlarged and oedematous, and the teats take on a waxy, tumefied appearance. The abdominal wall, particularly in the region of the umbilicus, may also become swollen by oedema. In the dry milch cow, mammary enlargement occurs during the last 14 or so days of pregnancy. After the fourth month a honey-like secretion may be withdrawn from the teats of pregnant heifers.

Abdominal Ballottement. This is often possible as early as 7 months of gestation in some small breeds such as the Jersey. However, in fat cows of large breeds it is sometimes impossible even at term. The method involves fairly vigorous pummelling of the ventral abdomen and flank with clenched fists. The object is to push the fetus, which is floating in the fetal fluids, away from the body wall and then identify it as it swings back against the fist, which is kept pressed against the abdominal wall.

Laboratory Methods

Identification of Early Pregnancy Factor/Early Conception Factor. Early pregnancy factor (EPF) is an immunosuppressive glycoprotein associated with pregnancy. It was first identified in the mouse (Morton et al. 1974) and subsequently in a large number of domestic species; in the cow it has a molecular weight of 200,000 (Threlfall 1994). Commercially available test kits have been available to detect early conception factor (ECF) in serum and milk from as early as 3 days after artificial insemination, although more accurate results are obtained if samples are taken later, at 7 to 8 days (Adams & Jardon 1999, Threlfall & Bilderbeck 1999). However, in a more recent report the accuracy of a commercial test still appeared to be unacceptably low (Cordoba et al. 2001). Obviously an accurate early pregnancy test would have important practical application in the early identification of the nonpregnant cow in the luteal phase after an unsuccessful insemination; thus the cow can be treated with $PGF_{2\alpha}$ to induce a premature oestrus, when it can be rebred, thus saving time (Chapters 8 and 22). It may be that, in time, such a test will be available.

Assay of Bovine Pregnancy-Specific Proteins B or Bovine Pregnancy-Associated Glycoproteins. These bovine pregnancy-specific proteins B (bPSP-Bs), also known as bovine pregnancy-associated glycoproteins (bPAGs), are members of a large family of glycoproteins that belong to the subclass of aspartic proteinases. Their biochemical and structural characteristics have been extensively reviewed by Sousa et al. (2001). They have been identified in the maternal serum and milk of cows from 24 days of gestation onwards; their concentrations are measured by radioimmunoassays (Sasser & Ruder 1987, Zoli et al. 1992a). Plasma levels rise progressively between the 6th and 35th week of gestation, but they increase steeply during the final 6 weeks and reach very high levels (on average 2460 ng/ml) a few days before calving (Zoli et al. 1992a). The proteins, present in many different glycosylated isoforms, are secreted by the binucleate cells of the trophoblastic ectoderm (Reimers et al. 1985, Zoli et al. 1992b), and thus their presence can be used to confirm pregnancy. However, because they have a long biological half-life (some 3 days) and plasma levels are extremely high around calving, the proteins can also be identified in serum for up to 7 weeks postpartum; for the same reason false positives (i.e., noncalving cows tested as pregnant) can occur after spontaneous (Szenci et al. 2000, Chavatte-Palmer et al. 2006) or induced embryonic or fetal death (Szenci et al. 2003, Breukelman et al. 2005a).

PSPBs or bPAGs were initially mainly measured by autologous or heterologous radioimmunoassay, but development and testing of suitable enzyme-linked immunosorbent assay (ELISA) methods have been developed, enabling the use of an on-farm diagnostic test (Sasser & Ruder 1987). Using radioimmunoassay to detect PSPB, Humblot et al. (1988) reported 90% accuracy at 30 days of gestation. It has been shown that there is a good correlation between PSPB in peripheral plasma concentrations and fetal numbers, and thus the method could be used to identify twins (Dobson et al. 1993, Patel et al. 1995). However, such a test does not appear to be sufficiently accurate before day 85 (Szelenyi et al. 2015). In a field study (Szenci et al. 1998), the accuracies of both a bPAG and PSPB radioimmunoassays method were compared with that of transrectal ultrasonography (Table 5.5).

Karen et al. (2015) performed a study in which 100 cows were examined 28 days after AI, and 41 were confirmed pregnant, based on the actual gold standard for pregnancy diagnosis: Transrectal ultrasonography (TRUS) at Day 42. The sensitivity of TRUS, a commercial PAG-ELISA test and a PAG-RIA test for diagnosing pregnant cows at Day 28 were 92.7%, 90.2% and 100%,

TABLE 5.5 Comparison of the accuracies of three different methods of early pregnancy diagnosis, applied in the same cows at three different stages after artificial insemination

	ULTRASONOGRAPHY			BPAG-1			BPSP-B		
Days After Artificial Insemination	29/30	33/34	37/38	29/30	33/34	37/38	29/30	33/34	37/38
Sensitivity (%)	90	97	100	95	95	96	92	98	100
Specificity (%)	96	99	99	69	77	72	83	87	84

Detection of allantoic fluid during transrectal scanning with a 7.5 MHz linear array transducer was used as a positive criterion in the ultrasound test. In the bPAG-1 radioimmunoassay a value > 0.8 ng/ml and in the bPSP-B assay a value > 0.5 ng/ml was used as a positive criterion.
(After Szenci et al. 1998)

VetBooks.ir

respectively, whereas the specificity of the three tests for diagnosing nonpregnant cows were 91.5%, 98.3% and 94.4%, respectively. The degree of agreement (Kappa±S.E.) between PAG-RIA and PAG-ELISA test was 0.90 ±0.04. The degrees of agreement between PAG-RIA and PAG-ELISA and TRUS at Day 28 were 0.80±0.05 and 0.76±0.06, respectively. Thus the commercial PAG-ELISA test is a highly accurate method for diagnosing early pregnancy in dairy cows on Day 28 after AI, and may be used as an alternative method to the TRUS and the PAG-RIA test.

Recently, circulating nucleic acids (CNAs) have been used successfully as biomarkers for the detection of early pregnancy in cattle (Mayer et al. 2013).

Progesterone Concentration in Plasma and Milk. In 1971 Robertson and Sarda described a method of diagnosing pregnancy by the determination of the progesterone concentration in the plasma of cows. Because the CL persists as a result of the pregnancy, if a blood sample is taken at about 21 days after the previous oestrus, progesterone levels will remain elevated. If the cow is not pregnant and is close to or at oestrus, then the progesterone levels will be low; this can be seen if the progesterone curves in Figs 1.29 and 5.3 are studied. Although this is a perfectly valid and reliable laboratory method, it has the one disadvantage in that it requires the collection of a blood sample.

In 1969 Heap et al. showed that progesterone crossed the mammary gland and appeared in milk. Laing and Heap (1971) confirmed that the changes in progesterone concentrations in the milk closely followed those in the blood or plasma. Furthermore, because progesterone is very soluble in milk fat, there were higher concentrations per unit volume in milk than in the blood or plasma. Heap et al. (1973) described the use of the technique to diagnose pregnancy, and since then a large number of different workers in many different countries have described similar methods. Initially, the technique depended upon the herdsperson collecting about 20 ml of milk, usually at the afternoon milking because the fat content is higher, into a glass or plastic bottle. Then a tablet of potassium dichromate and mercuric chloride as a preservative is added, and provided that the sample is not exposed to high temperature or excessive ultraviolet light, there is very little loss of progesterone activity. At present, an 'in-line' milk progesterone assay is not available, although one system, the 'Delaval Herd Navigator Advanced Analysis System', can measure P4 values in milk; however, this is done after removal of milk from the 'milk line' for analysis by an adjoining instrument (Dobson 2016). So far an 'in line' method has not been developed, but it is likely that one will be designed fairly soon.

Initially, progesterone concentrations in the milk were assayed using radioimmunoassay, which is an effective method of measurement but requires the use of radioisotopes and the equipment to measure radioactive emissions. It can only be performed in a specialist laboratory and hence has the big disadvantage of taking several days before a result is known.

A number of qualitative cow-side tests have been developed that can be used on the farm and hence enable the herdsperson to obtain a result within 1 hour of collecting the milk sample. All the necessary reagents and equipment are provided in kit form. Semiquantitative or fully quantitative tests are also available, but these are designed for use in a veterinary practice laboratory because they require a minimum amount of equipment and some expertise. Both tests are based on ELISA.

The laboratory-based quantitative tests have a series of progesterone standards that enable a standard curve to be drawn. It is usually recommended that duplicate assays are done for each sample, at least until the operator becomes conversant with the procedure. There are a few problems in using the assay on the farm. These can be summarised as follows:

- Instructions are not always readily understood by persons not used to laboratory procedures.
- Simple equipment requires a fair degree of manual dexterity.
- Instructions should be closely adhered to, particularly with regard to timing of incubation and quantities of reagents.
- The kits should be kept in a refrigerator at 4°C and should be allowed to warm to room temperature before use; they should not be heated.
- Interpretation of the colour differences can be difficult for some persons.
- Milk samples should be kept at 2°C to 8°C until assayed, and the recommended preservative tablets must be used.

The optimum time for collecting the milk sample is 24 days after service or artificial insemination (Heap et al. 1976). This time interval prevents those cows with a longer-than-average interoestrous interval from giving false-positive results; however, in those animals with a shorter-than- average interoestrous interval, false positives will occur. The accuracy of the method in the diagnosis of pregnancy is between 80% and 88% (Heap et al. 1976, Hoffmann et al. 1976, Koegood-Johnsen and Christiansen 1977); the accuracy of the method for detecting the absence of pregnancy is nearly 100%. However, Pieterse et al. (1990) reported quite different values from a field study in which milk samples were taken on the day of insemination and on day 21: sensitivity was 86% and 93% for a radioimmunoassay and a cow-side enzyme immunoassay test respectively, whereas specificity was only 48% (radioimmunoassay) and 39% (enzyme immunoassay). Recently, a milk progesterone lateral flow test (LFT) has been described (Waldmann and Raud 2016). It is an immunochromatographic method that utilises an immunostrip for nonlaboratory diagnostic purposes; thus it is a true 'on-the-farm' method. The level of accuracy of the LFT compared with the EIA was 95% for milk samples containing less than 2 ng/ml progesterone and 97% for milk samples containing more than 10 ng/ml progesterone. The validation of oestrus by the LFT was 98.6% accurate using 2 ng/ml progesterone as the EIA estimate for oestrus. The test performance for a nonpregnancy diagnosis was subject to the day of milk sampling, showing the highest accuracy on day 24 post insemination for both tests. When optimised for maximum specificity and compared with rectal palpation, the LFT had a sensitivity and specificity for nonpregnancy diagnosis on day 24 post insemination of 75% and 100%, respectively, with an overall accuracy of 84.4%. The corresponding characteristics for the quantitative EIA were 85%, 100% and 90.6%, respectively. The LFT results compared favourably with the quantitative milk progesterone EIA.

The reasons for false-negative results are:

- Mistaken identity of the animal either on the farm or in the laboratory,
- Milk storage problems due to excessive heat or ultraviolet light,
- Low progesterone production by the CL, and
- Inadequate mixing of milk so that a low-fat sample is obtained.

The reasons for false-positive results are:

- Cows with shorter-than-average interoestrous intervals, i.e., 18 days: When milk samples are taken 24 days after service or artificial insemination, if the cow is not pregnant she will already be in the early luteal phase of the next cycle;
- Embryonic death, if it occurs after the day when the milk was collected (see Chapter 22);
- Luteal cysts that produce progesterone (see Chapter 22);
- Incorrect timing of insemination: Several reports (Hoffmann et al. 1976) have shown that up to 15% of cows are presented

VetBooks.ir

for artificial insemination when they are not in oestrus. Thus if a milk sample is taken 24 days after the cow was incorrectly inseminated in early dioestrus or middioestrus and the intervening oestrus has not been observed, then she will be in the subsequent dioestrus with a functional CL and elevated milk progesterone concentrations; and

- Pathological prolongation of the life span of the CL; this will be discussed in Chapters 22 and 23.

The main advantage of the milk progesterone test is that it identifies those cows that are not pregnant before it is possible to do so by some other methods such as transrectal palpation. A 24-day sample will then enable the herdsperson to anticipate the return to oestrus 42 days after the service if the cow is not pregnant or enable the veterinarian to examine the animal if she is a problem before she returns again. Cows that are found to be pregnant at 24 days should be examined at a later date by transrectal ultrasonography or palpation. The on-farm tests can be used as early as 19 days after service because a low progesterone concentration at this time is indicative of nonpregnancy, and thus the first return to oestrus can be anticipated. Daily sequential samples can be taken at or around this time, but it is expensive and time-consuming.

Isobe et al. (2005) have demonstrated that faeces collected between days 18 to 24 after artificial insemination or days 11 to 17 after embryo transfer can be used to measure progesterone for the purpose of pregnancy diagnosis in dairy and beef cattle.

Oestrone Sulphate in Milk. Oestrone sulphate is quantitatively one of the major oestrogens in the milk of pregnant, lactating cows (Hatzidakis et al. 1993). During gestation the concentration increases gradually, so that after day 105 it is present in the milk of all pregnant animals, whereas in nonpregnant individuals it is low or undetectable; the source of the hormone is the placenta. The identification of oestrone sulphate in the milk of a cow at 105 days of gestation or later is a very reliable method of pregnancy diagnosis (Hamon et al. 1981). Furthermore, unlike progesterone assays, the precise date of sampling is not required. However, it has limited applications because of the lateness of the time that a positive diagnosis can be made.

Clinical Methods

Transrectal Palpation

Despite the increasing availability of ultrasonic methods (see later in this chapter), traditional palpation will always be important as part of the normal clinical examination of the reproductive tract in cows.

Palpation of the Amniotic Vesicle. This method involves the palpation of the amnion towards the end of the first month of pregnancy. It proceeds briefly as follows: The bifurcation of the uterine horns is located; then the horns are uncoiled and gently palpated along their entire length between the thumb and middle two fingers. The amniotic sac can be felt as a distinct, round, turgid object, 1 to 2 cm in diameter, floating in the allantoic fluid. The vesicle should not be compressed directly but gently pushed backwards and forwards. Some (Rowson & Dott 1963, Ball & Carroll 1963, Zemjanis 1971) consider that this technique is dangerous because of the possibility of rupture of the amniotic sac or of the embryonic heart. As with all rectal techniques, care is the rule, and excessive pressure and rough handling should be avoided.

Palpation of the Allantochorion (Membrane Slip). This method is dependent upon the facts that, in the cow, attachment of the allantochorion to the endometrium occurs only between the cotyledons and the caruncles and that the intercotyledonary part of the fetal membrane is free. The method was first described by Abelein in 1928 (see Cowie 1948), who reported that it could be used from the fifth week of gestation. The method is as follows: Identify the bifurcation of the uterine horns, pick up the enlarged gravid horn between thumb and either index or middle finger, just cranial to the bifurcation and gently squeeze and roll the whole thickness of the horn. The allantochorion will eventually be identified as a very fine structure as it slips between the thumb and finger, before the uterine and rectal walls are lost from the grasp. It is important in the early stages of pregnancy to grasp the whole width of the horn because as the allantochorion is very thin at this stage the structure that can be more readily identified is the connective tissue band that contains the blood vessels supplying the allantochorion (see Figs. 4.5, 5.11, and 5.12). Fincher (1943) recommended that this method should not be used before 40 days of gestation and that it was infallible up to 95 days. The advantage of the method is that it enables the differential diagnosis of pregnancy from mucometra or pyometra. In some cases, particularly after 60 days of gestation, it can be more readily elicited in the nongravid horn because the tension on the wall is less, and this allows it to be grasped more readily. For the beginner it is a worthwhile exercise to practice it on a fresh gravid genital tract from the abattoir.

Unilateral Horn Enlargement. Unless there are twin conceptuses, one in each horn, it is possible to detect a difference in the size of the two horns. This is largely due to the presence of fetal fluids, in particular allantoic fluid, which gives the uterine horn a fluctuating feel with good tone. It can be likened to the feel of a balloon that has been filled with water to a point when the wall just starts to stretch. At the same time, if the wall of the horn is squeezed, it is noticeable that it is much thinner than that of a nongravid tract.

In many cases, a definite diagnosis of pregnancy can be made on these signs alone. The presence of a CL in the ovary adjacent to the enlarged horn is a useful confirmatory sign although a false diagnosis of pregnancy may be made in cases of pyometra, mucometra or incomplete uterine involution (see Chapter 7).

Palpation of the Early Fetus. At about 45 to 50 days of gestation, the amniotic sac becomes less turgid, and it is sometimes possible to palpate directly the small developing fetus. This should be done with care.

Palpation of Placentomes. Placentomes first become recognisable by rectal palpation at 10 to 11 weeks as roughened elevations when the fingers are passed back and forth over the surface of the enlarged gravid horn. From about 3 months they can be identified as discrete structures in the midline, about 8 to 10 cm in front of and over the pelvic brim, by pressing down upon the uterine body and base of the horns. In the early stages it is difficult to identify them as distinct, individual structures. The uterus feels as if it has an irregular corrugated surface; it has been likened to palpating a 'sackful of small potatoes'. As pregnancy proceeds, the placentomes become larger, but once the uterus has sunk into the abdomen between 5 and 7 months, it is sometimes impossible to palpate them. Substantial pressure should be placed on the body of the uterus just cranial to the cervix with the flat portion of the fingertips, as if attempting to palpate the udder transrectally. Identification of placentomes is virtually diagnostic of pregnancy, but in the immediate postpartum uterus, they can also be felt.

Palpation of the Cervix. Evidence of pregnancy can be assumed when there is tension on the cervix. In the nonpregnant or early pregnant cow or heifer, the cervix is freely movable from side to side. However, as pregnancy advances the cervix becomes less mobile and is pulled forwards and downwards over the pelvic brim.

Hypertrophy of the Middle Uterine Artery and Development of Fremitus. In a nongravid or early pregnant cow, identification of the middle uterine artery by palpation is usually not possible

VetBooks.ir

transrectally. The artery runs in the broad ligament, along a tortuous course, passing downwards, forwards and towards the midline over the pelvic brim close to the junction between pubis and ilium. Usually, it is identified 5 to 10 cm lateral to the cervix. Inexperienced persons sometimes confuse it with the iliac and obturator arteries, but the middle uterine artery is mobile and can be encircled within the thumb and forefinger. At some stage during pregnancy it will cease to have the usual pulse, and instead, this will become a thrill or tremor, which is called fremitus.

There is considerable variation in the time at which the change can first be felt and also when it becomes continuous. The earliest one of the authors (D.N.) has been able to detect it is 86 days. During the period 100 to 175 days, cases will frequently be met in which the initial fremitus becomes a conventional pulse. It is probable that the degree of pressure applied to the artery influences the feeling imparted to the fingers – light pressure detects fremitus whereas a pulse wave is apparent to heavy pressure. Fremitus generally becomes continuous after day 175, although cases will be met in which there is distinct pulsation as late as day 200. During the terminal stages of gestation, the uterine arteries become greatly hypertrophied and tortuous and can be distinctly felt about 8 to 10 mm in diameter with a continuous, tremor-like pulse, laterally situated 2 cm or so in front of the cranial border of the iliac shaft. A difference in size of the two uterine arteries is usually recognisable from about day 100, and this indicates the side of the pregnant horn. Palpation of the middle uterine artery is usually possible in even the biggest cow and thus is particularly useful in large suckler cows.

Palpation of the Late Fetus. Palpation of the fetus, either per rectum or by abdominal ballottement, is diagnostic of pregnancy. The ease of palpation depends upon the size of the cow, the degree of stretching of the suspension of the uterus and the degree of relaxation of the rectum and uterine wall.

Accuracy of Pregnancy Diagnosis by Transrectal Palpation. The most likely reason for an apparent false-positive diagnosis is that there is subsequent embryonic or fetal death. Other reasons for false positives are: incomplete uterine involution (see Chapter 7), pyometra, mucometra, and hydrometra (see Chapters 23 and 24) and failure to retract the uterus. The reasons for false negatives are incorrect recording of the date of service or artificial insemination, so that when the cow is examined she is pregnant but a cycle length earlier than expected, and incomplete retraction of the uterus. There are two reasons for false negatives. Firstly an error in the recording of the date of service or artificial insemination, so that when the cow is examined she is pregnant, but a cycle length earlier than expected, secondly incomplete retraction of the uterus. The latter reason is worthy of further consideration and can be a particular problem in large pluriparous cows with deep abdomens. In order to make a complete examination of the uterus by palpation, full retraction is necessary. The inexperienced person may well make a diagnosis of pregnancy because the uterus is 'out of reach' and cannot be palpated. It is important that the diagnosis should be made on the identification of positive signs. It is perfectly permissible to admit uncertainty, to note in writing the changes that can be identified and to reexamine the animal 2 to 3 weeks later.

Induced Prenatal Death Due to Transrectal Palpation. Concern is sometimes expressed that rectal palpation can induce embryonic or fetal death. There have been several studies to evaluate the risks, by recording if a cow failed to calve having previously been diagnosed as pregnant either by rectal palpation or, more recently, in association with milk progesterone assays or ultrasonography. The results have been equivocal, but although it is possible that certain methods and certain individuals may increase the incidence of prenatal death, it is likely that the rectal palpation of cows from 42 days of gestation is a safe and reliable method when performed carefully and skillfully. In those cows in which the pregnancy failed, it would probably have occurred irrespective of the procedure used. In a recent controlled, randomised, block-design experiment, it was convincingly demonstrated that the single use of the fetal membrane slip as a diagnostic tool between days 34 and 41 of pregnancy does not affect embryonic/fetal viability, as judged by transrectal ultrasonography at days 45 and 60, in comparison with nonpalpated animals (Romano et al. 2006). Furthermore, in experiments in which attempts have been made to induce abortion by damaging the fetus at rectal palpation, extensive trauma has frequently been necessary (Paisley et al. 1978).

Vaginal Examination

Examination may be manual or visual. In the latter case an illuminated speculum is used. The condition of the vaginal mucous membrane does not afford definite clinical evidence of pregnancy, for the degree of dryness and blanching that occur during the dioestrus are very similar to those of pregnancy. It is to the external os of the cervix that attention is directed. During pregnancy the secretion of the cervical glands becomes gelatinous and tough, forming a plug for sealing the canal. In many cases the seal covers or protrudes from the external os. It has developed by day 60.

Ultrasonographic Methods

Using the ultrasonic fetal pulse detector, which employs the Doppler principle, it is possible to identify the fetal heart from 6 to 7 weeks using a rectal probe. Ultrasonic depth analysers (A-mode) have also been used to detect pregnancy as early as 40 days. Although a level of accuracy of 85% to 95% has been achieved in positively identifying pregnant cows, a large percentage of nonpregnant cows (57%–87%) were incorrectly diagnosed as being pregnant (Tierney 1983). Neither of these two ultrasonic methods would appear to have any advantage over rectal palpation with regard to time of examination or accuracy of the diagnosis.

Real-time B-mode grey-scale ultrasound scanning is the method of choice for the early diagnosis of pregnancy in the cow and has replaced traditional transrectal palpation as the method of choice. Details of the principle of the technique and the equipment available have been described earlier in this chapter. For an excellent description, the reader is advised to consult Ginther (1998) and Boyd and Omran (1991).

Using a transrectal approach to image the uterus and contents, a 7.5 MHz linear transducer is preferable for early pregnancies, whereas a 3.5 to 5.0 MHz transducer is more useful for late pregnancies. After insertion of the transducer, both ovaries should be examined to determine the presence of a CL, followed by the right and left horns. Because of the shape of the probe, the diameter of the rectum and the coiled nature of the horns, it is impossible to scan each horn along its length at the same time, thus cross-sectional images of the horns are frequently identified (Fig. 6.16 C–F). A tentative diagnosis of an early pregnancy can be made on the identification of a nonechogenic (black) area within the lumen of the uterine horn due to the presence of allantoic fluid; however, it must be remembered that fluids other than those associated with pregnancy can give a similar result. Because this occurs first in the horn ipsilateral to the CL of pregnancy, ovarian imaging for the presence of this structure is important. However, the definitive determination of pregnancy is dependent on the identification of an embryo or fetus.

VetBooks.ir

Using a 7.5 MHz transducer, Boyd et al. (1988) were able to recognise pregnancy as early as 9 days, whereas Pierson and Ginther (1984), using a 5 MHz transducer, were able to do so at 12 and 14 days in heifers before the blastocyst had elongated (see Chapter 4). One has to realise that these very early diagnoses took place under controlled experimental conditions, with animals repeatedly scanned at short intervals. This is very different from the on-farm situation, in which the veterinarian is usually asked to make a conclusive diagnosis upon a single examination. By 17 days, the blastocyst will have elongated and extended into the contralateral horn; this can usually be easily identified with ultrasonography by 26 days. Using a 12-MHz multifrequency linear array rectal probe, diagnosis of pregnancy was made between 18 to 21 days after AI, based on CL blood flow, the size of the CL, and uterine echotexture (Scully et al. 2014).

Experienced persons may accurately diagnose pregnancy around the time of the expected date of return to oestrus in the non-pregnant cyclical animal, but published data indicate that both sensitivity and specificity markedly increase between days 24 and 30 days (Szenci et al. 1998, Romano et al. 2007); after this stage an accurate and rapid diagnosis can be made relatively easily. The data in Table 5.5 illustrates this. Fig. 5.16 shows images at various stages of pregnancy.

Transrectal ultrasonography can also be used to estimate fetal age up to 140 days of gestation (White et al. 1985, Ginther 1998) by the measurement of a number of different fetal dimensions. Of these, the crown–rump length was least frequently capable of being measured, whereas the trunk diameter was the most readily assessed. In addition, it can also be used to determine the sex of the fetus by assessing the relationship between the genital tubercle and surrounding structures. Thus in the male the genital tubercle migrates towards the umbilicus, whereas in the female it migrates towards the tail. The optimum stage for determination is 55 to 70 days (Curran et al. 1989, Stroud 1996) in which they obtained almost a 100% success rate in determining gender. More recently, a study was reported in which the procedure was done from 51 days, although the accuracy, though still very good, was not 100% (99.5% for males and 98.8% for females) (Quintela et al. 2011). It is important to stress that the technique requires considerable experience of transrectal ultrasonography and good equipment. With respect to the plane used for diagnosis, the sagittal view was poor when used for early pregnancy diagnosis; as a consequence, the longitudinal and crosssectional planes were used most frequently. These results demonstrate that ultrasound can be routinely applied under farm conditions to accurately determine the fetal sex in cattle between days 51 and 111 of gestation without apparent influence of cow age, ultrasound scanning plane or fetal sex. However, with the use of sexed sperm in the AI industry, the interest in the use of ultrasound for sexing fetuses has declined.

Optimum Time for Diagnosing Pregnancy

The aim of pregnancy tests is to identify, as early and as accurately as possible, the absence of pregnancy so that steps can be taken to ensure that the cow is served again and thus ensure an optimum calving pattern (see Chapters 25 and 26).

Pregnancy and Its Detection in the Pig

Endocrinology

In the nonpregnant sow the plasma progesterone concentration falls rapidly 15 to 16 days after the previous oestrus, but if conception occurs the CLs persist and the peripheral progesterone concentrations remain elevated at between 30 and 35 ng/ml. Although there is a slight fall to 17 to 18 ng/ml on day 24, the elevated concentration persists for most of gestation, decreasing rapidly just before farrowing. The ovaries and CLs are always necessary for the maintenance of pregnancy. The number of embryos present in utero does not influence the progesterone concentration (Monk & Erb 1974). The minimum concentration of progesterone in the peripheral circulation for the maintenance of pregnancy is about 6 ng/ml (Ellicott & Dziuk 1973); if the levels are lower the pregnancy is lost, but higher levels do not appear to increase embryonic survival.

Total oestrogen concentrations remain fairly constant in plasma during pregnancy, but about 2 to 3 weeks prepartum they begin to increase to about 100 pg/ml, with a sudden surge to values about 500 pg/ml a few days before farrowing. This is followed by a rapid decline after parturition. The early pig blastocyst synthesises substantial amounts of oestrogens (mainly oestrone and oestradiol-17beta), which pass through the uterine wall where they are sulphoconjugated (Heap et al. 1981). These oestrogen metabolites in maternal blood and urine or the deconjugated oestrogens in the faeces reach a temporary peak between 23 and 30 days of gestation (Robertson & King 1974, Choi et al. 1987). This rise can be exploited for the early diagnosing of pregnancy, using either plasma or faecal samples (see later in this chapter).

Methods of Pregnancy Diagnosis

Management Methods

Traditionally, failure to return to oestrus at 18 to 22 days after service or artificial insemination has been regarded as a possible first sign of pregnancy. However, the detection of oestrus can be difficult, and it is time-consuming; even the back pressure or riding test, which is generally accepted to be the most reliable (Reed 1969), is inconsistent. Failure to return to oestrus may be due to a reluctance to show signs, anoestrus or ovarian cysts (see Chapter 22). It is important to know as soon as possible if a sow or gilt is not pregnant, so that she can be served again, treated or culled. A reliable method is also necessary so that breeders can certify that an animal is pregnant before sale. Any technique must be accurate, capable of being used early in gestation and fairly inexpensive.

Clinical Methods

Transrectal Palpation

This method has been described in detail by Meredith (1976) and Cameron (1977). It is dependent upon palpation per rectum of the cervix, uterus and middle uterine arteries. Although the method can provide an immediate result without the need for a specialist and expensive equipment, it is rarely used now. Changes in the middle uterine artery are an important feature of the method; an excellent description is given by Cameron (1977).

Ultrasonographic Methods

The use of the Doppler technique to diagnose pregnancy in the sow (on the basis of detecting a pulsating uterine artery and/or fetal heart beats) was first described by Fraser and Robertson (1968). The earliest diagnosis made using a rectal probe is about 25 days of gestation. The accuracy of the method is reasonable for the diagnosis of pregnant sows (92%–100%), but it is less reliable for nonpregnant sows (25%–100%) (McCaughey 1979). With a single investigation at 5 weeks after mating, a sensitivity of 98.9% and a specificity of 67.2% were obtained (Atkinson et al. 1986),

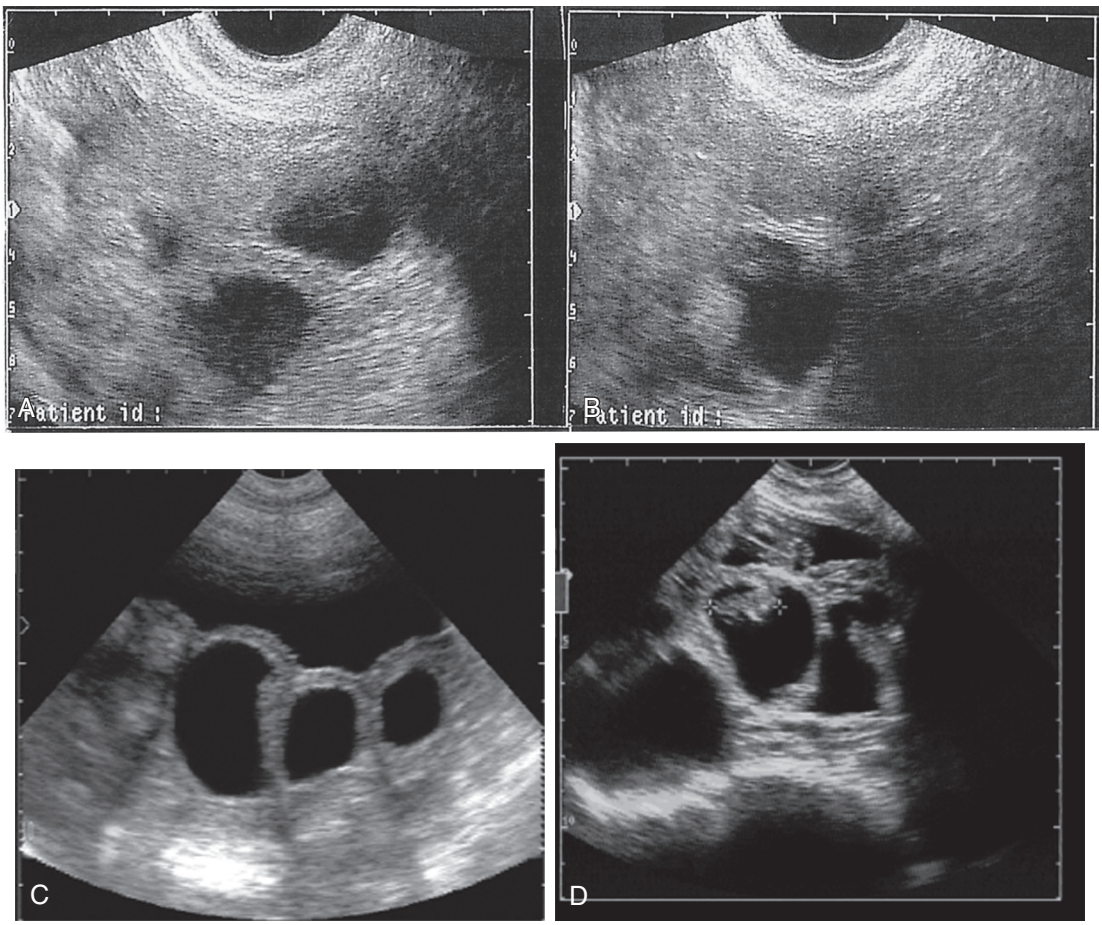
• **Fig. 5.16** Detection of pregnancy in the cow by transrectal ultrasonography. (A) Transverse sectional ultrasonogram of the uterine horn in a nonpregnant cow. Note the alternating bands of anechoic and hyperechoic tissue, which gives a 'rosette-like' appearance due to the endometrial and muscularis layers of the uterine wall. Note that there is no evidence of fluid (which would be anechoic) in the uterine lumen. (B) Transverse sectional ultrasonogram of the uterine horn of a cow at 22 days of gestation. Note that, as in (A), there are alternating bands of anechoic and hyperechoic tissue. The uterine lumen contains fluid, which is anechoic, and just above this *(arrow)* a bright hyperechoic band, which is the allantochorionic membrane. (C) Transverse sectional ultrasonogram of the uterine horn of the same cow as in Fig. 3.16B at 28 days of gestation. As well as the fluid-filled horn, the embryo is now clearly visible *(arrow).* In the real-time image it is possible to see the heart beating. (D) Transverse sectional ultrasonogram of the uterine horn of a cow at 28 days of gestation. Note the embryo's heart *(arrow)* and anechoic allantoic fluid. (E) Transverse sectional ultrasonogram of the uterine horn of a cow at 32 days of gestation. Note that the embryo has visible forelimbs buds *(arrows).* (F) Transverse sectional ultrasonogram of the uterine horn of a cow at 35 days of gestation. The embryo is about 17 mm long. The amnion *(arrow)* and allantochorion *(arrow head)* can be identified. (G) Transverse sectional ultrasonogram of the uterine horn of a cow at 42 days of gestation. Note the fetal body, head and limbs. (H) Transverse sectional ultrasonogram of the uterine horn of a cow at 63 days of gestation showing a placentome *(arrow).* (From Sheldon & Noakes 2002, by permission of *In Practice*, BVA publications.)

and these figures did not improve when testing took place both at 5 and 8 weeks.

Ultrasonic amplitude-depth analysis (A-mode ultrasound) has proved to be more reliable and was the most frequently applied technique until B-mode ultrasonography was introduced. In a study involving 1001 sows using a 2 MHz external transducer probe, Lindahl et al. (1975) reported a 99% accuracy in identifying pregnant sows and a 96% accuracy for nonpregnant sows. These results were obtained between 30 and 90 days of gestation; unreliable results were obtained before 30 days. Taverne et al. (1985a) reported an equally high sensitivity (97.5%) but a much lower specificity (55.8%) when this technique was used between days 31 and 37.

B-mode direct imaging has proved to be very successful in the sow (Martinat-Botté et al. 2000). The transducer probe (or even the entire small-sized scanner) is applied to the abdominal wall of the standing sow about 5 cm caudal to the umbilicus, to the right or the left of the midline and just lateral to the teats, and is directed towards the caudal abdomen; a coupling medium is always required. Pregnancy diagnosis is based on the recognition of nonechogenic irregularly shaped black spots, representing sections through allantoic fluid-filled fetal sacs within the uterus

VetBooks.ir



• **Fig. 5.17** Transrectal B-mode (5 MHz transducer) ultrasound images of pregnant sows at 23 days (A–C) and 24 days (D) after service. Black areas represent sections through the allantoic fluid-filled allantoic cavity within the uterine horns in (C) there are three visible below the bladder. In one of these sections in (D) an embryo is visible. (Figs. A and B courtesy of Dr. Roy Kirkwood.)

(Fig. 5.17B and D). Frequently, the embryos can be identified (Fig. 5.17) but are usually not required to reach a positive diagnosis. This implies that accumulation of pathological (mucometra) or physiological (oestrus, semen) fluid within the uterus may result in a false-positive diagnosis. In a study of 145 sows, Inabe et al. (1983) reported a 100% accuracy for the diagnosis of pregnancy from 22 days of gestation. Jackson (1980) reported a 100% accuracy for identifying nonpregnant sows and a 99% accuracy for diagnosing pregnancy from 24 to 37 days of gestation. The small number of errors in this study of 285 sows was due to prenatal death. In a study with 881 animals scanned with a 3.0 MHz linear array transducer between days 24 and 32, Taverne et al. (1985a) also reached 100% sensitivity, but specificity was 90.6%, mainly because of embryonic/fetal death occurring after the day of scanning. A similar conclusion was reached by Szenci et al. (1997) and Vos et al. (1990) when comparing the results of ultrasonography and a faecal unconjugated oestrogen test (see later in this chapter) concurrently performed in the same animals between days 26 and 32.

Transrectal scanning (with an elongated transducer) has also been used (see Fig. 5.17A and C). It usually improves the quality of the ultrasound pictures and enables a slightly earlier diagnosis (Thayer et al. 1985), although after the fourth week, results with a 3.5 and 5.0 MHz were equally accurate, regardless of whether transabdominal or transrectal methods were used (Fraunholz et al. 1989). However, the transrectal approach takes slightly longer and is more difficult to perform, especially when sows are not restrained.

Laboratory Methods

Estimation of Plasma Progesterone. Because there is a decline in progesterone concentrations in the peripheral blood from about day 16 in nonpregnant cyclical animals (see Fig. 5.3) estimation of progesterone concentrations from this time after service is worthwhile. Ellendorff et al. (1976) reported that when sows were bled 16 to 24 days after service a sensitivity of 99.6% and a specificity of 85.3% was achieved. Subsequently, much lower specificities have been reported by several other workers, mainly attributable to late embryonic and fetal mortality of whole litters after the day of testing. However, the biggest problem with this technique remains the difficulty of obtaining blood samples.

Plasma Oestrogen Assay. Robertson et al. (1978) were unable to detect oestrone sulphate in the blood of nonpregnant cyclical sows, yet in pregnant animals it was detectable from day 20 of gestation. Therefore this can be used as a method of diagnosing pregnancy. A small volume of blood sufficient for the assay can be collected from the ear vein; the optimum time for diagnosis, maximum concentrations of oestrone sulphate are present at about 24 to 28 days. Because these oestrogens appear in an unconjugated form in the faeces (Choi et al. 1987), they can be assayed within the same time period. In this way, Vos et al. (1999) obtained a

VetBooks.ir

sensitivity of 96.5% and a specificity of 93.5%, using an oestrone concentration of 3.65 ng/g faeces as a discriminatory value.

Other Potential Laboratory Methods. In some sows it is possible to detect early pregnancy factors present in the sera of pregnant pigs, particularly by 3 or 4 weeks postmating, which could be detected by the rosette inhibition test. However, the test is not sensitive enough to allow specific diagnosis of early pregnancy in pigs (Grewal et al. 1985; Koch & Ellendorff 1985).

Pregnancy and Its Detection in the Sheep and Goat

Endocrinology

Sheep

In the nonpregnant cyclical ewe, progesterone concentrations in the peripheral blood fall rapidly just before the onset of oestrus (see Fig. 1.30). Following conception, the CL persists and peak dioestrus values are maintained and gradually increase to about 60 days of gestation, when there is a considerable increase, a rise due to the placenta contributing to progesterone production. Levels remain high until the last days of pregnancy, when they decline rapidly to 1 ng/ml at parturition. The concentration of progesterone is significantly higher in multiple pregnancies (Bassett et al. 1969) because it has been calculated that, in late pregnancy, the placenta produces five times as much progesterone as the corpus luteum (Linzell & Heap 1968). Maximum progesterone concentrations in the peripheral blood of ewes with a single lamb were 3.8 ng/ml between days 105 and 110, with twins 5.1 ng/ml between days 125 and 130, and with triplets 9.2 ng/ml between days 125 and 130 (Emady et al. 1974) (Fig. 5.18).

Oestrogen concentrations in the peripheral circulation remain low throughout gestation. A few days before parturition, they start to gradually rise, then suddenly increase to about 400 pg/ml at the time of lambing, followed by a rapid fall (Challis 1971).

Prolactin concentrations fluctuate during pregnancy between 20 and 80 ng/ml towards the end; however, they start to increase and reach a peak of between 400 and 700 ng/ml on the day of lambing (Davis & Reichert 1971, Kann & Denamur 1974).

Placental lactogen has been detected in maternal plasma from 48 days of gestation; it reaches a maximum by about 140 days, gradually decreasing until lambing. It has been identified in trophoblast tissue from 16- to 17-day blastocysts (Martal & Djiane 1977). The role of this hormone is still unclear: it may have a role in the luteotrophic complex of the pregnant ewe and also in controlling fetal growth and mammary development.

Bilateral ovariectomy after 55 days will not result in abortion because by this stage of gestation the placenta has taken over the major role of progesterone production. However, it should be remembered that the CLs persist for the duration of the pregnancy and regress only at the time of parturition (see Chapter 6).

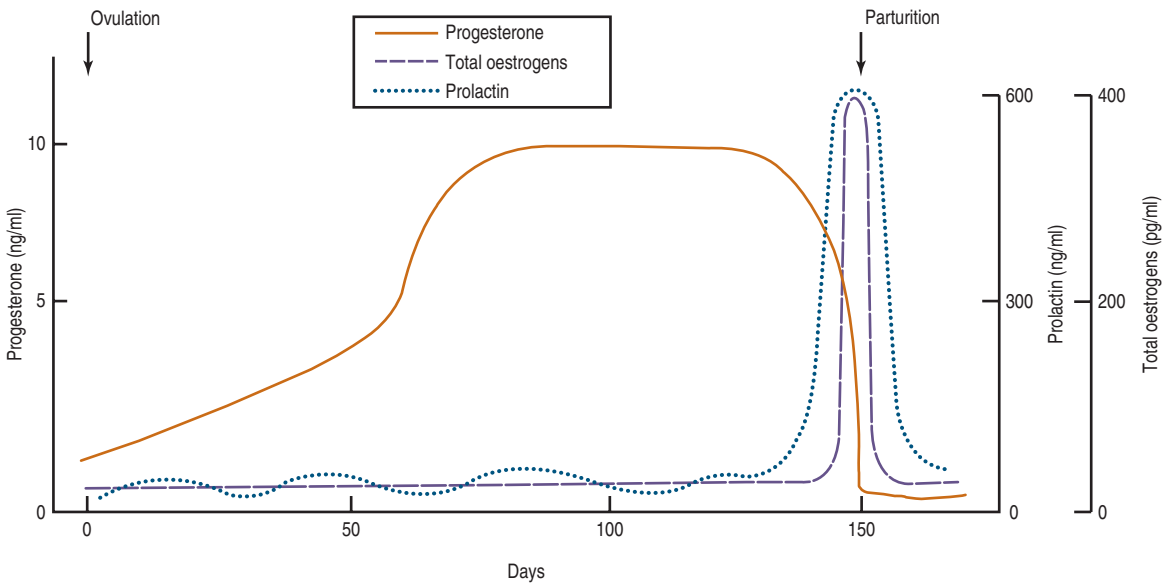
Goat

As in the ewe, progesterone concentrations in the peripheral blood and milk decline around the time of oestrus; thus sampling approximately 21 days after service or artificial insemination will enable a distinction to be made between nonpregnancy and pseudopregnancy or pregnancy. In the latter, they increase until a plateau is reached and then decline rapidly a few days before parturition. Total oestrogens in the peripheral circulation are much higher than those recorded in the ewe. They increase gradually from 30 to 40 days of gestation, reaching a peak value greater than 600 pg/ml just before parturition (Challis & Linzell 1971). Prolactin remains low during pregnancy but rises rapidly just before parturition.

Bilateral ovariectomy at any stage of gestation will result in loss of the pregnancy; thus extraovarian sources would appear to be unable to produce sufficient progesterone for the maintenance of pregnancy.

Methods of Pregnancy Diagnosis in Sheep

There are a large number of published methods of diagnosing pregnancy in the ewe, many of which are historical, and these have been reviewed in detail (Richardson 1972, Karen et al. 2001). The number and variety of methods point to the fact that there was not



• **Fig. 5.18** Schematic representation of the trends in hormone concentrations in the peripheral circulation of the ewe during pregnancy and parturition.

VetBooks.ir

a simple, accurate and inexpensive clinical method of diagnosing pregnancy in the ewe until the advent of B-mode ultrasonography, which is without doubt the method of choice. Given the rather high fertility of sheep, determination of fetal numbers (for a more efficient use of feedstuffs in late pregnancy and to prevent the occurrence of pregnancy toxaemia), rather than diagnosing the pregnancy itself, appears to offer the main economic benefit of sheep farmers (Russell 1989).

Management Methods

Traditionally, the method used by shepherds is the observation that ewes, which have been marked by a 'keeled' or 'raddled' ram, fail to be marked again within 16 to 19 days. This is a sufficiently reliable sign of pregnancy for most purposes, but subsequent embryonic death will reduce its accuracy, and 20% to 30% of pregnant ewes will show oestrus during early pregnancy. It is important to ensure that the colour of the raddle crayon is changed regularly every 16 days, that it is sufficiently soft to produce a mark and that the colour sequence allows easy colour identification.

Beyond 100 days of gestation the fetus may be palpated through the abdominal wall, and development of the udder is then obvious in primipara. The best way to ballotte the fetus is to have the ewe standing normally and to lift the abdomen repeatedly immediately in front of the udder; the fetus can be felt to drop on to the palpating hand.

Ultrasonographic Methods

The fetal pulse detector (Doppler) has been used to diagnose pregnancy in ewes, and two types of probe are available. The external probe is applied to the skin surface of the abdomen just cranial to the udder. The fleece in this region is sparse and, with transmission gel applied to the end of the probe, it is slowly moved over the surface. The ewe can be restrained either standing or sitting on her haunches. Characteristic sounds indicate the presence of the fetal heart or vessels; the frequency greatly exceeds that of the mother's pulse and heart rate, except in late gestation when the fetal heart rate is reduced. Between 40 and 80 days of gestation the accuracy of detection is no better than 60% (Hulet 1968, Richardson 1972). However, after 110 days, with a reasonable amount of practice, it is nearly 100% accurate, and it takes an average 3 or 4 minutes per ewe to make a diagnosis (Watt et al. 1984).

Using a rectal probe, Lindahl (1971) obtained a sensitivity of 90% or more at the start of the second trimester, whereas Deas (1977) obtained a sensitivity of 82% and a specificity of 91% between days 41 and 60 of gestation. There are several reports giving similar results. The rectal probe is safe and relatively easy to use and requires limited restraint of the ewe. With the fetal pulse detector the diagnosis of false positives should be virtually nil, with the major source of error being the confusion of the maternal pulse sounds with those of the fetus. However, false negatives are always a possibility, especially when testing is taking place too early or too quickly. The external probe can also be used between 80 and 100 days to differentiate between single and multiple pregnancies, although the accuracy in identifying the precise number of fetal lambs is poor.

The B-mode ultrasound (sector) transducer probe, using the transabdominal approach, has proved to be an early, accurate and rapid method of not only differentiating pregnant from nonpregnant ewes but also accurately determining fetal numbers (Fig. 5.19 and Crilly et al. 2017). The cost effectiveness of such a procedure is obvious because it is possible not only to eliminate barren ewes but also to adjust feeding levels to accommodate the number of lambs. Not only does this save on feed cost, but it also reduces the chances of pregnancy toxaemia occurring. Pregnancy can be detected as early as 30 days, although the optimum time to differentiate fetal numbers is 45 to 50 days. White et al. (1984), using a 2.25, 3 or 3.5 MHz transducer, examined a total of 1120 ewes, 36 to 90 days after tupping. The fleece was shorn on the abdomen of each ewe extending some 20 cm cranial to the udder and across the whole width. The ewe was restrained on her back and, using vegetable oil as a coupling medium, the abdomen was scanned. A positive diagnosis of pregnancy, based upon the imaging of a fluid-filled uterus and placentomes, could be made quite quickly. Care was taken to examine the limits of the uterus so that fetal numbers could be detected accurately. An experienced person could examine on average 75 ewes per hour. It is also possible to examine the ewe in a sitting position. An experienced person was over 99% correct in differentiating pregnant from nonpregnant ewes and 98.9% in identifying fetal numbers (Fowler & Wilkins 1984). The most common source of error was failing to identify the third fetus in ewes with triplets. Inexperienced persons soon developed a high level of accuracy, especially at differentiating between pregnant and nonpregnant ewes. Commercially, B-mode ultrasound scanning is done with the ewe placed in a rotating handling system to allow easy movement of the transducer over the (shorn) area in front of the udder and over the uterus (White et al. 1984, Russell 1989), or with the animal in standing position in an elevated restraining crate, with the transducer probe placed on the hairless area just cranial and lateral to the udder (Taverne et al. 1985b). Yet, with the animals in the supine position and without shaving, Karen et al. (2006) reported rather low accuracies for discriminating between single and multiple pregnancies during a field study with Awassi x Merino sheep between days 43 and 87 of gestation. Transrectal scanning has also been explored in sheep, although often with smaller numbers of animals (Buckrell et al. 1986, Garcia et al. 1993, Karen et al. 2004) and allows for a somewhat earlier diagnosis.

Laboratory Methods

Milk and Plasma Progesterone. Pregnancy can be diagnosed on the fact that, in the pregnant ewe, the CLs persist and hence peripheral progesterone concentrations will remain elevated at 15 to 18 days after mating. The presence of a persistent CL in the absence of a pregnancy may occur, resulting in an incorrect result. Furthermore by using a 2.5 ng/ml discriminatory value using an enzyme immunoassay for samples collected 19 days after intravaginal progestogen sponge removal, Boscos et al. (2003) obtained a sensitivity of 98.3% and a specificity of 85.5%. Plasma levels, when measured using radioimmunoassay, did not prove accurate in discriminating between single and multiple pregnancies in samples taken between days 43 and 87 after artificial insemination in synchronised ewes (Karen et al. 2006).

Pregnancy Specific Proteins. As in cattle, the binucleate cells of the ovine placenta produce pregnancy-specific proteins (ovPSPBs), also known as pregnancy-associated glycoproteins (ovPAGs) (Ward et al. 2002). They are detectable in the maternal circulation from week 3 of gestation until 2 to 3 weeks after lambing. With antibodies to bovine PSPB, Ruder et al. (1988) obtained a sensitivity of 100% and a specificity of 90% in a pregnancy test with blood samples taken between days 35 and 106. By using a heterologous, double antibody radioimmunoassay against a bovine PAG 67 kDa subunit, Karen et al. (2003) obtained high sensitivity and specificity from days 22 of pregnancy onwards. Measurements of PAG were unreliable for an accurate prediction of fetal numbers (Vandaele

et al. 2005, Karen et al. 2006). More recently, early pregnancy diagnosis in sheep, using near-infrared spectroscopy (NIRS) on blood plasma samples taken at day 18 and 25 after AI, has been described (Andueza et al. 2014); the results were very accurate compared to those obtained by assaying plasma P4 and PAG (Table 5.6).

Methods of Pregnancy Diagnosis in the Goat

Many of the methods which have been described above for the ewe are also applicable to the goat. Using the fetal pulse detector, a reliable diagnosis of pregnancy is possible at 50 days using an abdominal probe and at 25 days with a rectal probe. Excellent results have also been obtained with B-mode direct imaging with rectal or abdominal probes from about 30 days of gestation (Lavoir & Taverne 1989, Hesselink & Taverne 1994, Gonzalez et al. 2004, Holtz 2005), and the method also enables the accurate determination of fetal numbers (Fig. 5.20A). Scanning at an early stage after mating or artificial insemination (before day 30) may result in a false-positive diagnosis if the presence of fluid in the uterus of pseudopregnant does (mucometra/hydrometra; see Fig. 5.20B) is mistaken for a sign of pregnancy (Hesselink and Taverne 1994, Lopes Juacutenior et al. 2004). Transrectal ultrasound is an

effective method of early pregnancy diagnosis and determining fetal number at days 24 to 29 and days 31 to 36, respectively, with comparable accuracy with the transabdominal approach days 39 to 51. The breed and age of does might influence the accuracy of ultrasonography for pregnancy diagnosis and fetal numbers estimation (Karen et al. 2014). Ultrasonographic fetometry has been used to estimate gestational age in goats (Karen et al. 2009).

The milk progesterone test has been used extensively because most parous goats are lactating at the time of mating. Whole milk samples are collected from the bucket after thorough mixing on or about the day of mating and in the absence of return to oestrus, 22 and 26 days later (Holdsworth & Davies 1979). The accuracy for identifying the absence of pregnancy was 100%; however, some false-positive results were obtained due to pseudopregnancy, ovarian cysts and elevated progesterone values at oestrus. However, given the advantages of B-mode ultrasonography, it seems unlikely that the method will ever become routine in goat husbandry.

Oestrone sulphate is produced by the placentomes, and its presence in plasma, milk, or faeces is a positive indication of pregnancy, thus enabling differentiation from pseudopregnancy. Although it has been shown that oestrone sulphate concentrations from 30 days of gestation exceed those in nonpregnant individuals (Heap et al. 1981), the earliest optimum time is 50 days or later after service (Chaplin & Holdsworth 1982).

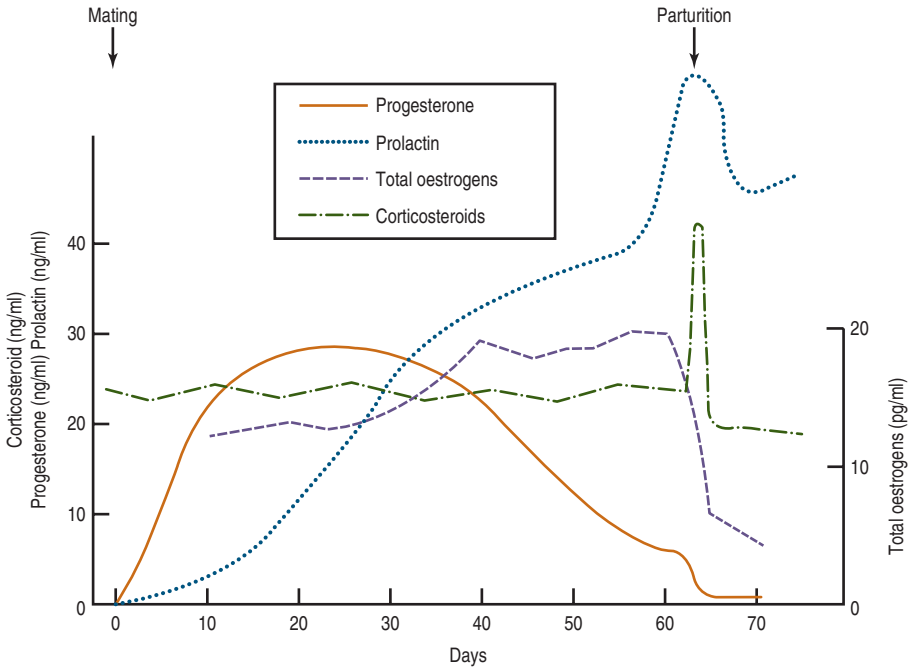
Determinations of PSPB (Humblot et al. 1990) or PAGs (Sousa et al. 1999, Gonzalez et al. 2004) in plasma have also been used for pregnancy diagnosis in goats and appeared accurate from 3 to 4 weeks of pregnancy onwards. Because the proteins also appear in the milk, this might become an attractive test for dairy goat farms.

Pregnancy and Its Detection in the Dog

Endocrinology

The bitch has a prolonged luteal phase, with the CLs remaining active for 65 to 75 days in the nonpregnant animal. The uterus does not appear to have a role in influencing the life span of the CL in the nonpregnant state (Okkens et al. 1985). The ovaries of the bitch are necessary for the maintenance of pregnancy; their

VetBooks.ir



• **Fig. 5.21** Schematic representation of the trends in hormone concentrations in the peripheral circulation of the bitch during pregnancy and parturition.

removal even as late as 56 days resulted in abortion (Sokolowski 1971). Progesterone concentrations in the peripheral circulation of pregnant bitches are similar to those of nonpregnant individuals and, for this reason, unlike in other species, cannot be used to diagnose pregnancy. Concannon et al. (1975) obtained mean maximum values of 29 ng/ml for pregnant and of 27 ng/ml for nonpregnant bitches. However, there was a lot of individual variation, with peak values obtained between 8 and 29 days after the LH peak in pregnant bitches and between 12 and 28 days in nonpregnant bitches. From about 30 days of gestation, there is a gradual decrease in progesterone so that by about day 60 values of 5 ng/ml are obtained, followed by a sudden decline just before parturition, to zero just after. In the nonpregnant bitch there is no rapid fall; low levels of progesterone persist. The number of days in which values greater than or equal to 1 ng/ml were obtained were 68 days in nonpregnant compared with 63.8 days in pregnant bitches (Concannon et al. 1975).

Peripheral plasma oestrogen (Fig. 5.21) values are slightly, but not significantly, higher in the pregnant bitch than in the nonpregnant bitch, with some evidence of an increase at the time of implantation (Concannon et al. 1975). They remain fairly constant, though variable, during the rest of gestation (Luz et al. 2006), before declining significantly to basal nonpregnant values by the day of parturition (Baan et al. 2008).

Prolactin is the main luteotrophic hormone, especially during the second half of gestation (Okkens et al. 1990, Onclin et al. 2000). Although prolactin concentrations increase during the first half of the luteal phase in both pregnant and nonpregnant bitches, there is a much greater rise in the second half of the former. The gradual rise during pregnancy ends with a sudden surge during the rapid decline in progesterone that occurs 1 to 2 days before whelping (De Coster et al. 1983, McCann et al. 1988, Verstegen-Onclin & Verstegen, 2008).

Relaxin has been detected in the peripheral circulation of pregnant Labrador and Beagle bitches at 20 to 30 days of gestation, reaching maximum concentrations around 5 to 7 weeks; it is absent in nonpregnant bitches at all stages of the reproductive cycle (Steinetz et al. 1989). The main source of relaxin appears to be the placenta (Klonisch et al. 1999), but the ovaries also contribute because serum levels decreased after ovariectomy in pregnant dogs (Steinetz et al. 1989). Significantly lower plasma relaxin levels have been found in pregnant bitches with a high incidence of embryonic/fetal death (Gunzel-Apel et al. 2006).

The average gestation length in the bitch is normally quoted as 63 to 64 days, but the interval from first mating to whelping can vary from 56 to 71 days. However, if gestation length is measured from the time of the preovulatory LH peak, it is very constant at between 64 and 66 days (Concannon et al. 1983). When the preovulatory increase of plasma progesterone was used as a guide for the optimum time of mating, an average gestation length of 61.4 days was calculated (Okkens et al. 2001). In a recent retrospective study, breed and litter size, but not age and parity, appeared to influence gestation length in dogs (Eilts et al. 2005).

Methods of Pregnancy Diagnosis

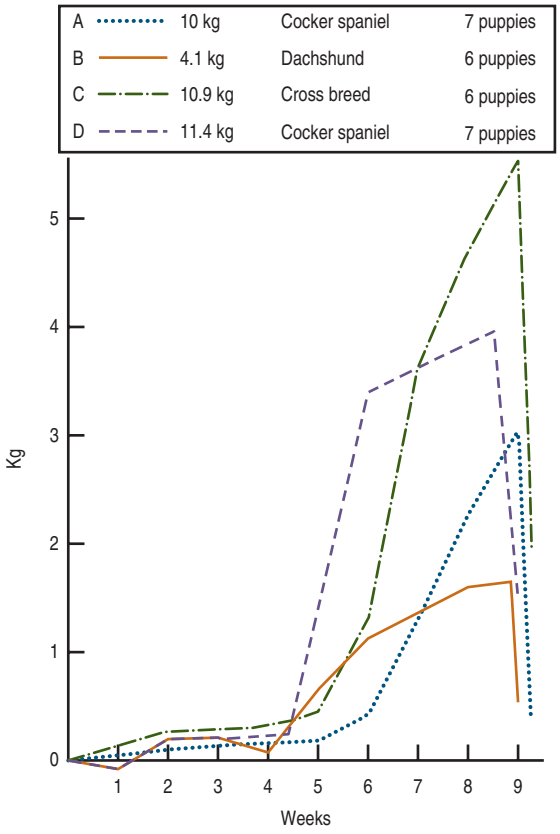
Because the bitch is not polycyclic, pregnancy cannot be anticipated by a failure to return to oestrus. It is generally accepted that the period of oestrus ends more abruptly when fertilisation has occurred, although the reason for this has remained unclear. One of the problems in diagnosing pregnancy in the bitch is that overt pseudopregnancy is rather common, the intensity of the signs varying from individual to individual.

The deposition of abdominal and subcutaneous fat during pregnancy is often marked. This is to support the demands of the subsequent lactation because it is generally lost again during the period of nursing. The gravid uterus and its contents cause no appreciable increase in body weight during the first 5 weeks. From this point, body weight rapidly increases according to the number of fetuses. The increase will vary from 1 kg in a 5 kg bitch

VetBooks.ir

to 7 kg or more in one of 27 kg, but by the time the increase in body weight has occurred, there are other very definite signs of pregnancy (Fig. 5.22). When there are a large number of fetuses, abdominal distension becomes progressive and obvious from the fifth week onwards, but in animals gravid with one or two fetuses only, particularly when the bitch is large or very fat, distension may not be noticeable.

There are several causes of abdominal distension in the bitch that must be differentiated from pregnancy. The most important is pyometra (see Chapter 33); others are ascites, peritonitis with effusion, splenic enlargement, and neoplasia of the liver abdominal lymphatic glands or uterus and are less common.



• **Fig. 5.22** Increase in body weight in bitches during pregnancy.

Clinical Methods

Mammary Glands. Characteristic changes occur in the mammary glands. Unfortunately, similar but less definite changes may occur during pseudopregnancy. These changes are more easily recognised in primigravidae. At about day 35, in unpigmented skins, the teats become bright pink in colour, enlarged and turgid, and they protrude. This condition persists until about day 45, when the teats become larger still but softer and tumefied; they may become pigmented. Appreciable hypertrophy of the glands commences at day 50 and progresses until, at term, the mammary glands comprise two parallel, enlarged and oedematous areas with a depression between them, extending from the pelvic brim to the cranial thorax. A watery secretion can generally be expressed from the teats 2 to 3 days before parturition; however, the onset of milk secretion coincides with parturition. In multigravidae, mammary hypertrophy commences about 7 days before term, and in some cases milk can be expressed from the teats several days before parturition.

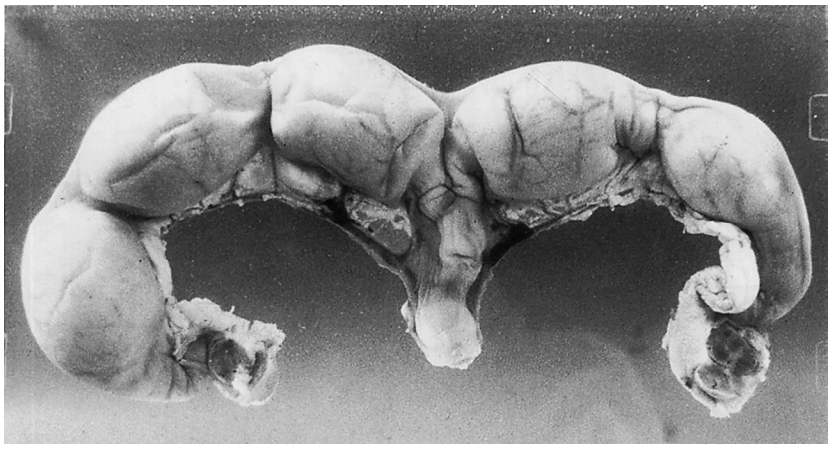
Abdominal Palpation

The ease and accuracy of abdominal palpation will depend upon the following factors:

- The size of the animal: the smaller, the easier
- Her temperament: whether palpation is resisted
- The period in gestation at which examination is made
- The number of fetuses in utero
- Whether the bitch is of normal size or grossly obese

Days 18 to 21. At this stage the embryos represent a series of tense, oval distensions in the horns, about 12 mm long by 9 mm broad. In small bitches that can be readily manipulated, it may be possible to estimate approximately the number present. Those situated in the caudal parts of the horns are most easily felt if there are only one or two; if they are located cranially, they may not be identified. In large or fat bitches it is unlikely that the conceptuses will be detected at this stage. Care must be taken not to confuse the conceptual swellings with faeces in the colon.

Days 24 to 30. This is the optimum period for the early diagnosis of pregnancy. By day 24 these distensions have become spherical in outline, from 6 to 30 mm in diameter. They remain tense and are easily recognised (Fig. 5.23). Sometimes, there is variation in size, the caudal ones being rather smaller than the cranial ones, but impending late embryonic or fetal mortality may also have caused a size difference. The embryonic units maintain this spherical form until about day 33.



• **Fig. 5.23** Uterus and ovaries of a bitch, pregnancy of about 30 days. Note five conceptual swellings.

VetBooks.ir

Days 35 to 44. The constricted portions of the horns between the embryonic units become progressively dilated; the distensions become elongated and lose much of their tenseness. At this time the uterus comes into contact with the abdominal wall and, in the bitch pregnant with many fetuses, the abdominal distension is starting to become obvious. Nevertheless, palpation of the fetuses themselves is not yet possible. As the uterus itself has lost much of its tension and the amount of fetal fluids has reached its maximum volume, a positive diagnosis may be difficult, particularly in those pregnant with only one or two pups.

Days 45 to 55. During this stage, increase in the size of the fetuses is rapid. At day 45 it may be possible to detect the caudally situated ones between the fingers; in a 9 kg bitch they are approximately 63 mm long and 12 mm broad. It is during this stage that the disposition of the uterus in the abdominal cavity changes. In animals pregnant with many fetuses, each horn represents an elongated cylinder, 38 to 51 mm in diameter and 228 to 300 mm long. Caudally, they extend into the uterine body, which has by this time become dilated. Each horn is in two segments: the caudal, which lies on the abdominal floor and passes forwards to the margins of the liver; and the cranial, which lies dorsal and lateral to it, with its long axis directed backwards towards the pelvis. In the last stages the uterus almost entirely fills the abdomen.

Days 55 to 63. During this period there should be no difficulty in diagnosing pregnancy provided the bitch readily accepts palpation of the abdomen. The size of the fetuses is such that they can readily be detected. High in the flank, the one occupying the apex of the horn will be felt, whereas in the midline just in front of the pelvic brim is the one with its extremity in the uterine body. If manipulation is resisted, digital examination per rectum is helpful. The bitch's foreparts should be raised, and the uterus pressed backwards towards the pelvic inlet by pressure on the abdomen. The presented part of the caudal fetus will be detected beneath the finger. In big or fat bitches pregnant with only one or two, doubt may still exist although by this time the mammary glands afford valuable confirmatory evidence.

The accuracy of abdominal palpation is sometimes questioned, particularly in differentiating pregnancy from overt pseudopregnancy. Allen and Meredith (1981) and Taverne et al. (1985c) have reported on the accuracy of this method. The former authors found that, although pregnancy was detected at 21 to 25 days of gestation, the accuracy was only 52% compared with 87% from 26 to 35 days. However, in the case of the correct diagnosis of bitches that did not subsequently whelp, the accuracies were 92% and 73%, respectively, for the same gestational ages. The optimum time for accuracy is between 26 and 35 days of gestation. Taverne et al. (1985c) concluded, on the basis of 91 investigations between days 25 and 35 after first mating, that sensitivity of abdominal palpation (by an experienced clinician) was 90% and specificity 91%. These accuracies were only slightly lower than the ones obtained with transabdominal ultrasonography (with a 3 MHz transducer) in the same period. Small litters appeared to be the major cause of false-negative diagnoses with both techniques. The authors suggested that it is worthwhile for small animal clinicians to practise the technique of abdominal palpation. It is important for a high level of accuracy that the interval from mating to examination is known because assessment of whether a bitch is pregnant or not is dependent upon the identification of conceptual swellings of a size comparable with the gestational age of the bitch.

Radiography

Radiography is a particularly useful diagnostic aid in the terminal stages of pregnancy, especially in the obese dog in which a differential diagnosis from pseudopregnancy is required, or in bitches with a presumed small number of fetuses that may suffer prolonged gestation. It may also be valuable in dystocia cases to disclose the presence of retained puppies and the disposition of a presenting puppy, although ultrasonography will usually be the technique of first choice in such cases.

At the end of 7 weeks it is normally possible to identify the whole fetal skeleton. At this stage radiography is the preferable and most accurate technique to count fetal numbers. The accuracy of radiographic diagnosis is very much dependent upon the quality of the radiograph that is obtained (Fig. 5.24).

Ultrasonographic Methods

Using the Doppler method with an external transducer placed on the abdominal wall adjacent to the mammary glands, fetal heart

VetBooks.ir

sounds were detected as early as 29 days of gestation (Helper 1970), although in all the 25 bitches confirmed to be pregnant, the fetal hearts were heard by 32 days; they were consistently twice the maternal heart rate. Riznar and Mahek (1978) found that the earliest time a positive diagnosis could be made was at 44 days. They stressed its value in late gestation, 61 to 70 days after mating, especially as a method of confirming the presence of live or dead puppies. Using two different instruments, Allen and Meredith (1981) found a low level of accuracy between 25 and 35 days of gestation, which improved with advancing gestational age to reach 100% with one instrument between 43 and 64 days.

A-mode ultrasound depth analysers have been employed to diagnose pregnancy using an external transducer probe. Smith and Kirk (1975) were able to detect pregnancy as early as 18 days after mating; these authors stressed the importance of not scanning too far caudally because of the chance of reflections from a full urinary bladder. Using a similar instrument with a 2.25 MHz transducer probe, the earliest correct positive diagnosis of pregnancy was made at 26 days (Allen & Meredith 1981). From 32 days to term a level of accuracy of about 90% was obtained for the correct diagnosis of pregnant and nonpregnant bitches.

As with other domestic species, B-mode ultrasonography is now the most frequently used method of diagnosing pregnancy in the bitch (Fig. 5.25). In addition, the technique has been widely explored to predict the day of whelping in bitches with an unknown mating date (Son et al. 2001, Kutzler et al. 2003 Luvoni & Beccaglia 2006). With the development of improved transducers, it became a highly accurate diagnostic tool not only for pregnancy diagnosis, but also for the study of pregnancy failure (England & Russo 2006). The initial studies reported in the literature mainly used low-frequency transducers. Using a 2.4 MHz linear array probe placed on the abdominal wall, positive identification of pregnancy at a high level of accuracy was achieved 28 days after natural mating or artificial insemination (Bondestam et al. 1984). Of 77 bitches that whelped, only one was incorrectly diagnosed as being nonpregnant, an accuracy of 99.3%, and she expelled a macerated fetus, whereas all 58 that were diagnosed as nonpregnant failed to give birth to puppies. In a study including some 135 bitches, investigated between days 20 and 49 after first mating, Taverne et al. (1985c) found a sensitivity of 92.9% and a specificity of 96%. Early identification of the conceptus has been reported at 14 days (Tainturier & Moysan 1984) and 21 days (Taverne 1984). However, the former workers suggested that it was preferable to wait until 20 days.

The accurate estimation of litter size has proved to be difficult, especially in larger breeds of dog. A figure of 40% accuracy at 29 days after mating and 83.3% accuracy from 50 days to term has been reported (Bondestam et al. 1984), with overestimation of small litters and underestimation of large litters.

For merely diagnosing pregnancy it is generally unnecessary to clip the hair of dogs, even in those breeds with long coats, provided that the hair is parted and plenty of coupling gel is used. Many owners do not object to the clipping of the hair between the two rows of teats, enabling more clear and detailed imaging through the midventral abdominal wall.

Laboratory Methods

Measurement of Serum Proteins. Gentry and Liptrap (1981) observed a threefold rise in serum fibrinogen concentrations during pregnancy, with peak values occurring 4 to 5 weeks after mating. Because this phenomenon did not occur at the corresponding stage of the luteal phase in nonpregnant bitches, it can be used as a method of detecting pregnancy. Eckersall et al. (1993) have reported an acute phase response in pregnant bitches as demonstrated by the rise in serum C-reactive protein (CRP) in midgestation. More recently, significant differences have been reported between pregnant and nonpregnant bitches for a wide range of serum acute-phase proteins (Vannucchi et al. 2002), and the authors also suggested that determination of some of these proteins might be useful for (early) pregnancy diagnosis. They are likely to be produced in response to the implantation of the embryo causing tissue damage. However, precise mating dates are required for these tests, and there is always the danger that false positives may arise if there is infection and inflammation elsewhere.

Measurement of Hormones in the Peripheral Circulation. Whereas persistent elevated progesterone concentrations in the peripheral circulation are used to detect pregnancy in the polyoestrous species, they are of no value in the bitch because of the prolonged luteal phase (pseudopregnancy) in nonpregnant animals. Yet, the initial rise in preovulatory progesterone concentrations appeared to be an accurate predictor for the parturition date (Kutzler et al. 2003). The canine placenta does not produce gonadotrophic hormones, but it does produce relaxin (Steinetz et al. 1987, 1989, Klonisch et al. 1999). Peripheral plasma concentrations are elevated from 20 to 30 days of gestation, whereas they are not in the nonpregnant animal; pregnancy detection kits are now commercially available.

Pregnancy and Its Detection in the Cat

Ovulation occurs 23 to 30 hours after mating (Concannon et al. 1980), and serum progesterone concentrations rapidly increase from the baseline of under 10 nmol/l to reach peak values of around 100 nmol/l between the first and fourth weeks of pregnancy (Verhage et al. 1976) (Figs 5.26 and 5.27).

Cats are unusual in that queens may continue to display oestrous behaviour and accept mating even though ovulation has occurred, and there is significant production of progesterone (Stabenfeldt 1974). This evidently favours the occurrence of superfecundation, the presence of offspring from more than one sire in a single litter (see Chapter 9).

At 3 to 4 weeks of pregnancy hyperaemia of the teats occurs. This is particularly prominent in maiden queens. It is a progesterone-dependent phenomenon and is also seen in pseudopregnancy. There is conflicting evidence concerning the relative roles of the CLs and the placentas in the synthesis of progesterone during pregnancy. Scott (1970) and Gruffydd-Jones (1982) have reported the maintenance of pregnancy, following ovariectomy after 45–50 and 49 days respectively when 3-beta-hydroxysteroid dehydrogenase activity, an enzyme essential for progesterone synthesis, is present in the feline placenta (Malassine & Ferre 1979). Yet Verstegen et al. (1993a) have reported abortion following ovariectomy at 45 days of gestation. Progesterone concentrations gradually fall from their peak values during the first month of pregnancy, the fall becoming precipitous during the last 2 days prior to parturition. In many, but not all, queens there is a slight preparturient increase in oestrogen concentrations, but this declines just before parturition.

Relaxin is produced by the placenta during pregnancy and is thought to contribute to its maintenance by inhibiting uterine activity. It appears during the third week of pregnancy, with concentrations declining just before parturition (Stewart & Stabenfeldt 1985). Prolactin is considered a luteotrophic hormone during the last third of pregnancy (Jöchle 1997), and concentrations decline as weaning takes place (Banks et al. 1983).

• **Fig. 5.26** Mean (+/- SD) plasma concentrations of progesterone throughout pregnancy (four cats). Day 0 represents the day of mating. (Courtesy Prof. T. J. Gruffydd-Jones.)

The average gestation length is 63 to 65 days (Prescott 1973) but is reported to vary between 59 and 70 days. Kittens born after a gestation length shorter than 59 days generally show decreased viability. The fact that ovulation may not necessarily occur after the first mating may partly explain the considerable variation in gestation length.

The modal litter size for nonpedigree cats is four, with a range of two to seven, but there is variation in litter size between pedigree breeds. Oriental breeds tend to have larger litters, sometimes in excess of 10 kittens, whereas pedigree longhair queens tend to have smaller litters, often of only two or three kittens. Singleton litters are unusual, which may reflect fetal resorption due to inadequate fetoplacental endocrine contribution to the maintenance of pregnancy.

A proportion of queens will display oestrous behaviour while pregnant. Some of these cats will mate, and this could lead to superfetation (see Chapter 9), although this has not been convincingly proved (Root Kustritz 2006a). Free-living queens may mate with several competing toms during oestrus, and hence superfecundity is common (see Chapter 9).

Methods of Pregnancy Diagnosis

Cats lend themselves particularly well to pregnancy diagnosis by abdominal palpation. This is most satisfactorily performed 16 to 26 days after mating, when conceptuses are readily identifiable as individual, turgid, spherical swellings. Pregnancy may be confirmed as early as 13 days after mating, but at this stage the conceptuses may be confused with faecal boluses. After 6 weeks the conceptual swellings increase markedly in size, elongating and merging, thus making palpation more difficult. However, by this stage there will usually be significant abdominal enlargement. Radiography has also been used for pregnancy diagnosis and for an accurate prediction of parturition date in cats (Haney et al. 2003).

The first report on the use of ultrasonography in pregnant cats was published in 1980 (Mailhac et al. 1980). Detailed descriptions of B-mode ultrasonographic images of the pregnant feline uterus have been reported for the first (Zambelli et al. 2002) and second half of gestation (Zambelli et al. 2004). The earliest ultrasonographic observation of a gestational sac was on day 10 after mating (with a 10 MHz transducer), whereas the embryo proper could be visualised from day 18 onwards (Fig. 5.28). Davidson et al. (1986) were the first to report the use of ultrasonography for pregnancy diagnosis. Fetal cardiac activity can be detected from day 16 to 17 onwards to assess fetal viability (Root Kustritz 2006b). In a recent study (De Haas van Dorsser et al. 2006) urinary relaxin levels in domestic and nondomestic felids appeared to mirror the profiles in plasma, and measurements of relaxin in urine therefore provide a sensitive and specific biochemical method for pregnancy diagnosis in cats. 'Bench-top kits' have been developed to detect relaxin in urinary samples of both domestic and wild felids for a rapid pregnancy test (De Haas van Dorsser et al. 2007, Harris et al. 2008). Measurements of prostaglandin-F metabolite (PGFM) levels in faecal samples of domestic and several wild cat species also appear promising as a noninvasive test for pregnancy (Dehnhard et al. 2011).

Prevention and Termination of Pregnancy

In all domestic species there will be occasions when it will be desirable to either prevent pregnancy from occurring or terminate it prematurely. Such occasions may follow an unintended mating (misalliance), in which pregnancy and parturition may present a severe risk to the dam's health or in which the owners of the animal do not want the pregnancy to continue.

Horse

The management and treatment of twinning are discussed in detail in Chapter 31. If the pregnancy needs to be curtailed for this and other reasons, such as mismating, the treatment of choice is $PGF_{2\alpha}$ or an analogue administered after the CL has become responsive to the hormone, i.e., 4 days after ovulation (see Chapters 1 and 5) and before the formation of the endometrial cups, i.e., about 35 days. Therefore it is preferable to treat approximately 10 to 15 days after mating. Alternatively, intrauterine infusion of 250 to 500 ml of physiological saline during the same period will also be effective because, as well as a physical effect in flushing out the conceptus, it also stimulates the release of endogenous $PGF_{2\alpha}$.

Cattle

Pregnancy can be terminated from 4 to 100 days after ovulation with $PGF_{2\alpha}$ or an analogue, and even up to 150 days many cows will respond. Subcutaneous injections of a progesterone-receptor antagonist at days 46 and 47 appeared also effective as an abortive treatment in cattle (Breukelman et al. 2005b). After 150 days the placenta forms an additional source of progesterone for the maintenance of pregnancy, until about 270 days of gestation; this implies that in many cases the use of $PGF_{2\alpha}$ alone will not be effective. During this period long-acting corticosteroids either alone or in combination with $PGF_{2\alpha}$ are required (see Chapter 6).

Goat

Pregnancy can be terminated at any stage with a luteolytic dose of $PGF_{2\alpha}$ (Day and Southwell, 1979).

Sheep

$PGF_{2\alpha}$ is effective in terminating pregnancy after day 4 and before day 12. During the days 12 to 21 period there will be no response because of the protective effect of oIFN-tau, which ensures the

survival of the CL. There is also some suggestion of another refractory period between days 25 and 40. After 45 to 55 days the CL is no longer the main source of progesterone for the maintenance of pregnancy, and the placenta starts to be the dominant production site. During the third and fourth month of gestation, induction of abortion is more difficult, although the use of the progesterone-receptor antagonist aglepristone appears to be effective in some ewes at this stage (Taverne et al. 2006). During the final weeks of gestation, corticosteroids will be necessary to terminate pregnancy (see Chapter 6).

Pig

Pregnancy can be terminated at any stage with $PGF_{2\alpha}$, although repeated injections are sometimes necessary to accomplish expulsion of all conceptuses.

VetBooks.ir

(Courtesy of Professor Marco Russo.)

Dog

Pregnancy can be prevented in the bitch by the strategic use of oestrogens during the first 5 days after mating. They exert their effect by interfering with the transport of the zygotes from the uterine tube to the uterine horns, probably by causing oedema of the endosalpinx and thus a temporary tubal occlusion. For many years estradiol benzoate was used as a single intramuscular or subcutaneous injection at a dose rate of 5 to 10 mg. More recently, the use of lower doses of estradiol benzoate 0.01 mg/kg administered on the third, fifth and possibly seventh days after mating has been advocated because it is possibly a safer option.

Attention has also focused on the termination of pregnancy at a later stage. Natural $PGF_{2\alpha}$ rather than analogues has been found to be effective when administered at a dose rate of 150 to 270 mug/kg subcutaneously twice daily consecutively on days 10 to 14 after the bitch has entered metoestrus or pregnancy, as confirmed by exfoliative vaginal cytology (see Chapter 1) (Romagnoli et al. 1993). Earlier reports, in which pregnancy was terminated at a later stage, namely 25 to 30 days, resulted in unacceptable side effects (Lein et al. 1989). At present it is doubtful if $PGF_{2\alpha}$ should be used for this purpose. The use of progesterone-receptor antagonists appeared a more effective and acceptable treatment (Concannon et al. 1990, Linde-Forsberg et al. 1992, Galac et al. 2000, Fieni et al. 2001). Abortion can be induced not only by blocking the effect of progesterone at the level of its receptors but also by inhibiting its synthesis by the CLs with an antiluteotrophic therapy.

Dopamine agonists, such as cabergoline that inhibit prolactin secretion and hence indirectly withdraws the luteotrophic support for the CLs, have been used to terminate pregnancy in bitches. It has been used at a dose rate of 1.65 mug/kg subcutaneously for 5 days at 25 to 40 days of gestation (Onclin et al. 1993). Unlike the prolactin inhibitor bromocriptine, it does not have unpleasant side effects but, because a resultant uterine inertia (see Chapter 13), may result in retention of puppies that become macerated (see Chapter 9), it is not without dangers. Most commonly, cabergoline is administered orally daily (5 mug/kg), whereas cloprostenol (5 mug/kg) is given by other parenteral routes on alternate days. Abortion/resorption usually follows within 10 days after the start of treatment. The use of the above mentioned therapeutics for pregnancy termination has recently been reviewed extensively by Lamm and Makloski (2012). Termination of an unwanted pregnancy in the bitch should always be closely monitored, particularly with sequential transabdominal B-mode ultrasonography (Taverne et al. 1989).

Cat

Estradiol cypionate, by intramuscular injection at a dose rate of 125 to 250 mug within 40 hours of mating, has been shown to be effective in preventing pregnancy, probably by interfering with the normal transport of the zygotes within the uterine tubes (Herron & Sis 1974). Similarly, injections of diethylstilbestrol have been used. However, there are few data on possible side effects, and such treatments should only be used in exceptional circumstances. A single 5 mg dose of megestrol acetate is used by some within 1 day of mating.

Both $PGF_{2\alpha}$ and the dopamine agonist cabergoline have been shown to be fairly effective in causing abortion; however, the former has unpleasant side effects (Verstegen et al. 1993b). Regimens using cabergoline and low-dose cloprostenol appear to be most promising (Onclin & Verstegen 1997). More recently, aglepristone was shown to be effective in midpregnancy in a controlled clinical study with 66 queens with known breeding dates (Fieni et al. 2006). Two subcutaneous injections, given 24 hours apart, resulted in expulsion of all fetuses in 88.5 % of the animals within 14 days after the first injection. The use of the above mentioned therapeutics

VetBooks.ir

for pregnancy termination in cats has been reviewed extensively by Lamm and Makloski (2012).

Parturition and the Care of Parturient Animals and the Newborn

MARCEL TAVERNE AND DAVID E. NOAKES

Parturition

It is essential for the veterinarian to be perfectly familiar with the normal course of parturition in domestic species in order to be able to differentiate between physiological and pathological birth. This implies that it is important to spend time observing normal parturitions in these species, although this cannot always be achieved easily. An appropriate intervention at the correct time can increase the likelihood of a successful outcome by ensuring that both mother and offspring survive.

Initiation of Parturition

Parturition is one of the most fascinating of biological processes, for although its physiology is explicable and its associated endocrine changes have been fairly well established, the factors which initiate birth and thereby terminate pregnancy after a constant length of gestation for a given species are still imperfectly understood. The modern concept, which is firmly based on experimental studies and clinical observations (mainly in farm animals and to some extent in horses) is that the fetus exerts an overriding control on the length of gestation and that the mother can influence the time of birth only within narrow limits.

The uterine musculature is the key component of labour, and the essential physiological changes between gestation and birth are a biochemical ripening of the cervix and liberation of the contractile potential of the myometrium; the factors involved in these transformations are humoral, biochemical, neural, and mechanical.

Of the humoral factors, the most important is the reversal of those mechanisms that are necessary for the maintenance of pregnancy—in particular the removal of the progesterone block, which ensures that, during this phase of the animal's reproductive life, the myometrium is largely quiescent. Together with the changes in the synthesis and secretion of relaxin, oestrogen, and prostaglandin, it also enhances the biochemical ripening of the connective tissues within the cervix in preparation for the dilatation of the latter.

The mechanisms that are responsible for the initiation of parturition vary slightly between species. Initially, much of the experimental work to determine them was done in the ewe because the sheep was used as a research model for parturition in women. This, together with circumstantial evidence obtained from cattle, sheep, and goats in which it was observed that prolonged gestation was usually associated with abnormalities of the fetal brain and adrenals, supported the hypothesis first advocated by Hippocrates that the fetus is responsible for controlling the time when parturition occurs.

The mechanisms are fairly well defined in the domestic ruminant species, but in the pig, horse, dog, and cat there are a number of important areas that are not well understood (Taverne & van der Weijden 2008). Because much of the work has been reported in sheep, it is proposed to describe in detail the mechanisms in this species and, subsequently, to indicate those differences that have been identified in other species.

Ewe

Parturition in the ewe occurs as result of activation of the fetal hypothalamus–pituitary–adrenal (HPA) axis; the areas of the hypothalamus involved in this process are the paraventricular nuclei. The fetal HPA axis is similar to the adult HPA axis, except that the fetal brain is still developing in late gestation, and the former communicates with the latter via the placenta. There is still uncertainty about the mechanisms responsible for the activation of the fetal hypothalamus. A number of theories have been proposed. These are:

- Maturation of the fetal hypothalamus which might result in the development of critical synapses in the paraventricular nucleus, allowing an increase in fetal neuroendocrine function;
- Ability of the hypothalamus to respond to the effects of placental hormones; and
- Fetal stressors such as hypoxia, hypercapnia, changes in blood pressure, and blood glucose (Wood 1999).

It is also postulated that placental-derived hormones, such as oestrogens, progesterone, PGE_2, or corticotrophin-releasing factor (CRF), may also act on the hypothalamus.

Let us consider the interactions between the pituitary and adrenal cortex. Before 120 days of gestation, much of the cortisol present in the circulation of the fetal lamb is derived from the ewe via transplacental transfer. During this period a possible fetal overexposure, for example in cases of maternal stress, is prevented by the action of the placental enzyme 11ß-hydroxysteroid dehydrogenase II that converts cortisol into cortisone. During the last 15 to 20 days of gestation, there is a progressive rise, in a semilogarithmic pattern in fetal cortisol concentrations, which reach a peak 2 to 3 days before birth, thereafter declining 7 to 10 days postpartum. The source of the increase in fetal cortisol is the fetal adrenal, which is due to both an increase in the size of the organ in relation to total body

VetBooks.ir

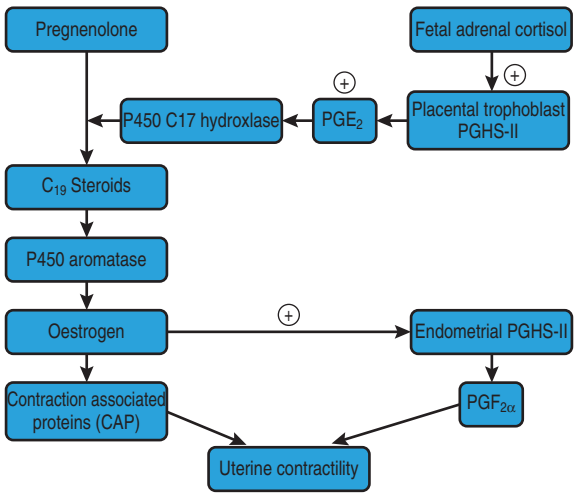
weight, and an increase in its sensitivity to adrenocorticotrophic hormone (ACTH), as a result of accelerated processing of ACTH from proopiomelanocortin (POMC); maternal cortisol concentrations only rise around the time of parturition (Wood 1999). At the same time the binding capacity of the fetal plasma increases, thus reducing the amount of free cortisol in the fetal circulation and thereby reducing the negative feedback effect on the secretion of ACTH by the fetal pituitary.

In sheep fetal pituitaries, the 'fetal' corticotrophs are replaced (probably accompanied by a change in the distribution of POMC peptides) by smaller stellate cells, the so-called 'adult' corticotrophs, around 125 days of gestation, which might reflect an increased potential for ACTH secretion (Antolovich et al. 1988). There is an increase in corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP) from the paraventricular and supraoptic nuclei in the fetal hypothalamus, and these are thought to be responsible for the initial (CRH) and late (AVP occurring in the last 10 days) rise in fetal plasma ACTH levels. Endogenous opioids may also play a role in stimulating ACTH secretion via their effect upon the fetal hypothalamus rather than the pituitary. It has been shown experimentally that when exogenous opioids are infused into the fetal lamb, there is an increase in ACTH which can be abolished by the administration of the opioid antagonist naloxone (Brooks & Challis 1988).

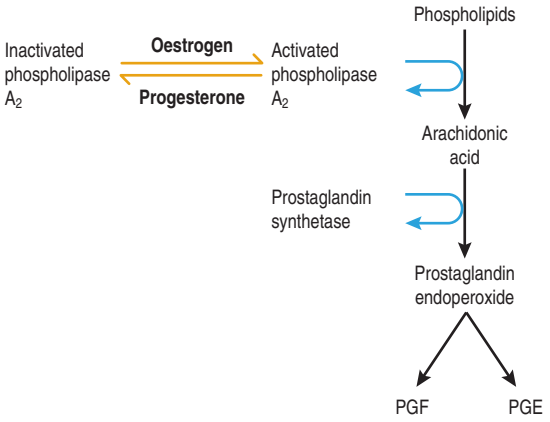
The fetal adrenal becomes more responsive to ACTH stimulation with advancing age (Glickman & Challis 1980). Maturation is induced by ACTH, particularly the pulse pattern of its secretion. It has been shown that insulin-like growth factors (IGFs) may have an autocrine and/or paracrine role in regulating ovine fetal adrenal function (Hann et al. 1992). Fetal growth hormone, which is elevated from 50 to 70 days of gestation and then falls until 100 days, before increasing to term, may also modify the response of the fetal adrenal to ACTH (Devaskar et al. 1981). There is recent evidence that maternal undernutrition around the time of conception, resulting in a loss of maternal body weight of some 15%, may programme the development of the fetal HPA axis in such a way that its activation (see later in this chapter) and the resulting birth of lambs take place some 7 to 10 days earlier (Kumarasamy et al. 2005).

An adapted version of the original hypothesis suggests that intrauterine prostaglandin synthesis is affected by this rise in cortisol by two different pathways (Whittle et al. 2000, 2001). The first, oestrogen-independent pathway, involves the enhanced expression of prostaglandin synthetase (PGHS-II) within the fetal trophoblast cells of the placenta. The resulting release of PGE2, as reflected by an early rise in fetal plasma E2 levels, stimulates the placental conversion of pregnenolone to C-19 steroids and their subsequent aromatisation to oestrogens in the placenta, by activating the enzymes 17α-hydroxylase and aromatase (Fig. 6.1). One of the consequences of the rise in oestrogens is a stimulation of PGHS-II in the maternal endometrium, leading to enhanced PGF production and release within the uterine wall; this will stimulate myometrial contractility. This represents the second, oestrogen-dependent pathway by which fetal cortisol affects PG production (Fig. 6.2). In ruminants such as the cow and goat, in which progesterone is predominantly produced by the corpus luteum, this PGF might also induce luteolysis (see later in this chapter).

Oestrogens themselves also have a direct effect upon the myometrium by increasing several so-called contraction-associated proteins (CAP's), such as connexins (to form gap junctions; these special areas of contact between smooth muscle cells, allow the passage of electrical pulses, thus ensuring coordinated contractions), oxytocin



• **Fig. 6.1** Model of endocrine events associated with the onset of ovine parturition. (From Whittle et al. 2000.)



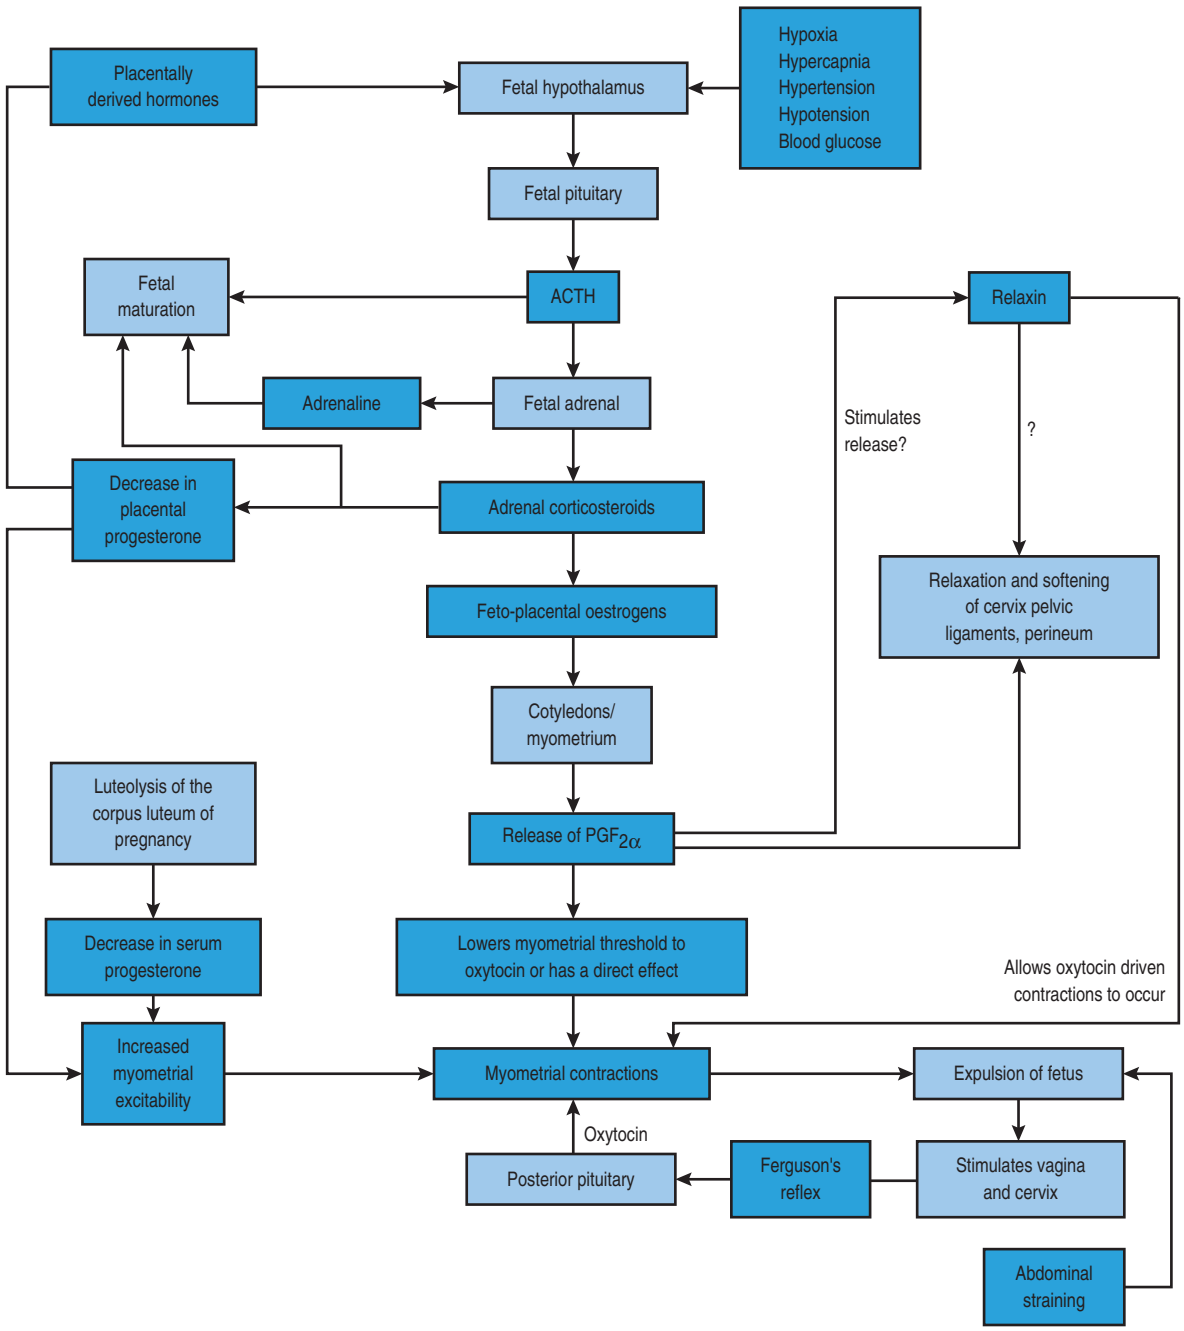
• **Fig. 6.2** The induction of prostaglandin E (PGE) and prostaglandin F (PGF) release (after Liggins 1982).

and prostaglandin receptors, and calcium channels. Oestrogens also stimulate softening of the cervix by altering the structure of collagen fibres. Prostaglandins thus play a key role in initiating parturition and are considered to be the main intrinsic stimulating factor of smooth muscle cells (Csapo 1977); thus its release is crucial in initiating myometrial contractions. Prostaglandin synthase inhibitors have shown to be effective in delaying onset of parturition in a wide range of species, including sheep, pigs, and women (Rac et al. 2006, Taverne et al. 1982).

The effect of the parturient contractions of the myometrium is to force the fetal lamb towards the cervix and vagina where it will stimulate sensory receptors and initiate Ferguson's reflex, with the release of large amounts of oxytocin from the posterior pituitary. However, in ruminants this oxytocin release is mainly detected in peripheral plasma during the expulsive stage of parturition (Hydbring et al. 1999), i.e., many hours after the switch from a gestational to a parturient-type of myometrial activity has already taken place. At this rather late stage of parturition, oxytocin will further stimulate myometrial contractions and enhance release of $PGF_{2\alpha}$ from the myometrium, and this positive feedback system of increasing magnitude thus supports a rapid expulsion of the fetus.

Other important changes which are brought about by the endocrine events of parturition have been observed. For instance,

VetBooks.ir



• **Fig. 6.3** The endocrine changes that occur before and during parturition in the sow, ewe, and cow and their effects.

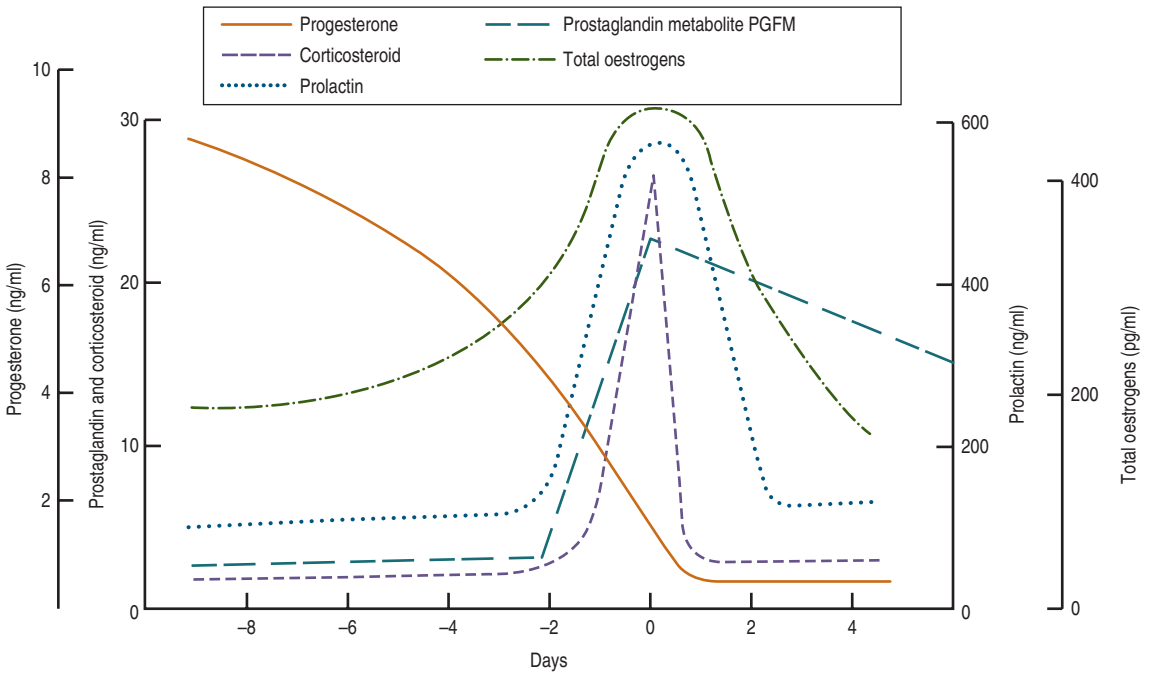
maturation of the fetal lamb's lungs, especially the production of alveolar surfactant, is stimulated by cortisol, as are many other changes in fetal function and structure that enable the lamb to survive after birth (Fowden 1995, Fowden et al. 2016).

A schematic, representation of the endocrine changes that are involved in the initiation of parturition in the ewe and some other species is shown in Fig. 6.3. Overall trends in reproductive and other hormones occurring in the peripheral circulation of the ewe around the time of parturition are shown in Fig. 6.4.

Cow

The corpus luteum is the main source of progesterone throughout bovine pregnancy, but as stated in Chapter 5, the placenta assumes a role of progesterone production between about 150 and 200 days of gestation. So if the ovary containing the corpus luteum (CL) or the CL itself is removed during this stage, pregnancy may continue in some or all cases (McDonald et al. 1953, Lindell 1981). Although the CL is not required to maintain pregnancy at all stages of gestation, it has been shown that its regression plays an important role in the endocrine changes that are necessary for the initiation of parturition. There is no evidence to suggest that the prepartum decline of maternal plasma progesterone levels is due to withdrawal of a maternal luteotrophic support. Although other mechanisms, such as a direct effect of glucocorticoids, may be involved, it is most likely that luteal regression is initiated by the action of $PGF_{2\alpha}$. The prepartal rise in fetal cortisol stimulates

VetBooks.ir



• **Fig. 6.4** Trends in hormone concentrations in the peripheral plasma of the ewe around the time of parturition. Day 0 at parturition.

the expression of the enzymes 17α-hydroxylase-C17 (CYP17) and cyclooxygenase 2 (COX2) in the uninucleate trophoblast cells of the bovine placenta (Schuler et al. 2006a, b). These enzymes play a key role in the synthesis of oestrogens and prostaglandins by the placenta. Yet the release of prostaglandins into the maternal circulation, as mirrored by its main metabolite, shows only a gradual prepartum increase during the rapid and final prepartum decline of plasma progesterone. However, unlike during the oestrous cycle, its amplitude is relatively small and does not show clear pulses (Königsson et al. 2001). Apart from the (fetal) placenta, the bovine uterus itself appears to be able to produce prostaglandins, and this becomes even clearer during the postpartum period (see later in this chapter). The endocrine changes responsible for initiating parturition are rather similar, but not identical, to those described in the sheep (see Fig. 6.3 and Shenevai et al. 2012), on which much of the experimental work has been done. In fact, the first reports on a possible involvement of the fetal hypophyseal–adrenal axis in the initiation of parturition came from pathological observations in cows with a hereditary form of prolonged gestation. Fetuses from these animals showed aplasia of the pituitary and adrenal hypoplasia (Kendrick et al. 1957).

The overall trends in reproductive and other hormones occurring in the peripheral circulation of the cow around the time of parturition are shown in Fig. 6.5.

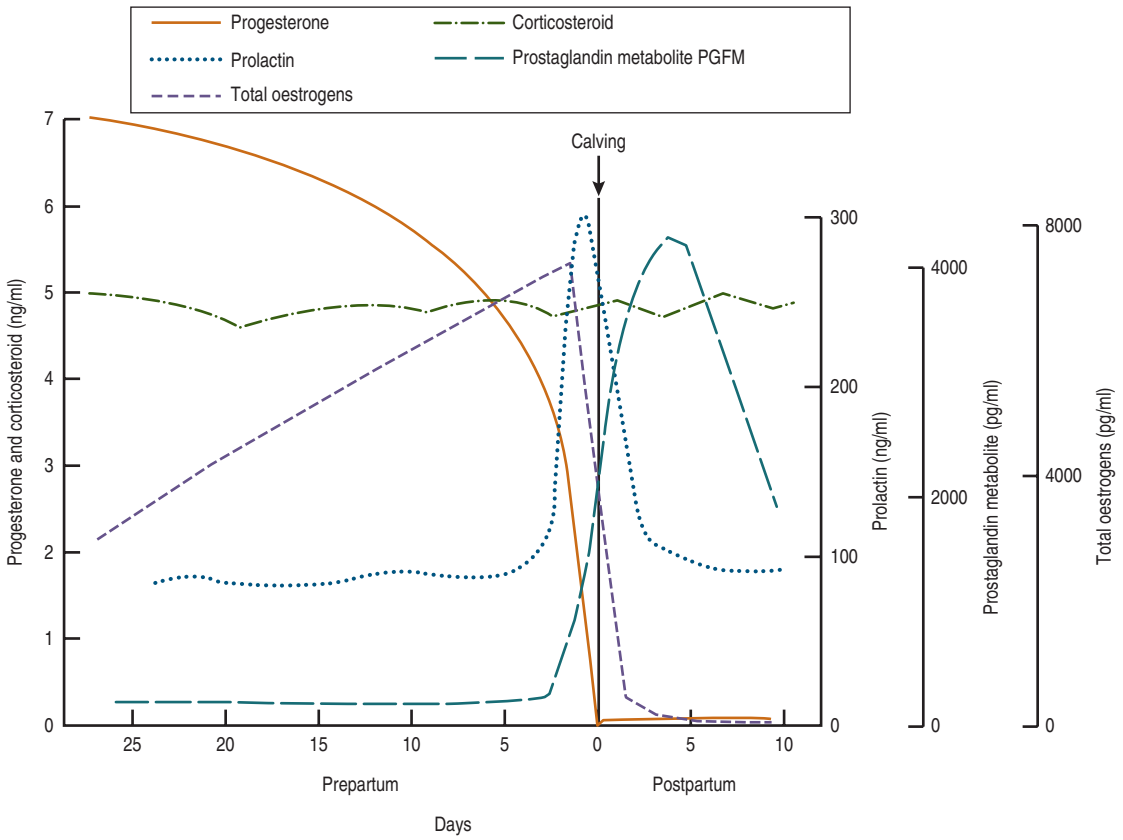
Doe (Nanny) Goat

In this species the CLs provide the essential source of progesterone necessary for the maintenance of gestation because ovariectomy or extirpation of the CLs will terminate pregnancy (Irving et al. 1972). There is a positive association between fetal plasma ACTH and the prepartal increase of fetal cortisol levels (Ford et al. 1998). Placental 17α-hydroxylase, which is stimulated by the rise in fetal cortisol (Flint et al. 1978), diverts the synthesis of progesterone by the CLs into oestrogen. The change in the oestrogen to progesterone ratio stimulates $PGF_{2\alpha}$ synthesis as in the ewe (see Figs 6.1 and 6.2), resulting in luteolysis with a further decline in progesterone. Progesterone disappears from the circulation before parturition can occur. Yet this sequence of events has been disputed by Ford and associates (1998), who found no clear evidence that prepartum luteolysis in goats is associated with changes in the basal concentrations of PG's in maternal arterial or uterine–ovarian–venous plasma.

Sow

In the sow, progesterone from the CLs is necessary for the maintenance of pregnancy throughout its entire duration. Fetal participation in the initiation of farrowing is indicated by the prolongation of pregnancy after fetal decapitation and hypophysectomy. If only one fetus survives to term in a litter, this fetus appears capable of initiating the farrowing process, but in the presence of four or more decapitated litter mates, a single intact fetus is incapable of doing so (Stryker & Dziuk 1975). Furthermore, when fetal plasma cortisol is raised prematurely in all or part of a (reduced) litter, then farrowing is not induced (Randall et al. 1990). These observations indicate that the mechanisms of fetal participation in the initiation of farrowing are far from clear at the moment. Parturition is preceded initially by increased levels of cortisol in the fetal plasma, although the pattern of fetal plasma cortisol concentrations is quite different in individual piglets, even when fetuses within one litter are compared (Randall 1983). It is assumed that the rise in fetal cortisol results in a rise in the maternal blood oestradiol and $PGF_{2\alpha}$ metabolites and a decrease in progesterone. Yet on the day of farrowing, progesterone levels are well higher than baseline, and the decrease continues during the first 24 hours after parturition (Peltoniemi & Oliviero 2011). Although the prepartum decline of plasma progesterone coincides with the first increase of $PGF_{2\alpha}$ metabolites according to some authors (Kindahl et al. 1982), others found no such clear relationship (Silver et al. 1979, Randall et al. 1986). It is unlikely that oestrogens are responsible for stimulating the release of $PGF_{2\alpha}$ as occurs in the other species

VetBooks.ir



• **Fig. 6.5** Trends in hormone concentrations in the peripheral plasma of the cow around the time of parturition. Day 0 at parturition.

(First 1979), and exogenous oestrogens will not induce farrowing. The hormonal changes in the maternal peripheral circulation are illustrated in Fig. 6.6.

Mare

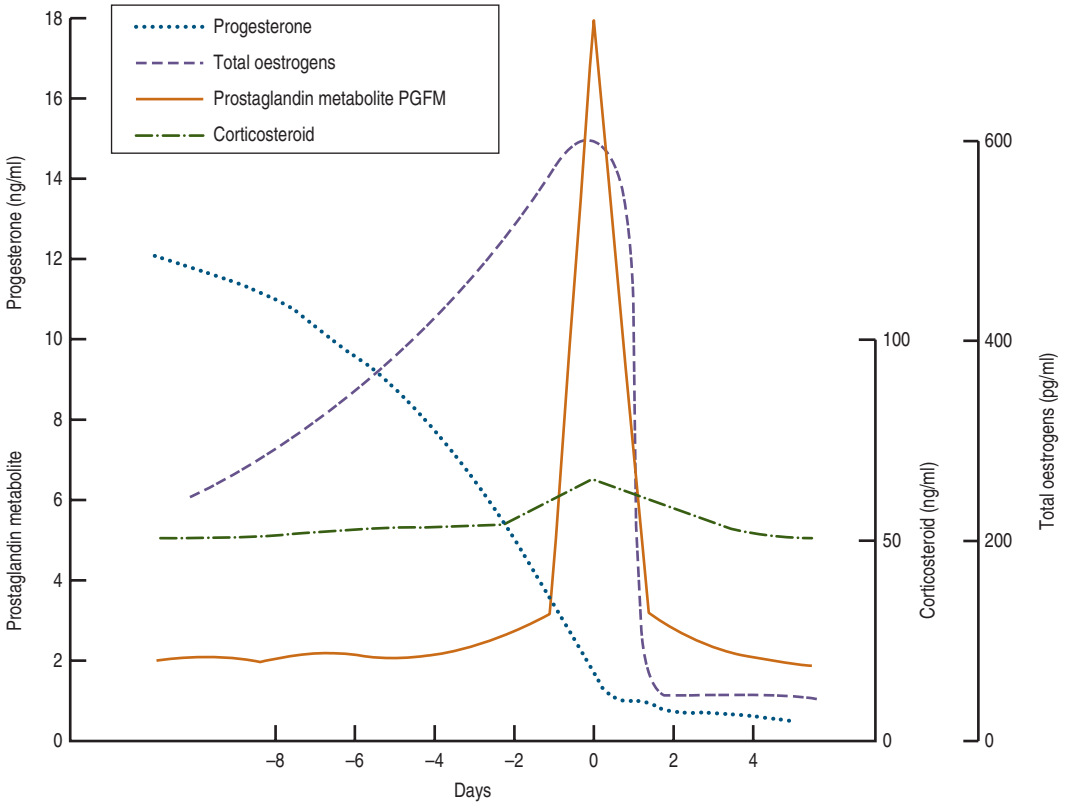
The mechanisms responsible for the initiation of parturition are not yet as well understood as those of the ruminant species. However, it is likely that the fetal foal is responsible for the initial trigger mechanism because the fetal adrenal undergoes rapid hypertrophy immediately before parturition (Comline & Silver 1971), and fetal plasma cortisol concentrations have been shown to increase nearly 10-fold during the last days before foaling (Card & Hillman 1993, Cudd et al. 1995). The main differences from the ewe relate to a much wider range of gestational length (Davies Morel et al. 2002) and the timing and magnitude of key endocrine changes that occur in the maternal circulation (see Fig. 5.1). When the secondary corpora lutea on the ovaries stop producing progesterone, maternal progesterone reach very low levels during the last third part of pregnancy, and it appears that during this stage metabolites of both progesterone and pregnenolone, collectively named progestagens, are responsible for myometrial quiescence (Ousey 2004, Fowden et al. 2008). In fact, during the last 20 to 30 days of gestation, total progestagen levels increase and reach a peak about 48 hours before parturition. It is only very close to the time of delivery (during the last 24–48 hours) that these levels show a steep decline (Conley 2016). These changes in progestagen levels appear to be under the control of the fetal HPA axis.

When the fetal adrenal cortex grows and differentiates, the fetal adrenals start to secrete pregnenolone that serves as a precursor for progestagens synthesis by the uteroplacental tissues. This explains why maternal plasma progestagens decline immediately upon intrauterine death of the fetus. When the adrenal cortex becomes further differentiated and activated by the prenatal rise of fetal ACTH, it switches from pregnenolone to cortisol production, which appears to be responsible for the final precipitous drop in maternal plasma progestagen levels (Fowden et al. 2008). Plasma oestrogen concentrations decline during the last 100 days of gestation rather than increase as in other species, reaching relatively low levels at parturition. However, this is largely a reflection of the decline in oestrone and the species-specific oestrogens, equilin and equilenin, because concentrations of oestradiol–17ß remain fairly constant. However, during the final 24 to 48 hours before delivery, maternal oestradiol–17ß concentrations double again (Barnes et al. 1975). Maternal prostaglandin levels are low during the major part of gestation, rising only slightly towards term, and then show a steep increase only at parturition (Vivrette et al. 2000, Davies Morel 2008, Fowden et al. 2008); this is probably because synthesis of primary PG's is stimulated whereas their conversion into metabolites is inhibited by the influence of the very rapid change of the progestagen/oestrogen balance.

Bitch and Queen Cat

Even less is known about the mechanisms that are responsible for initiating and controlling parturition in either of these two species. There are no published data on fetal cortisol secretion during late gestation. In the bitch a prepartum rise of cortisol has been detected in the peripheral circulation, with peaks obtained 8 to 24 hours prepartum (Concannon et al. 1975), but this increase is believed

VetBooks.ir



• **Fig. 6.6** Trends in hormone concentrations in the peripheral circulation of the sow around the time of parturition. Farrowing at day 0.

to reflect the stress associated with nest building, physical activity, and the onset of uterine contractions. Progesterone concentrations start to decline gradually from about the 30th day of gestation, and there is a precipitous fall between 12 and 40 hours before the birth of the first puppy (Concannon et al. 1975, Baan et al. 2008). This latter change coincides with an increased release of $PGF_{2\alpha}$ because, during the 48 hours before whelping, there is a rise in the metabolite PGFM. This prostaglandin production appears to originate from fetal trophoblast cells in the placentas; expression of the PG-synthesis regulating enzyme COX-2 is strongly upregulated in these cells during the immediate prepartum period (Kowalewski et al. 2010). It is tempting to speculate that this PG release causes luteolysis, but there is also evidence that other intraluteal processes, such as invasion of macrophages, massive expression of apoptotic enzymes, and significantly decreased expression of the steroidogenic regulatory, are involved in completion of luteolysis when the influence of progesterone is declining (Kowalewski 2014). Maternal plasma oestrogens remain at a fairly constant and very low level throughout pregnancy and start to decline about 2 days prepartum, reaching nonpregnant values at the time of parturition (see Fig. 5.21). Prolactin increases as progesterone concentrations decrease 1 to 2 days before whelping (Concannon et al. 1977, Baan et al. 2008); it is not known if this hormone plays any role in parturition. The few published data on maternal oxytocin levels indicate that oxytocin is not responsible for the initiation of whelping because levels were found to be elevated only once the expulsive stage had started (Olsson et al. 2003, Klarenbeek et al. 2007).

In the queen cat, progesterone remains at between 20 and 50 ng/mL for the first two-thirds of gestation before starting to decline gradually towards term. Just before parturition it declines more rapidly from 4 to 5 ng/mL to levels lower than 2 ng/mL at the time of parturition (Verhage et al. 1976, Schmidt et al. 1983). Prostaglandins levels in plasma are still unexplored in cats, but in pregnant wild and domestic cats, faecal PG levels were found to be elevated during pregnancy, peaking towards parturition (Dehnhardt et al. 2012). Oestradiol concentrations reach peak levels about 1 week before parturition and have declined substantially on the day of parturition.

The Role of Relaxin

Sources of Relaxin

Relaxin, a polypeptide hormone, belongs to the insulin superfamily of which the peptides consist of two chains connected by disulfide bridges. Except for humans and higher primates, in which three peptides are present in the genome, most mammals have two genes of which the RLN1 gene is the functional one (Klein 2016). Relaxin was shown to be responsible for causing relaxation of the pubic symphysis of guinea pigs by Hisaw in 1926. The most potent sources of this hormone are the CLs of the pregnant sow; however, it is now known to be produced by a number of other tissues such that it has a wide diversity of chemical structure and physiological effects between species (Bathgate et al. 2006, Klein 2016).

In the pig, as well as being present in the CLs of the pregnant sow, it is also produced by preovulatory follicles. Plasma levels are low, but physiological, during the final weeks of gestation and peak shortly before the onset of farrowing at the time of the prepartum decline of progesterone (Sherwood et al. 1981, Taverne et al. 1982). In the horse, dog, and cat the main or sole source of the hormone is the placenta. In horses the noninvasive trophoblast of the early equine embryo expresses relaxin (Klonisch et al. 1997). In

VetBooks.ir

a pregnant mare's plasma, concentrations start to rise from about 80 days of gestation and peak during parturition, although there is considerable breed variation (Stewart et al. 1992). In the bitch relaxin increases from about 4 weeks of gestation and remains elevated until term, whereas in the cat there is a sudden rise from 23 days of gestation with a peak at 36 days and a dramatic decline just before parturition (Stewart & Stabenfeldt 1985). The RLN1 gene has not been discovered in ruminants, and a relaxin peptide has not been isolated (Bathgate et al. 2006). Yet in the cow the CL appears to be the main source of a relaxin-like hormone (insulin-like peptide 3; INSL3), thus early studies, reporting that relaxin values increase just before calving (although still at relatively low concentrations), have to be interpreted with caution because it is not clear what substance was measured by the assay. In the ewe there is also conflicting data concerning the presence and secretion of a relaxin hormone, and it appears possible that in sheep, INSL3 substitutes for relaxin (Bathgate et al. 2006).

Actions of Relaxin

Crude extracts and purified forms of the hormone have a wide range of actions on a variety of target tissues, including the pubic symphysis, pelvic ligaments, cervix, myometrium, and the mammary gland (Bathgate et al. 2006).

In the sow relaxin stimulates the growth of the vagina, cervix, uterus, and mammary gland during late pregnancy (Min et al. 1997) and causes softening of the cervix before parturition, as judged by the ability to pass a series of rods of different diameters into the cervical canal during the last 3 days before farrowing (Kertiles & Anderson 1979). The latter changes, which are also influenced by the oestrogen to progesterone ratio, involve changes at a biochemical level by influencing the glycosaminoglycans to collagen ratio (O'Day-Bowman et al. 1991) and histological structure (Winn et al. 1993).

Despite the fact that there is not a reliable assay for relaxin in the cow and that the cow only produces a relaxin-like protein, there is circumstantial evidence that relaxin can influence cervical relaxation at term. Studies have shown that when highly purified porcine relaxin was placed directly on the external os of the cervix at 276 to 278 days of gestation, cervical relaxation occurred 8 to 12 hours later (Musah et al. 1986). Similar results have been obtained when parturition has been induced with dexamethasone (Musah et al. 1987). The reports on the effect of porcine relaxin on the cervix of the sheep are equivocal. Studies by Roche and associates (1993) has shown that a relaxin-like mRNA cannot encode a functional relaxin molecule, which suggests that sheep may not produce relaxin, and thus in this species, cervical relaxation may not be relaxin-dependent.

Relaxin also exerts an influence on myometrial activity, with several studies reported in domestic species, in particular the pig. In general, relaxin reduces both the frequency and amplitude of uterine contractions, particularly the former. It appears to act in concert with progesterone, oestrogens, oxytocin, and prostaglandins. Thus in the sow, although the progesterone concentrations have fallen significantly 10 to 24 hours before farrowing, with the removal of the progesterone block (see later in this chapter), myometrial activity is low (Taverne et al. 1979a). At this time, relaxin concentrations increase significantly. Furthermore, in sows there is a relationship between relaxin concentrations and the duration of farrowing (Wathes et al. 1989). After farrowing relaxin is present in the milk of the sow, and uptake during the first 48 hours may affect developmental programming of uterine and other somatic tissues of the newborn piglets (Yan et al. 2006).

Fetal Maturation

As has already been described, the fetal endocrine changes that occur in late pregnancy not only initiate parturition, but also stimulate a variety of maturational changes that enable the newborn animal to survive (Silver 1990, Mellor 1993). In the absence of these changes, sometimes referred to as 'preparation or readiness for birth' (Liggins et al. 1979, Rossdale & Silver 1982), neonatal death may occur because of malfunction of immature organs. Examples of some of the changes that occur are: physical, such as closure of the ductus arteriosus and foramen ovale; and functional, such as production of surfactant, the development of glucose homeostatic mechanisms, and changes in the structure of haemoglobin from the fetal to the adult form.

If premature induction with the exogenous hormones bypasses some of the endocrine changes that normally occur, the newborn may be unprepared. This has been demonstrated when goat kids, which were born after the injection of $PGF_{2\alpha}$, were compared with those that were born after induction with ACTH (Currie & Thorburn 1973). The link between parturition and maturation of the fetus appears to be related to the adrenal cortex and the prepartum surge of fetal cortisol (Liggins 1978, Silver 1992, Fowden et al. 2016).

During its intrauterine life the fetus is in a thermally neutral environment, but at birth it has to be able to maintain its own body temperature. The mechanisms which enable this are the accumulation of brown fat and glycogen in late gestation and maturation of the thyroid gland. The latter process occurs as a result of the prepartum rise in fetal cortisol, which stimulates the monodeiodination of the thyroid hormones, thus enhancing their biological activity (Liggins et al. 1979, Fowden 1995).

The maintenance of glucose homoeostasis immediately after birth, when the newborn loses its placental source of glucose, is dependent on adequate stores of liver glycogen. There is strong evidence that in sheep the stimulus for the accumulation of glycogen stores in late gestation is the rise in fetal cortisol (Jost et al. 1966; review by Fowden 1995). The glycogen stores are just sufficient to provide energy before sources of glucose become available from food. A similar stimulus to the production of insulin by the pancreas has also been attributed to the effect of elevated fetal cortisol, which enables the newborn to respond quickly to maintain glucose homoeostasis.

The fetal adrenal medulla also shows evidence of maturational changes in that its ability to produce catecholamines, especially adrenaline, is increased in response to asphyxia (Comline & Silver 1971, Hooper 1995) and hypoglycaemia (Fowden et al. 1998). There is also evidence that adrenaline, together with fetal ACTH and cortisol, stimulates lung maturation, and it promotes resorption of fetal fluids within the lung, thus enabling normal respiratory function to occur upon birth.

Although it is usually possible to predict approximately when parturition will occur in domestic species, there are obvious advantages in being able to predetermine when the event will occur. Many of the methods that are used have originated from studies of the endocrine changes responsible for the initiation of normal parturition. Since the first published reports of preterm induction by Van Rensburg (1967) in the ewe and Adams (1969) in the cow, a large number of successful reports have been published in these two species as well as in the doe, sow, and mare; recently, also some success has been achieved in the bitch and the cat.

VetBooks.ir

Mare

The indications for the preterm induction of foaling are few, the main one being to ensure that it occurs in the presence of skilled assistance; then if dystocia occurs it is possible quickly to correct the difficulty so as to ensure survival of the foal and reduce the danger to the mare. There are also a few occasions when, because of disease or illness in the mare, it may be advantageous for preterm foaling to be induced. The main problems with this in mares are in fact not related the effectiveness of the agents used (see later in this chapter) but with estimating the optimum time for the birth of the fetus, given the wide range of normal gestation lengths. Even when induction takes place close to an estimated time based on the time of mating and ovulation, as well as physical changes in the mare, foals can be premature or dysmature at birth. Therefore it is recommended to examine the degree of relaxation of the sacrosciatic ligaments and the cervix and to measure the ionic composition of mammary secretions (as signs of readiness for birth) before a treatment is initiated.

A number of different hormone preparations have been used. Early reports (Britton 1972, Purvis 1972) described the successful induction of over 1500 foalings with an intramuscular injection of very high doses of oxytocin, either with or without priming with stilboestrol dipropionate. If the cervix showed evidence of 'ripening', i.e., was soft on palpation and able to allow the insertion of one or two fingers into the external os, and the foal was in the normal disposition for birth, oxytocin was given at a dose of 120 IU to mares between 360 and 600 kg live weight. Foaling occurred 15 to 60 minutes later. Purvis (1972) recorded no difficulty with placental retention, although this was a problem in the cases described by Rossdale and Jeffcoat (1975). A relationship between the dose of oxytocin and placental separation has been demonstrated (Hillman 1975); doses of < 60 IU resulting more often in retention.

Close to term, much lower doses of oxytocin (< 10 IU) appear effective (Pashen 1980, Chavatte-Palmer et al. 2002). In a more recent study (Villani & Romano 2008) 174 standard-bred mares were treated with daily intramuscular injections of 3.5 IU oxytocin once the calcium concentrations in mammary secretion had reached a level of ≥ 200 ppm; another 176 mares were allowed to foal spontaneously. Of the treated mares 68.9% foaled within 2 hours after the first (51.3%), second (14.2%) or third (3.4%) daily injection. No significant differences were found in gestational length, duration of foaling, incidence of dystocia, and incidence of retained fetal membranes between the treated and untreated mares. Induction of foaling with oxytocin is based on a direct stimulating effect on the myometrium and indirectly by stimulating uteroplacental prostaglandin release (Pashen & Allen 1979). There is evidence that intracervical application of prostaglandin E2 to ripen the cervix before induction favours a shorter delivery (Rigby et al. 1998).

In the experience of one of the authors, dystocia has sometimes occurred at induced foalings due to the lateral position of the foal (see Chapter 14), as a result of incomplete rotation before the onset of the second stage of parturition. Furthermore, foal viability can be poor due to anoxia during expulsion because of premature placental separation. It is important to know the precise gestational age because induction should not be attempted before 320 days; even then, because of the wide variation in the gestation length in the mare (as already stated previously), foal viability is poor.

Dexamethasone, a quick-release synthetic corticosteroid, has been used successfully to induce foaling in ponies (First & Alm 1977) and large 'saddle-type' mares (Alm et al. 1975). A dose rate of 100 mg every day for 4 days resulted in parturition 6 to 7 days after the start of treatment in the latter type, although the ponies responded more rapidly. The regimen was started at 321 days of gestation, with satisfactory foal survival and subsequent growth rate. The inconvenience of the repeated dosing and the delay and unpredictability in completion of foaling makes this method unattractive to clinicians.

$PGF_{2\alpha}$ and its analogue fluprostenol have also been used to induce foaling (Ousey et al.1984, Ley et al. 1989). A single dose of $PGF_{2\alpha}$ is not always effective; quite often, it is necessary to use repeated injections of 1.5 to 2.5 mg every 12 hours. In some cases these prostaglandins can cause serious discomfort and can result in a high incidence of dystocia due to abnormalities in the position of the foal (Allen 1980). Fluprostenol will successfully induce foaling between 322 and 367 days of gestation when given as a single dose of 250 µg to ponies, and 1000 µg to thoroughbred mares (Rossdale et al. 1976). The time from injection to the onset of second stage labour ranged from 33 to 183 minutes; the second stage lasted 5 to 33 minutes, and the placenta was shed by 112 minutes. The viability of the foals was generally good, although a number suffered rib damage.

Cow

The indications for the preterm induction of calving are as follows:

- Advancing the time of calving to coincide with the availability of suitable pasture for milk production. This is used in New Zealand and parts of Ireland. In the latter country it is important that the cows calve over a period of 3 months as close to 23 March as possible (O'Farrell 1979). O'Farrell has calculated that for every day that a cow calves after this date the yield is reduced by an average of 6.4 litres per day; he found that over 40% of the cows were in this category. This indication for induction might face farmers and their veterinarians with an ethical problem, in cases in which the induction results in the birth of an immature or premature calf that will not survive after birth.
- Ensuring that cows calve at a predetermined time when skilled assistance is available so that prompt attention can be given. This should reduce calf mortality and injury to the cow.
- Reducing the birth weight of the calf by shortening the length of gestation. During the last weeks of gestation the growth rate of the calf is rapid; in some of the exotic breeds, such as the Charolais, the live weight of the calf can increase by between 0.25 and 0.5 kg per day. Thus if the dam is immature with a small pelvis or pregnancy is prolonged beyond 280 days, as occurs in some more exotic breeds, the calf may be too large to traverse the birth canal. Premature induction can thus reduce the likelihood of dystocia due to fetomaternal disproportion (see Chapter 15). With this indication the stage at which calving is induced must be a compromise between the birth of the calf which is small enough to be born unaided and yet is large enough to be viable, and subsequently to have an adequate growth rate. This threshold weight will vary from breed to breed. In the pluriparous Aberdeen Angus and Hereford cow it is 40 kg, for the pluriparous Friesian 42 to 45 kg, for the 2-year-old Charolais 35 kg, and for the 3-year-old Charolais 40 to 45 kg (Meniscier & Foulley 1979).
- In diseased or injured cows in which the termination of pregnancy will alleviate the condition or in which a live calf can be obtained before slaughter, premature induction may

VetBooks.ir

be used. Cows suffering from hydrallantois will frequently respond.

A number of different hormones have been used successfully to induce calving so that a live calf is born. Because induction before 95% of the breed's normal gestation length has been passed will usually result in the birth of a small, weakly calf with poor prospects of survival (Nakao 2001), it is important that the date of service or insemination is accurately known. For the Holstein-Friesian breed, calves delivered before days 260 to 265 have a poor prognosis for spontaneous survival.

Although ACTH has been used to induce calving, because it exerts its effect by stimulating endogenous corticosteroid production, it is best replaced by the direct administration of corticosteroids. A number of potent synthetic ones are available. There are three main categories; these are referred to as long-acting, medium-acting, and short-acting, their classification being based upon the duration of the latent period (time interval from treatment to effect). Thus when given at a normal therapeutic dose rate, the long-, medium-, and short-acting corticosteroids have latent periods of 11 to 18, 5 to 11, and 1 to 6 days, respectively (Parkinson 1993). It is important to give large breeds of cows an adequate dose; in the case of betamethasone, up to 35 mg is necessary in the Charolais. Corticosteroids are also immunosuppressive, and thus they should not be given without broad spectrum antibiotics if infection is present; the lungs and udder should be carefully examined beforehand.

PGE_1, PGE_2, $PGF_{2\alpha}$, and analogues of the latter have been used. In the first reported use of prostaglandins (Zerobin et al. 1973), a minority of calvings were described as being associated with 'explosive expulsions', a 42% incidence of dystocia due to poor cervical dilation was also reported by Hendricks and colleagues (1977). However, both $PGF_{2\alpha}$ and the analogues have been successfully used from about 275 days of gestation with a latent period of 2 to 3 days (Kordts & Jöchle 1975, Day 1977, Breeveld-Dwarkasing et al. 2003a, Shenevai et al. 2012).

Good results have been obtained by using a combination of corticosteroid and prostaglandin. Beal and associates (1976) injected $PGF_{2\alpha}$ if no effect had occurred 40 hours after treatment with dexamethasone. Day (1978) obtained good results using a prostaglandin analogue, cloprostenol, administered 8 or 12 days after pretreatment with dexamethasone trimethylacetate; all the cows calved within 72 hours. In a similar trial involving 26 adult Friesian cows ranging in gestation from 237 to 270 days, 20 mg of dexamethasone phenylpropionate was given and induced calving in 13 cows on average 5.6 days later. Those that failed to respond received 500 µg of cloprostenol after 10 days, and all calved within 3 days; all live born calves survived (Murray et al. 1982). In summary, for early induction (250–270 days of gestation, when the placenta might still contribute to progesterone production), a long-acting corticosteroid is administered followed by a short-acting corticosteroid or $PGF_{2\alpha}$ after 8 days if calving has not occurred; the latent period is about 48 hours. After 270 days a medium-acting corticosteroid, with either a short-acting corticosteroid or $PGF_{2\alpha}$ after 8 days if the cow has failed to calve, is used. After 275 days, $PGF_{2\alpha}$ or short- or medium-acting corticosteroids are effective on their own. Experimental use of the progesterone receptor antagonist aglepristone demonstrated that, although calving could be initiated with complete opening of the cervix, expulsion of the calves was impaired, apparently because of insufficient myometrial contractility (Shenevai et al. 2010).

However, there are some disadvantages of preterm induction of calving:

- It is not always effective.
- The birth weight of the calf is lower than it would have been at term.
- There is also a high incidence of retained fetal membranes, up to 53% when 'short-acting' preparations are used (Wagner et al. 1971), although it is less common after the use of slow-release preparations (Welch et al. 1973, O'Farrell & Crowley 1974). Even inductions close to term pregnancy may still result in a high incidence of placental retention (Hartmann et al. 2013).
- Milk yield is initially affected, with a delay in reaching peak lactation, although there appears to be very little influence on the overall yield (Bailey et al. 1973, Welch et al. 1977, O'Farrell 1979).
- Subsequent fertility is fairly normal (Mansell et al. 2006, Nakao 2001), although the calving to conception interval and the number of services per conception are slightly increased in those cows that retain their fetal membranes.
- There is a reduction in the quality and quantity of colostral immunoglobulins, especially after the use of slow-release corticosteroid preparations, although it is unlikely that the calf will not acquire an adequate passive immunity.

Sow (See Also Chapter 19)

On average 5% to 7% of all piglets are stillborn, and it is estimated that 75% of stillbirths occur during parturition. The time interval between the birth of the first and last piglets is associated with the stillbirth rate (Randall 1972, van Dijk et al. 2005), so that prolonged farrowing results in an increase. Probably 80% of the stillbirths occur in the last third of the litter to be born.

It has been shown that the time interval between the births of two live piglets is generally shorter than the time interval which precedes the birth of a stillborn piglet (van Dijk et al. 2005). The death of the piglet may have been due to a delay in expulsion, although there is good evidence that dead piglets are expelled more slowly. One of the causes of stillbirth is the premature rupture of the umbilicus; surveys have shown that 94% of stillborn piglets had ruptured umbilical cords at birth, compared with 39% when all piglets were included (Randall 1972).

The stillbirth rate can be reduced by intensive care and attention during farrowing (Holyoake et al. 1995); however, the time of farrowing can be difficult to predict. For this reason the induction of farrowing of groups of sows at predetermined times has many attractions because this can enable a skilled person to be in attendance to a group of sows during normal working hours. Because there is also evidence that delayed or prolonged parturition can increase the stillbirth rate, then methods which accelerate the process, or at the very least prevent delays, have obvious attractions. There are also a number of other management requirements that have stimulated the application of methods to plan and regulate the timing of farrowing:

- Group farrowing facilitates multiple suckling and allows crossfostering to take place. Thus the piglets from sows with large litters or agalactia have a greater chance of surviving and being reared.
- Groups of sows and litters can be managed on an 'all in, all out' principle, thus enabling disinfection and cleaning to be performed more efficiently.
- Group farrowing facilitates group weaning.
- Farrowing can take place on certain days of the week and during normal working hours; as well as reducing the stillbirth

VetBooks.ir

rate, it can reduce the death rate due to overlaying of newborn piglets.
- It might increase the reproductive efficiency by reducing the farrowing interval by a few days.

Although synthetic corticosteroids have shown to be effective for preterm induction of farrowing, there are cheaper and more attractive alternatives for treatment (Guthrie 1985). Since the first reports of successful induction of farrowing using $PGF_{2\alpha}$ (Diehl et al. 1974, Robertson et al. 1974) or a synthetic analogue (Ash & Heap 1973, Willemse et al. 1979), a large number of reports have been published worldwide. It is now an accepted procedure in the pig industry. More recently, attempts have been made to improve its efficiency by combining prostaglandins with other hormones to even further reduce the interval between treatment and onset of expulsion of piglets.

The basic procedure using prostaglandins is that either natural $PGF_{2\alpha}$ or a synthetic analogue, such as cloprostenol, is injected intramuscularly on days 111 to 113 of gestation; farrowing will occur on average 28 hours later. Thus, if the timing of injection is between 0800 and 1000 hours, the majority of sows will farrow during normal working hours. Adjustments have to be made for herd variations in the average gestational length. In general, the earlier the time of induction, the lower the birth weights; however, piglets delivered after PG induction at 92% gestational length were behaviourally immature and few survived after 24 hours (Silver et al. 1983). If attempts are made to delay the time of induction in order to obtain larger birth weight, the degree of synchronisation is not as good.

In an interesting study involving the use of dinoprost to induce farrowing on 229 occasions (Young & Harvey 1984), it was found that 95% of farrowings occurred within 48 hours of injecting dinoprost, the majority (76%) within 24 to 36 hours, which corresponded with normal working hours on the farm. Those sows that did not farrow within 48 hours were deemed not to have responded to the injection of prostaglandin. Apart from very small litters (up to five piglets), litter size had no effect upon the response to prostaglandin; however, the duration of farrowing was directly related to litter size.

There is apparently no difference in the efficiency of $PGF_{2\alpha}$ (dinoprost) or the analogue cloprostenol, although it is generally recognised that side effects such as biting cage bars and increased respiration rate are greater after natural $PGF_{2\alpha}$ (Boland et al. 1979, Einarsson et al. 1981, Widowski et al. 1990). Recently, the use of vulvar injections of a split-dose (50% of the label dose at a 6-hour interval) was recommended to obtain a higher proportion of responding sows (De Rensis et al. 2012).

Improved expulsion of the piglets was observed when cloprostenol was combined with oestradiol benzoate. Bonte and colleagues (1981) reported that the best expulsion occurred when 10 mg of oestradiol benzoate was given 24 hours before cloprostenol, although there was some improvement when 1 mg of oestradiol benzoate was given 5 to 6 hours after cloprostenol. Kirkwood and Thacker (1995a) treated sows with 3 mg oestradiol on day 112 followed by 10 mg $PGF_{2\alpha}$ on day 113 and found that 38% of sows farrowed before 0800 hours on day 114 compared with 5% in the control group. It should be noted that within the European Union the use of oestrogens has been legally banned.

The induction with prostaglandins is based on its luteolytic effect, with the peripheral plasma progesterone rapidly declining within 12 hours after injections. Yet natural prostaglandin $F_{2\alpha}$ also causes a temporary stimulation of the myometrium and oxytocin release (Ellendorff et al. 1979b), and this even results in a transient hypoxia of the piglets in utero (Randall 1990). Oxytocin has also been used routinely in combination with $PGF_{2\alpha}$ as part of induction protocols, the most common approach being to administer it 24 hours after prostaglandin. This usually resulted in a significant reduction in the interval to farrowing, although the response may be related to the litter size (Chantaraprateep et al. 1986). Others have used repeated injections of oxytocin (Zarro et al. 1990). It is important that dose rates of oxytocin of about 10 IU should be used because higher dose rates will cause myometrial spasm and may even delay farrowing. In a study in which 20 IU of oxytocin was given at 24 hours after PG administration, a high proportion of manual intervention was needed for those sows that had the best synchrony of the onset of delivery (Dial et al. 1987).

Ewe

Parturition can be induced in the ewe by means of corticosteroids or by drugs that will either inhibit the synthesis of progesterone (such as epostane) or block progesterone at the receptor level. The indications for preterm induction are limited because dystocia due to fetomaternal disproportion is not as common as in cows (see Chapter 15). However, a system that can guarantee that lambing will occur only during the hours of daylight when skilled assistance is available might reduce any problems due to dystocia and increase lamb survival rates. However, it is not possible to shorten gestation length by more than 7 to 10 days without increasing lamb mortality.

As with other species, an accurately known gestational age is important. When corticosteroids such as dexamethasone, flumethasone, and betamethasone are given by a single intramuscular injection within 5 days of term, normal parturition occurs in 2 to 3 days (Bosc 1972, Bosc et al. 1977, Penning & Gibb 1977, Kastelic et al. 1996). Cahill and associates (1976), using similar methods, had a higher than normal incidence of dystocia with poorer lamb survival. Unfortunately, attempts to concentrate lambing during the hours of daylight by premature induction with corticosteroids have not been very successful (Bosc 1972). Induction of lambing in groups of ewes that have been synchronised with progestogens (see Chapter 8) can ensure that ewes lamb over a relatively short period of time in a single batch. When the 3β-hydroxysteroid dehydrogenase inhibitor epostane was given (orally, intravenously, or intramuscularly) between days 136 and 142, birth of viable lambs occurred between 33 to 36 hours after application (Silver 1988). The intramuscular injection of the progesterone receptor antagonist RU 486, both on day 144 and 145 days of pregnancy, significantly advanced the birth of viable lambs (Gazal et al. 1993). Recently, Özalp and colleagues (2017) demonstrated that two injections (on day 140 and 141) of aglepristone (either 5 or 10 mg/kg body weight) could precisely control the lambing time without any adverse side effects in either mothers or lambs.

Doe (Nanny) Goat

Preterm induction of parturition in goats can be achieved by using a luteolytic dose of natural prostaglandin $F_{2\alpha}$ (Romano et al. 2001) or its synthetic analogues (Batista et al. 2008). Some 80% of the treated animals delivered their kids between 30 and 40 hours after injection given on day 145 of gestation. Dystocia and retention of the fetal membranes did not occur.

Bitch and Queen Cat

Because of side effects and the need for repeated treatment, $PGF_{2\alpha}$, is not an attractive option for the induction of parturition at term. The steroid enzyme inhibitor epostane, the prolactin inhibitors

VetBooks.ir

cabergoline and bromocriptine, and progesterone receptor blocking agents have been used successfully for the induction of abortion in dogs and cats (Lamm & Makloski 2012). Studies by Fieni and colleagues (2001) and Baan and colleagues (2005) demonstrated that progesterone receptor blocking agents such as mifepristone and aglepristone can also be used for the induction of whelping, without any adverse effects on the progress of delivery, birth weights, and pup survival rates. However, in a more recent study with different breeds (Fontbonne et al. 2009) the duration of the mean interval between two successive expulsions was significantly longer in the induced group than in the control group.

Accelerating Parturition

Oxytocin, administered as a bolus injection, has long been used to treat sows that appeared to be suffering from uterine inertia as shown by prolonged farrowing times. In such cases this treatment should always be preceded by a vaginal exploration to detect if a piglet within the pelvic canal or a piglet in faulty disposition cranial to the pelvic inlet is the primary cause of the prolonged farrowing. Routine use of oxytocin 1 to 2 IU used repeatedly in delayed farrowing was effective in accelerating the process. Doses in excess of 10 IU induce uterine spasm and are contraindicated (Zerobin 1981, Taverne 1982). Depot or slow-release oxytocin preparations are not effective.

Studies by Pejsak and Tereszczuk (1981) in which 10 IU of oxytocin was given to 836 primiparous and pluriparous gilts and sows by the intramuscular or intranasal route as a routine procedure (during apparently normal parturitions and in the absence of prolonged farrowing) demonstrated some favourable results. In their regimen, oxytocin was given immediately after the birth of the first piglet and was repeated if there was a delay of more than 1 hour before the birth of the next piglet. If no response was observed in 10 to 20 minutes, a vaginal examination was performed. All the oxytocin-treated sows farrowed within 10 hours, although some in the control group exceeded this duration. However, more recent studies (Mota-Rojas et al. 2002, 2005, Alonso-Spilsbury et al. 2004), using injections of 20 to 50 IU of oxytocin (depending on maternal body weight) after the birth of the first piglet, clearly demonstrated that such treatment increases stillbirth rate, despite a significant shortening of the expulsive phase.

Apart from oxytocin, a wide range of other drugs have been tested in the past to control the timing and speed of delivery in piglets (review by Guthrie 1985) but very few of these treatments have become standard procedures. A beta-blocking agent, carazolol, has been used to shorten the duration of farrowing with encouraging results. The rationale behind its use is that during pregnancy, because ß-receptors in the uterus become dominant, the stress resulting in adrenaline release will cause relaxation of the uterus. If these receptors are blocked with carazolol, then in stressed animals (especially gilts) the adrenaline will have little or no effect upon the myometrium, the uterus will retain its tone, and parturition will not be delayed (Taverne 1982). In a double-blind trial involving 1000 sows using a dose rate of 0.5 mg/50 kg given at the beginning of labour, there was a significant reduction in the duration of farrowing ($P < 0.05$), a reduction in the stillbirth rate, and in the incidence of obstetrical complications, especially in gilts (Bostedt & Rudolf 1983). However, a study in which parturition was induced on day 113 with a PGF analogue and was followed (24 hours later) by an injection of the beta-blocking agent propranolol failed to show any effect on the onset or duration of parturition (Kirkwood & Thacker 1995b).

Delaying Parturition

ß-Adrenergic Agents

As already mentioned previously, delaying parturition has been accomplished in sheep, goats, and pigs (but not in mares) by the pharmacological inhibition of prostaglandin synthesis. In pigs this delay was based on the postponement of prepartum luteolysis (Taverne et al. 1982).

ß-Adrenergic agents, which stimulate the $ß_2$ receptors of uterine muscle cells, can abolish uterine contractions and delay parturition for a short time. One such substance, clenbuterol, has been used successfully in cows, sows, and ewes (Ballarini et al. 1980, Collins et al.,1980, Jotsch et al. 1981, Garcia-Villar & Toutain 1991). In cows, provided that the cervix is not fully dilated and second stage has not commenced, an injection of 0.3 mg of clenbuterol hydrochloride (10 ml), followed by a second injection of 0.21 mg (7 ml) 4 hours later, will inhibit calving for 8 hours after the second injection. As well as being used as a management tool, it can be effective in ensuring improved relaxation of the vulva and perineum in heifers. When the drug was given to cows in labour, it inhibited myometrial activity only briefly (< 3 hours), without adversely affecting fetal outcome (Jonker et al. 1991). In Welsh mountain pony mares, intravenous injections of clenbuterol failed to delay parturition (Palmer et al. 2002).

In sows clenbuterol causes relaxation of the myometrium and hence interrupts expulsion of the piglets. After several hours there is a return of spontaneous myometrial contractions without any adverse effects upon the viability of piglets. Zerobin (1981) obtained good responses with a dose rate of 150 µg. He also reported that the use of oxytocin will reverse the effect of the clenbuterol. In pregnant and parturient bitches, intravenous injections of the calcium-channel antagonist nifedipine were effective in inhibiting the mechanical and electrical activity of the myometrium in vivo (van der Weyden et al. 1989).

Course of Parturition: Physiology

The essential components of the birth process are the expulsive forces, the fetus(es) together with their associated fetal membranes and fluids, as well as the soft and bony parts of the birth canal. Normal birth will result when these forces are sufficient to expel a normal, correctly disposed fetus in the correct disposition (see Chapter 14) and fetal membranes through a dilated cervix into the birth canal of adequate dimensions.

The expulsive forces consist of the contractions of the myometrium and the abdominal musculature; the relative importance of these two components varies from species to species. During pregnancy the fetus occupies as small a space as possible; in order to do this it flexes its limbs and neck and, particularly in the monotocous species, assumes a disposition so that its dorsum is adjacent to the greatest curvature of the uterus. In order to negotiate the birth canal, the fetus must be correctly disposed so that its body conformation is as 'streamlined' as possible to match the shape and direction of the birth canal; this is particularly important in monotocous species. Finally, the birth canal must allow the passage of the correctly disposed fetus. Changes occur in the maternal structures that allow this to occur. The cervix must dilate, the bony pelvis and its related ligaments must relax, and the vagina, vulva, and perineum must soften. For extensive reviews on the comparative physiology of parturition, with special reference to the control of myometrial and cervical functioning, the reader is referred to: Gibb et al. (2006), Zakar & Hertelendy

VetBooks.ir

2007, Taverne & van der Weijden (2008), Aguilar & Mitchell (2010), and Yellon (2017).

Myometrial Contractions

The hormones that bring about some of these changes have already been discussed; however, the mechanisms involved in the myometrial contractions have not. The myometrium is formed from two main types of muscle protein, namely myosin and actin. The contractions of the myofibrils occur because of the formation of covalent crosslinked bonds between the actin and myosin filaments. Contractions are initiated when the ATPase of myosin light chain (MLC), which is one of the myosin components, is phosphorylated by the action of MLC kinase (MLCK). This enzyme, MLCK, is activated by the calcium-binding protein Calmodulin. Myometrial relaxation occurs because of dephosphorylation of MLC by the action of MLC phosphatase or cAMP-dependent protein kinase that inhibits MLCK, and hence phosphorylation of MLC. It is important to consider the structural arrangement of the smooth muscle bundles. In domestic species with a bicornuate uterus, the myometrium comprises two layers. In the outer layer the bundles are arranged parallel to the long axis of the uterus, so that when these contract, the uterus is shortened cephalocaudally. The myometrium is continuous with the cervix, which is fairly well secured within the pelvic cavity; thus when the longitudinal bundles contract, the uterine horns will be pulled caudally. When the uterus contains a full-term fetus, the ability of the uterus to shorten is reduced and, as a result, the contractions may cause some dilatation of the cervix. The inner layer of the myometrium is formed by bundles of fibres arranged concentrically around the longitudinal axis; thus these contractions will constrict the uterine lumen (Porter 1975).

During pregnancy, as a result of the stimulus of both progesterone and oestrogens on protein synthesis and the localised influence of distension by the developing conceptus, there is hypertrophy of the myometrium. In early pregnancy there is also some evidence of hyperplasia. As a result of this, the length of the myofibrils is increased ten-fold, and the width two-fold. Because the myometrial mass is increased, its work capacity is increased. Progesterone is necessary for the stretch-induced hypertrophy, but during the final days of gestation, when progesterone levels decline and/or progesterone effects subside, there will be discordance between fetal growth and uterine size, resulting in increased wall tension and formation of gap junctions between smooth muscle cells (Gibb et al. 2006). As well as the physical changes in the myometrium, there are also changes in the electrophysiology of the smooth muscle. It has been demonstrated that in many species during pregnancy, there is an increase in the resting membrane potential. With the prepartum rise in oestrogens and the removal of the progesterone block, there is discharge of action potentials and the initiation of myometrial contractions. The resting membrane potential of the oestrogen-dominated myometrial cell is also close to the threshold level for the spontaneous firing of action potentials. Thus if the myometrium is stretched, there is slight depolarisation and discharge of action potentials. In rats mechanical stretching induces the expression of several contraction-associated proteins (CAP's) such as Connexin-43 (involved in gap junction formation) and oxytocin receptors, and these effects could be antagonised by progesterone. These findings may have clinical implications for the progression of the expulsive stage, especially in polytocous species when embryonic or fetal mortality has resulted in more or less empty, i.e., nondistended segments within a uterine horn.

Effects of Progesterone and Oestrogens on Myometrial Activity

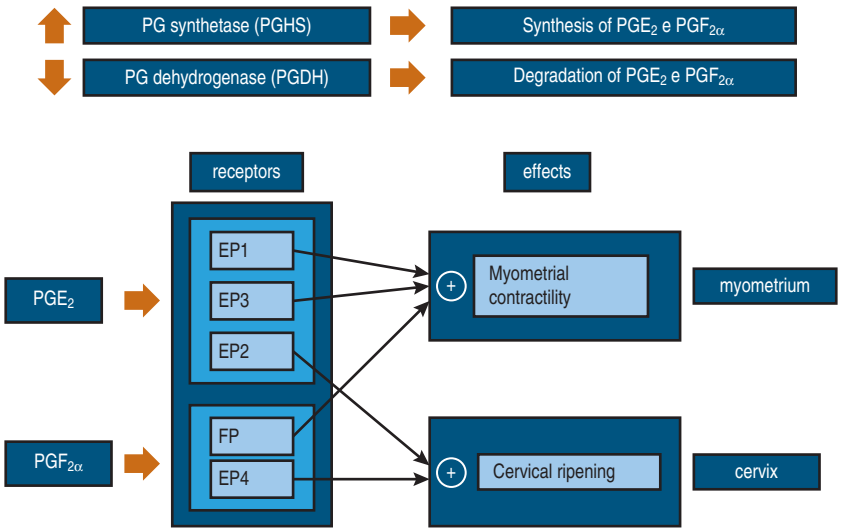
Progesterone dominance during pregnancy ensures that the myometrium remains relatively quiescent, although there is some evidence in some species that relaxin and PGI_2 may also play a role (see later in this chapter). Oestrogens have the reverse effect. Although the mechanisms involved are not fully understood, it has been suggested that oestrogens might exert their effect by: (1) increasing contractile protein synthesis; (2) increasing the number of agonist receptors for oxytocin and prostaglandins; (3) increasing calmodulin synthesis; (4) increasing MLCK activity; and (5) increasing the number of gap junctions, which are low-resistance pathways for the transmission of electrical and molecular information between smooth muscle cells. Oestrogens, in this way, increase the efficiency of the myometrium as a contractile unit. Progesterone has the opposite effects. It: (1) reduces the number of gap junctions; (2) reduces the number of agonist receptors; (3) inhibits the synthesis of prostaglandins and the release of oxytocin; and (4) increases calcium binding.

Role of Prostaglandins and Oxytocin

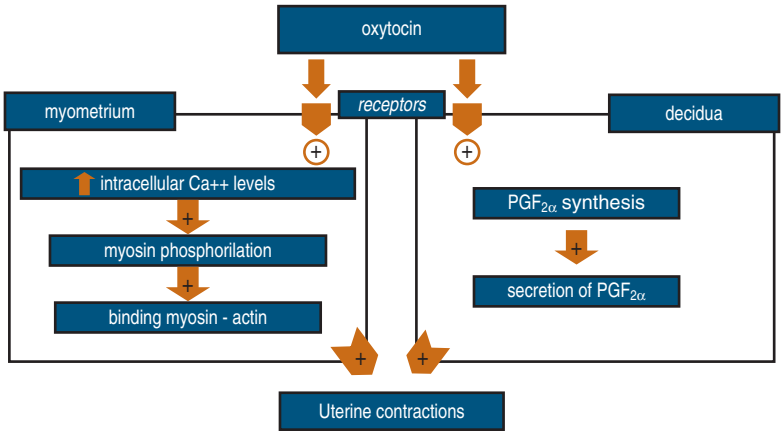
Prostaglandins play a critical role in parturition, not only in the initiation of the process but in the control of myometrial contractions. These actions are facilitated because the molecular structure of prostaglandins enables them to move freely through extracellular fluids and lipid cell membranes. In general, $PFG_{2\alpha}$ and PGE_2 are responsible for stimulating uterine contractions (although this may depend, at least in some species, on the localisation within the pregnant uterus), whereas PGI_2 inhibits uterine contractions (Omini et al. 1979). Availability of these prostaglandins within the uterine tissues depends on the relative expressions of enzymes involved in their synthesis and metabolism, and these are under the control of wide range of different steroids, peptide hormones, and cytokines. In general, the expression of enzymes catalysing the synthesis of PGF in uterine tissues is upregulated during parturition, whereas that of enzymes involved in PG inactivation are downregulated (Vannuccini et al. 2016; Fig. 6.7). Prostaglandins actions are mediated through specific receptors, and, as a consequence, they influence the number of gap junctions and also the intracellular mobilisation of Ca^{2+} of smooth cells; $PGF_{2\alpha}$ and PGE2 enhance and PGI_2 inhibits these changes.

The pattern of oxytocin release during late pregnancy and parturition has been studied in the ewe (Fitzpatrick 1961, Glatz et al. 1981), goat (Chard et al. 1970, Hydbring et al. 1999), mare (Allen et al. 1973, Vivrette et al. 2000), cow (Schams & Prokopp 1979, Hydbring et al. 1999), sow (Forsling et al. 1979a & b, Gilbert et al. 1994), and dog (Olsson et al. 2003, Klarenbeek et al. 2007). It is interesting that in all these species the oxytocin levels during late pregnancy and the early stages of parturition remain fairly low. In the cow, sheep, and goat, they rapidly increase to peak values at the time when the fetal head emerges from the vulva and when the fetal membranes are expelled. In the mare the first significant increase of oxytocin in samples taken from the intercavernal sinus was detected between 18 and 72 hours before delivery of the foal, clearly after an increase had already taken place in the plasma dihydro-15-keto $PGF_{2\alpha}$ levels (Vivrette et al. 2000). In pigs they only increase shortly before the start of the expulsive stage, remain elevated, but with considerable pulsatile fluctuations, during delivery of the piglets and decline thereafter. In dogs the release pattern still needs further investigation because pulses were detected in conjunction with, but also in the absence of, the birth of a pup (Klarenbeek et al. 2007). So at least in some

VetBooks.ir



• **Fig. 6.7** Prostaglandin effects on myometrium and cervix at parturition. (From Vannuccini et al. 2016.)



• **Fig. 6.8** Oxytocin effects on myometrial contractility. (From Vannuccini et al. 2016.)

of the species, oxytocin plays only a minor role in the initiation of uterine contractions.

The main release of this hormone occurs as a result of the stimulation of sensory receptors in the anterior vagina and cervix (Ferguson's reflex). There is certainly a good correlation between electromyographic activity and oxytocin release in the sow (Ellendorff et al. 1979a), which is suggestive of a local, positive feedback mechanism operating in the uterus of this species.

Oxytocin receptors increase during late gestation and with the onset of parturition; this is dependent mainly on the decline in progesterone and increase in oestrogens (pig: Lundin-Schiller et al. 1996; sheep: Wathes et al. 1996; cow: Fuchs et al. 1992). Little is known in domestic species about their distribution in the circular and longitudinal muscle layers. Oxytocin stimulates uterine contractions in two ways (Vannuccini et al. 2016; Fig. 6.8): first, by increasing prostaglandin release, with which there is a synergistic effect; second, by increasing Ca^{2+} release from the endoplasmic reticulum that increases MLCK phosphorylation (MacKenzie et al. 1990). An integrated view on oxytocin and its participation in the regulation of pregnancy and parturition is given by Burbach and colleagues (2006).

Stages of Labour

From a physiological point of view, parturition has been subdivided into four phases (Gibb et al. 2006):

- Phase 0 comprises some 95% of the duration of gestation, with the myometrium more or less quiescent and with the cervix hard and unyielding.
- Phase 1 is the activation phase, during which rapid softening of the cervix takes place and the myometrium becomes prepared for contractions to occur. This is induced by increased expression of CAP's, which occurs as a result of the removal of inhibitory factors (such as progesterone, relaxin), an increase of uterotrophic factors (such as prostaglandins, oestrogens), and increased stretching of the uterine wall. Thus this phase comprises all of the final endocrine events by which the fetal initiating signals are translated into functional changes in the cervix and myometrium.
- Phase 2 the stimulation phase, involves the first and second stages of labour (see later in this chapter) and is characterised by increasing myometrial contractility (by steep increases of PG in oxytocin release), dilatation of the cervix, and expulsion of the fetus(es).

VetBooks.ir

- Phase 3 comprises the afterbirth stage (but in fact only in those species in which the fetal membranes are expelled one or more hours after the fetus) and the start of uterine and cervical involution (see Chapter 7).

More traditionally, and from a more practical perspective, the process of parturition has been divided into three separate stages which are referred to as 'the stages of labour'. Although it is convenient to consider the process in this way, it is important to remember that these stages do not start and end abruptly, but pass gradually from one to the other.

First Stage of Labour

The changes that occur during this phase of parturition are not visible externally but are important because they prepare the birth canal and the fetus for expulsion. A number of important changes occur. First, the structure of the cervix changes so that it can dilate; second, there is the onset of myometrial contractions; and finally, the fetus assumes the disposition for expulsion, which involves (in monotocous species) rotation about its longitudinal axis and extension of the extremities.

The changes in the structure of the cervix have been studied and reviewed (Fitzpatrick 1977a and b, Fitzpatrick & Dobson 1979, Dobson 1988, Breeveld-Dwarkasing et al. 2003b). They involve a loosening of the ground substance of its structure due to changes in the composition of collagen components. There is also increased incorporation of water, which permits the collagen fibres to separate from each other particularly under the extension forces, and possibly also allows ready access of previously inactive proteases to susceptible sites for the breakdown of the collagen molecules. These biochemical changes are mediated by complex interactions between cytokines and prostaglandins, as well as peptides and steroid hormones; these show many of the characteristics of an inflammatory process (see reviews by Kelly 2002, Keelan et al. 2003, Yellon 2017). In all of the species investigated so far, these processes already start under the dominance of progesterone during the second half of pregnancy.

The cervix of the cow dilates, with the external os opening before the internal os (Abusineina 1963); the same has also been reported in the ewe (Fitzpatrick 1977b). The time taken for cervical dilatation varies. In the sow, using sequential vaginal exploration, it was found that it takes between 1 hour and 2 days, with 50% taking 6 to 12 hours (Schmid 1937). In the cow the dilatation of the external os has been measured in vivo during PG-induced calvings (Breeveld-Dwarkasing et al. 2002, 2003a). It started, on average, 28.5 hours after PG injection at a rate of 2.6 cm per hour. The mean interval between the onset of dilatation and expulsion of the calf was about 9 hours. The mechanism responsible for dilatation is still not fully understood. For many years it was assumed to be a passive process brought about by the passage of the fetus and the fluid-filled fetal membranes through the ripened cervix. It has also been suggested that it is mainly an active process caused by the contraction of the longitudinal muscle bundles. More recently, it has been demonstrated that the outer smooth muscle layer of the cervix displays clear electromyographic activity during dilatation at (induced) calving, usually in conjunction with that of myometrial EMG activity (van Engelen et al. 2007). However, it has been found that in some ewes only weak myometrial contractions precede dilatation (Hindson et al. 1968), and in some women the cervix can dilate in the absence of uterine contractions (Liggins 1978). Ledger and associates (1985) demonstrated that in ewes, even when the cervix and uterus were isolated surgically, cervical softening still occurred. Thus the biochemical changes, previously described, are possibly more important than the contributions from the smooth muscle of the cervix or myometrium. These changes are probably not just the degradation of collagen, but rather a remodelling of the cervical matrix with new collagen and proteoglycan synthesis (Challis & Lye 1994). It is likely that in normal parturitions it is a combination of active and passive mechanisms.

In the cow there is initially wide dilatation of the external os, whose perimeter is palpable as a frill at the cranial end of the vagina. The cone-shaped cervix then undergoes a simultaneous shortening, before the internal os dilates, and when this has occurred, the vagina and uterus form a continuous canal which becomes tightly engaged by the distended allantochorion. In women this process has been visualised by ultrasonographic imaging, but this still awaits exploration in domestic animals.

The first stage of labour is also characterised by the onset of regular myometrial contractions, which frequently produce signs of discomfort and mild colic, the degree of response varying from species to species and from individual to individual. However, in most cases there is restlessness with elevated pulse and respiratory rates; the body temperature usually (but not consistently) falls a degree or so. In the sheep and goat during late gestation, uterine contractions, either measured by intrauterine pressure changes or by EMG activity, occur once every 30 to 60 minutes; they are of low amplitude but of 5 to 10 minutes' duration. To discriminate them from the typical labour-like contractions, they have also been labelled as 'contractures'. This pattern continues until some 48 to 24 hours before parturition; thereafter their frequency and amplitude increase and their duration decrease. It is only in the last 12 hours, and in some ewes in the last 2 hours, that clearly coordinated contractions occur at a regular frequency (30 per hour), of short duration (1 minute) and substantial amplitude (20–25 mm Hg) (Fitzpatrick & Dobson 1979). Ward (1968) found that there is a significant increase in myometrial activity during the last 4 hours before the expulsion of the lamb.

In the cow, contractures last on average some 12 minutes during late gestation, and they predominantly occur when the animals are recumbent (Taverne et al. 2002). They are gradually transformed to a more regular coordinated peristaltic type, which started (in induced calvings) some 16 hours after PG injection (Breeveld-Dwarkasing et al. 2003a). The frequency of intrauterine pressure waves increases from 12 to 24 per hour in the last 2 hours, and 48 per hour just before expulsion (Gillette & Holm 1963, Burton et al. 1987). One feature identified in the cow (Gillette & Holm 1963, Taverne et al. 1979c), which will also be discussed later in this chapter in the sow, was the presence of cervicotubular and tubular–cervical contractions. The function of the former type is not known in the cow.

The myometrial contractions in the sow are more complex, which is not surprising because each pregnant uterine horn may reach a length of 1.5 to 2 metres at the end of gestation. In sows, contractures have been found during pregnancy using EMG recordings, and they switch to a more regular and coordinated pattern between 6 and 9 hours before the birth of the first piglet (Taverne et al. 1979a). Using pressure measurements, this transition was found to occur somewhat earlier: IUP waves increased in frequency and amplitude and became more regular 12 to 72 hours before the onset of the second stage (Zerobin & Spörri 1972, Ngiam 1977). Contraction frequencies of 8 to 24 per hour and durations of 0.5 to 3.5 minutes at amplitudes up to 60 mm Hg have been recorded from about 24 hours prepartum. A change in the pattern of the contractions was observed by Zerobin and Spörri (1972) at the time that milk appeared in the teats. The same authors, using pressure

VetBooks.ir

recordings, and Taverne and colleagues (1979b), using myoelectrical techniques, identified the presence of cervicotubular and tubular–cervical contractions. The latter authors observed that once one of the horns was empty, cervicotubular contractions decreased or disappeared, yet tubular–cervical contractions remained present in the opposite horn as long as it contained piglets. Because it has been known for some time that uterine volume is important in regulating myometrial activity by altering myoelectrical activity (Csapo et al. 1963), it has been postulated that the cervicotubular contractions prevent the premature displacement of piglets, thus ensuring orderly expulsion from the horns (Taverne et al. 1979b).

In late pregnant bitches, contractures of the myometrium have been recorded using electromyography (van der Weijden et al. 1989). During the last 7 days before delivery, there is a progressive increase of more short lasting EMG bursts that is correlated with a gradual decline of the plasma progesterone levels. A significant increase of total EMG activity and burst frequency occurred between 24 and 13 hours before delivery, coinciding with a sudden fall in body temperature and plasma progesterone.

The contractions of the uterine musculature cause other changes in the uterus and probably also in the fetus. In the placenta the attachments to the endometrium become less intimate, and the superficial cells undergo fatty degeneration, whereas in those species with a deciduate placenta, separation of the margins, with haemorrhage, is beginning. Yet placental attachment normally stays intact during parturition and is only disrupted at expulsion (dog and cat) or after expulsion of the fetuses (pig, mare, ruminants). The increased resistance to blood circulation in the maternal side of the placenta during contractions causes a correspondingly reduction of blood gaseous exchange in the placenta, and this may be reflected by temporary changes in fetal P_{O_2} and fetal heart rate (Jonker et al.1996). On the maternal side this impediment to circulation may aid diversion of blood to the mammary glands.

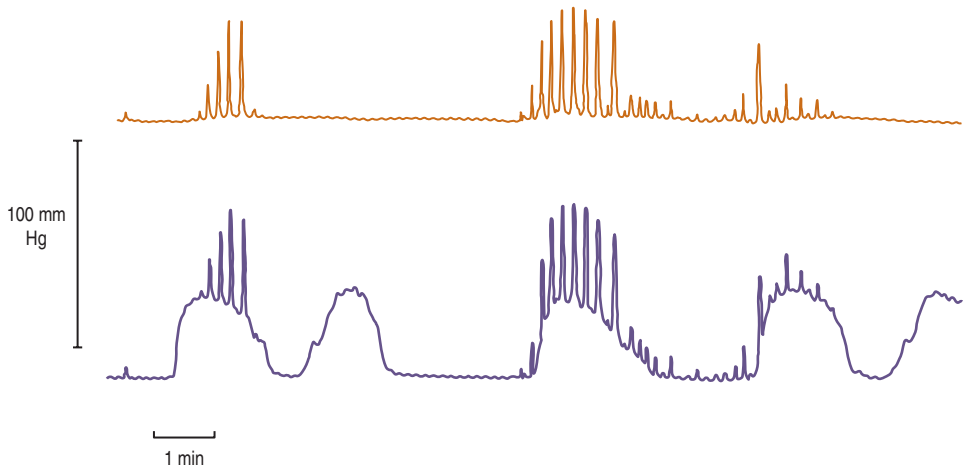
As regards the fetus in first stage labour, it becomes more active and disposes itself in a manner that will allow it to negotiate the birth canal. Thus in the foal there is a progressive rotation from the ventral to the dorsal position, whereas the forelimbs, head, and neck become extended (Jeffcott & Rossdale 1979). Also, in the case of the calf and lamb, rotation to a dorsal position and extension of the forelegs is necessary to change the fetus from its gestational position and posture to that for parturition (Fraser & Terhurne 1977). The nature of the mechanism whereby the forelimbs become straightened in front of the body is unknown. In the bovine species this is a unique attitude that is never repeated after birth. In his studies of the first stage of labour, Abusineina (1963) noticed that the flexed knees of the calf first occupied the dilating cervix and 30 minutes later the digits were in the cervix. It has been suggested that at this time the fetus is 'practising' righting reflexes and that it extends the carpal joints in its efforts to 'stand up in utero'. It is likely also that these spontaneous fetal movements occur in response to increased uterine pressure caused by the myometrial contractions during the first stage. If this view is correct, then the mother, through the medium of an indifferent myometrial function, could be partly responsible for fetal dystocia due to postural errors (see Chapter 14). With further reference to the importance of myometrial function, it is significant that, when birth is premature, cervical dilatation is often incomplete, and fetal postural defects are then common; also retention of the afterbirth is likely. All these clinical effects may be partly due to relative uterine inertia, which may result from a disordered sequence of preparturient endocrine events.

Second Stage of Labour

In the monotocous species this refers to the expulsion of the fetus; however, in polytocous species the fetal membranes are sometimes voided together with fetuses, and hence there is no clear differentiation between the two stages.

The sign of the onset of second stage is the appearance of abdominal contractions. In the cow it has been shown that 8 to 10 of these are superimposed upon the onset of each myometrial contraction, whose frequency at this stage is 24 to 48 per hour, so that one contraction is almost immediately followed by another (Gillette & Holm 1963, Zerobin & Spörri 1972). Similar observations were made in the ewe in which the frequency of contractions increased to 40 per hour, with only very short periods of rest, and intrauterine pressure was increased to 30 to 40 mm Hg with each contraction (Fitzpatrick & Dobson 1979).

In many species the superimposition of abdominal contractions upon myometrial contractions has been demonstrated; this is shown in an intrauterine pressure recording obtained from a sow (Fig. 6.9). It should be remembered that these abdominal contractions, which cause straining, are not related directly to the release of oxytocin and should not be confused with Ferguson's



• **Fig. 6.9** Pressure changes at parturition in the sow. Upper trace is from a balloon-tipped catheter placed in the peritoneal cavity. Lower trace is from an intrauterine balloon-tipped catheter.

VetBooks.ir

reflex. The coordination between the two is due to the fact that the myometrial contractions force the fetus into the pelvic inlet, which activates the pelvic reflex and stimulates straining; this is a similar response to the one that stimulates defecation. The straining forces the fetus against the cervix and anterior vagina, thus initiating Ferguson's reflex, so that the oxytocin that is released causes further contractions of the myometrium. As already indicated previously, especially in the monotocous species, it is during this stage that peak levels of plasma oxytocin are present.

The allantochorionic sac ruptures as a consequence of its caudal movement being restricted by its placental attachments, and a gush of urine-like fluid escapes from the vulva. The distended amnion, together with parts of the fetus, are forced into the pelvic inlet, thus stimulating the pelvic reflex, which induces powerful contractions of the abdominal muscle. Similar, substantial straining occurs later when first the fetal shoulders and later the fetal hips engage the pelvis. These distensions of the maternal birth canal cause great increases in the release of oxytocin from the posterior pituitary, which in turn stimulates myometrial contractions; thus there is a conjunction of uterine and abdominal expulsive efforts. As the intermittent straining continues, the amnion traverses the vagina and appears at the vulva as the 'water bag'. With further straining, fetal limbs appear in the water bag; in the case of the monotocous species, one limb slightly precedes the other. The amnion is progressively expelled and may or may not become ruptured by a fetal foot, with escape of some of the lubricant amniotic fluid. The fetal head next occupies the vulva, and at this time the contractions of the uterine and abdominal muscles reach a climax of expulsive effort, maximum effort coinciding with the birth of the fetal occiput. When the head is born, the mother may rest for a bit, but soon a further bout of straining causes the fetal thorax to pass through the vulva. Usually, birth of the hips quickly follows, and the hindlimbs may be expelled at the same time; in many cases in the monotocous species, there is no further expulsive effort after the birth of the hips with the hindlimbs remaining in the vagina until they are freed either by movement of the newborn or by the mother rising from recumbency.

If the fetus is born in the amnion, or if the partially ruptured amnion covers the face of the offspring, fetal movement quickly causes it to be ruptured or drawn away; respirations, often accompanied by a cry, then begin. There seems to be very little risk of a healthy fetus being suffocated by an enveloping amnion. The stimulus to breathing is apparently the impact of air at the nostrils and/or fetal hypercapnia, for occasionally. during the expulsive phase of equine and bovine births when the protruding face has become uncovered, breathing had commenced before delivery was completed. On the other hand, sometimes expulsion apparently occurs so quickly (especially in pigs) that the newborn lies completely immobile behind the sow and will start to breathe many seconds later.

When the mother gives birth in lateral recumbency, the offspring is often born with an intact umbilical cord, and some minutes may elapse before the cord is ruptured by movement of the young animal or mother. This is especially true at foaling. It is important to allow this to happen naturally, for artificial and premature rupture, or ligation, of the cord may deprive the newborn of a large volume of blood, which would normally pass to it from the placenta. In piglets the umbilical cord may become stretched or may even rupture during delivery (see later in this chapter). In ruminants rupture occurs close to the umbilicus, at which point the umbilical arteries and the vein have a 'weak spot' where there is an abundance of circular smooth muscle in their walls. After rupture the arteries and urachus retract towards, or into, the fetal abdomen, which prevents haemorrhage. In foals the cord also ruptures at a preformed 'weak spot' close to the umbilicus where a smooth muscle sphincter surrounds the blood vessels and urachus (Naaktgeboren & Slijper 1970).

The second stage of labour is complete when all fetuses have been delivered; it lasts from an average of 17 minutes in the mare to an average of 4 hours in the sow (see later in this chapter). Its duration and the degree of effort associated with it are usually greater in primigravida than in multigravida.

In the mare, cow, doe goat, and ewe (when monotocous), the fetus is usually delivered in anterior presentation, dorsal position, and extended posture (see Chapters 11 and 14), although a small proportion of normal deliveries may occur in posterior presentation, dorsal position, and extended posture. In the polytocous bitch, cat, and sow, up to 40% to 45% of fetuses may be delivered in posterior presentation, and thus posterior presentation represents a normal physiological phenomenon in these species. During passage of the fetus from the uterus to the exterior, the fetus follows an arched route. During the straining movements of the dam the height of the pelvic cavity is enlarged, especially by the dorsal excursion of the sacrum. This facilitates final fetal expulsion.

Third Stage of Labour

After birth of the young, regular abdominal contractions largely cease, but myometrial contractions persist. In general, they decrease somewhat in amplitude but become more frequent and regular. These contractions are important for dehiscence and expulsion of the fetal membranes. Not only do the waves of contractions passing from uterine tube to cervix persist (Taverne et al. 1979c), but in the cow there is the reappearance of contractions in the reverse direction within 10 minutes of the expulsion of the calf (Zerobin & Spörri 1972). Taverne and colleagues (1979b) reported in the sow the presence of regular contractions of a frequency of 15 to 27 per hour, which predominantly progressed in a peristaltic tubocervical fashion over the entire length of the uterus.

During the last days of gestation, maturational changes occur in the placenta; these are likely to be related to the changes in the endocrine environment that trigger parturition. Collagenisation of the placentome, flattening and loss of the maternal crypt epithelium, increased infiltration and activity of leucocytes, and a decline in the number of trophoblast giant cells in the cow have been identified (Grunert 1984, Gunnik 1984, Woicke et al. 1986, Williams et al. 1987, Peter 2013). Using mRNA microarray analysis, differential gene expression in placentomes obtained from cows before (around day 270) and during calving revealed some interesting data on placental detachment (Streyl et al. 2012). Whereas mRNA levels from genes related to mitotic and tissue differentiation were higher found in the samples from the antepartum animals, a shift to a higher expression of genes involved in apoptosis, degradation of the extracellular matrix, and the innate immune response occurred in tissue from intrapartum animals. That (failure of) immune-mediated rejection appears to be involved in placental detachment (retention) was already indicated by several earlier studies (see, for example, Gunnik 1984, Joosten & Hensen 1992, Benedictus et al. 2012). Two-way compatibility of major histocompatibility class I molecules (MHC I) of both the dam and her calf gave a higher risk of retained placenta by influencing the activity of fetal macrophages and the release of inflammatory cytokines from both maternal and fetal macrophages in the

VetBooks.ir

uterus (Benedictus et al. 2015). As a result, the maternal immune system does not reject the fetal membranes, and the fetal immune system does not raise an immune response against maternal MHC class I antigens that could influence rejection of the membranes by the mother.

Expulsion of the fetal membranes is caused by uterine contractions. The effect of the contractions is to open up the endometrial crypts, which in the case of those species with cotyledons, resemble the opening of the blades of a fan. The fetal villi shrink, due mainly to the sudden loss of turgidity related to the escape of blood from the fetal side of the placenta when the umbilical cord ruptures. Exsanguination of the placenta is also aided by the squeezing effect of myometrial contractions. These actions, together with the degenerative or maturational changes described previously cause separation and shedding of the fetal membranes. As a result, the apex of the allantochorionic sac becomes inverted, and as the sac is 'rolled' down the cornua, the fetal villi are drawn out of the crypts. When a large portion of the afterbirth becomes detached and inverted it forms a mass within the maternal pelvis that stimulates reflex contractions of the abdominal muscles; this straining completes the expulsion of the allantochorionic sac, which is seen to have its smooth, shining allantoic surface outermost. In the dog and cat the dehiscence and expulsion of the placentas are interspersed with the fetal births; but only the expulsion of the last afterbirth simulates the third stage of the monotocous species. In the sow most of the (fetal) placentas remain attached to the endometrium during expulsion of the piglets; only occasionally are fetal membranes expelled in association with, or in between, the expulsion of piglets. The bulk of the fetal membranes is normally expelled within 4 hours after the last piglet. In the mare the third stage lasts from an average of 1 hour (Steven 1982). In the majority of the cases the bovine fetal membranes is shed within 6 to 8 hours after birth of the calf (van Werven et al. 1992). With the exception of the mare, domestic animals normally eat the afterbirths if they have access to them.

The nature of the third stage uterine contractions can be easily appreciated with the exercise of a little patience by direct palpation of the cow's uterus transrectally. At intervals of a few minutes, profound waves of contractions are generated, during which the texture of the uterus is transformed from a flaccid state into one of intense tone. Both the frequency and strength of uterine contractions significantly decrease by about 50% during the first 24 hours after calving (Bajcsy et al. 2005).

With the exception of the sow, the females of the other domestic species indulge in intensive licking of the newborn offspring. Within an hour of birth, it is normal for the young of all species to be suckling, and it is known that the stimulus of suckling causes release of oxytocin, which promotes the 'let down' of milk as well as an augmentation of myometrial contractions. This has been clearly demonstrated in the sow, in which suckling resulted in greater synchrony of the contractions and an increase in the number of tubocervical contractions (Ngiam 1977). Hence suckling exerts a favourable influence on expulsion of the afterbirth. In the mare, suckling appeared not to be significantly related to oxytocin release (Vivrette et al. 2000). Although there are no reports in the literatures of physiological measurements of postpartum uterine contractility in mares, it is most likely that the resumption of substantial contractions of the uterine musculature in the third stage cause abdominal pain, and it is quite common for expulsion of the membranes to be preceded by mild symptoms of colic.

Care of Parturient Animals

Mare

Mares approaching term should be put in a convenient paddock during the day and brought in at night. As soon as the udder and teats become distended or waxing occurs, the mare should be put in a foaling box at night and kept under continuous but unobtrusive observation. The majority of mares foal between 1800 hours and midnight, so that by daybreak in their natural wild environment, the foal has suckled and can gallop away. In this respect, it is noticeable that during the week before foaling myometrial EMG activity showed a progressive, reversible rise at night (McGlothlin et al. 2004). It is still uncertain to what extent foaling may be delayed as a result of some (to the mare) untoward environmental influence. There is experimental evidence showing that endogenous opioids suppress oxytocin release in pregnant mares, although this inhibition tended to decrease towards foaling (Aurich et al. 1996). When a continuous insensitive vigil is kept resulting in the mare being repeatedly disturbed, the mare seems as likely to foal by day as during the night. The cervix does not apparently require the same degree of preparatory changes as occur in the cow. A mare may even foal with ease soon after a gynaecological examination has been made when the cervix seemed relaxed but not at all dilated.

If the presentation is seen to be normal, i.e., two feet and muzzle at the vulva, then the mare is almost certain to deliver the foal; an exception is 'dog-sitting position' in which, with forelimbs and head showing, the presentation looks normal (see Chapters 11 and 14). As soon as faulty presentation, position, or posture is recognised (see Chapters 11 and 14) or if no progress occurs within 10 minutes of the onset of straining, a veterinary examination should be requested. In these ideal circumstances the obstetrician will have little more than an hour in which to arrive and deliver a live foal. The early dehiscence of the allantochorion in equine dystocia makes stillbirth the rule rather than the exception.

Cow

In order to follow the best management practices, cows and particularly heifers should be moved to a dedicated 'maternity unit' based on their 'due date' and/or signs of impending calving; namely complete relaxation of the posterior border of the sacrosciatic ligaments and a sudden enlargement of the udder. The accommodation should be clean, well-bedded, and the animals kept under frequent observation. If after 12 hours of restlessness there is no straining, a veterinary examination should be made to exclude primary uterine inertia, failure of the cervix to dilate, and/or uterine torsion (see Chapter 13). If a cow enters what appears to be a normal second stage and there is no progress after an hour's straining, she should be examined to ascertain the cause of the obstructive birth.

Ewe

Heavily pregnant ewes should be kept in a convenient paddock, lambing enclosure, or, preferably, a dedicated pen, where ewes can be kept isolated from the rest of the flock but with their own lambs. The location can be frequently changed during the lambing season to assist in infection control. Goats and sheep show a clear tendency to deliver more frequently during the day (Lickliter 1984, Fitzgerald & Jacobson 1992). However, constant obtrusive interference or farm management measures can override the natural tendency for parturition to occur during more quiet times.

VetBooks.ir

Goat

A similar system to that for ewes should be used, although frequently doe goats are kept in very small numbers and are treated individually.

Sow

This is discussed in Chapter 19. The majority of sows farrow during the evening and at night, when there are fewer disturbances in the farrowing barn.

Bitch and Queen Cat

A clean, comfortable, and warm bed in a quiet environment with minimal disturbance is preferable.

In all domestic species, the mother by reacting to the environment influences, can exert some control over the time of parturition. This is shown in a study involving five Beagle bitches in which it was observed that, it was observed that electromyographic activity of the uterus during late gestation was influenced significantly by external stimuli (van der Weyden et al. 1989). Parturient bitches that are transferred for whelping to a strange environment may suffer from nervous voluntary inhibition of labour. The maternal stress occasioned by the adverse surroundings is considered to inhibit the release of oxytocin and/or the resultant adrenaline secretion stimulates the ß-receptors of the myometrium, causing relaxation. The former mechanism has been very elegantly demonstrated in pigs (Lawrence et al. 1992).

Studies of 1151 calvings of beef cattle in Canada (Yarney et al. 1979) and of 522 parturitions in Friesian cows in Britain (Edwards 1979) showed that the distribution of calvings was fairly uniform throughout the 24-hour period but that the disturbances caused by farm staff at feeding and milking times exerted significant inhibiting effects, particularly in milking cows of third and later parities. When late pregnant dairy cows were offered silage in the evening, after a period of restricted access, a significant reduction of the incidence of night time calvings was observed (Gleeson et al. 2007).

There was also evidence from the beef cattle study and from data on lambing times collected by George (1969) that there can also be a genetic effect on the time of parturition; thus of the several beef breeds studied, 55.9% to 59% of cows with a Hereford grandparent calved during the day (between 0700 and 1900 hours), and under uniform husbandry, more Merino ewes lambed at night and more Dorset Horn ewes during the day.

The Process of Partuition

Mare

The imminence of labour can be recognised by the degree of mammary hypertrophy, waxing of the teats, and possibly the escape of milk from the glands (Fig. 6.10). Increasing calcium levels in mammary secretions indicate that foaling is impending (Cash et al. 1985). The best indication that the first stage has begun is the onset of patchy sweating behind the elbows and about the flanks. Although it occurs in the majority of mares, it is by no means invariable. It commences about 4 hours before the birth of the foal and increases as the stage progresses. Initially, the mare yawns, there are no obvious indications of pain, and food is generally taken readily. Respirations are normal and the pulse is about 60. (This increase in pulse rate is not significant of the onset of labour for it develops during the terminal stages of pregnancy.) There is evidence that body temperature may become slightly subnormal during the first stage (36.5°–37°C), but using this to predict the onset of foaling is unreliable.

• **Fig. 6.10** Mammary hypertrophy, tumefaction of the teats, and waxing in a thoroughbred mare 4 hours before the birth of the foal.

As the stage advances the mare becomes restless and tends to wander aimlessly around the loose box. The tail is frequently raised or held to one side. There may be swishing of the tail or slapping of it against the anus and kicking at the abdomen. As the end of the stage approaches the mare becomes very restless. This is indicated by crouching, straddling of the hindlimbs, going down on the knees or sternum and rising again, glancing at the flank. The stage terminates with rupture of the allantochorionic membrane and the escape of urine-like, allantoic fluid from the vulva. Its quantity is not copious. It will be noticed that there is no reference to visible straining during this period in the mare.

The onset of the second stage occurs abruptly. It is characterised by the appearance of the amnion or the commencement of forcible straining. There is never very much delay between them, and they often coincide. Very soon after straining begins, the mare goes down. She passes on to her side with limbs extended and generally remains in this position until the foal is born. The presence of the transparent bluish-white water bag (amnion) at the vulva is quickly followed by the appearance in it of a digit. Straining efforts recur at fairly regular intervals; each bout comprises three or four powerful expulsive efforts followed by a period of rest, generally of about 3 minutes. When the mare rises during this stage, the foal may partly slip back into the abdominal cavity. During expulsion one forelimb precedes the other by a distance of about 7 to 8 cm and this position is maintained until the head is born. The point is a significant one, for it indicates that one elbow passes through the bony pelvic inlet before the other and in this way nature has provided for the foal to present the minimum obstruction at the pelvic inlet. During its delivery, the head is generally in the oblique position; it may even be transverse—the cheek lying on the limbs—but this is probably due to rotation of the cervical joints within the pelvis and should not be taken as evidence that the presentation was oblique. The second stage is illustrated in Fig. 6.11.

The greatest and longest effort is associated with birth of the head; the chest presents less difficulty, and after this the hips slip

VetBooks.ir

out easily. Although equine delivery is comparatively rapid, it constitutes a tremendous effort, and after expulsion of the foal the mare may remain lying on her side exhausted for anything up to 30 minutes.

The umbilical cord is intact when the foal is born. It subsequently ruptures, 5 to 8 cm beneath the belly, at a point where there is a sphincter of smooth cells lying beneath the amniotic covering, as the result of movement by either the mare or the foal. Usually also, the foal is born within the amnion, the membrane being ruptured by the movements of the foreparts of the fetus. Respiratory movements may be seen within the intact amnion. The lower portions of the foal's hindlimbs often remain within the mare's vagina for some minutes after the rest of the foal is born. Their final emergence is due to movement of the foal rather than to the expulsive efforts of the mare.

The duration of the second stage in the mare is about 17 minutes; it may be as short as 10 minutes. The longest the writer has observed within normality was 70 minutes, and in this case, it was seen that the greater part of the placenta came away with the fetus. It is probable that this is near the limit of the time available if parturition is to remain normal, for in the mare separation of the placenta tends to proceed rapidly once the second stage begins,

• **Fig. 6.11** The second stage of labour in the mare. Note the relative positions of the forelimbs and head. The foal is born in the amnion but breaks out of the sac without difficulty. In the final photograph much of the allantochorion has been passed but the umbilical cord is still intact. *Continued*

VetBooks.ir

and if delivery occupies too long a time it is likely the fetus will succumb from this cause.

In the majority of mares the membranes are expelled quickly after the birth of the foal, generally within 3 hours; in fact, they may fall away in about 30 minutes. The average duration of the third stage is about 1 hour (Steven 1982). Occasionally, however, cases are met in which periods up to 24 hours elapse before the membranes fall away, yet the animal suffers no ill effect. Straining is not a feature of the third stage, the afterbirth being expelled by the myometrial contractions. The recognition of the exact time at which a case becomes pathological and interference is necessary is difficult (see Chapter 32). The definition of when fetal membranes are considered to be retained in the horse is not consistent in the published literature (Sevinga et al. 2004). As has already been pointed out, the membranes are passed with the allantoic surface (smooth and shiny) of the allantochorion outermost. This statement holds for those cases in which expulsion occurs early after parturition, but it has been noticed that in those in which there is delay, the fetal placental surface (roughened and red) is outermost, indicating that separation was complete before expulsion began.

Cow

There are many signs of impending parturition (also called *prodromi*), but the question is which ones are the most useful in the management of calving. Swelling of the vulva, discharge of mucus,

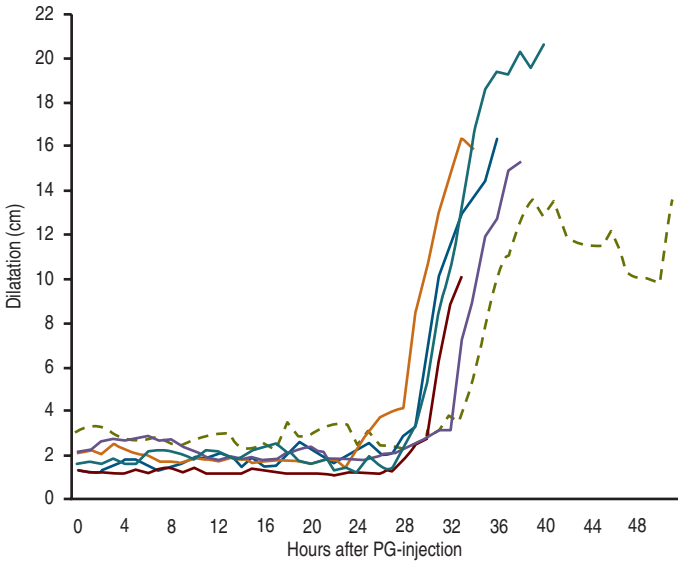
VetBooks.ir

changes of the udder, and relaxation of the pelvic ligaments have been studied in detail in relation to the time interval to the moment of birth of the calf (Berglund et al. 1987). However, given the rather subjective nature of these parameters and the wide range of the intervals found in such studies, these prodromi are not very helpful in making an accurate prediction.

About 54 hours before birth of the calf, Ewbank (1963) noticed a fall in the cow's body temperature of 0.6°C. He observed that a cow showing signs of imminent labour would be unlikely to calve during the succeeding 12 hours if its temperature was 39°C or more. Parturition will usually begin within 12 hours of the appreciation of complete relaxation of the posterior borders of the sacrosciatic ligaments. Changes in vaginal temperatures have been used to predict parturition in beef cows with single and twin pregnancies (Aoki et al. 2005). Behavioural characteristics, such as the recording the time and duration of when and for how long the cow is standing or recumbent can be useful, provided it is done remotely and the animal is not disturbed. On the last day before calving, cows spend a significantly greater number of periods in a standing position (Huzzey et al. 2005). In a recent study from Hungary (Kovács et al. 2015), changes in maternal heart rate (HR) and heart rate variability (HRV) were recorded around unassisted calvings on a large dairy farm. It was concluded that changes in HRV are more immediate predictors of the onset of calving than behaviour or HR, as they occurred before the onset of calving restlessness. So it can be anticipated that, with the further development of automatic recording devices in farm animals, fairly accurate prediction of calving time will become one of the possible applications.

The first stage of labour can easily be recognised by direct palpation of the cervix. There is great variation in the intensity of the symptoms of the first stage; in fact, many subjects, particularly multigravida, show none. Others, usually heifers, may show signs of abdominal pain for periods up to 24 hours before the cervix is completely dilated. The first stage usually lasts some 6 hours. By suturing two ultrasonic crystals (one transmitting, the other receiving pulses) opposite to each on the caudal cervical rim of the cervix, continuous changes in the distance between these crystals has been used to assess dilatation during induced calvings (Breeveld-Dwarkasing et al. 2002). By combining this technique, with in vivo electromyography of the myometrium, the relationship between dilatation, uterine activity, and hormonal changes was examined during induced calvings (Breeveld-Dwarkasing et al. 2003). Fig. 6.12 demonstrates that after a single injection with $PGF_{2\alpha}$ on day 274 of gestation, the increase of cervical diameter follows a rather consistent pattern. On average the cervix started to dilate 28.5 hours after prostaglandin injection. From this time point on, uterine diameter increased linearly at an average rate of 1.6 cm per hour in the calvings in which the calf is in anterior presentation. The mean interval between onset of dilatation and birth of the calf (when the crystals were removed again from the cervix) was 9.3 hours.

Another feature of the cow is that occasional straining may occur during the first stage. Food is only 'picked'; rumination is irregular; there may be 'lowing' or kicking at the belly. The animal is obviously restless; she may stand with her back arched and tail raised; she may go down and rise again frequently. The line of demarcation between the first and second stages is therefore not always clear-cut, as it is in the mare. Body temperature is generally normal, but the pulse rate is often increased to between 80 and 90. In 40% of normal calvings observed by the authors, the intact allantochorion reached the vulva as a 'first water bag'.



• **Fig. 6.12** Dilatation curves of the caudal part of the cervix of 5 cows with calves in anterior presentation (straight lines) and of one cow with her calf in posterior presentation during the hours after a single injection with $PGF_{2\alpha}$. (From Breeveld-Dwarkasing et al. 2003a.)

The second stage is less intense but of longer duration than in the mare. Straining is less frequent, and the animal often remains standing at first (Fig. 6.13). During the passage of the head through the vulva, however, the cow generally goes down and remains recumbent until the calf is born. She may lie on her side but more often adopts sternal recumbency. Detailed observations of 463 calvings in a dairy herd revealed some interesting data on the duration of this expulsive stage in relation to the survival of the calves (Gundelach et al. 2009). They defined the second stage of labour (SSL) as the interval from rupture of the allantoic/amniotic sac to passage of the forehead or pelvis of the calf through the vulva (Table 6.1).

In twin births, Owens and colleagues (1984) noted that intense straining for the birth of the second calf began 10 minutes after the delivery of the first calf. During the second stage, temperature may rise to 39.5° or 40°C, but this is by no means constant and is probably dependent on the degree of effort required. The pulse rate may increase to 100 or more. About 20% of calves are born almost completely enclosed in the amnion.

Placental separation occurs more slowly in the cow than in the mare, and thus the stage of expulsion may be considerably longer without jeopardising the life of the young one. The process of expulsion is similar to that described for the mare. The umbilical cord is shorter in the calf than in the foal, and its rupture generally occurs as it falls from the vulva.

Expulsion of the fetal membranes usually takes place within 6 hours after calf expulsion (Van Werven et al. 1992); occasionally, it may be delayed to 12 hours, but when 24 hours elapse and the membranes are still in the uterus, it is probable that the cause is pathological. Unless prevented from doing so, it is customary for the cow to eat the fetal membranes. It will also be noticed during the first and second stages there is a tendency to lick up vulval discharges.

Ewe and Doe Goat

In the ewe the course of parturition is fairly similar to that described for the cow, except that the incidence of twinning and even triplets

VetBooks.ir

• **Fig. 6.13** The second stage of labour in the cow. Note the relative positions of the fetal head and forelimbs. The allantoic and amniotic sacs can be clearly distinguished in (C).

is high in those ewes that have been flushed before the mating time or in those breeds with high fecundity. Increased restlessness, walking (in circles), isolation seeking, and vocalising are the most prominent signs of impending lambing (Arnold & Morgan 1975). Australian authors Arnold and Morgan reported that most ewes had a labour of less than 1 hour with very few more than 2 hours. Length of labour for second born lambs was significantly shorter than that for first born twins. The interval between the birth of the first and second lamb of a twin pair was most commonly between 11 and 20 minutes and generally less than 45 minutes. Factors affecting this interval have not been systematically investigated. However, in ewes with bilaterally disposed twins, sequential radiographs have shown that both fetuses assume the normal disposition for birth more or less synchronously, but subsequently only one of them will engage the birth canal; in the other the postural changes regress so that the carpal joints are no longer extended, and the head returns towards a vertex presentation from a facial one (Fraser & Terhurne 1977). Which of the two fetuses is destined to be expelled first seems to be regulated by the degree of contractility of the two uterine horns. Once pressure waves have become established in the parturient ewe, one horn develops contractions of about double the amplitude of those in the other horn but with no difference in the frequency; as a consequence, it is the dominant horn that subsequently expels the first fetus (Hindson et al. 1968). Although this study has never been confirmed by others, further experimental evidence suggests that functional differences

TABLE 6.1 The duration of second stage labour in dairy heifers and cows in relation to the occurrence of stillborn calves (classified as being dead at birth or failed to survive for 24 hours after birth)

Mean (± SD) Duration of Second Stage Labour	
Heifers with live calves:	135 ± 86 min
Heifers with stillborn calves:	250 ± 120 min
Cows with live calves:	77 ± 68 min
Cows with stillborn calves:	156 ± 100 min

From Gundelach et al. 2009.

between the two uterine horns at parturition may exist. When premature parturition was induced in bilaterally pregnant sheep with ACTH infusion of only one fetus, it was the infused fetus which was expelled first (Liggins et al. 1977).

Some 94% to 97% of lambs are born in anterior presentation (Naaktgeboren & Slijper 1970), and spontaneous birth may occur despite retention of a forelimb. Ewes expel the afterbirth within 2 or 3 hours of the expulsion of the lamb.

Observations of parturitions in goats (Beetals and crossbreds with Alpine and Saanen; Das & Tomer 1997) revealed that more than 90% of the kids are born in anterior presentation. The average duration of expulsion (interval between appearance of the allantoic sac and complete expulsion of the fetus) was 20 minutes for the first kid and 6 minutes for the second one. Male kids took some 20% to 35% longer to be expelled. On average the fetal membranes were expelled 2.5 hours after birth of the (last) kid.

Sow

Sixty to 75% of sows farrow at night (Bichard et al. 1976, Kovenic & Avakumovic 1978). The fetal membranes of adjacent piglets are usually fused (see Chapter 4) and because individual or aggregated afterbirths may be expelled during the phase of fetal expulsion as well as after the birth of the last fetus, it is unrealistic to speak of separate second and third stages of labour in porcine species. Good descriptions and quantitative data of normal farrowing have been given by Jones (1966), Randall (1972), and van Dijk and colleagues (2005).

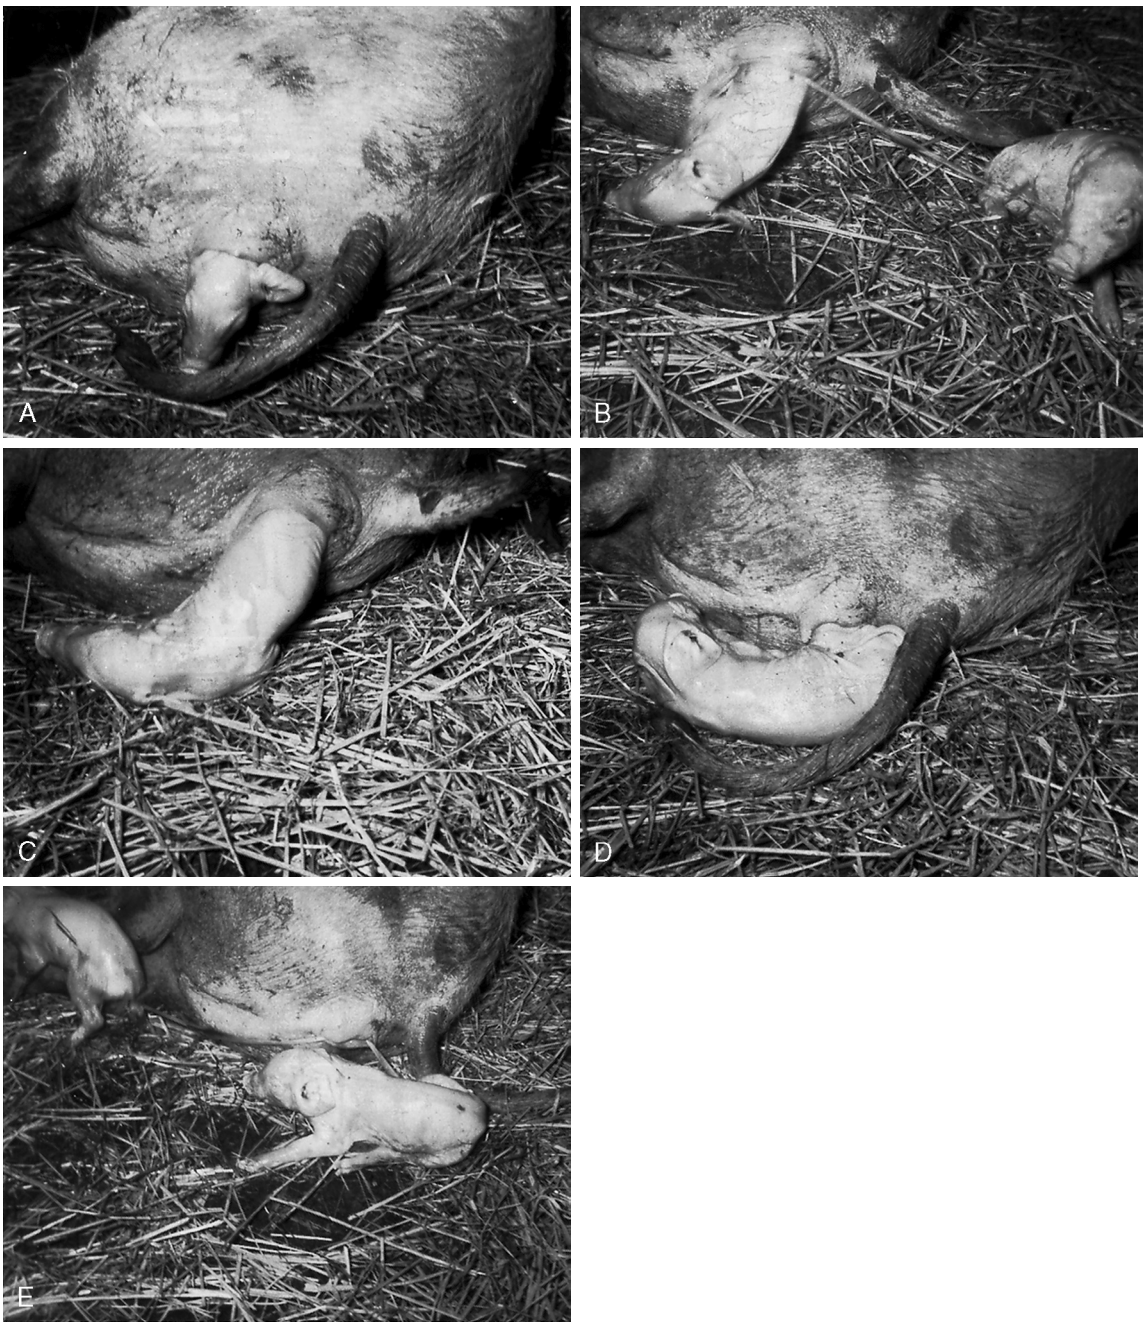
Sows in late pregnancy are quiet resting and frequently sleeping in lateral recumbency, but within 24 hours before the birth of the first piglet, a marked restlessness develops, accompanied by bed-making activity (if they have access to suitable materials). Endogenous $PGF_{2\alpha}$ appears to be involved early in an endocrine pathway that involves the brain and is responsible for most of the prepartum behavioural components (Gilbert 2001). The intensely active period is followed by recumbency and rest. The onset of the parturient pattern of myometrial activity occurs between 6 and 9 hours before the first piglet is born (Taverne et al. 1979a). There are several alternating periods of rest and restlessness, and then, in the hour preceding the birth of the first piglet, the sow settles quietly into lateral recumbency. Conspicuous mammary growth is a feature of late gestation; 1 to 2 days before farrowing the individual glands are clearly demarcated, turgid, tense, and warm, and milk can be expressed from the prominent teats during the final 12 to 24 hours. There is progressive swelling of the vulval labia from about 4 days before parturition and the mucosa becomes reddened. Prepartum temperature variations of between 37.5° and 38°C, but with no constant temperature change, have previously been reported, but Elmore and associates (1979) recorded a 1°C rise at 12 to 15 hours before the birth of the first piglet.

Parturient sows usually remain in lateral recumbency, but gilts more particularly may stand after the birth of the first or second piglet or change from one side to the other or from lateral to ventral recumbency. After the prepartum quiet period, there is intermittent straining accompanied by paddling leg movements. The birth of the first pig (and subsequent ones) is heralded by the passing of a small quantity of fetal fluid and by marked tail-switching. The greatest parturient effort is expended over the first piglet, with succeeding fetuses being expelled with surprising ease and sometimes with projectile force. The allantochorion and amnion usually rupture as the conceptus traverses the birth canal, but occasionally piglets are born within the amnion, and, not uncommonly, a fetus becomes surrounded by the membranes of another fetus. Only small amounts of fetal fluid are voided.

The expulsive phase of parturition is illustrated in sequence by Fig. 6.14. By means of laparotomy and transuterine marking of the uterine location of fetuses of the miniature pig between 80 and 105 days of gestation and then observing their birth sequence, Taverne and colleagues (1977) found that the offspring were delivered randomly from both uterine horns. As had previously been observed by Perry (1954), there were occasional instances of a piglet apparently 'overtaking' its neighbour in the uterus. In 18 of 95 piglets the observed presentation at birth differed from that previously detected at laparotomy, but it was not determined whether these changes of polarity occurred in the uterus during gestation or within the uterine body during delivery. Both explanations would seem valid, although we postulate that the polarity change is most likely to occur because a piglet passes down from one horn into the base of the other and is then expelled into the uterine body and then the outside. Observing the birth of 1078 piglets in 103 litters Randall (1972) recorded 55.4% anterior and 44.6% posterior presentations. In both presentations the fetus was usually in dorsal position with the presenting limbs flexed alongside the fetal body; thus the fetal snout or tail was the first part to protrude. The mean interval between consecutive births was 16 minutes, and the mean duration of the expulsive stage was 2 hours 36 minutes. In the analysis of data from some 211 litters of several breeds, van Dijk and associates (2005) found that breed, litter size, and gestation length significantly affected the duration of the expulsive stage. A curvilinear relationship between birth interval and rank (relative position in the birth order) of the piglets was found; piglet birth intervals increased with an increasing birth weight, and both stillborn and posteriorly presented piglets were delivered after significantly longer birth intervals than live born and anteriorly presented piglets. Between 60% and 70% of piglets were born with intact umbilical cords; in the case of the early born fetuses the elasticity of the cord allowed the newborn piglet to reach the middle of the sow's abdomen without the cord breaking. The later born piglets were more likely to be expelled with broken cords (Randall 1972). Newborn piglets are usually remarkably active and may reach a teat within 30 minutes after expulsion and attempt to suck, although this largely depend on their viability and floor of the farrowing crate.

The porcine fetal membranes tend to be expelled as two or three masses of joined allantochorions, with the placental stalks of the umbilical cords indicating the number of separate conceptuses in each mass; single afterbirths may also be voided. One or more of the coalesced masses are commonly expelled before all the fetuses

VetBooks.ir

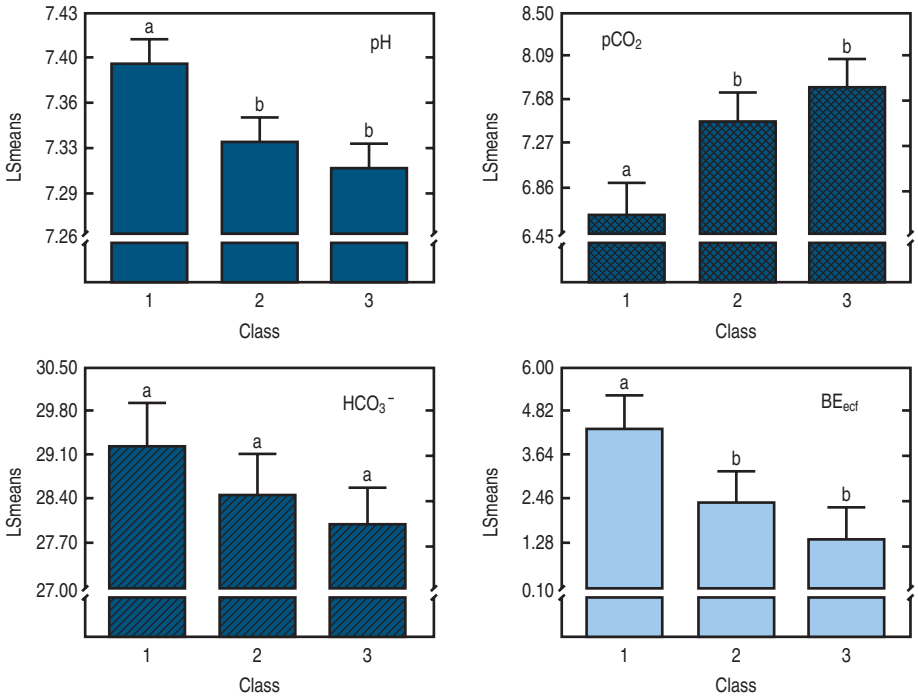


• **Fig. 6.14** The second stage of labour in the sow. Note the lack of extension of the forelimbs. The intact umbilical cord can be seen in (E).

are born, but the largest mass is usually expelled about 4 to 5 hours after the last piglet; prolonged parturition impairs placenta expulsion (Bjőrkman et al. 2017). When all the piglets have been expelled, the sow usually stands up and micturates profusely. She then lies down again, sometimes very clumsily—with consequent risk of crushing the surrounding piglets; the feature of the next phase is that the sow lies quietly for a long time and allows the piglets to suck.

A notable economic feature of porcine parturition is the frequency of stillbirths. They occur in about 30% of apparently normal farrowings, and the overall stillbirth percentage in unassisted deliveries is 3% to 6% (Randall & Penny 1970, Leenhouwers et al. 1999). Because piglets are nearly always found alive when premeditated hysterectomies or hysterotomies are performed just before the onset of parturition, it is concluded that stillbirths occur during farrowing. Early born piglets are more likely to survive than either the middle born ones or the late born ones from the tips of the uterine horns (Dziuk & Harmon 1969, Sprecher et al. 1974, Leman et al. 1979). The stillbirth rate is also influenced by litter size, being greatest in litters of four or less or in those of 14 or more, and by the polarity of the expelled fetus (Sovjanski et al. 1972, van Dijk et al. 2005). Piglets at the ovarian ends of the uterine horns have to traverse the entire length of the respective horn and, in the case of small litters, they may have to negotiate a previously unoccupied and nondilated length of horn. Piglets born in posterior presentation are nearly four times as likely to

VetBooks.ir



• **Fig. 6.15** Acid–base values in blood samples taken from the cord of liveborn piglets, delivered during the first, second, and last third part of the litter (class 1, rank ≤ 0.33; class 2, 0.33 < rank ≤ 0.66; class 3, 0.66 < rank ≤ 1). (From van Dijk et al 2006.)

be born dead as those presented anteriorly; also piglets born alive in posterior presentation or expelled during the final third of the litter show significantly worse acid–base balance values in blood samples taken from the cord at birth (Fig. 6.15; van Dijk et al. 2006). As already mentioned previously, extension of the intervals between successive births of up to 20 minutes or more also predisposes to stillbirth.

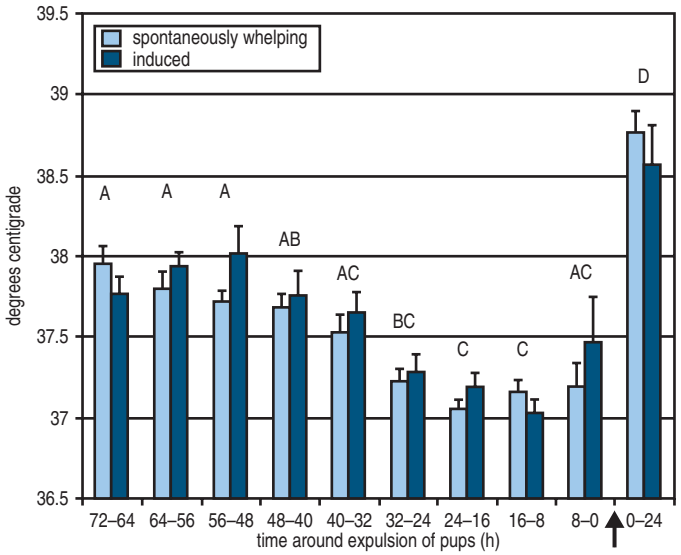
High progesterone and/or low oestrogen levels, produced experimentally in the preparturient sow's blood, can delay farrowing and increase the stillbirth rate from 10% to 97% (Wilson et al. 1979). It is not known if such hormonal derangements also occur naturally.

Bitch

The imminence of parturition is indicated by the animal preparing her bed and becoming restless. In primigravida the onset of lactation more or less coincides with parturition, but in multigravida milk may be expressed from the teats for several days before its onset. In most bitches there is a transient fall in body temperature of at least 1.2°C within the 24 hours before the onset of labour, but it needs repeated measurements to detect a temporary lower value. The prepartum temperature drop also occurred when whelping was induced (Fig. 6.16; Baan et al. 2005).

There is nothing characteristic about the first stage, but it is generally noticed that the bitch is restless, indifferent to food, and inclined to pant. It is most obvious in primigravida and occupies about 12 hours.

Electromyographic (EMG) pattern during late pregnancy comprises episodes of myoelectrical activity (EMEAs) lasting 3 to 10 minutes and recurring at a low frequency (maximum 2.5/hour). During the last 7 days before whelping and especially during the last 48 hours, more short bursts (<3 minutes) appeared between the EMEAs; this was closely correlated with the decline in progesterone concentrations. The total duration of EMG and the burst



• **Fig. 6.16** Rectal temperatures measured every 8 hours from 64 to 72 hours before expulsion of the first pup *(arrow)* until 0 to 24 hours after expulsion of the last pup in 6 spontaneously whelping dogs *(light blue bars)* and in 6 dogs in which parturition was induced with the progesterone-blocking agent aglepristone. (From Baan et al. 2005.)

frequency increased dramatically as the progesterone concentration and body temperature fell 12 to 24 hours before whelping (van der Weyden et al. 1989). Bitches apparently are aware of the uterine contractions at this stage, because they frequently stand or change their position but remaining recumbent when contractions occur. The onset of the second stage is indicated by abdominal straining, but at first this may be difficult to recognise because

VetBooks.ir

of the positional changes of the bitch. In the majority of cases the animal remains in her bed in sternal recumbency, although sometimes she may stand and move about during straining efforts. The allantochorionic membrane of the first fetus appears at the vulva, and after a series of expulsive efforts attains the size of a golf ball. It is generally ruptured by the bitch, who licks vigorously at her vulva. As with other species, delivery of the head coincides with the greatest effort; in the majority of instances, once this is born the remainder of the fetus follows easily. Expulsion of the first fetus, as judged by the duration of abdominal straining, may occupy up to an hour, but seldom longer if the process is normal. It is often quicker, a matter of a quarter of an hour or so. Although some 40% of all puppies are born in posterior presentation, repeated measurements of acid–base balance in jugular blood samples after birth showed that pups born in posterior presentation experienced a more severe metabolic acidosis (van der Weijden et al. 1989).

The umbilical cord is intact at the birth of the puppy, and occasionally, they can be seen attached to their cord when the mother rises immediately after expulsion. The cord is either quickly torn or the bitch bites it when eating the placenta. Normally, the bitch rests for a time after the birth of her first puppy. She lies licking it, and soon it begins to move and tries to suckle when it is lively enough to reach a nipple. She pays frequent attention to her vulva and licks up any discharges. The placenta is generally voided in 10 to 15 minutes (or even together with the pup) and is promptly eaten by the bitch.

Straining recommences after a variable delay. This delay is usually less than 30 minutes, but it may frequently be as long as 1 to 2 hours; the author has seen it occupy 7 hours in a bitch pregnant with two fetuses only. The effort required and time occupied for the delivery of the second fetus is usually less than for the first, but this is mainly dependent on the presentation, position, and weight of the pup. The pattern of expulsion of the fetuses is most irregular; one bitch may have her first puppy, then rest for several hours, then deliver two or three more in quick succession, and then rest again before expelling several more. Another may expel them at fairly regular intervals throughout the period. Mean intervals between the births of two successive puppies ranged between 30 and 60 minutes in most breeds (Naaktgeboren et al. 2015). In exceptional cases a bitch may deliver the whole of her litter in an hour or so. In a study involving spontaneous whelping in Beagle bitches, the mean interpuppy interval was 1.9 ± 08 hours (Baan et al. 2005); however the progress may have been influenced by the experimental protocol involved in the study with blood sampling and other interventions. Parturient bitches are indeed very sensitive to environmental disturbances, and stress may easily cause a delay of the expulsion stage, probably by elevating maternal catecholamines and decreasing oxytocin levels (Naaktgeboren et al. 2015). Plasma oxytocin levels are elevated during the expulsion stage (Olsson et al. 2003), and there are temporary elevations, although not exclusively, around the time of expulsion of a pup (Klarenbeek et al. 2007). In bitches with primary uterine inertia, plasma oxytocin levels were found to be significantly lower than in normal whelping controls (Bergström et al. 2006). Unlike the sow (see earlier in this chapter), there is a significant tendency for the puppies to be expelled from alternate horns (van der Weijden et al. 1981). In addition, reversal of the presentation or 'leapfrogging' of puppies is very uncommon.

Expulsion of the placentae is also irregular. They may come individually (immediately) after each pup. In other instances a puppy may be born with the membranes of its predecessor around its neck, indicating that this pup has passed its predecessor's placental girdle when still attached to the uterine wall. Exceptionally, there is a delay of up to 24 hours before all placentas are expelled and parturition is finally completed.

The total time occupied by the second stage will depend chiefly on the number of fetuses in the litter, but as a general rule, when the litter is within the usual limits (four to eight) it occupies some 4 to 8 hours. The question arises over what is the maximum normal time it may occupy, especially when the number of fetuses is very high (10–14); Naaktgeboren and colleagues (2015) reported up to 13 hours for the largest breeds with the largest litters. It is very improbable that puppies born after this time, even without assistance, will be alive, although the birth of a live pup has been reported even after an interval of 34 hours (Romagnoli et al. 2004). Compared with other domestic species, stillbirth rate in dogs appears relatively high. In a study from Norway, stillbirths and deaths within the first week were responsible for the majority of puppy losses (Indebrø et al. 2007). A stillbirth rate of 10.9% in 98 litters from four different large breeds occurred, and litter size significantly affected stillbirth rate. A previous study of Boxers (a brachycephalic breed) in The Netherlands (Nielen et al. 1998) reported that in a group of 571 bitches, deaths between birth and day 49 postpartum, 25.7% were stillborn. In contrast, a much lower stillbirth rate was reported more recently in a large cohort study involving 224 breeds involving data from the time of birth for all purebred litters registered by the Norwegian Kennel Club (Tønnessen et al. 2012). Perinatal mortality was defined as the sum of stillborn puppies (4.3%) and puppies that died before 8 days after birth (3.7%); it was present on 24.6% of the litters. However, the variable sources of the original whelping data (individual breeders, research, and commercial breeding colonies) may be responsible for the large variation in perinatal losses.

A feature of parturition in the bitch is that much of the uterine discharge is dark green in colour. This is due to the breakdown of the marginal haematoma ('green border') and to the escape of the blood pigment, biliverdin or uteroverdin.

Queen Cat

During the last week of pregnancy, the queen will seek out a suitable nesting area for kittening. Most cats are secretive about kittening and will select a quiet, undisturbed spot, but some socialised pet cats show less interest in selecting a suitable nesting position and become more demanding of human contact.

Mammary development becomes noticeable in the last week of pregnancy, and this may be particularly prominent in maiden queens. Unlike in bitches, rectal temperature does not fall before the onset of parturition.

During the first stage of parturition some queens may become restless, frequently visiting the site selected for kittening, whereas other queens hide away quietly in the chosen nesting area, occasionally lying down and straining unproductively. Frequent licking of the vulval area and panting are other signs that parturition has started. The second stage begins with straining, with the queen usually in lateral or ventral recumbency or in a defecating position. There are only few published data on the course of parturition in cats, and the ones now available are based on questionnaires returned by individual breeders. Sparkes and colleagues (2006) reported a median interval, between the first observed contractions and birth of the first kitten, of 0.5 to 1 hour and with more than 80% of the queens taking less than 2 hours. The duration of the entire expulsive stage (interval between first and last kitten; n = 858) also varied considerably, but in some 85.7% of the animals, it took less than

VetBooks.ir

6 hours, and in three queens more than 48 hours elapsed to the completion of expulsion. The interval between individual kittens within a litter (n = 1001) also varied; in 73.6% of the recorded events (n = 1001), it was less than 1 hour and in 21.1% between 1 and 3 hours. Another study (Musters et al. 2011) reported a median interkitten time of 30 minutes (range 2–343 minutes), with 95% of the kittens born within 100 min after the preceding kitten. The latter study also found that interkitten time was not influenced by the kitten's gender, presentation at expulsion, birth weight, stillbirth, or parity of the queen. Sixty-nine percent of the kittens were born in anterior presentation and 31% in posterior presentation, indicating that both presentations can be considered as normal. A stillbirth rate of 7.2% was reported by Sparkes and associates (2006), whereas in the study of Musters and colleagues (2011), some 5% of the kittens were born dead.

The placentas with fetal membranes are usually expelled still attached to the fetuses or separately shortly afterwards. The mother vigorously licks the newborn kitten and quickly consumes the placenta, thereby severing the umbilical cord. It may take some 30 to 40 minutes after birth for the kittens to reach a nipple and start sucking.

Care of the Newborn

Readers of this section of the chapter might wish to consult Mee (2008) for an authoritative description of the management of the newborn calf. Much is applicable to all domestic species. The sudden change at birth from the constant, controlled, cosseted environment of the uterus to the variable and frequently stressful free-living environment demands great adaptability from the newborn. In domestic species, however, provided that parturition is normal, most survive this transition without assistance. It should also be remembered that during the latter part of gestation the fetus is already undergoing a number of maturational changes, probably stimulated by the hormonal changes that occur in the initiation of parturition, in preparation for the free-living state. However, there is often a high mortality rate more often associated with dystocia; in cattle, for example, it has been estimated that 64% of calf losses occur within 96 hours of birth (Patterson et al. 1987), and those born after dystocia are 2.4 times more likely to develop infectious diseases within the first 45 days of life than those born as a result of a normal birth (Toombs et al. 1994). A data set of Holstein calving records, comprising 4103 herds with 2,304,278 calving events representing 1,164,233 cows and 96,069 twin births, reported twinning trends and calf mortality across time (Silva del Rio et al. 2007). Overall, the reported twinning rate was 4.2%; calf mortality was greater after twin births, with 28.2% of twin calving events reporting one or both calves as dead, compared with 7.2% for singleton births (OR = 6.5). Calf mortality for primiparous and multiparous cows was 5.0% after a single birth and 25.5% after twin births, whereas for nulliparous heifers, mortality was 10.4% for singletons and 38% for twins (OR = 3.4). Although these data refer to calvings, it clearly shows the need for increased surveillance of primigravid animals of all species. In dogs a large survey in France involving 27,221 bitches and 37,946 litters recorded a stillbirth rate of 0.4% and a combined stillbirth and perinatal mortality rate of 13.4% (Chastant-Maillard et al. 2017). In a similar survey in cats involving 5303 queens from 45 breeds, the stillbirth rate involving 28,065 kittens was 8.5% (Fournier et al. 2017). At birth and for a variable period of time afterwards, a number of important events must occur, and it is the responsibility of the person involved in supervising or assisting at the parturition to assist the newborn so that the likelihood of survival is enhanced.

Recently, in the bitch, attempts have been made to utilise some of the methods that have been used in human obstetrics to monitor the dam and the new born puppies. In human obstetrics/neonatal paediatrics, the APGAR system has been used to assess the newborn baby; APGAR is an acronym derived from: Appearance, Pulse, Grimace, Activity, Respiration. Although this is not directly applicable to veterinary medicine, a comparable scoring system based on the following has been evaluated, namely assessment and scoring of: heart rate, respiration, irritability reflex, motility, and membrane mucus colour (Veronesi 2016). Similarly, Groppetti and associates (2010) not only evaluated the modified APGAR system, but also assessed puppy acidosis by measuring umbilical vein lactate concentrations and myometrial activity using a commercially available tocodynamometric system.

Onset of Spontaneous Respiration

During fetal life, episodes of muscular movements similar to those of respiration have been observed in a number of species; whether these are truly the precursors of the continuous respiratory movements of the newborn is debatable. However, if parturition occurs normally, then spontaneous respiratory movements will occur within 60 seconds of expulsion; if there is a delay, then respiratory movements can sometimes occur before the offspring has been completely expelled.

There are probably a number of factors that are responsible for the initiation of spontaneous respiration. During the birth process, P_{O_2} and blood pH are falling and P_{CO_2} is rising due to the start of placental separation and occlusion of the umbilicus, thus restricting gaseous exchange. These changes have been shown in the lamb to stimulate chemoreceptors in the carotid sinus (Chernick et al. 1969). Tactile and thermal stimuli are also important, for it has been shown that if the face of the fetal lamb is cooled, there is stimulation of respiratory movements (Dawes 1968); the licking and nuzzling of the dam probably provides some stimulus.

The first respiratory movement is usually a deep, forceful inspiration that is necessary to force air into the lungs. It has been demonstrated in the fetal lamb that a pressure of 18 cm of water is necessary to force air into the lungs at the first inflation; once this occurs, only a small pressure is needed to cause full inflation thereafter (Reynolds & Strang 1966). Pulmonary surfactant, produced by type 2 pneumocytes during the maturation of the fetus at the end of gestation, assists in the initial lung expansion and alveolar stabilisation. Although the initial work done in the first breath is greater in mature than in immature fetal lungs, for the second and subsequent breaths it is much less; this is because the alveoli remain partially inflated after exhalation. As a result of lung inflation, the pulmonary vascular bed opens up followed by a sudden increase in pulmonary blood flow. Such changes in the vascular dynamics result in the rapid closure of the ductus arteriosus and foramen ovale, followed by the ductus venosus several hours later; the consequence of these changes are that instead of gaseous exchange occurring via the placenta, it now occurs via the lungs (Grove-White 2000). Survival of the newborn is dependent on the rapid onset of normal, spontaneous respiration. In a normal calf, respiration usually commences after 30 seconds of birth, being irregular at first before settling down to 45 to 60 breaths per minute (Grove-White 2000). Once birth is complete, it is important first to ensure that the upper respiratory tract is cleared of fluid, mucus, and attached fetal membrane. This

TABLE 6.2 Equipment for resuscitation of foals

Endotracheal tubes 7–12 mm diameter
Oxygen cylinder and regulator
Resuscitator bag
Doxapram
Adrenaline (epinephrine)
Sodium bicarbonate 4.2%
Dextrose saline 5%
Valium
Dexamethasone phosphate
Lidocaine
Intravenous catheters
Drip sets
Enteral feeding tubes
Needles, syringes, blood collection tubes
Glucose meter

From McGladdery 2001.

can be done with the aid of fingers or, preferably, with a simple suction device. Elevation of the rear of the calf, particularly by suspension from the hindlimbs, results in the escape of copious quantities of fluid. Some of this comes from the stomach, and it may not necessarily be beneficial because it has been shown that one-third of this fluid can be absorbed from the lungs of the newborn via the lymphatic system (Humphreys et al. 1967). In addition, pressure on the diaphragm by the abdominal viscera can itself interfere with normal respiratory movements. Brisk rubbing of the chest with straw or towels frequently provides the necessary tactile stimulus to stimulate respiration, although a portable oxygen cylinder and resuscitator are useful pieces of equipment to have available. They comprise a small portable cylinder of oxygen, a reducing valve, a rebreathing bag, and either a face mask or an intranasal or endotracheal tube; the latter is preferable because, unless the oesophagus is occluded by pinching, the abomasum will also be inflated. Equipment suitable for resuscitation of foals, which should be available wherever there are parturient mares is listed in Table 6.2.

If spontaneous respiration does not commence, then it is necessary to provide positive pressure ventilation. This should be done with the calf, lamb, or foal in sternal recumbency; the person involved blows into the tube and compresses a rebreathing bag attached to an oxygen source. There are now currently available a number of resuscitators for most domestic species. An example is the McCulloch Resuscitator range, an example of one for use in newborn calves, shown in Fig. 6.17A and B; this also has the advantage that, by reversing the pump, fluid can be aspirated from the upper respiratory tract before attempts are made to inflate the lungs using the pump. Overenthusiastic compression of the chest can sometimes cause injury to the ribs and the thoracic organs. In most cases, if resuscitation does not result in spontaneous respiration in 2 or 3 minutes it is unlikely that the newborn will survive, even though there is a good strong pulse and heartbeat. Respiratory stimulants such as coramine and adrenaline are not particularly useful; however, a mixture of solutions of crotethamide and corpropamide placed on the tongue can stimulate respiratory activity in some cases.

Acidosis

The fetus at the time of a normal birth will usually have a mild metabolic and respiratory acidosis; in the case of the former, this is corrected within a few hours, whereas the latter may last up to 48 hours (Szcenci 1985). Dystocia is likely to cause a severe respiratory and metabolic acidosis. Severe acidosis will have an adverse effect on both respiratory and cardiac function, and in the case of the calf will reduce vigour and the suck reflex, resulting in reduced colostrum intake and impaired passive immunity (Grove-White 2000). One of the simplest methods of assessing the degree of acidosis is to determine the time to the calf assuming sternal recumbency. After a normal calving, this was 4.0 +/– 2.2 minutes, whereas after traction, it was 9.0 +/– 3.3 minutes; a time greater than15 minutes was found to have a high predictive value for death of the calf (Schuijt & Taverne 1994). The presence of good muscle tone and a pedal reflex are indicators of a well-oxygenated calf with fairly normal acid–base status. The presence of scleral and conjunctival haemorrhages is indicative of hypoxia and acidosis and carries a poor prognosis; similar lesions are present extensively at necropsy in calves that die at birth (Grove-White 2000).

A calf requiring resuscitation is likely to be suffering from both a metabolic (low plasma bicarbonate concentration) and a respiratory (high PCO_2) acidosis. The PCO_2 will be reduced with improved alveolar gas exchange and tissue perfusion; however, the metabolic acidosis may be treated with sodium bicarbonate (Grove-White 2000). The origin of the metabolic acidosis is due primarily to the production of lactic acid by tissues. When sodium bicarbonate is used to neutralise the acid, CO_2 and H_2O are produced; the former will exacerbate any respiratory acidosis. Thus it is important that the calf is breathing normally so that it can exhale this additional CO_2.

Preferably, treatment of a metabolic acidosis should be carried out after its degree has been assessed after blood gas analysis or the use of the Harleco apparatus. However, under field conditions it is seldom possible, and thus has to be computed according to the recommendations of Grove-White (2000). Thus for a newborn calf whose history and clinical signs suggest that it is acidotic, sodium bicarbonate at a dose rate of 1 to 2 mmol/kg as a bolus intravenous injection of 50 to 100 ml (35 gm in 400 ml of lukewarm water) can be used quite safely.

Injuries at Parturition

Manipulative obstetrical procedures, particularly traction (see Chapters 11 and 14), can result in injury to the newborn. In a study involving the postmortem examination of 327 calves that died during the perinatal period (within 48 hours of birth), 13.2% had fractured ribs, 4.3% diaphragmatic tears, and 2.8% fracture of the spine in the thoracolumbar region (Mee 1993).

Thermoregulation

In the period immediately after birth, the newborn has to adjust to an environment whose temperature may fluctuate widely and which is also usually lower than that of the uterus.

VetBooks.ir

After birth the body temperature of the newborn falls quickly from that of the dam before it eventually recovers; the degree of decline and speed of recovery vary from species to species and with the environmental temperature. In the foal and calf, the fall is transient; in the lamb, recovery occurs within a few hours; the piglet takes up to 24 hours or even longer in cold conditions; in the kitten and puppy the period before the temperature recovers to approximately that of birth is 7 to 9 days.

In the newborn, thermoregulation is controlled in two ways. First, the metabolic rate is increased to three times the fetal rate soon after birth. The increased rate is dependent on adequate substrate, and because glycogen and adipose tissue reserves are low in the newborn, it is very important that immediate and adequate food is available. However, the metabolic rate can increase only to a certain level, known as summit metabolism; if this is insufficient to maintain body temperature, then hypothermia occurs (Alexander 1970). The second method of thermoregulation is to reduce heat loss. The newborn has little subcutaneous fat, and hence insulation is poor. The body surface is wet, and thus heat is lost due to evaporation, whereas in species such as the pig, the coat provides little protection. Heat loss is greatest in smaller individuals because they have a greater surface area per unit of body weight.

Thermoregulation in the newborn can be improved in a number of ways:

- Ensure that there is adequate food intake.
- Arrange for birth to occur in at least a thermally neutral environment, and in those species in which thermoregulation is delayed, this environment should be maintained. The newborn puppy should be placed in an environmental temperature of 30° to 33°C for the first 24 hours, which can be reduced to 26° to 30°C by 3 days. Puppies born at a normal room temperature of 18° to 22°C can suffer a fall in rectal temperature of 5°C.
- Reduce heat loss by ensuring that the coat is adequately and quickly dried. A proper nest area should be provided with good insulation and supplementary heating in polytocous species, which will also encourage the huddling together of the litter, thus reducing the overall surface area. In the case of lambs, simple plastic jackets can be an effective way of reducing heat loss.

Umbilicus

At birth the umbilicus usually ruptures passively or in some species, such as the dog, the dam bites through the structure; there are few indications for ligation. Premature severance, especially in the foal, should be prevented because it has been shown that, in the foal, the pulse can persist for up to 9 minutes after expulsion, thereby ensuring an adequate blood volume (Rossdale 1967).

Provided that birth occurs in a clean environment with adequate hygiene, it should not be necessary to handle the umbilicus. However, if there is an outbreak of 'navel ill', it may be necessary to introduce some prophylactic measures. The navel should be carefully cleansed with an antiseptic solution; chlorhexidine is the agent of choice for most species, and then dried.

Nutritional Deficiencies and Infectious Agents

In a study involving the perinatal death of 22 calves born after an unassisted calving, there was some evidence that deficiencies of selenium, iodine, and other trace elements were involved (Mee 1991). When there is a high neonatal mortality rate in the absence of dystocia, the possibility of such deficiencies should be investigated, as well as the possibility of the presence of infectious agents because these may cause not only pregnancy failure but also stillbirth and weakly offspring (see Chapters 24 and 26).

Protection From an Excitable or Vicious Dam

Occasionally, the dam will attack or savage the newborn, in which case it may be necessary to provide some physical protection and resort to the use of tranquilliser drug.

Physiology of the Puerperium

DAVID E. NOAKES

The puerperium is the period after the completion of parturition, theoretically after completion of the third stage of labour (although if the latter is prolonged some of the changes may start before the fetal membranes are voided), when the genital system is returning to its normal nonpregnant state. In the nonseasonally breeding polyoestrous species (the cow, mare, and sow) it is important that the puerperium should be normal because it is the practice under many systems of husbandry to breed from individuals of these species fairly soon after they have given birth. Thus any extension of the puerperium may have a detrimental effect on the reproductive performance of the individual animal concerned. The genital system does not completely return to the original pregravid state because, particularly after the first gestation, certain changes are not completely reversible. Most notable is the size of the cervix and uterus, neither of which ever return to their prepregnant, nulliparous dimensions.

There are four main areas of activity:

- The tubular genital tract, especially the uterus, is shrinking and atrophying as a result of tissue loss; thus reversing the hypertrophy that occurs in response to the stimulus of pregnancy. Myometrial contractions, which continue for several days after parturition, aid this process and help in the voiding of fluids and tissue debris; this process is normally referred to as involution.
- The structure of the endometrium and deeper layers of the uterine wall are restored to their normal nonpregnant state.
- There is a resumption of normal ovarian function in polyoestrous species and a return to cyclical activity.
- Bacterial contamination of the uterine lumen, which is common even after a normal parturition, is eliminated.

Although postpartum infection of the uterus is not uncommon, in some species an acute postpartum inflammatory reaction has been identified in apparently normal healthy animals (see review by Bradford et al. 2015). During the puerperium there are major physiological changes taking place involving the genital system and the reversal of changes associated with pregnancy, as well as changes in the mammary glands in preparation for lactation.

Cattle

Although the stimulus for the changes that occur during the puerperium is primarily due to the removal of the fetus, hormones such as oxytocin and prostaglandin (PG)$F_{2\alpha}$ and inflammatory mediators such as cytokines are also involved. In the case of the latter, however, there is an increase after the end of parturition, in which peak values occur 3 days postpartum and do not return to basal levels until 15 days postpartum (Edquist et al. 1978, 1980).

The puerperium has been studied in detail by Rasbech (1950), Gier and Marion (1968) and Morrow and colleagues (1969), using sequential slaughter and both macroscopic and microscopic examination of the tissues. In recent years, with the advent of new diagnostic imaging techniques such as various ultrasonographic modes, it has been possible to sequentially monitor the changes in tubular genital tract as well as its vascular supply. In addition, it has also been possible to monitor inflammatory markers in the peripheral circulation.

Involution

The reduction in the size of the genital tract is called involution; it occurs in a decreasing logarithmic scale, the greatest change occurring during the first few days after calving. Uterine contractions continue for several days, although decreasing in regularity, frequency, amplitude and duration. The atrophy of the myofibrils is shown by their reduction in size from 750 to 400 μm on the first day to less than 200 μm over the next few days.

Gier and Marion (1968) found that the diameter of the previously gravid horn was halved by 5 days and its length halved by 15 days postpartum. The results of their study are summarised in Fig. 7.1 and show that, after the initial rapid phase of involution, the subsequent changes proceed more slowly. Similar results have been obtained using sequential transrectal ultrasonography (Fig. 7.2). Morrow and associates (1969) recorded a reduction in the rate of involution between 4 and 9 days postpartum, with a period of accelerated change from days 10 to 14 and a gradual decrease thereafter; however, this may have been an artefact. Associated with this phase of rapid involution is uterine discharge. The whole of the uterus is usually palpable per rectum by 8 and 10 days postpartum in primiparae and pluriparae, respectively. The speed of involution of the nongravid horn is more variable than that of the previously gravid horn, which depends upon its degree of involvement in placentation.

There is some dispute about when uterine involution is complete; the differences are probably only subjective. In six studies reported in dairy cattle the time taken for complete involution ranged from 26 to 52 days, whereas in three studies in beef cattle it was 37.7 to 56 days. The changes after 20 to 25 days are generally almost imperceptible.

The cervix constricts rapidly postpartum; within 10 to 12 hours of a normal calving it becomes almost impossible to insert a hand through it into the uterus and by 96 hours it will admit just two fingers. The cervix also undergoes atrophy and shrinkage due to the elimination of fluid and the reduction in collagen and smooth

• **Fig. 7.2** Changes in the diameters of the previously gravid and nongravid horns of postpartum cows as determined by B-mode real-time transrectal ultrasonography. (Courtesy Professor I. M. Sheldon.)

muscle. Gier and Marion (1968) found that the mean external diameter was 15 cm at 2 days postpartum, 9 to 11 cm at 10 days, 7 to 8 cm at 30 days, and 5 to 6 cm at 60 days. A useful guide that involution is occurring normally is to compare the diameter of the previously gravid horn with that of the cervix because at about 25 days postpartum the latter starts to exceed the former.

Prostaglandins may have a role in controlling uterine involution, although the postpartum rise in the metabolite of $PGF_{2\alpha}$ (PGFM) may be a reflection of the process of involution rather than the cause. Eley and colleagues (1981) have shown a positive correlation between PGFM concentrations in the peripheral circulation and the diameter of the uterine horn. Using exogenous $PGF_{2\alpha}$ twice daily for 10 days starting from 3 days postpartum, uterine involution has been accelerated by 6 to 13 days; however, the number of animals was small and the frequency and duration of the treatment regimen were very atypical of the normal situation (Kindahl et al. 1982). Because the increase in the uterine mass during pregnancy is due to a combination of increases in both collagen and smooth muscle, then involution must be associated with a reduction of these tissues. This has been shown very clearly in the study of Kaidi and associates (1991) in relation to collagen degradation, but in relation to the loss of smooth muscle the results were equivocal (Tian & Noakes 1991a). The studies of the latter authors also showed that exogenous hormones such as oestrogens, $PGF_{2\alpha}$, and long-acting oxytocin analogues do not influence the rate of involution (Tian & Noakes 1991b). Various dietary supplementations such as beta carotene (Kaewlamun et al. 2011) have been tried in an attempt to hasten involution, but with limited success.

Restoration of the Endometrium

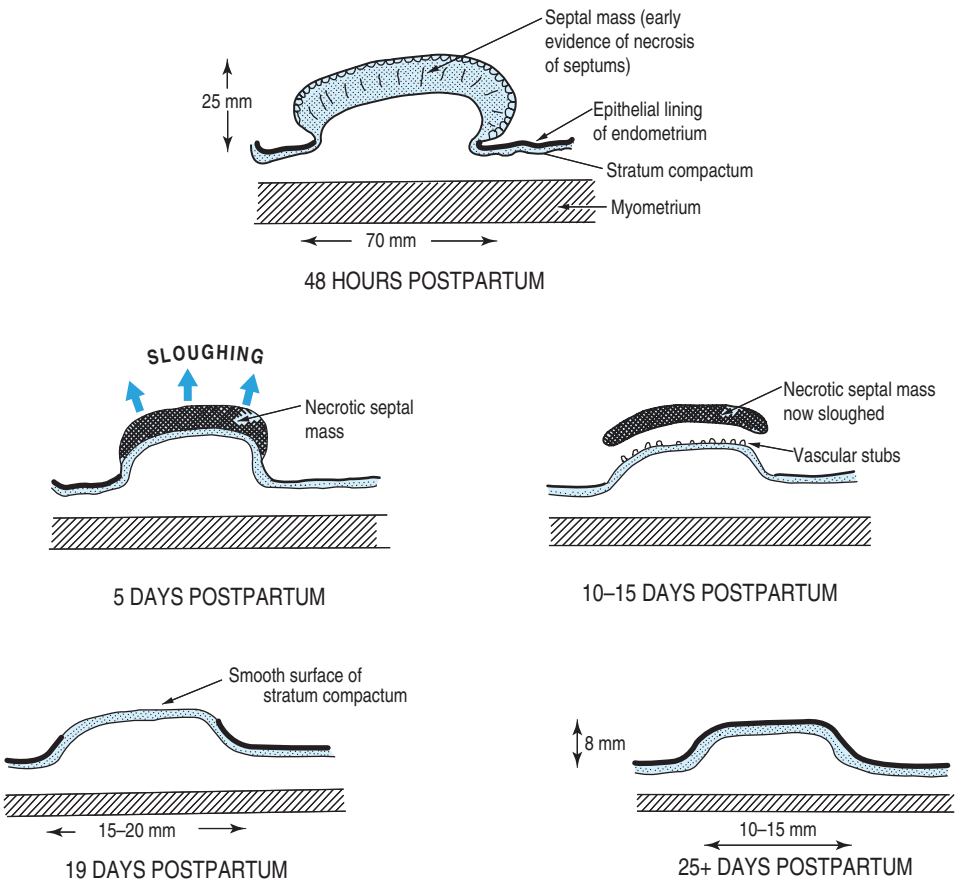
Although placentation in the cow is considered to be of a non-deciduous type, it is well recognised that, during the first 7 to 10 days after calving, there is usually a noticeable loss of fluid and tissue debris. This is sometimes referred to by the herdsperson as the 'second cleansing' or 'secundus'. In human gynaecology the postpartum vulvar discharge is referred to as lochia. The presence of such a discharge in cows is normal, although sometimes individuals will mistake it for an abnormal discharge due to uterine infection and request treatment.

The lochial discharge is usually yellowish brown or reddish brown in colour; the volume voided varies greatly from individual to individual. Pluriparae can void up to a total of 2000 ml, although it is more usually about 1000 ml. In primiparae it is rarely more than 500 ml, and in some animals it is occasionally nil because of the complete absorption of the lochia. The greatest flow of lochia occurs during the first 2 to 3 days; by 8 days it is reduced, and by 14 to 18 days postpartum it has virtually disappeared. At about 9 days it is frequently bloodstained, whereas before it ceases it becomes lighter in colour and almost 'lymph-like'. Normal lochial discharge does not have an unpleasant odour.

The lochia are derived from the remains of fetal fluids, blood from the ruptured umbilical vessels and shreds of fetal membranes, but mainly from the sloughed surfaces of the uterine caruncles. The slough occurs following degenerative changes and necrosis of the superficial layers, first described by Rasbech (1950). The changes that occur are illustrated diagrammatically in Fig. 7.3.

After the shedding of the allantochorion, the caruncle is about 70 mm long, 35 mm wide and 25 mm thick. The endometrial crypts frequently contain remnants of the chorionic villi, which were detached from the rest of the allantochorion at the time of placental separation. Within the first 48 hours postpartum, there is evidence of early necrotic changes in the septal mass of the caruncle; the caruncular blood vessels become rapidly constricted and are nearly occluded. At 5 days the necrosis has proceeded rapidly, so that the stratum compactum is now covered by a leukocyte-laden, necrotic layer. Some of this necrotic material starts to slough and contributes to the lochia. Small blood vessels, mainly arterioles, then protrude from the surface of the caruncle, from which there is oozing of blood, causing a red coloration of the lochia. By 10 days, most of the necrotic caruncular tissue has sloughed and undergone some degree of liquefaction and by 15 days postpartum sloughing is complete, leaving only stubs of blood vessels protruding from the exposed stratum compactum. This eventually becomes smooth by 19 days, as a result of the disappearance of the vessels. A systemic response is observed, probably due to the tissue damage and inflammation associated with the degenerative changes described above, as shown by a rise in the peripheral circulation of acute phase proteins produced by the hepatocytes. These increase rapidly after calving, reaching a peak at 1 to 3 days before declining to basal levels by 2 to 4 weeks (Alsemgeest et al. 1993, Sheldon et al.

VetBooks.ir



• **Fig. 7.3** The changes that occur in the caruncles of the cow during the puerperium. (Data from Gier & Marion 1968).

2001). Acute phase proteins limit tissue damage and also promote tissue repair (Baumann & Gauldie 1994).

Regeneration of the epithelium of the endometrium occurs immediately after parturition in those areas that were not seriously damaged and is complete in the intercaruncular areas by 8 days. Complete reepithelialisation of the caruncle, which is largely derived from centripetal growth of cells from the surrounding uterine glands, is complete from 25 days onwards, although the stage at which complete healing occurs is variable.

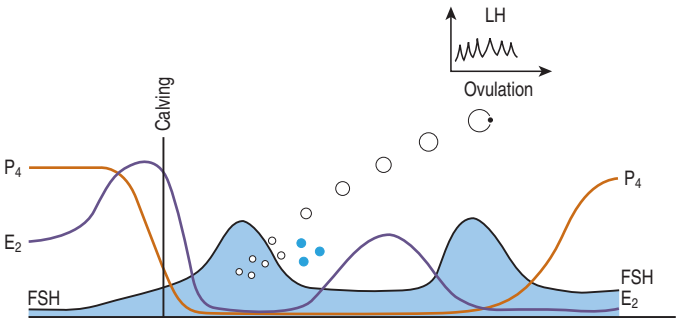
As these changes are taking place, the caruncles are becoming smaller (see Fig. 7.3), so that at 40 to 60 days they consist of small protrusions, 4 to 8 mm in diameter and 4 to 6 mm high. Caruncles of pluriparae differ from those of nulliparae in that they are larger and have melanin pigmentation and a more vascular base.

Return of Cyclical Activity (Ovarian Rebound)

Except during the last month, anovulatory follicular waves occur periodically during pregnancy, with the emergence of follicles up to a maximum of 6 mm in diameter. However, because of the prolonged period of inhibition during pregnancy, due to the continuous negative feedback effect of high steroid concentrations in late pregnancy (particularly progesterone secreted by the corpus luteum and placenta), the pituitary is refractory postpartum, as demonstrated by a lack of response, immediately postcalving, to the administration of gonadotrophin-releasing hormone (GnRH) (Lamming et al. 1979). Between days 7 and 14 postpartum there is an increase in follicle hormone stimulating (FSH) concentrations (over a 3- to 5-day period), associated with the emergence of the first postpartum follicular wave. Using transrectal ultrasonography from 6 to 8 days postpartum, the first follicular wave can be detected with the first dominant follicle larger than 9 mm in diameter being identified at around 10 days (Savio et al. 1990); this tends to occur earlier in dairy than in beef cows. The consequence of this is that the oestradiol and inhibin produced by the follicles suppresses FSH secretion; thus the growing follicles are faced with a decline in FSH. One follicle, usually the largest of the cohort, develops increased numbers of luteinising hormone (LH) receptors and insulin-like growth factor (IGF)-1 binding protein proteases, which allow the maintenance of high levels of bioactive IGF-1 by degrading IGF-binding proteins (Roche 2006). This remaining large follicle continues to grow because of the local paracrine changes within the follicle, despite the reduction in systemic FSH secretion, which prevents other follicles within the cohort from developing. The fate of this follicle (the dominant follicle) is now dependent on the LH-pulse frequency because it is mainly LH-responsive (Fig. 7.4). Thus, according to Roche (2006), one of the following will occur: it ovulates in 30% to 80% of cows; it becomes atretic in 15% to 60% of cows; it becomes cystic in 1% to 5% of cows (see Chapter 24).

Whether or not ovulation occurs is dependent on the following: the size of the dominant follicle; the LH pulse frequency; the concentration of IGF-1. Follicles less than 1 cm rarely ovulate, and the LH pulse frequency required is about one per hour. Thus the first ovulation occurs on average at 21 days in dairy cattle and 31 days in beef cattle (Adams 1999). IGF-1 stimulates follicular

VetBooks.ir



• **Fig. 7.4** The changes in FSH, LH (see inset), oestradiol (E_2) and progesterone (P_4) in relation to the first follicular wave postpartum. (After Roche 2006.)

granulosa cell aromatase activity and thus oestradiol synthesis, therefore potentiating the positive feedback effect of oestradiol on the preovulatory LH surge. After ovulation, there is a luteal phase, which may be of normal length with a return to oestrus after 18 to 24 days, or it may be much shorter, less than 14 days; the latter occurred in 25% of dairy and in 78% of beef cattle (Adams 1999). These short luteal phases probably arise because of premature release of $PGF_{2\alpha}$ arising from the increased oestradiol produced from the formation of the postovulatory dominant follicle on days 5 to 8 of the cycle (Roche 2006). These short luteal phases are more prevalent the earlier the return of normal ovarian activity, i.e., 100% at 0 to 5 days, 60% at 10 to 15 days and 10% at 25 to 30 days postpartum (Terqui et al. 1982).

Many of the ovulations of the first dominant follicle are not associated with behavioural signs of oestrus (so called 'silent heats' or suboestrus; see Chapter 22) (Moller 1970, King et al. 1976, Kyle et al. 1992). This is because the central nervous system requires prior exposure to progesterone to elicit behavioural signs; a similar phenomenon occurs in ewes at the beginning of the breeding season (see Chapter 24). Using continuous time-lapse video recording of herds, 50%, 94% and 100% of cows were identified in oestrus at the first, second and third postpartum ovulations (King et al. 1976); however, with daily observations the frequencies of detected oestrus were only 16%, 43% and 57%, respectively. Sequential milk progesterone assays have enabled the onset of cyclical activity to be determined by the presence of elevated progesterone concentrations. In a survey of 533 dairy cows in four herds (Bulman & Wood 1980), nearly half (47.8%) of the cows had resumed normal cyclical ovarian activity within 20 days of calving, and by 40 days this had increased to 92.4%. In this study only 4.9% appeared to have a delayed return to cyclical activity, i.e., had not returned by 50 days postpartum, and 5.1% of the cows subsequently ceased normal cyclical activity having initially returned to oestrus. A small number, 1.9%, had prolonged luteal activity, presumably due to a persistent corpus luteum or luteal cyst (see Chapter 24). These ovarian abnormalities depressed fertility, as measured by the calving to conception interval, which was 98 days for those with a delayed start to ovarian activity, 102 days for those with persistent luteal function and 124 days for those cows in which there was cessation of cyclical activity, compared with 85 days for normal cows (see Chapter 24). Cows with either shorter or longer luteal phases than normal, resulting in shorter or longer cycles and atypical progesterone patterns before the first service, have longer calving to conception intervals, more services per conception and lower first-service pregnancy rates (Lamming & Darwash 1998). The incidence of prolonged cycles has increased from 3% in the mid-1980s to 11% to 22% in the late 1990s and early 2000s (Roche 2006).

The uterus also exerts an influence on ovarian function because it has been known for some time that the majority of ovulations postpartum occur in the ovary contralateral to the previously gravid horn (Gier & Marion 1968) – the effect being less the later ovulation occurs. It has also been shown that PGFM usually returns to normal levels before the first postpartum ovulation (Thatcher 1986). Similarly, the ovario–uterine axis exerts an inhibitory effect on pituitary LH secretion during the early postpartum period; experimental hysterectomy results in a rapid increase in plasma gonadotrophin concentrations (Schallenberger et al. 1982). There is substantial evidence of an interaction between the uterus and ovaries postpartum, as shown by the observation that the ovary on the side adjacent to the previously gravid horn (the ipsilateral ovary) is less active compared with the contralateral ovary (Nation et al. 1999). The majority of first dominant follicles (70% to 82%) and thus ovulations occur in the ovary contralateral to the previously gravid horn (Nation et al. 1999), with the effect persisting for 20 to 30 days postpartum. The consequence of the difference in folliculogenesis between the two ovaries is that larger follicles on the ipsilateral ovary are associated with better fertility, which is associated with shorter calving–conception intervals and improved pregnancy rates (see Chapter 24; Bridges et al. 2000, Sheldon et al. 2000). As will be discussed later in this chapter, the postpartum uterus in most cows (more than 90%) is contaminated with a wide range of bacteria; there is good evidence that the bacterial load has an influence on folliculogenesis. Sheldon and associates (2002) found that when bacterial growth scores were high on day 7 and 21 postpartum, fewer first or second dominant follicles were selected in the ipsilateral than in the contralateral ovary, respectively. Furthermore, the diameter of the first dominant follicle was smaller, slower growing and had reduced oestradiol secretion in cows with a high bacterial score on day 7 postpartum. Because no effect was seen on FSH secretion or follicular wave emergence, it is likely that this effect is mediated locally. However, bacterial endotoxins and intermediary cytokines have been shown to exert an influence at both the hypothalamic and anterior pituitary level (Peters & Lamming 1990; Williams et al. 2001).

Adrenocorticotrophic hormone (ACTH) (Liptrap & McNally 1976) and corticosteroid administration (da Rosa & Wagner 1981) suppress the secretion of LH. Stimulation of the teat and removal of milk cause a rise in glucocorticoids (Wagner & Oxenreider 1972, Schams 1976). Suckling, which is known to delay the return of cyclical ovarian activity, may exert its effect by modifying the tonic release of GnRH and LH by the release of opioid peptides. The role of prolactin is equivocal for, although bromocriptine treatment during lactation had little or no effect on LH release in cows, there appears to be a reciprocal relationship between the hypothalamic control of LH release and prolactin release. Opioid antagonists increase LH and decrease prolactin secretion; the effects of the agonists are the reverse. The mammary gland has also been shown to have an endocrine role (Peters & Lamming 1990).

Elimination of Bacterial Contamination

At calving and immediately postpartum, the vulva is relaxed and the cervix is dilated, thus allowing bacteria to gain entry into the vagina and thereafter the uterus. A wide range of bacteria may be isolated from the uterine lumen; Elliott and associates (1968) identified 33 different species, those most frequently isolated being *Trueperella* (formerly *Arcanobacterium*) *pyogenes, Escherichia coli*,

VetBooks.ir

streptococci and staphylococci (Johanns et al. 1967, Elliott et al. 1968, Griffin et al. 1974). Recent studies (Gilbert & Santos 2016) have shown that in the first 7 days postpartum, E. coli were most frequently isolated, but was uncommon after that time, whereas *T.pyogenes* were the most prevalent at 3 weeks and were more likely to be isolated from cows from which E. coli had been previously isolated. The presence of *T pyogenes* at three weeks increased the likelihood of concomitant or subsequent infection with gram negative anaerobes. The isolation of *T pyogenes* at 3 weeks postpartum significantly reduced the chances of pregnancy after 150 days in milk, whereas the presence of α–haemolytic streptococci spp at 7 days improved reproductive performance. In earlier studies there was little reference to the presence of anaerobic bacteria, either because anaerobic culture was not performed or because the methods of culture and isolation were not strict enough. A number of studies (Noakes et al. 1991, Sheldon et al. 2002, Sheldon & Dobson 2004, Foldi et al. 2006) have identified the frequent presence of Gram-negative anaerobes, which play an important role in the pathogenesis of metritis/endometritis because of their synergism with other species of bacteria (Ruder et al. 1981, Olson et al. 1984) (see Chapter 25). Table 7.1 shows the three categories of bacteria isolated from the uterus of postpartum cows and their pathogenicity in relation to uterine disease. The most common isolates in this study were: *E. coli*, streptococci, T *pyogenes, Bacillus licheniformis, Prevotella* (formerly *Bacteroides*) species and *Fusobacterium necrophorum* (Sheldon et al. 2002). Griffin and colleagues (1974) stressed that the flora fluctuates as a result of spontaneous contamination, clearance and recontamination during the first 7 weeks postpartum. In all studies, there is a decrease with time in the percentage of uteri from which bacteria are isolated. This is exemplified in the study of Elliott and associates (1968), in which 93% of uteri examined within 15 days of calving were contaminated, compared with 78% between 16 and 30 days, 50% between 31 and 45 days and only 9% between 46 and 60 days. Other studies (Griffin et al. 1974, Sheldon et al. 2002) have shown a similar very high bacterial contamination rate during the first 20 to 30 days postpartum, with a subsequent decline so that, in normal, healthy cows, the uterus is usually sterile by 6 to 8 weeks postpartum.

TABLE 7.1 Categorization of bacteria isolated by aerobic and anaerobic culture of uterine swabs, based on their potential pathogenicity

BACTERIAL CATEGORY		
1	2	3
Trueperella pyogenes	Acinetobacter spp.	Aerococcus viridans
Prevotella spp.	Bacillus licheniformis	Clostridium butyricum
Escherichia coli	Enterococcus faecalis	Clostridium perfringens
Fusobacterium necrophorum	Haemophilus somnus	Corynebacterium spp.
Fusobacterium nucleatum	Mannheimia haemolytica	Enterobacter aerogenes
	Pasteurella multocida	Klebsiella pneumoniae
	Peptostreptococcus spp.	Providencia rettgeri
	Staphylococcus aureus (coagulase-positive)	Providencia stuartii
	Streptococcus uberis	Proteus spp.
		Propionibacterium granulosa
		Staphylococcus spp. (coagulase-negative)
		α-haemolytic streptococci
		Streptococcus acidominimus
		Coliforms
		Aspergillus spp.
		Fungi
		Bacteroides spp.
		Aeromonas spp.

Categories: (1) recognized uterine pathogens associated with uterine endometrial lesions; (2) potential pathogens frequently isolated from the bovine uterine lumen and cases of endometritis but not commonly associated with uterine lesions; (3) opportunist contaminants transiently isolated from the uterine lumen and not associated with endometritis.
Data from Sheldon et al. 2002.

Blood, cell debris and sloughed caruncular tissue provide an ideal medium for bacterial growth; however, in most cases the bacteria do not colonise the uterus to produce a metritis/endometritis (see Chapter 25). The main mechanism involved in the elimination of the bacteria is phagocytosis by migrating leukocytes, the bacteria being ingested and then killed intracellularly by enzymes, reactive oxygen species, nitric oxide, proteases, and phospholipids released by the cytoplasmic granules (Sheldon 2004). In addition, the phagocytes also release proinflammatory cytokines such as tumour necrosis factor α and interleukins, which stimulate the acute phase protein response. Persistence of uterine contractions (for up to 4 days), sloughing of caruncular tissue, and uterine secretions all assist in the physical expulsion of the bacteria. In addition, the early return to cyclical activity is probably important because the oestrogen-dominated uterus is more resistant to infection. However, there is evidence that in some cases early return to oestrus may be disadvantageous (Olson et al. 1984; and see Chapter 25) in that, if the bacteria are not eliminated at the first oestrus, then the cow enters the first luteal phase in which progesterone is the dominant hormone.

Factors Influencing the Puerperium

Uterine Involution

Many of the methods used to measure the rate of involution have been largely subjective and thus inaccurate; however, with the advent of transrectal ultrasound imaging, accurate measurements of uterine and cervical dimensions are now possible (Okanu & Tomizuka 1987, Tian & Noakes 1991a, Risco et al. 1994, Sheldon et al. 2000, Mateus et al. 2002). Some of the factors include the following:

- **Age.** Most observers have found that involution is more rapid in primiparae than pluriparae.
- **Season of year.** Equivocal, but if there is any influence, involution is probably most rapid in spring and summer.
- **Suckling vs milking.** Results are contradictory; it may be a breed influence on the effect of time to return of cyclical ovarian activity.
- **Climate.** There is evidence that heat stress can accelerate and inhibit the speed of involution.
- **Periparturient abnormalities.** Dystocia, retained placenta, hypocalcaemia, ketosis, twin calves, and metritis delay involution. Periparturient problems cause an overall delay in the completion of this process of 5 to 8 days (Buch et al. 1955, Tennant & Peddicord 1968, Maizon et al. 2004).
- **Subclinical hypocalcaemia**. Delayed reduction in uterine horn length (Heppelmann et al. 2015).
- **Delayed return to cyclical ovarian activity.** Both a cause and an effect because there is good evidence that the uterus can also influence the ovary (see previous mention and Bridges et al.

VetBooks.ir

2000, Sheldon et al. 2000) as well as the ovary influencing the uterus.
- **Metritis.** This affects uterine diameter.

Restoration of the Endometrium

Retained fetal membranes and metritis inhibit healing, whereas ovarian rebound to cyclical activity may have an influence.

Return of Cyclical Activity (Ovarian Rebound)

Factors that may cause delay include the following:
- **Periparturient abnormalities.** A number of authors have shown that a whole range of periparturient problems delay ovarian rebound.
- **Milk yield.** There is much contradictory evidence on the influence of current milk yield; some authors have demonstrated an effect of the lactation preceding calving. It is frequently difficult to differentiate the influence of nutrition and milk yield.
- **Nutrition.** In both beef suckler and dairy cows, inadequate feeding, especially of energy, during the dry period and after calving inhibits ovarian rebound. This will usually be shown as poor body condition score. Ovulation of the dominant follicle will occur after 3.2 ± 0.2 or 10.6 ± 1.2, follicular waves in beef cows in good or poor body condition score, respectively (Crowe, personal communication, 2000). The effect of nutrition on ovarian function is likely to be mediated by insulin, IGFs and leptin (see Chapters 1 and 24).
- **Breed.** There is a longer delay in beef compared with dairy cows as well as evidence of a breed effect within the two groups, especially in the former.
- **Parity.** Most observers have recorded a delay in primiparae compared with pluriparae – up to the fourth lactation. Conflicting opinions have probably arisen because of the problems of separating the influences of nutritional status, milk yield, and weight loss.
- **Season of the year.** There is good evidence that photoperiod has an effect. This has been shown by experimentally subjecting heifers to continuous darkness, which inhibited the return of cyclical activity (Terqui et al. 1982). Peters and Riley (1982) showed that suckler cows that calved between February and April were acyclic significantly longer than those that calved between August and December. By stimulating the effects of short day length using exogenous melatonin, it has been possible to delay the return to oestrus and ovulation in postpartum beef cows (Sharpe et al. 1986).
- **Climate.** Cows in tropical climates show a delay compared with those in temperate zones.
- **Suckling intensity and milking frequency.** The greater the frequency of milking and the intensity of suckling (number of calves), as well as calf presence, the longer the period of acyclicity. This can be reversed in beef suckler cows by restricting the access of the calf to suckle from 30 days postpartum.

Elimination of Bacterial Contamination

Failure to do this will result in the development of metritis and endometritis (see Chapter 25). Factors that delay this include the following:
- **Magnitude of bacterial contamination:** a massive bacterial flora may overwhelm natural defence mechanisms.
- **Nature of bacterial flora:** Many obligate Gram-negative anaerobes, such as Fusobacterium necrophorum and Prevotella spp., exhibit synergy with Gram-positive aerobic contaminants.
- **Delayed uterine involution**
- **Impaired uterine defence mechanisms**
- **Retained fetal membranes**
- **Calving trauma to the uterus**
- **Return of cyclical ovarian activity:** There is contradictory evidence because, with an early return to oestrus, there is an early oestrogen peak, which should assist in the elimination of the bacteria. However, if the level of contamination is such that a significant bacterial flora persists after the first oestrus, the subsequent luteal phase may allow the bacteria to proliferate (Olson et al. 1984).

Horse

The puerperium is shorter in the mare than in the cow, with rapid involution and relatively good conception rates at the first postpartum oestrus. One of the early papers published by Gygax and associates (1979) is worthy of reading.

In pony mares it is usually possible to identify the outline of the uterine body and horns by rectal palpation at about 12 hours postpartum; in thoroughbreds it is longer. Studies have shown that the uterine horns reach their pregravid size by 30 to 32 days postpartum, and the cervix remains slightly dilated until after the first oestrus. Using transrectal ultrasonography, it has been shown that involution is very rapid between days 1 and 3 postpartum, the reduction being less rapid after day 7. It was complete in the previously gravid horn by day 24 and nongravid horn by day 21, as shown by the absence of any further reduction in size (Lemes et al. 2017). Lochial discharge is relatively slight in most mares and usually ceases by 24 to 48 hours after foaling, although in a few cases it can persist for up to a week. One interesting feature of the mare's uterus postpartum is that fluid accumulates in the uterine lumen. Lemes and colleagues (2017) found that, although no fluid could be detected using transrectal ultrasonography on the first day postpartum, it was present in all of their mares by day 3, thereafter gradually disappearing so that by day 16 it was present in only 1 of the 10 mares examined sequentially. Interestingly, no fluid was observed in any mare by 3 days after ovulation. The cervix remains slightly dilated until after the first oestrus.

Ovarian rebound is rapid, the foal heat occurring 5 to 12 days postpartum. Evidence of follicular activity can be determined as early as the second day. Although conception rates at this first oestrus are lower than at other times, because uterine involution and endometrial repair is not complete, remarkably a large number of mares are fertile, which proves that the endometrium is capable of sustaining a pregnancy. Andrews and McKenzie (1941) found that the endometrium was fully restored by 13 to 25 days postpartum.

There is nothing comparable with the degeneration and sloughing of the endometrium that occurs in ruminants. On the day of foaling, the microcaruncles (see Chapter 4) of the endometrium are unchanged; the stratum spongiosum compactum is oedematous, with a small number of distended glands. However, by day 1 postpartum, there are obvious signs of degenerative changes in the microcaruncles and endometrial glands, and by 2 to 5 days the epithelium of the microcaruncles shows evidence of cytoplasmic vacuolisation, karyorrhexis and an inflammatory reaction with neutrophils and phagocytic cells. On day 7 postpartum the endometrium is similar to that of a mare just before oestrus, with the whole regenerative process complete by 9 to 10 days, when the histological structure is typical of that of a mare in oestrus (Gomez-Cuetara et al. 1995). The maternal crypts disappear as a result of lysis and shrinkage of the epithelial cells of the endometrium, with

VetBooks.ir

condensation of their contents and collapse of the lumen of the crypt. Gygax and associates (1979) reported that the endometrium is usually quite normal, apart from some pleomorphism of the luminal epithelium at 14 days, but in some mares inflammatory changes may persist for several weeks. Compared to ruminants, the uterus returns to its normal nonpregnant state very quickly, thus being able to sustain and support pregnancy following early mating postpartum.

As in the cow, bacterial contamination of the uterus from the environment is a frequent occurrence. In study by Purswell and colleagues (1989), in 7 out of 13 mares swabbed (54%) aerobic bacteria were isolated from uterine swabs at foaling; the species most frequently isolated being streptococci spp. *Truperella pyogenes* and coliforms. Gram-negative anaerobes were isolated from 3 of 13 (23%). By the first foal heat, in 3 out of 13 mares aerobes were isolated, and by the second foal heat all swabs were sterile. Thus most bacteria are eliminated at the foal heat, and by the second postpartum oestrus in normal healthy mares, all of them are eliminated.

Retained fetal membranes delay involution, although exercise is said to hasten it. The process is more rapid in primiparae than in pluriparae.

Sheep and Goat

The puerperium in both these species is very similar to that in the cow, being typical of ruminants in general. The main difference is that, because they are both seasonal breeders, parturition is followed by a period of anoestrus. There is less information available for the doe, but changes are similar in the two species.

Involution

There is rapid shrinkage and contraction of the uterus, particularly during the third to tenth days postpartum, as determined by measurements of uterine weight and length, diameter of uterine body and previously gravid horn. According to these measurements, involution is complete in the ewe by 20 to 25 days (Uren 1935, Hunter et al. 1968, Foote & Call 1969). In the doe goat, as determined by sequential slaughter, involution is complete by 28 days (Tielgy et al. 1982), although using a combination of slaughter and transabdominal ultrasonography involution was found to be complete by 19 days in Balady goats (Ababneh & Degefa 2005). Using sequential radiography and radio-opaque markers, uterine involution has been shown to be complete by about 28 days in suckling ewes, although an unexplained increase in uterine dimensions has been reported at 42 days (Tian & Noakes 1991b, Regassa & Noakes 1999). Using sequential transrectal and transabdominal B-mode ultrasonography little change in uterine size occurred after day 17, but it was not complete until day 30 (Hauser & Bostedt 2002). Involution is largely due to collagen breakdown because, although tissue collagen concentrations remain fairly constant with advancing pregnancy, there is a seven- to eightfold increase in uterine mass; the reduction in size can only be a reversal of this process.

Restoration of the Endometrium

As in the cow, there are profound changes in the structure of the caruncles with degeneration of the surface, necrosis, sloughing, and subsequent regeneration of the superficial layers of the endometrium. There is evidence, determined by the slaughter of animals 3 days before the expected date of lambing, of prepartum hyaline degenerative changes. This occurs in the connective tissue at the base of and adjacent to the endometrial crypts and also involves both directly and indirectly the walls of the arteries and veins, thus reducing their lumens; the fetal villi are unaffected (Van Wyk et al. 1972).

After dehiscence and separation of the placenta, there is further hyaline degeneration of caruncular tissue, which results in constriction of the blood vessels at the base of the maternal crypts. There is necrosis of the surface layer of the caruncle so that, at about 4 days postpartum, the most superficial layers are undergoing autolysis and liquefaction, which are responsible for the dark reddish brown or black coloration of the lochial discharge at this time. By 16 days postpartum, necrosis of the whole superficial part of the caruncle has occurred with, in most cases, separation of the brown necrotic plaque so that it is lying free in the uterine lumen. The caruncles now have a clean, glistening surface, and the process of regeneration is completed by the reepithelialisation of the caruncles by about 28 days. Similar timing of events has been reported by Gray and associates (2003); however, they also found that the tissue remodeling also occurred in the intercaruncular regions, as well as in the more obvious caruncles. As in the cow, there is also a rise in acute phase proteins in the peripheral circulation, which may well reflect a systemic response of the hepatocytes to the degenerative and inflammatory changes in the caruncles or the presence of bacterial contamination (Regassa & Noakes 1999). They increase rapidly after lambing, before declining 2 to 3 weeks later.

The quantity of lochia voided is variable. Initially, it arises from blood, fetal fluids and placental debris, but as the puerperium proceeds the liquefied, sloughed caruncular tissue is the main source.

Return of Cyclical Activity (Ovarian Rebound)

Although in temperate climates ewes normally become anoestrus after lambing, there are numerous reports of ovarian activity occurring within a few days to 2 weeks postpartum; Gray and associates (2003) found that oestrogen concentrations in the peripheral serum were high at the time of parturition, declined rapidly to day 4 postpartum but then peaked at day 6. Thus follicular growth is common, but ovulation is unusual; when it does occur it is usually associated with a silent heat. Failure of follicular maturation and ovulation is probably due to inadequate release of LH as a result of a deficiency in GnRH synthesis and secretion. As a result, basal LH levels and the pulse frequency of episodic LH secretion are inadequate to stimulate normal ovarian function (Wright et al. 1981). It is possible that the time of the year when the ewes lamb has a profound effect, with those that lamb early and within the normal breeding season being more likely to have normal ovarian rebound. Hafez (1952) has suggested that it is most likely to occur in those breeds that have a longer than average breeding season.

Elimination of Bacterial Contamination

Although it might have been expected that there would be a similar pattern of bacterial contamination to that previously described for the cow and mare, bacteria could not be isolated from uterine swabs obtained from 10 ewes, 1 to 14 days postpartum, at surgical hysterotomy. More recently, using sequential transcervical swabbing of 13 ewes during the first week postpartum, bacteria were isolated from four ewes; thus in the other nine ewes the uterus was sterile (Regassa & Noakes 1999). Similar results were described by Ababneh and Degefa (2006) in Balady goats in their study, with

VetBooks.ir

bacterial contamination of the uterus, but not the vagina, absent by 10 days postpartum. Until then, E. coli and staph aureus were the most common isolates.

Pig

There are a number of studies that describe the changes that take place during the puerperium of the sow (Palmer et al. 1965, Graves et al. 1967, Svajgr et al. 1974). It is important that the changes should occur rapidly, with a return to a normal pregravid state, so that pregnancy can be established as quickly as possible after weaning.

Involution

Apart from the rapid initial uterine weight loss, which occurs in the first 5 days postpartum, involution is fairly uniform and is complete by 28 days. After day 6, most of the loss of weight is due to changes in the myometrium, notably a reduction in cell numbers, cell size and amounts of connective tissue. Reduction in the latter can be determined by measuring collagen degradation markers in urine, notably hydroxylsyl pyridinoline (HP), as well as lysyl pyridinoline (LP) that occurs mainly in bone. The results were consistent with a postpartum increase of soft tissue collagen catabolism because bone has a low HP:LP ratio of 4 whereas soft tissues such as the uterus have a high HP:LP ratio of 20 or higher because they contain only trace amounts of LP, which is related in parallel with uterine involution (Belstra et al. 2005).

Restoration of the Endometrium

The uterine epithelium 1 day after farrowing is of a low columnar or cuboidal type, and there is evidence of the extensive folding that is present during pregnancy. The epithelial cells at 7 days are very low and flattened and show signs of degenerative changes; however, there are also signs of active cell division, which is subsequently responsible for regeneration of the epithelium. This latter process is complete by 21 days and is capable of sustaining pregnancy.

Return of Cyclical Activity (Ovarian Rebound)

Suckling and subsequent weaning have a profound effect upon ovarian rebound and indirectly on other puerperal changes in the genital tract. In most cases there will be no return to oestrus and ovulation until the piglets are removed. In the study by Palmer and associates (1965), there was no evidence of ovulation during suckling periods of up to 62 days. In general, the later the time of weaning, the shorter the time interval to the first oestrus; for example, if the litter is weaned at 2, 13, 24 and 35 days postpartum the mean times to first oestrus were 10.1, 8.2, 7.1 and 6.8 days respectively (Svajgr et al. 1974). The time to the first ovulation can also be shortened by the temporary removal of the whole litter for varying periods during the day (partial weaning) or the permanent removal of part of the litter (split weaning) (Britt et al. 1985; Chapter 33).

There is rapid regression of the corpora lutea of pregnancy, with signs of cellular degeneration by 3 days postpartum, so that by day 7 they consist mainly of connective tissue. There is considerable follicular activity during suckling, with follicles sometimes reaching a diameter of 6 to 7 mm. This is sometimes associated with behavioural oestrus shortly after farrowing but in no cases is there ovulation: the follicles become atretic.

In a study of the endocrine changes of the postpartum sow, Edwards and Foxcroft (1983) showed that, irrespective of whether weaning occurred at 3 or 5 weeks, the great majority of sows showed a preovulatory LH surge within 7 days of weaning. At the time of weaning there was a transient rise in basal LH of about 2 days' duration but, unlike the cow, there was no consistent change in the episodic release of LH. Prolactin concentrations are high during lactation but decline rapidly to basal levels a few hours after weaning; mean FSH concentrations rise 2 to 3 days after weaning. Follicular growth and ovulation are inhibited during lactation because of suppressed LH secretion; this probably occurs as a result of direct neural inhibition of GnRH synthesis and release. Inadequate nutrition, particularly severe weight loss, can delay the onset of cyclical ovarian activity, as can the season of the year (Britt et al. 1985). It is generally accepted that exposure to the boar has the reverse effect.

The time of weaning, and thus the time of first oestrus, also has other effects on reproductive function, owing to the time taken for the completion of the puerperium. Fertilisation rates and pregnancy rates are improved the later the time of weaning, and hence the later sows are served after farrowing.

Dog

Because the bitch is monocyclic, parturition is followed by anoestrus, the onset of the next heat being unpredictable. Regression of the corpora lutea of pregnancy is initially rapid, so that by 1 or 2 weeks postpartum they have been reduced in size. However, thereafter it is much slower, so that even after 3 months the nonfunctioning corpora lutea measure 2.5 mm in diameter.

The rate of involution is similar to that of other species, and the uterine horns are restored to their pregravid size by 4 weeks. The lochial discharge immediately postpartum is very noticeable because of its green colour due to the presence of uteroverdin; unless there are complications, this should change to a blood-stained, mucoid discharge within 12 hours. In some bitches a blood stained vulvar discharge can persist many months postpartum; this is due to subinvolution of the endometrium where the placenta was attached and was first described in 1966 by Beck and McEntee. In a large study in which reproductive tracts were examined from 95 bitches, 20 had subinvolution of the placental sites. On gross examination the affected sites were haemorrhagic in appearance and about twice the size of the normally involuted sites. Microscopically, large masses of collagen, haemorrhage, and dilated endometrial glands were present. In one study (Voorhorst et al. 2013) a discharge persisted for many months in one bitch – 270 days postpartum. The same authors found that treatment with low doses of megestrol acetate (0.1 mg/kg) per day for one week followed by half the dose for the second week was successful in eliminating the discharge.

In the nonpregnant bitch, the surface of the endometrium undergoes desquamation followed by regeneration, with repair completed by 120 days after the onset of oestrus (see Chapter 1). After pregnancy and normal parturition the time taken for regeneration of the endometrium is about 2 weeks longer. The areas of previous placental attachment are dark green/grey in colour, subsequently becoming dark brown and visible macroscopically up to 12 weeks postpartum. Desquamation of the epithelial lining of the endometrium starts at 6 weeks postpartum and is complete by 7 weeks; the whole process of regeneration has ended by 12 weeks, when involution can be considered to be complete (Orfanou et al. 2009).

VetBooks.ir

Cat

Studies on uterine involution and restoration of the endometrium during the puerperium show that they are more rapid than in other species. One study involving Turkish Van cats, using transabdominal ultrasonography, suggested that morphological involution was complete as early as 5 to 6 days (Sendag et al. 2016). Queen cats will normally have an obvious serosanguinous vulvar discharge for up to a week or more after kittening, gradually declining so that by about 2 weeks it will have disappeared. Transabdominal ultrasonography has shown that uterine involution is complete by 25 days postpartum when the dimensions become comparable with those of anoestrus (Blanco et al. 2015). Lactation will usually suppress oestrus effectively (Schmidt et al. 1983), but if the queen has no kittens to suckle, or only one or two, she may show a postpartum oestrus 7 to 10 days after parturition, and thus if mated she may conceive.

Pharmacological Agents in the Control of Reproduction

RICHARD LAVEN

Manipulation of normal cyclic activity can be used simply for convenience, e.g., ensuring a bitch is in oestrus when a particular dog is available for mating or avoiding the need for oestrus detection in a group of dairy heifers kept at pasture in a remote rural location. However, it is most commonly used, especially in livestock, to improve productivity. Potential benefits include: producing offspring out of season in species that are seasonal breeders and also in nonseasonal breeders by reducing the interval from birth to the next pregnancy.

Non-Exogenous Hormone Methods

There are also a variety of methods of manipulating cyclic activity, without using reproductive hormones are available. These include altering exposure to light (which can be mimicked using exogenous melatonin), the timing of weaning, and exposing females to a fertile male.

Light

Ensuring that parturition occurs at a time when resources are available and sufficient to feed the neonate is vital for reproductive success, as is ensuring that, when resources are limited, they are used for functions other than reproduction that are critical for animal survival such as immune functions, thermoregulation and cellular maintenance. This is particularly important in temperate regions where there is significant seasonal variation in the availability of resources.

In such situations the ability to detect variations in photoperiod can be very useful in determining where to put resources. This requires that the animal to be able to reliably estimate current day length and identify whether it is increasing or decreasing. Identifying changes in day length is critical, as without this ability, distinguishing between spring and autumn is impossible. So mammals that respond to photoperiod are often divided into those in which reproductive activities are apparently stimulated to activity by a lengthening photoperiod (e.g., horses and cats) and those in which the stimulus appears to be decreasing day length (e.g., sheep and goats). Interestingly, the process does not appear to be principally one of stimulation but is driven by the development of refractoriness to photoperiod. So, for example, in sheep and goats, the onset of the breeding season in autumn occurs when the animal becomes refractory to the suppressive effect of long day length, whereas in winter the breeding season ends when the animal becomes refractory to the stimulatory effect of the short days (Delgadillo et al. 2011, Walton, et al. 2011). These results suggest that, in seasonal breeders, there is an endogenous circannual rhythm involved in regulating seasonal reproductive changes that is synchronised by changes in photoperiod.

In mares artificial alterations to photoperiod are commonly used to advance the onset of the breeding season. The most commonly used programme is a fixed 15-hour daylight programme, but there are alternatives such as a 2-hour pulse of artificial light starting 9 hours after the onset of darkness (Nagy et al. 2000). As these programmes take 60 to 90 days to be effective, in the Northern hemisphere they need to start in early December in order to maximise the chance of the mare being mated at the optimal time. There is significant individual variation in response, i.e., the timing of the onset of cyclical ovarian activity to these changes in photoperiod. To overcome this and improve the synchronisation of the first ovulation, artificial photoperiod programmes can be combined with exposure to exogenous progesterone for 12 to 15 days at the end of the programme (Nagy et al. 2000).

Artificial alteration of the photoperiod has also been used to control cyclicity in sheep and goats. However, these species need decreasing daylight to stimulate activity. The production of short days in midsummer requires special daylight-proof housing, significantly adding to costs (Chemineau et al. 1992). However, reproductive activity can also be stimulated by exposing animals to artificially long days and then returning them to the natural shorter day; for example, exposing ewes in late pregnancy or at parturition to 22 hours of 'daylight' for at least one month followed by a return to natural day length will stimulate reproductive activity as the exposure to the long days results in the ewes no longer being refractory to the stimulatory effect of the short natural day length (Chemineau et al. 1992). This treatment will result in ewes having a fertile oestrus 3 months after lambing without the need for daylight-proof housing. These regimes seem to be more effective in the doe than the ewe, which may be the result of the increased seasonality in the latter species. However, in both goats and sheep, modifying photoperiod is not used on many commercial farms, often because of the anticipated costs but also because of the wide range of response to such programmes, particularly in sheep.

The Male Effect

Introducing a male into a group of females can induce an oestrus even in animals that were in seasonal anoestrus. This 'male effect'

VetBooks.ir

has been studied extensively in goats and sheep and is produced in response to a range of signals from the male, including odour and behaviour. Exposure to these signals stimulates LH secretion followed by ovulation and the return of cyclical ovarian activity (Vielma et al. 2009). There is some synchronisation of oestrus, but it is far from complete. Another issue is that, although the most obvious photoperiod response is seen in the doe and the ewe, there are also seasonal differences in male fertility. Out-of-season males can fail to produce the signals that stimulate female cyclicity; this can be prevented by using the same lighting regimes for males that are effective in females (Vielma et al. 2009) or by using melatonin.

Weaning and Lactational Anoestrus

In many mammalian species lactation is associated with suppression of cyclical activity. In the sow lactation has been shown to inhibit the release of LH, although as lactation progresses this inhibition decreases. Weaning, which removes both the suckling-induced neuroendocrine reflexes and the nutritional impact of milk production, results in rapid restoration of cyclicity as the inhibition of LH secretion disappears. If litters from a number of sows are weaned at the same time, this will result in some degree of synchrony of oestrus (see Chapter 33). Early weaning of piglets (3–4 weeks) is commonly used in order to optimise reproductive performance on commercial pig farms. However, this early weaning has significant impacts on piglet health and performance, particularly in the postweaning period (Downing 2015), so there needs to be a focus on inducing oestrus in lactating sows. Several strategies that stimulate sows into oestrus and ovulation are available, including group housing, boar exposure and intermittent suckling (Downing 2015); these are likely to become more important in the future.

Hormonal Control of the Oestrous Cycle

Cyclic activity is a complex process that involves many coordinated effects. As such, there are a large number of stages in which cyclic activity is (or can be) influenced by specific hormones, and thus a large number of hormones have been used exogenously in an attempt to influence normal cyclic activity.

The hormones that are commonly used in these attempts can be divided into six categories: (1) melatonin (described earlier in the chapter); (2) oestrogens; (3) progestagens; (4) prostaglandins; (5) compounds that stimulate the release of anterior pituitary hormones; and (6) compounds that replace or supplement anterior pituitary gonadotrophins.

Melatonin

Photoperiod affects fertility by influencing the synthesis of melatonin (see Chapters 1 and 3), a hormone produced by the pineal gland. The light signal is transmitted from the retina to the pineal gland and produces a circadian rhythm in the synthesis and secretion of melatonin, with high concentrations at night and low concentrations during the day. Melatonin concentration influences a range of physiological processes, including the reproductive functions described earlier, but also appetite and food intake and body temperature.

In species which respond to short days and, consequently, respond to increasing concentrations of melatonin (e.g., sheep and goats), exogenous melatonin has proven to be an effective method of advancing the onset of cyclical ovarian activity. Such regimes are, unsurprisingly, ineffective in 'long-day' breeders (which respond to decreasing melatonin concentrations). As yet, no effective method other than exposure to light has been shown to reliably reduce melatonin secretion in long-day breeders.

In susceptible species melatonin can be supplemented orally or, more commonly, by using a subcutaneous implant. Ewes (and does) need to be separated from males for at least 7 days before the insertion of the implant and then remain separated for 30 to 40 days after insertion. Males should be introduced at this point, even though peak mating activity will occur approximately 60 days after implant insertion. In receptive animals the breeding season can be advanced by 2 to3 months with good fertility. However, the optimal timing of insertion relative to the expected onset of the breeding season is significantly affected by breed, particularly in sheep (Mura et al. 2017). These breed effects are probably related to the differences between sheep breeds in their sensitivity to changes in photoperiod. Melatonin implants can be used in bucks and rams to stimulate reproductive behaviour, but doses required are higher than in the equivalent females. Melatonin should not be used in nulliparous females.

Oestrogens

Oestradiol is an essential part of the hormone cascade that leads to ovulation; it is also responsible for the behavioural changes associated with oestrus as it stimulates sexual receptivity and increases attractiveness to the male. It also has effects on follicular dynamics and corpus luteum (CL) formation. Therefore exogenous oestrogens are an obvious choice of a hormone that should influence cyclical ovarian activity. Both synthetic and natural oestrogens have been used in a wide range of species. However, especially when used alone, the main effects in many species of exogenous oestrogens are changes in the uterus/oviduct and in sexual behaviour, without necessarily influencing ovarian activity and ovulation. A further barrier to the use of oestrogens was the decision in 1999 of the EU Scientific Committee on Veterinary Measures relating to Public Health that oestradiol was carcinogenic, exerting both tumour-initiating and tumour-promoting effects. This led to an immediate ban on the use of oestrogens as growth promoters and, 7 years later, a complete ban on oestrogen use in food-producing animals. This EU ban has led to a large number of countries also banning the use of oestrogens in food animals. However, oestrogens are still approved for use in the US and Canada and are commonly used for oestrus synchronisation in many South American countries (as part of a multihormone programme).

Progestagens

Similar to oestrogens, changes in progesterone concentrations are a critical part of the process that leads to ovulation. Progesterone and synthetic progestagens have therefore been used extensively in most domestic species as a method of controlling the oestrous cycle, particularly for synchronising oestrus activity within groups. In general, the principle behind the use of exogenous progestagens is that they mimic the function of the CL; i.e., they produce negative feedback effects on the anterior pituitary, which suppress cyclical activity by inhibiting the release of gonadotrophin. When the supply of exogenous progestagens ceases, the inhibition disappears and cyclical activity resumes.

Uses in the Horse

In horses, although progestagens have been used to synchronise oestrus, the most common use for these products has been to prevent

VetBooks.ir

the effects of oestrus on training and performance in competition horses. Van Niekerk et al. (1973) showed that a daily injection of 0.3 mg/kg progesterone was effective in preventing oestrus and that, once treatment ceased, a normal fertile oestrus occurred 3 to 7 days later. There are two major issues with such a protocol: first, multiple daily injections are often not tolerated by the horse, especially as injection site reactions are common with progestagens; and second, progesterone has an anabolic effect that, depending on regulations, can prevent its use in competition horses. This led to the development of potent oral progestagens for use in the horse, the most common of which is allyltrenbolone or altrenogest. Unlike progesterone, this product has no anabolic activity. Altrenogest has been used to do the following:

1. Stimulate the onset of cyclical activity in the early breeding season. To be effective, the treated mare should have some follicle activity. Altrenogest is thus commonly used towards the end of an artificial lighting period as the latter increases the proportion of horses with some follicle activity. Treatment for 10 days at the standard dose rate of 0.044 mg/kg body weight is recommended.
2. Suppress oestrus in mares with prolonged oestrus or other aberrant sexual behaviour. Treatment for 10 days at the standard dose rate of 0.044 mg/kg body weight is recommended.
3. Suppress oestrus in mares with normal oestrus activity. Treatment for 15 days at the standard dose rate of 0.044 mg/kg body weight is recommended.
4. Control the timing of oestrus so that effective use can be made of a stallion or artificial insemination (AI). Treatment for 15 days at the standard dose rate of 0.044 mg/kg body weight is recommended. Once treatment ceases, the mare should come into oestrus 2 to 3 days later.

More recently a long-acting injection of altrenogest has been developed as an alternative to oral supplementation. (McConaghy et al. 2016) found that a single injection of 0.3 mg/kg altrenogest given to mares in oestrus suppressed oestrus within 24 hours and that this suppression lasted at least 6 days. They also showed that a 0.3 mg/kg dose was not associated with any significant injection site reaction.

Other synthetic progestagens such as medroxyprogesterone acetate and norgestomet have been tried in horses but are ineffective, probably because, unlike altrenogest, they do not bind adequately to the equine progesterone receptor (McCue 2016).

Progesterone-releasing devices have also been used to control oestrus in horses. Progesterone implants are not effective, probably because they release progesterone too slowly. Intravaginal devices are more effective and can be used to increase the proportion of mares that become pregnant early in the breeding season (Newcombe 2002), although the degree of synchronisation is often much lower than after oral altrenogest.

Uses in Cattle

Progestagens can be used to suppress oestrus in cows as described for the mare, but such use tends to be specialised (e.g., confined research cattle). However, by far the most common use is to synchronise groups of cows and heifers for artificial insemination, without requiring the need for long periods of oestrus detection.

Progesterone was first used by daily injection to synchronise oestrous cycles in groups of cows in 1948 (Christian and Casida 1948). Initial experiments used long courses of injections (typically 16–21 days) that exceeded the expected lifespan of any naturally occurring CLs. This type of programme resulted in fairly good synchronisation of oestrus 4 to 6 days after the cessation of treatment; however, fertility at the first oestrus was often markedly depressed. The development of orally active progestagens (such as melengesterol acetate) revived interest in progesterone-based synchronisation; however, the poor fertility issue remained. The most likely reason for the poor fertility was impaired sperm transport as a result of the atypical hormone balance after withdrawal of the progestogen. The depression in fertility was inversely related to the length of treatment, but, unfortunately, the degree of synchronisation was positively related.

These issues were solved by combining progesterone with additional hormones. The use of combinations meant that short periods of progesterone supplementation could be used (optimising fertility), as the additional hormones prevent the persistence of naturally-occurring luteal tissue (which would otherwise reduce synchronisation).

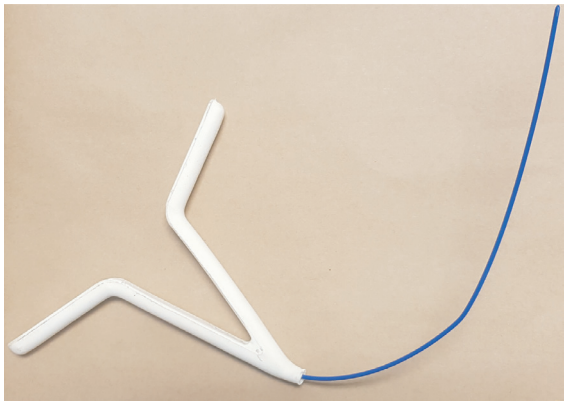
One widely used programme is the combination of a subcutaneous implant of the synthetic progestogen, norgestomet, together with the injection of oestradiol valerate. Removing the norgestomet implant after 9 days produces good synchronisation (95% within 5 days of removal), as well as satisfactory conception rates after two inseminations at 48 and 60 hours after removal (Wishart et al. 1977). The key disadvantage with this method is the requirement for a second handling to remove the implant. Nevertheless, this protocol is still in use more than 40 years after being developed, at least in countries in which the use of oestradiol in food animals is permitted.

However, by far the most common method of progesterone supplementation has been the use of intravaginal progesterone-releasing devices. The first device to be developed was a stainless steel coil covered with an inert elastomer (PRID) impregnated with 1.55 G progesterone; this has now been replaced by a polyethylene and ethyl vinyl acetate triangle in order to increase retention rates (Fig. 8.1). Most other intravaginal progesterone-releasing devices are based on a t-shape flexible arm design (Fig. 8.2).

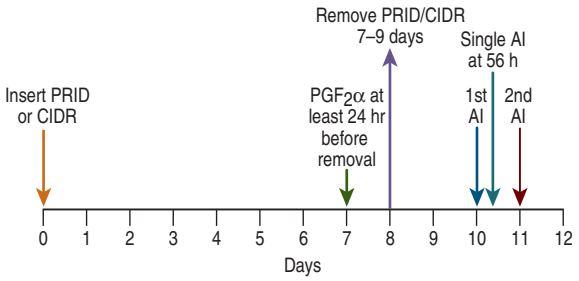
All devices are inserted into the vagina using an introducer, from where the progesterone is released and absorbed into the bloodstream, producing progesterone concentrations in the peripheral blood of between 3 to 5 ng/mL (vanWerven et al. 2013). Plasma progesterone concentrations depend on the type of product used (a higher progesterone content in the product leads to higher initial peripheral progesterone concentrations) and the time since insertion because a longer time results in lower plasma progesterone concentrations. Removal of the device after 7 to 10 days results in oestrus 2 to 3 days later, provided that there is no persistent luteal

• **Fig. 8.1** Progesterone-releasing intravaginal device (PRID) for use in cattle.

VetBooks.ir



• **Fig. 8.2** Controlled internal drug release (CIDR) device for use in cattle.



• **Fig. 8.3** Protocol used for oestrus-synchronization in the heifer or cow using a combination of either a PRID or CIDR together with Prostaglandin $F_{2\alpha}$ followed by a single or double fixed-time AI (if heat detection not used).

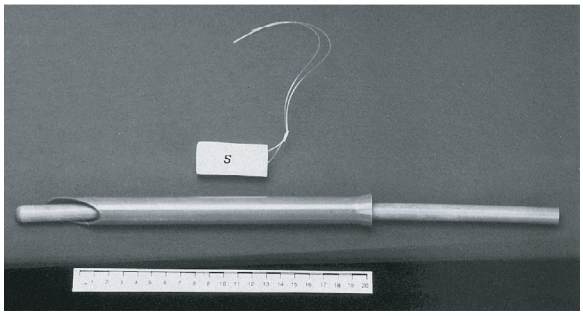
tissue. Initially, oestradiol was injected at the time of insertion to prevent this, but subsequently, $PGF_{2\alpha}$ has been increasingly used, especially after the EU ban on the use of oestradiol. The standard protocol with $PGF_{2\alpha}$ is: insertion of progesterone-device (day 0), followed by $PGF_{2\alpha}$ injection on day 6 and device removal on day 7 (Fig. 8.3). Good conception rates can be achieved following two fixed-time inseminations at 48 and 72 hours after device removal (vanWerven et al. 2013).

Progesterone devices can also be used to synchronise oestrus in nonpregnant cows before being inseminated. For example, in the Fastback programme in the US, a progesterone device is inserted on day 14 after insemination. This is removed on day 21, and on days 22 to 25 the treated cows are observed for oestrus. This increases the proportion of nonpregnant cows that are reinseminated at the first oestrus following the initial insemination. Progesterone-based resynchronisation programmes are also used in New Zealand in cows treated for anovulatory anoestrus. The evidence of efficacy is equivocal and, at the herd level, focusing on reducing the proportion of cows that have anovulatory anoestrus is likely to be more beneficial than resynchronisation (Bates et al. 2016).

Progesterone devices are also useful in treating anoestrous cows. The effectiveness of these devices was first demonstrated by Lamming and Bulman (1976), who showed that 14-days treatment with progesterone alone induced a posttreatment oestrus in 5 out of 7 cows. However, such a programme suffers from the same issue as other long progesterone programmes, i.e., good synchronisation but reduced fertility. Solving this issue requires combination treatments, which are discussed later in this chapter.

Uses in the Sheep

Progestagens have been widely used in controlling reproduction in the ewe, either on their own or in conjunction with other



• **Fig. 8.4** Progestogen-impregnated intravaginal sponge or tampon *(s)* with speculum and introducer. For use in sheep and goats.

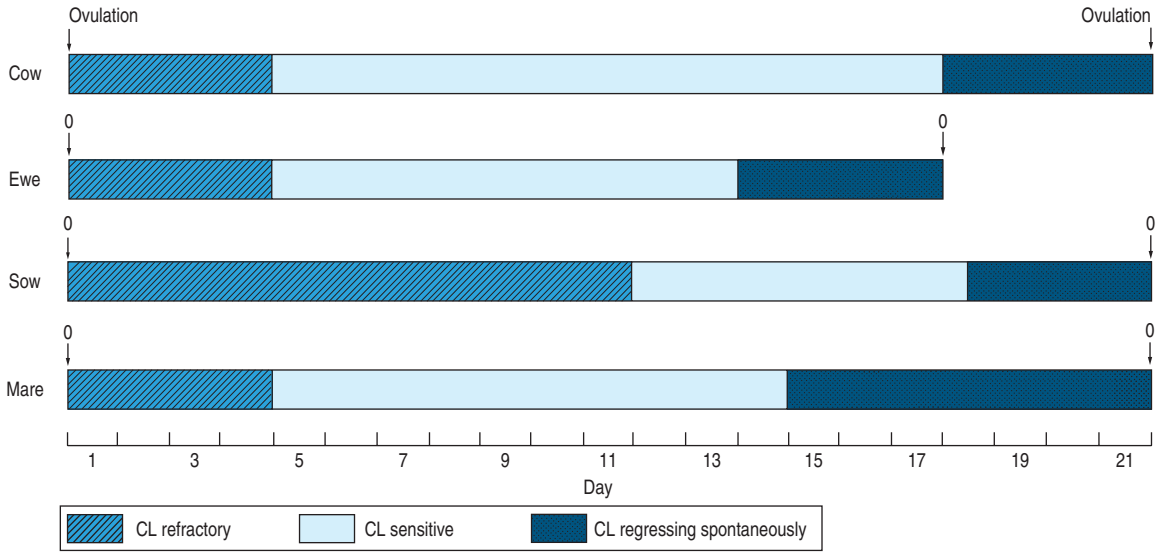
• **Fig. 8.5** Controlled internal drug release (CIDR) device for use in sheep and goats.

hormones. They have been used to induce oestrus in the anoestrous ewe during the nonbreeding season and also for synchronisation of groups of ewes that are already showing cyclical activity. The most common route of supplementation is the intravaginal route in the form of impregnated sponges (Fig. 8.4) or t-shaped silicone devices (Fig. 8.5). As in cattle, provided that the progestogen is correctly incorporated into the sponge, it will be readily absorbed at a sufficient rate to ensure a full negative feedback effect on pituitary function. Initially, progesterone was used in the sponges but was superseded by the potent short-acting progesterone-analogues such as fluorogestone acetate (FGA) and medroxyprogesterone acetate (MAP). However, the introduction of small versions of the t-shaped cattle devices such as DICO and CIDR for sheep has meant that progesterone is again being used to control cyclicity in the sheep.

The standard recommendation for intravaginal progestagens in the ewe is a 14-day treatment programme. Outside of the normal breeding season, using eCG at the end of the progesterone–priming period, i.e., on device removal, is essential even if melatonin is used to advance the breeding season. During the breeding season this is not the case, although the addition of eCG will improve synchronisation.

Shorter 6- or 7-day programmes have also been developed. Outside of the breeding season the recommended programme is

VetBooks.ir



• **Fig. 8.6** Sensitivity of the corpus luteum (CL) of different species to $PGF_{2\alpha}$ during the oestrous cycle.

that the device is removed on day 6, concurrent with the injection of eCG; during the breeding season the addition of $PGF_{2\alpha}$ is required if shorter programmes are to be effective, either at the time of device insertion or 24 hours before removal. Irrespective of the programme, fertility is slightly lower in synchronised sheep that are outside their breeding season than in sheep that are naturally cycling.

Uses in the Goat

The devices used in the goat tend to be the same as those in the sheep. Goats object to the insertion of the sponges more than sheep, so the lower discomfort resulting from the use of t-shaped silicone devices is advantageous. Goats show intense oestrus 36 to 48 hours after device removal. There is no convincing evidence that doses of either progestagens or eCG are different from those recommended in the sheep.

Uses in the Pig

In pigs oral treatment with progestagens has been the only widely used method of progesterone supplementation. Currently, altrenogest is the only progestogen that is available commercially. Details of the use of progestagens in breeding programmes are described in detail in Chapter 33.

Uses in the Dog and Cat

Progestagens have been used for many years to suppress oestrus in both the bitch and queen cat. They act via a negative feedback effect on the hypothalamic–pituitary axis, probably producing their effect by preventing a rise in gonadotrophin secretion, the trigger for the natural progression from stage to stage of the oestrous cycle (England 1998). Progestogen treatment causes a decline in FSH concentrations in the peripheral blood but not LH, although there is a decreased responsiveness to GnRH. Details of the use of progestagens in the dog and cat are described in Chapter 35.

Prostaglandins

The length of the interoestrus interval in most domesticated species is controlled by the life span of the CL; thus removing the CL will induce oestrus. Exogenous $PGF_{2\alpha}$ (or its analogues) can be used to induce luteolysis and manipulate the normal pattern of cyclic activity.

Of the key domestic species the CLs of the cow, mare, sow, ewe, and goat normally respond to the administration of exogenous prostaglandins, but the CLs of the bitch and the queen require repeated doses. Prostaglandins are therefore not of clinical use in the latter two species.

In species which do respond there are differences in when the CLs become responsive to exogenous prostaglandins (Fig. 8.6). In the cow, ewe and goat the new developing CL is generally refractory for 3 to 5 days after ovulation; the mare is similar although large doses of $PGF_{2\alpha}$ may be effective from 2 days after ovulation. Once the natural process of luteolysis has started, exogenous prostaglandins will have no effect; this means that the cow, doe goat, mare, and ewe have a responsive CL for 13, 13, 10 and 9 days, respectively. However, the sow is different because the CL is refractory for up to 11 days after ovulation and is thus responsive for a much shorter period of only 7 or 8 days.

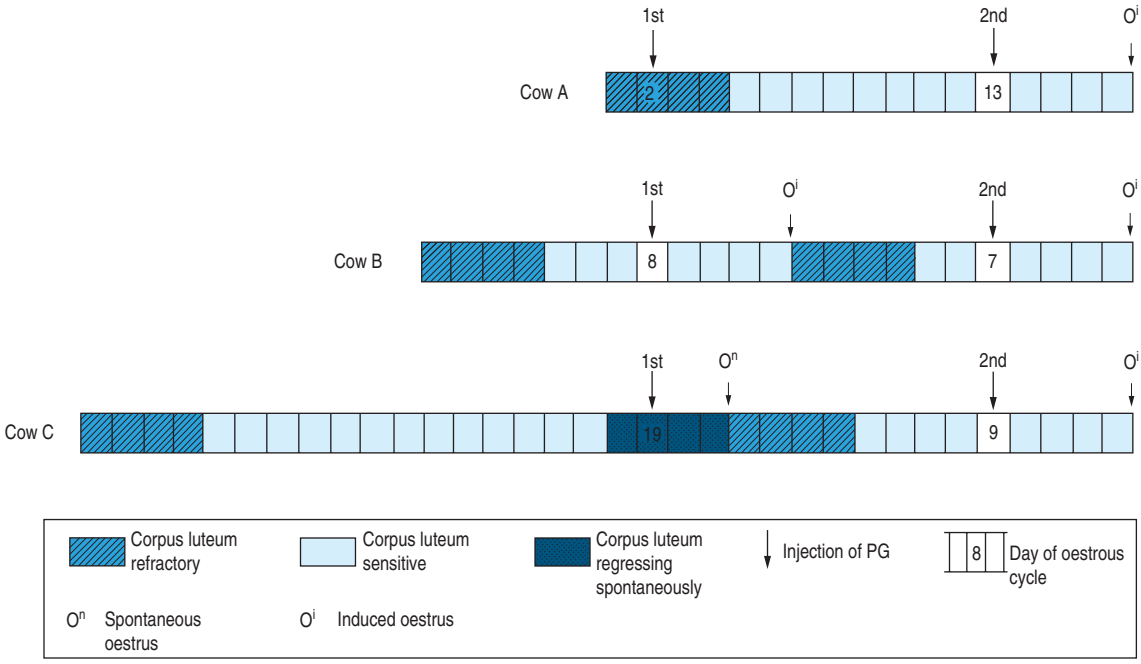
Because prostaglandins are abortifacients, they must not be used in animals that might be pregnant. If there is any doubt, pregnancy diagnosis must be performed.

Uses in Cattle

Prostaglandins have been used successfully to synchronise oestrus in groups of cows and heifers. This technique has applications in beef cows and heifers and also in dairy heifers in which oestrus detection is frequently difficult, thus enabling the routine use of AI at a predetermined time. The availability of artificial insemination in such situations allows the use of semen from genetically superior sires and can thus result in improved genetic potential in the offspring.

Prostaglandin-based programmes can either use oestrus detection to determine the timing of AI or use fixed-time AI. If oestrus detection is feasible, then a group of cows can be injected, and those with a responsive CL will come into oestrus 2 to 7 days later (most coming into oestrus 3–5 days later) and can be inseminated. Those cows which do not respond or which have an unobserved oestrus can be injected again 11 to 14 days later, when all remaining cows, if they are cycling normally, should have a responsive CL (Fig. 8.7). Most cows will show oestrus between 3 to 5 days later and can be inseminated. If oestrus detection is not feasible, then a

VetBooks.ir



• **Fig. 8.7** Synchronization of oestrus in cows by the administration of two injections of $PGF_{2\alpha}$ or an analogue at an 11-day interval.

double fixed-time AI at 72 and 96 hours or 72 and 90 hours after the second injection will result in conception rates that are similar to those following insemination at a spontaneous oestrus. A single fixed-time insemination (at 84 hours) can be used but will result in reduced conception rates. A mixed programme, using oestrus detection after the first injection and then fixed-time AI after the second, can also be used. There is no evidence of any difference in efficacy between natural $PGF_{2\alpha}$ and synthetic analogues when used in such a programme.

When used on its own, prostaglandin does not produce tight synchronisation; this is because the time between injection and ovulation is dependent on the stage of development of the dominant follicle. This 'follicle effect' is likely to be one of the main reasons why synchronisation is improved by adding progesterone to a prostaglandin programme, as the use of progesterone controls follicular development. The importance of follicle stage in determining the response to prostaglandin was also the key driver behind the development of the Ovsynch programme (covered later in this chapter).

Uses in the Horse

Prostaglandin $F_{2\alpha}$ and its synthetic analogues are the compounds that are most commonly used to manipulate the oestrous cycle in mares (Coffman et al. 2016). If given more than 5 days but less than 14 days after ovulation, a single injection of $PGF_{2\alpha}$ will reliably induce oestrus (on average 3–4 days after treatment). The use of $PGF_{2\alpha}$ enables mares to be mated or artificially inseminated on predetermined days, eliminating the need for the frequent teasing of mares and simplifying travel arrangements for either the mare or the stallion. They can be particularly useful when an oestrus has been missed, especially the 'foal heat', as their use eliminates the need to wait for the next spontaneous heat.

However, as in cattle, the timing of ovulation after an injection of $PGF_{2\alpha}$ is very variable. The crucial factor is the size of the ovulatory follicle as there is an inverse correlation between follicle diameter at the time of treatment and the interval between treatment and ovulation (Burden et al. 2015). For very large follicles (larger than 35 mm), the response depends on the stage of development of the follicle, with most mares with follicles in the growing phase responding to treatment by ovulating around 5 days after treatment, although a small proportion (approximately 18%) will ovulate within 48 hours, often with no observable oestrus behaviour. Mares with atretic follicles will have a prolonged interval to oestrus (up to 15 days), as follicles will regress without ovulation followed by the emergence and, eventually, the ovulation of a new dominant follicle (Burden et al. 2015). It is thus recommended that $PGF_{2\alpha}$ treatment in the mare is accompanied by a veterinary examination pre- and posttreatment to identify the likely response (Coffman et al. 2016).

Uses in the Sheep

Provided there have been more than two days since ovulation, the injection of $PGF_{2\alpha}$ or its analogues will induce oestrus in responsive ewes approximately 36 to 46 hours later (Haresign & Acritopoulou 1978). The timing of ovulation is variable depending on the stage of the dominant follicle (Fierro et al. 2013). As in cattle, the use of a double-dose $PGF_{2\alpha}$programme (with the injections usually given 8–11 days apart) increases the proportion of animals responding and tightens the timing of ovulation compared with a single $PGF_{2\alpha}$ injection at a random stage of the oestrus cycle. Nevertheless, such protocols do not generally result in good reproductive outcomes when used with fixed-time AI (Fierro et al. 2013).

Uses in the Goat

Oestrus can be efficiently synchronised in goats by using two doses of $PGF_{2\alpha}$ (or an analogue) 10 days apart, but the fertility rate is reduced, compared with progesterone-based programmes (Duque-Bonisoli, et al. 2012).

VetBooks.ir

Uses in the Pig

Reliable synchronisation of oestrus in groups of sows and gilts would have many practical applications, particularly in conjunction with the use of AI to enable batch farrowing to occur. Unfortunately, prostaglandins and their analogues are not luteolytic until the 11th or 12th day of the oestrus cycle. Devising a regimen of prostaglandin injections that will synchronise groups of sows is therefore not possible.

Uses in the Dog and Cat

Prostaglandins do not readily cause luteolysis in these species.

GnRH and Its Analogues

GnRH, synthesised within the cells of the hypothalamus, is the hormone responsible for controlling the release of the anterior pituitary hormones. The development of artificial synthetic GnRH in the early 1970s and then the development of its synthetic analogues, e.g., buserelin, led to multiple studies in many species of the efficacy of GnRH and its analogues in controlling reproduction. In cattle GnRH (and analogues) have been used to treat cystic ovarian disease, delay luteolysis, and stimulate ovulation; however, their main use currently is as an integral part of synchronisation programmes designed to control the timing of ovulation, such as Ovsynch (Peters 2005). In small ruminants GnRH has been used much less commonly although it is effective at stimulating ovulation and has been shown to delay luteolysis (Newcombe & Peters 2014). In pigs there has been limited use of GnRH, though studies have shown that, especially when used after equine chorionic gonadotrophin (eCG) treatment, it can induce premature puberty in gilts, and it may also increase fetal survival when used during early pregnancy (Drost & Thatcher 1992, Newcombe & Peters 2014).

In mares GnRH does not stimulate ovulation in animals in deep anoestrus or in those with regressing follicles. However, cyclic mares with mature follicles or mares in the transitional period are more responsive, although this response, particularly in the latter, is less reliable than in cattle (Newcombe & Peters 2014) and requires significantly higher or repeated doses (Newcombe & Cuervo-Arango 2017). The need for repeated doses led to the development of implants, which release GnRH agonists (such as deslorelin). These are effective (over 90% of mares ovulate within 48 hours of administration) but expensive and, if used continuously, can result in suppression of FSH and LH secretion, with extension of the interoestrus interval (Newcombe & Cuervo-Arango 2017). This suppressive effect means that deslorelin implants can be used to suppress cyclical ovarian activity and testicular function, with commercial products currently available to suppress fertility for 12 months per implant in the male dog and ferret.

Compounds That Replace or Supplement Pituitary Gonadotrophins

Commercial products based on purified pituitary extracts are available that contain FSH and LH, but these are relatively expensive; thus in the majority of cases alternative hormones with similar activities are used rather than the specific gonadotrophins.

In domestic animals two substitutes are commonly used: (1) eCG, obtained from the serum of pregnant mares (see Chapter 5), which has a mainly FSH-like effect but also has some LH-like activity; and (2) human chorionic gonadotrophin (hCG), obtained from the urine of pregnant women, which has mainly an LH-like effect but with some FSH-like activity.

In pigs eCG has been used to induce oestrus after weaning and to stimulate puberty in gilts and oestrus in anoestrus sows. As eCG stimulates oestrus rather than ovulation, particularly in anoestrus sows and gilts, better results are achieved if eCG is used in combination with a product that specifically stimulates ovulation such as GnRH, hCG or porcine LH (Kirkwood & De Rensis 2016).

In cattle eCG treatment has been used to stimulate follicular development and ovulation. Large doses (1500–3000 iu) are used in embryo transfer programmes to induce superovulation; smaller doses are used in multihormone synchronisation programmes to increase follicle size and vitality at insemination. On its own, hCG has generally been used in cattle as an alternative to GnRH.

In ewes and does the use of eCG alone to induce oestrus in seasonally anoestrous ewes is not very successful, but if progesterone is administered to the ewes before the injection of eCG, then there is synchronised oestrus and ovulation. However, attempts to stimulate an early return to cyclical activity in lactating ewes have proved to be difficult, particularly in those that are lactating heavily. As in cattle, high doses of eCG have been used to produce superovulation.

In queen cats hCG has been used to induce ovulation (as an alternative to using a vasectomised tom or simulating coitus by swabbing the vagina). Ovulation stimulated in this way leads to pseudopregnancy and prevents the return to oestrus for 4 to 8 weeks.

Combinations of eCG/hCG have been used to induce oestrus in the anoestrous bitch, sometimes in combination with oestrogens. The induction of a behavioural response has usually been good, but the numbers of bitches that ovulated and subsequently conceived has usually been poor.

Surprisingly, eCG does not appear to stimulate ovarian activity when given to mares in winter anoestrus. The reasons for this are probably twofold: first, it may be that the dose required to stimulate follicular development is large; and second, it is likely that eCG alone is not responsible for stimulating the wave of accessory follicles during early pregnancy.

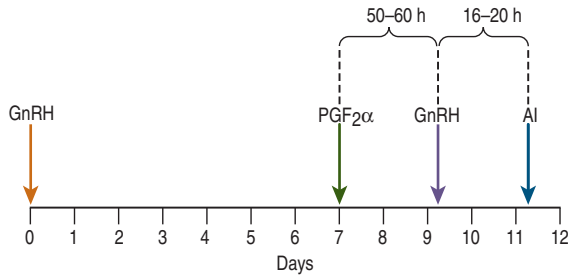
Hormone Combinations

Uses in Cattle

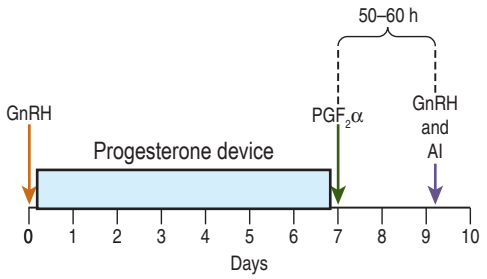
Oestrus, and thus ovulation, cannot be synchronised very closely using a simple synchronisation regimen such as prostaglandins or progestagens alone (Coulson et al. 1979). This can result in poor conception rates when fixed-time AI is used, especially in cows rather than nulliparous heifers (Pursley et al. 1997). The two key reasons for this failure are: first, the variability in the refractory period of the CL after ovulation to luteolytics such as $PGF_{2\alpha}$; and second, the complexity and variability of the follicular wave patterns that occur in cattle. If, for example, $PGF_{2\alpha}$ is given to a cow with a newly emergent dominant follicle, then ovulation will occur later than if it is given to a cow with an older dominant follicle. This led to the development of the 'Ovsynch' protocol that aimed to synchronise follicular waves so that ovulation occurred over a short enough period of time that a single fixed-time AI could produce reasonable conception rates (Pursley et al. 1995).

In the Ovsynch programme, GnRH is given on day 0, followed by $PGF_{2\alpha}$ on day 7, with a second GnRH 56 to 60 hours later (day 9) and a single fixed-time AI 16 to 24 hours after the second GnRH injection (Fig. 8.8). It is the GnRH injections that synchronise the follicular waves of the treated cows. In responsive cattle, i.e., those with LH receptors on dominant follicles (usually

VetBooks.ir



• **Fig. 8.8** Protocol used for oestrus-synchronization in cows using a combination of GnRH and Prostaglandin $F_{2\alpha}$ followed by a single fixed-time AI (Ovsynch programme).



• **Fig. 8.9** Protocol used for oestrus-synchronization in the heifer using a PRID or CIDR together with a combination of GnRH and Prostaglandin $F_{2\alpha}$ followed by a single fixed-time AI.

8 mm or larger in diameter), the first dose of GnRH will either induce ovulation or atresia of the dominant follicle, enabling the emergence of a new follicular wave approximately 1 to 2 days later. Nonresponsive cattle will generally have early stage follicles (fewer than 4 days), so even if nonresponders are included, the range of ages of the dominant follicles present when the $PGF_{2\alpha}$ is given on day 7 is significantly less than it would have been without the GnRH, with most having a dominant follicle that is capable of ovulating and producing a fertile egg. The second injection of GnRH brings the follicular dynamics of the treated cows even closer together, as it stimulates the preovulatory LH surge so that ovulation in the treated group is concentrated over a shorter period of time. This manipulation of the follicular waves means that a single fixed-time AI can be used, so that, even though the Ovsynch programme decouples oestrus behaviour from ovulation, this is not important as the programme does not depend on oestrus detection to be successful.

The programme is most successful in lactating cows; it is less successful in cows in anoestrus and, particularly, in nulliparous heifers. These cows need different programmes. However, even for lactating cows, there are still issues with the programme, with in some cases 40% of cows failing to respond to treatment (Martins & Pursley 2016). The key issues seem to be: (1) insufficient synchronisation of follicular waves; and (2) failure of luteolysis.

In the first case the problem is the cows that have dominant follicles that do not respond to the first GnRH, especially those that are about 3 to 4 days of age at the time of the injection. These dominant follicles may undergo atresia prior to the injection of $PGF_{2\alpha}$; if this occurs, the new dominant follicle will be too immature to respond to the second GnRH injection. The solution to this issue is to presynchronise the treated cows so that they start the Ovsynch programme in days 5 to 9 of the oestrous cycle (Vasconcelos et al. 1999). Presynchronisation programmes are now commonly used in the US prior to the Ovsynch programme. An example of such a programme is Presynch-10, in which two injections of $PGF_{2\alpha}$ are given 14 days apart, with the second injection 10 days before the first GnRH of the Ovsynch programme (Martins et al. 2017). However, Presynch-10 is only one of a large number of presynchronisation programmes that have been tried in order to further tighten the synchronisation of cows before they enter the Ovsynch program. One example is CIDR-PS (Rutigliano et al. 2008), in which cattle receive a 'progesterone insert' for 7 days, with removal and a $PGF_{2\alpha}$ injection 3 days before the start of the Ovsynch programme; other programmes include a double Ovsynch programme (with the first programme ending 7 days before the second) and the G6G programme ($PGF_{2\alpha}$ followed by GnRH 8 and 6 days before the Ovsynch programme, respectively) (Martins & Pursley 2016). Most of the tested presynchronisation programmes do increase the proportion of treated cows that become pregnant after the Ovsynch programme. However, for the more complex programmes the improvements in fertility probably do not cover the costs of the presynchronisation programme (i.e., the costs of handling in addition to the costs of the pharmaceuticals), especially when compared with the simpler programmes such as Presynch-10.

The other key issue is luteolysis. Failure to achieve complete luteolysis after the $PGF_{2\alpha}$ injection is strongly associated with failure to become pregnant after an Ovsynch programme. The proportion of cows in which luteolysis is not complete seems to be around 10% to 11%, and can be significantly reduced by including a second $PGF_{2\alpha}$ injection 24 hours after the first (Martins & Pursley 2016).

Synchronisation in Heifers

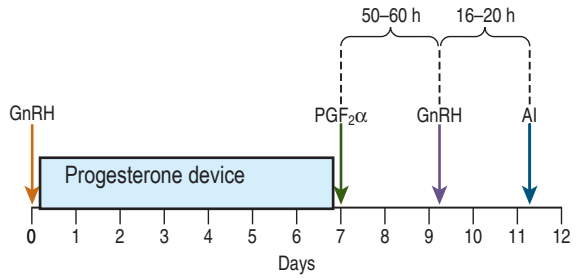
Ovsynch-type programmes significantly reduce the conception rate in nonlactating heifers compared with insemination after observed oestrus (Martins & Pursley 2016). So to synchronise heifers, alternative programmes are needed. McDougall et al. (2013) showed that in heifers at pasture, the combination of an intravaginal progesterone device with an Ovsynch-like programme, resulted in higher conception rates after fixed-time AI than insemination after observed oestrus produced in response to a $PGF_{2\alpha}$ injection (57% vs 48%, respectively), but only when the heifers were inseminated on day 9 of the programme alongside the second GnRH injection ('Cosynch'; Fig. 8.9). Cosynch programmes (with or without progesterone) have the advantage of less handling than Ovsynch programmes and so are commonly used in situations in which handling is an issue, such as in lactating beef cattle, even though using a Cosynch rather than an Ovsynch programme may reduce conception rates by 3% to 4% (Colazo & Mapletoft 2014).

However, Sahu et al. (2015) compared the Cosynch programme recommended by McDougall et al. (2013) with fixed-time AI after a standard 7-day progesterone programme with $PGF_{2\alpha}$ on day 6 (P+PG) and found no difference in conception rates between the two programmes (52.4% and 54.8%, respectively), despite the P+PG programme being significantly cheaper. However, P+PG did require four handlings rather than the three required by the Cosynch program, so Sahu et al. (2015) concluded that the choice of programme should be made at an individual farm level and take into account labour costs as well as pharmaceutical costs.

Synchronisation in Anoestrus Cows

In anoestrus cows the Ovsynch programme is much less effective than in cycling cows because of the lack of response of any of the follicles to the first GnRH injection, the low progesterone concentrations on day 7 (partly because of the lack of response to GnRH

VetBooks.ir



• **Fig. 8.10** Protocol used for oestrus-synchronization in the anoestrus cow using a PRID or CIDR together with a combination of GnRH and Prostaglandin $F_{2\alpha}$ followed by a single fixed-time AI.

but also because cows anoestrus will not have and endogenous CL), and the high risk of a short luteal interval even if ovulation is synchronised. Some presynchronisation programmes, e.g., G6G, have been shown to improve the response of anoestrus cows to the subsequent Ovsynch programme (Colazo & Mapletoft 2014), but probably the most commonly used programme to treat anoestrus cows is an Ovsynch programme with the addition of intravaginal progesterone device between Day 0 and Day 7 (Fig. 8.10). McDougall (2010) compared the Ovsynch programme alone to an Ovsynch programme with additional progesterone (O+P4) in pasture-based cattle that had not shown oestrus prior to 10 days before the start of the spring breeding season. They reported that, although both Ovsynch and O+P4 resulted in shorter intervals from the start of treatment to conception compared with untreated animals, the addition of progesterone decreased these intervals by a further 6 days compared with Ovsynch alone. In this study 73% of the cows did not have a detectable CL at the start of the synchronisation program, so this large controlled study of over 2000 cows confirms the value of using progesterone routinely in Ovsynch-based synchronisation programmes in which anoestrus is a significant problem, especially as even in cows with a visible CL on day 0, O+P4 resulted in a significantly shorter median interval to conception than Ovsynch alone.

The use of eCG at the same time as $PGF_{2\alpha}$ stimulates the growth of the dominant follicle. This effect has been shown to be beneficial alongside O+P4 programmes in anoestrus cattle, especially when the body condition of treated cattle is not optimal, as well as in *Bos indicus* cattle (Bó et al. 2013).

Hormone Combinations in Other Species

Of the other domestic species, hormone combinations are commonly used only in the doe and ewe. As discussed previously, the most commonly used regime is a combination of eCG and progesterone (or its analogues). However, $PGF_{2\alpha}$ is often added to an eCG/progesterone programme (either at the beginning or the end of the programme) to remove any active CLs.

Other Hormones

In bitches prolactin plays a role in determining the length of the interoestrus interval. The exact mode of action is unknown but may be related to an effect on gonadotrophin secretion and/or ovarian responsiveness to gonadotrophins. Prolactin inhibitors such as cabergoline and bromocriptine can be used to induce a fertile oestrus with normal pregnancy rates in anoestrus bitches. Results are generally better in bitches in midoestrus than those in early oestrus.

Immunological Methods

Immunocontraception

Immunocontraception, in which animals are vaccinated against specific proteins that have a crucial role in the normal functioning of the reproductive cycle, has the potential to be a significant tool in the management of reproduction in wild and domestic animals. The two most commonly targeted proteins have been the zona pellucida proteins and GnRH (Naz & Saver 2016). Zona pellucida vaccines have been shown to be efficacious in a wide range of wild and domestic mammals, from brushtail possums to elephants to wild and domesticated ungulates. Their efficacy in carnivores, including dogs and cats, is limited.

Although zona pellucida vaccines have been used widely, particularly in free ranging or wild animals, anti-GnRH vaccines are used far more commonly in commercial situations. In cows a standard two dose course of an anti-GnRH vaccine has been shown to induce a reversible suppression of oestrus activity for more than two months, whereas in horses efficacy for at least three months has been demonstrated. One advantage of GnRH-based vaccines over zona pellucida vaccines is that the former can be used in both males and females; vaccination reduces sexual and aggressive behaviour so can be a useful tool in managing groups of entire males.

Antiandrostenedione

Vaccination has also been used to increase fertility. Vaccines produced by conjugating a derivative of the natural ovarian hormone androstenedione with human serum albumen have been shown to significantly increase the number of lambs born and reared (usually by about 20%). This effect is mediated solely by an increase in the ovulation rate (Juengel et al. 2013). The initial vaccination protocol requires two doses four weeks apart, but only a single vaccination is required in the following season; using this vaccination procedure requires careful management. Mating must start at least 25 days after the final vaccination, as otherwise there may be detrimental effects on conception rate and early embryo development. Treated ewes must be fed adequately throughout pregnancy because of the dangers of pregnancy toxaemia occurring.

Many other compounds have been identified as being potential targets for the use of vaccines to modify reproductive function. For example, vaccination against bone morphogenetic protein has been shown to increase ovulation rate in ewes, but not in lambs born or weaned (Juengel et al. 2013). Perhaps the most common target for such vaccines has been against inhibin, in which vaccination has been shown in females to increase FSH concentrations and ovulation rates as well as promoting follicle development; in males it has been used to increase sperm production and advance the onset of puberty (Zhu et al. 2013).

Abnormalities of Development and Pregnancy

PETER WINDSOR

Introduction

The demand for improved understanding of the causes of abnormalities that occur during development in pregnancy, particularly those presenting as embryonic, fetal, or congenital malformations in human and other animal populations, is growing. There is increasing concern that teratogenic agents, including chemical toxicities, deficiencies, infections, and physical conditions such as heat, can alter fetal morphology or subsequent function. The embryo is most susceptible to teratogenic agents during periods of rapid differentiation, with the stage of development of the embryo determining the susceptibility to teratogens. The most critical period in the development of an embryo or in the growth of a particular organ is during the time of most rapid cell division.

There is also a growing need to distinguish abnormalities due to teratogens from genetic disorders affecting embryonic development or, more recently, to identify where genetic-environmental interactions are occurring. This has led to an increasingly vast amount of literature on the abnormalities of development and pregnancy. This is to be expected as reports of investigations of losses of pregnancy and of congenital disorders arising from naturally occurring and induced insults to embryonic development through teratogenicity in laboratory, farm animals, and, occasionally, companion animals may offer important comparative insights into clinical medicine and greatly assist understanding of the pathogenesis of congenital disorders.

Many chemical agents have been subjected to investigation for detrimental effects on the embryo or fetus during pregnancy; including cosmetics, food additives, fungicides, herbicides, insecticides, pesticides, and other agricultural chemicals, as well as environmental contaminants, drugs, hormones, and vaccines. These investigations have often been retrospective, occurring well after the emergence of a new syndrome of malformation has been associated with a previously unrecognised teratogen. With the growing history of the numerous environmental pollutants capable of causing teratogenic effects, it is surprising that protocols for determining teratogenicity are still arbitrary. Binding international agreements are required to prohibit the distribution and sale of teratogenic compounds (McGeady et al. 2017).

To investigate emerging syndromes of teratogenicity, an extensive knowledge of the recorded occurrences of losses in pregnancy and malformations in the various animal species is useful. This is important in farm animals in which losses in pregnancy causes reduced production efficiency and economic losses to producers, including the reputational losses to breeders when congenital malformations are suspected or confirmed as inherited. Knowledge of the aetiology of developmental disorders has become essential to enable breeders to manage the hazards causing losses in pregnancy and from congenital disease. Increasingly, genetic disease information is readily available on breed society websites to enable breeding management that avoids the mating of animals that are heterozygous carriers of the same mutation. Information is also increasingly available that enables farm animal managers to minimise the risks of exposure to teratogenic agents during pregnancy. In Australia, the National Arbovirus Monitoring Program regularly updates maps of places in which sentinel herd activity has identified seroconversion to potentially pathogenical arboviruses spread by insect vectors (https://www.animalhealthaustralia.com.au/our-publications/namp-report). This enables the livestock industries to demonstrate that the Bluetongue virus only occurs where few sheep are raised and assists producers to understand the importance of avoiding the movement of pregnant naïve animals into endemically infected zones where Akabane virus infection transmitted by *Culicoides* spp. threatens the embryo and fetus.

Developmental Disorders in Humans

Understanding congenital disorders in human populations associated with familial risk factors causing inborn errors of metabolism has been of importance for many generations of families. The database of human disorders transmitted by genetic factors, Online Mendelian Inheritance in Man (OMIM; https://www.omim.org), is now 50 years old and continues to expand rapidly, with mapping of the human genome enabling more accurate definition and recording of the mutant genes contributing to abnormal phenotypes, particularly the genetic defects that present at birth as congenital deformities. Further, the identification of chemical teratogens causing toxin-induced congenital disorders is well known because the notorious sedative thalidomide (α-phthalimidoglutarimide) was used widely as a sleeping pill and for the treatment of hyperemesis gravidarum, leading to a disastrous epidemic of phocomelia and other malformations (Lenz 1962). Studies in laboratory animals identified wide species differences in teratological susceptibility, with the characteristic limb malformations induced by thalidomide in humans only reproduced in rabbits. Significant differences within species were also demonstrated. Degenerative changes in the neurons and axons of dorsal root ganglia in 13-day-old rabbit embryos from mothers receiving thalidomide in doses of 150 to

VetBooks.ir

250 mg/kg/day on Days 8 to 12 of gestation suggested the abnormalities of the developing human fetal skeleton were caused by interference with the developing neural crest (neurulation). These lesions in sensory neural tissue were considered to induce a decrease in cell division before the onset of the limb bud outgrowth, at 10 days postcoitum (McBride et al. 1982). Since then, definition of deficiency syndromes causing congenital disorders in humans has advanced, for example, the response of increasing dietary folic acid to reduce risk of spina bifida. Recently, there has been an increase in appreciation of teratogenic viruses afflicting humans after the emergence of Zika virus causing abnormalities of fetal central nervous system (Kim & Shresta 2016).

Developmental Disorders in Animals

Veterinarians and animal scientists have also been managing abnormalities of pregnancy for many generations. Inbreeding is common in domestic animal breeding, particularly when artificial reproductive techniques have enabled vast numbers of progeny to be descendants to individual elite sires and their immediate progeny (Windsor & Agerholm 2009). Further, in some locations, embryonic and fetal infections of animals with teratogenic viruses or toxins, plus deficiency syndromes causing congenital disorders, occur regularly and are increasingly well described. However, obtaining an accurate diagnosis and determining the cause of losses in pregnancy or an abnormality of fetal development in an animal remain challenging for veterinarians and diagnosticians. This reflects both the rapidly expanding knowledge on the causes of the 'known disorders', plus the likelihood that unreported syndromes and the inevitability that 'newly emerging disorders' will continue to occur and demand attention and management. Importantly, few of these emerging disorders present initially with diagnostically characteristic or pathognomonic clinical signs and pathological lesions and may be readily confused with the known disorders (Agerholm et al. 2015). As differentiation of the various entities presented to veterinary diagnosticians can be challenging, particularly when the affected animal appears to be afflicted by an unfamiliar disorder, this chapter reviews some of the current and emerging knowledge of fetal developmental disorders in animals, particularly in livestock.

Aetiologies of Disorders of Development

Mammalian embryonic development is complex, involving delicate synchronisation of numerous events. Aberrations can potentially occur during gametogenesis, fertilisation, blastogenesis, embryogenesis, or in vulnerable periods during fetal development and growth. Historical estimates of the known causes of human congenital malformations suggested that only about 30% to 35% of the human congenital malformations have clearly identifiable aetiologies: about 20% genetic; 5% to 6% chromosomal; 4% to 5% maternal diseases; and 2% to 3% caused by drugs and environmental chemicals. The causes of a majority (65%–70%) of human congenital disorders remain unknown or are potentially caused by multifactorial interactions between genetic and environmental factors, representing complex host–pathogen–environment interactions occurring in the pathogenesis of disease.

Similar complexities occur in the study of losses in pregnancy and congenital disorders in animals. Identification of a single, predominant causative factor in an animal before or at birth, which is very likely to reflect a detrimental event that occurred much earlier *in utero,* is challenging as aberrations occurring during gametogenesis, fertilisation, blastogenesis, and embryogenesis that result in mortalities are usually only recognised as reproduction failure. However, lethal insults of fetal development later in gestation may present as abortions, fetal mummification, stillbirth, or neonatal mortality. Nonlethal aberrations may lead to lowered viability at birth, possibly accompanied by congenital abnormalities with grossly visible lesions that may suggest damage occurring during a particularly vulnerable period of fetal development and growth. It is now well understood that infection of a pregnant ruminant with a teratogenic arbovirus induces various lesions of the developing fetal nervous system once the fetus has commenced development of an immunological capacity at the end of the first trimester. The lesions produced are dependent on the stage of development of the fetus. For example, in cattle in Australia, Akabane virus (AKAV) induces hydranencephaly at the end of the first trimester, followed by arthrogryposis in midgestation, whereas bovine viral diarrhoea virus (BVDV) may induce cerebellar dysplasia from infection of the CNS in midgestation (Kirkland et al. 1988). However, if the agent only induces harm in the developing embryo when aligned with maternal nutritional deprivation or excess or some other maternal physiological disturbance, then identifying the aetiology of the loss or congenital disorder may become very complicated. An example was the suspected association of the plant *Dysphania glomerulifera* as an intoxication of sheep after drought in parts of Australia, leading to neonatal biliary atresia (Fig. 9.1) that required several decades of research before it could be confirmed that this plant was the source of a unique toxin involved in inhibiting posthepatic biliary development *in utero* (Harper et al. 1990, Koo et al. 2015).

Potentially, the simultaneous ingestion or administration of certain trace elements and a wide variety of chemical substances in food additives, fertilisers, fungicides, herbicides, and other chemicals used in agriculture can be problematic. Chemicals and therapeutics may well be shown not to be teratogenic when used separately (enabling their registration by regulatory agencies for the use intended), yet concurrent or inappropriate use of these agents may induce potentiating or synergistic effects with nonchemical environmental factors. This may make definitive identification of the primary aetiology extremely difficult. Further, physical agents, including maternal infections and noninfectious maternal disorders, hypoxia, hypothermia, hyperthermia, maternal immobilisation, seasonal variations in the occurrence of infections, and available dietary components, all potentially increase this complexity. These numerous and variable risk factors for developmental and congenital

VetBooks.ir

disorders, particularly in farm animals, requires that investigators possess considerable knowledge of the genetic and chromosomal, nutritional and dietary, physical, chemical, hormonal, viral, and other agents that can induce teratogenic pathogenical pathways in the embryo and fetus.

Investigating Disorders of Development

The first questions asked of a veterinarian by an owner of an animal that has lost a pregnancy or given birth to animal with a congenital disorder is usually 'what's caused this'. Owners are usually then interested in asking 'did this animal become infected or was it exposed to something that caused this loss, or is it affected by a known inherited disease (that has been recognised in this particular species and breed)'.

Answering the second part of this question on inherited disorders is facilitated by regularly examining the database of animal disorders similar to OMIM: Online Mendelian Inheritance in Animals (OMIA; http://omia.angis.org.au/). OMIA readily assists the process of reviewing known genotypes and phenotypes associated with inherited disorders, with convenient examination of the published literature of those disorders in which a referenced publication in a reputable journal has occurred. The increasing availability of molecular approaches that may be used for mutation detection, including sequencing of candidate genes, single nucleotide polymorphism array with genome wide association studies, and exome or whole genome sequencing, has greatly facilitated the recognition of disease-causing mutations in animals. As of early December 2017, OMIA listed 3372 disorders in animals, of which 1344 are Mendelian traits. Importantly, 741 have a disease-causing mutation identified; this includes: 144 of 243 Mendelian disorders of cattle; 49 of 102 disorders of sheep; 10 of 16 disorders of goats; 28 of 68 disorders of pigs; 234 of 306 disorders of dogs; and 62 or 95 disorders in cats. Several of the more important inherited developmental disorders in cattle and the mutations described are listed (Table 9.1).

Providing an answer to the first part of the question 'is this animal affected by a toxic plant, nutritional deficiency or excess, or an infectious agent that damaged the development of the embryo or fetus during gestation' involves consideration of epidemiological risk factors, including whether the animals are located in areas where infectious agents, teratogenic plants, or nutritional aberrations may occur. This requires diligent examination of all of the environmental conditions (e.g., plants, feeds, soil, water, housing, treatments, etc.) that occurred during the gestation period. Investigating embryonic and fetal losses due to infections requires extensive investigative protocols and usually requires laboratory tests aimed at gathering evidence of inclusion or elimination of the known infectious agents causing losses in that species.

Preferably, these investigations are assisted by information on breeding occurrence (numbers of females successfully mated), pregnancy status (numbers of females successfully maintaining pregnancy until the time of pregnancy testing), neonatal animals delivered, and marking (for initial interventions, including application of identification devices and health products including vaccination) and weaning rates. The calculation of these various rates of viable offspring in the population at each stage in the reproductive cycle enables identification of the stage at which the losses occurred. Knowledge of the differential diagnostic list for losses at that stage of the cycle then enables a more informed investigation.

The investigative process is greatly enhanced by collection of a fetus and/or placenta or, if available, several of these most valuable of specimens. Laboratory examinations for the presence of infectious agents can occur by culture of the pathogen or detection of antigens or PCR products. Furthermore, collection of presuckle serum or body cavity fluid from the fetus or affected neonates and serum from the dam enables laboratory examination for evidence that a teratogenic pathogen was formerly present and has produced a pathogen-specific antibody response or at least an elevation in nonspecific immunoglobulin (e.g., IgG), suggesting an infectious process occurred before birth. Extending this examination to include herd seroprofiling can be useful, enabling comparison

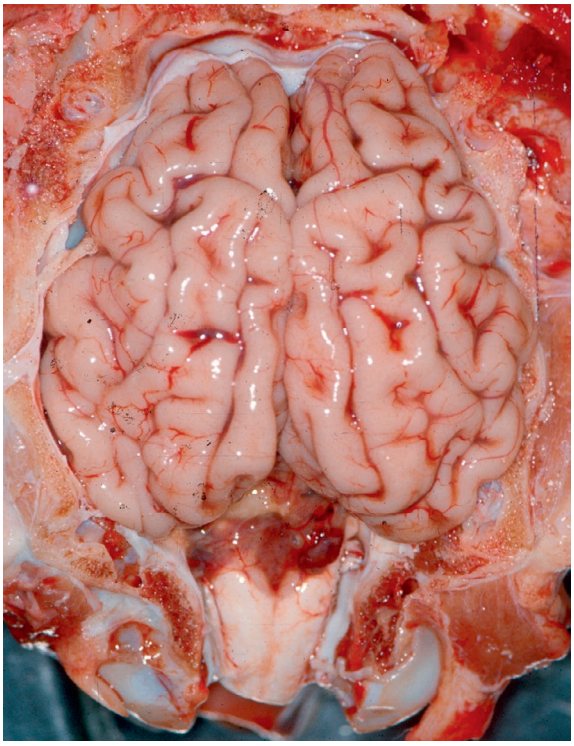
of the serological status of females that were 'affected' (i.e., lost a fetus) versus 'unaffected'. This enables definition of an 'at risk' population of animals with evidence for 'inclusion' or 'exclusion' of a pathogen in association with the problem and ensuring the investigation can proceed in a more systematic manner. For arbovirus infections, viral serological and insect distributions should be regularly consulted. Movements of arthropod vectors from known endemic areas are dynamic, as is the risk of exposure of the population to an arbovirus infection *in utero* (NAMP; https://namp.animalhealthaustralia.com.au/public). Infection of ruminants by the arboviruses, AKAV or Aino virus (AV) and BTV, plus Schmallenberg virus (SBV) in Europe, causes a range of congenital malformations in the fetus and neonatal calf, depending on the stage of fetal neural development when the dam is infected (Table 9.2). A complication of these investigations is that, in most cattle populations, BVDV remains endemic and is capable of causing an even wider range of congenital malformations in the fetus and neonatal calf over a longer period of the gestation. For investigation of potential teratogenic plants, accessing local veterinary knowledge and use of compiled knowledge resources (McKenzie 2012) can assist this process.

Despite widely available resources and informed local knowledge, diagnosing developmental disorders on the basis of gross morphology of the defective offspring often remains challenging. This is particularly problematic when determining whether the disorder is not due to a noninfectious cause. Knowledge of the genetic defects that cause similar lesions to teratogenic viruses, or so-called 'phenocopies', even in cases in which viral antigen or antibodies may be present in an animal, is required. In cattle and sheep consideration of any likelihood of exposure of the fetus in midgestation to an animal that is persistently infected (PI) with pestivirus, i.e., in cattle BVDV and in sheep ovine border disease virus, is advised.

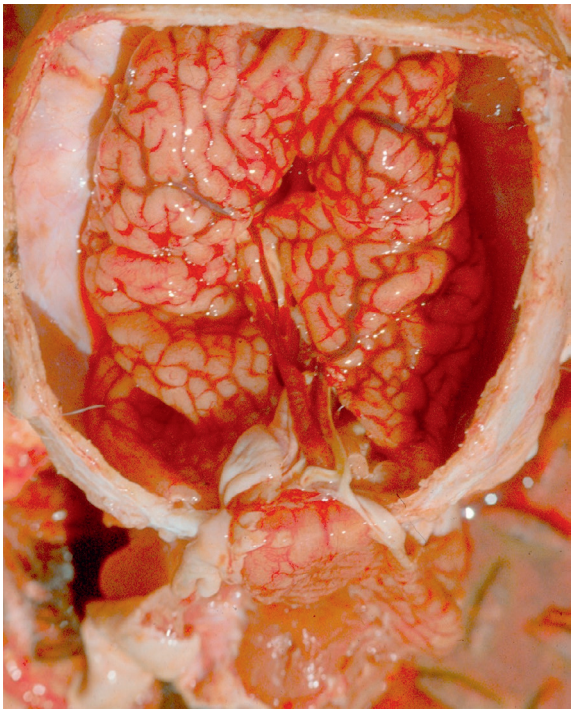
An understanding of the timelines that occur *in utero* when the fetal neuromuscular system is most vulnerable to a teratogenic virus is important, as the pathology that occurs after infection is determined by the stage of gestation at the time of fetal infection. For example, in cattle, intrauterine infection of the fetus by BVDV, AKAV/AV, SBV and BTV during the susceptible periods of development (Days 60–180 of gestation) may cause malformations in the central nervous system. Lesions in the brain of AKAV/AV occur from infection at Days 85 to 105 of gestation when, typically, hydranencephaly (Fig. 9.2) occurs. This may be accompanied by porencephaly and even secondary hydrocephalus (with or without the Arnold-Chiari malformation that occurs from progression of the cerebellum into the foramen magnum) (Fig. 9.3). Calves with cerebellar dysplasia from BVDV have typically been infected at around 150 days of gestation (Fig. 9.4) and need to be investigated for pestivirus (although numerous abnormalities are possible with BVDV, including porencephaly). Lesions in the spinal cord typically cause arthrogryposis when infection with the Simbu viruses (most commonly AKAV) at 120 to 160 days (Fig. 9.5), resulting in malformations of the axial and appendicular skeleton (Table 9.2). Interestingly, the endemic presence of these teratogenic viruses may delay the initial diagnosis of emerging inherited 'phenocopies' of these disorders. This situation occurred with arthrogryposis multiplex (OMIA 001465) in Angus calves, at least in eastern Australia, where an inherited disorder that presented as cases of arthrogryposis was attributed for several years to AKAV infection. For consideration of involvement of plant toxins as a cause of the disorder, knowledge of the epidemiology of and potential access of the pregnant dam to known potential teratogenic plants during the first trimester of gestation (e.g., *Verratrum californicum, Conium maculatum, Nicotiana glauca,* or grazing lupins or sorghum) is advised.

When conducting an investigation of a suspected inherited disorder, consideration of pedigree information and whether parentage verification (e.g., by blood typing or molecular methods) is required plus potential mode of transmission is advised

VetBooks.ir



• **Fig. 9.3** Hydrocephalus in a calf with posterior prolapse of the cerebellum causing Arnold-Chiari malformation.



• **Fig. 9.4** Cerebellar dysplasia in a severely ataxic calf after birth to a cow infected with BVD virus at about Day 150 of gestation.

(e.g., autosomal recessive disorders require both dam and sire to be heterozygous for the suspected defect). For flocks and herds that have consistently used registered sires, a simple pedigree analysis to determine whether familial relationships exist between the affected animals and their parents should be undertaken if sufficient cases

• **Fig. 9.5** Athrogryposis in a calf with fixation of the limbs born to a dam infected with Akabane virus at between Days 120 to 160 of gestation.

are available. This may enable a more rational and less expensive approach to laboratory investigations of nongenetic causes, as it may quickly become apparent that all the affected progeny have the same or closely related sire(s) and the dams of affected progeny are also related to the sire(s). DNA parentage analysis can also be used to determine whether more than one sire is involved. The important question to consider is whether the affected phenotype is present in the progeny of a particular animal at a prevalence that is greater than would be likely by chance, after considering other factors. Confusion can occur, for example, when one single-sire mating group is bred in the only paddock with a teratogenic plant, or at the time of year when insect vectors capable of transmitting teratogenic viruses were active, or in cattle and sheep when an animal persistently infected with BVDV or OBDV was in the vicinity.

With various pathogenical modalities in the genesis of embryonic and fetal losses or congenital disorders, obtaining the evidence to provide accurate diagnoses of the causes of abnormalities that occurred earlier in the developmental processes is one of the most challenging investigative procedures for veterinary practitioners, diagnosticians and researchers to undertake. However, as an understanding of congenital disorders in animals may have important scientific implications both as clues to the mechanisms of pathophysiology and as animal models of human disorders (e.g., biliatresone from *Dysphania spp.* plants in sheep as a model of toxic biliary atresia in infants), it is important that diligent surveillance for congenital disorders, accompanied by systematic investigations, be encouraged. A more rigorous approach to investigating developmental disorders has become particularly important because of the widespread adoption of international sharing of germplasm through artificial breeding. The dominant breeds (e.g., Holstein-Friesian, Angus and Brahman) around the world are rapidly sharing elite sires. All of these elite animals carry known or as yet unrecognised mutations capable of causing congenital abnormalities. This inevitably leads to increased inbreeding, and more rigorous requirements of identification and management of inherited disorders is required, particularly those presenting before birth. There is recent evidence, particularly with the Angus breed of cattle, that the need for this approach is now increasingly understood. This chapter aims, with examples mainly from farm animals, to provide readers with an appreciation of and, potentially, the motivation to more systematically approach investigations of the disorders of development in a manner that can be of benefit to knowledge informing improved welfare of man and other animals.

Abnormal Development Due to Genetic Disorders: Mutations and Chromosome Abnormalities

Mutations Causing Inherited Disorders

Inherited disorders arise from mutations involving errors in copying the DNA code, occurring at about $1x10^{-8}$ per base pair per generation in mammals (there are about $3x10^{9}$ base pairs in the mammalian genome). Only a small proportion of these mutations cause a sufficiently abnormal genotype to produce a significantly abnormal phenotype, although every individual animal and human is likely to be a carrier of multiple deleterious genes. Expression of a mutant gene depends on the influence it has on the synthesis and function of the protein encoded by the affected gene. Dominant inheritance occurs when only one copy of the abnormal DNA is required to produce the abnormal phenotype. Recessive inheritance requires two copies of the abnormal gene to produce the abnormal phenotype.

Dominant Mutations. In farm animals, a serious abnormal phenotype caused by a dominant mutation is usually recognised in the individual with the original mutation, enabling immediate recognition and removal of the mutation. This occurred with osteogenesis imperfecta (OMIA 000754), a collagen disorder described in Holstein–Friesian cattle, with recent confirmation of a mutation in COL1A gene (collagen type I alpha 1) (OMIA 002127). However, if the mutation during embryogenesis occurred after a sufficient proportion of embryonic cells had differentiated to enable subsequent normal tissue structure and function, so-called 'germ cell line mosaicism', the affected individual may have a relatively normal phenotype and the pattern of inheritance may initially appear to be recessive. However, as a significant proportion of germ cells carry the mutation, if the progenitor has many offspring, then the proportion of progeny affected can be useful in differentiating this pseudorecessive pattern of inheritance from true recessive inheritance. Furthermore, widespread dissemination of the mutation is unlikely because all progeny inheriting the dominant mutation will also have the abnormal phenotype, and the animal in which the mutation initially occurred is the only 'chimera' with a normal phenotype that can transmit the mutation. Thus dominant causal mutations are usually self-limiting, rarely achieving prevalence in the population of any significance.

Recessive Disorders. Mutations causing recessively transmitted disorders are far more significant in animal populations, particularly those in which widespread artificial breeding has occurred. The animal with a recessive causal mutation will transmit the mutation to half of its progeny, with the progeny that inherited the mutation then transmitting it to half their progeny. However, the abnormal phenotype will not occur at all until the successful mating of two descendants carrying the mutation. For Mendelian traits, 25% of the resulting progeny that inherit two copies of the mutation (one from each parent) will be homozygous and present with the disorder. An additional 50% of their progeny with normal phenotype will be heterozygous, carrying one copy of the mutation, and the other 25% will be genetically and phenotypically normal. If the recessive mutation is linked to a desirable trait, the prevalence of the mutant gene in the population will increase with selection, rising or declining as a result of changes in selection parameters and/or the structure of the population. The widespread use of an elite animal carrying the mutation is very likely to increase the prevalence of the mutation in the population, although the recognition of the abnormal phenotype as a heritable disorder is often delayed for many years and until after there are sufficient heterozygous matings to produce enough abnormal offspring for the disorder to be reported. This delay has enabled the spread of many mutations to continue until the disorder is spread globally and of economic significance, as occurred in Holstein–Friesian cattle, first with citrullinaemia (OMIA 000194), a defect in the urea cycle enzyme argininosuccinate synthase (ASS1), causing neonatal mortality due hyperammonaemia, and then with complex vertebral malformation (OMIA 001340), a defect in the solute carrier family 35 (UDP-N-acetylglucosamine transporter), leading to shortening of the spine and arthrogryposis.

When examining any animal with an unfamiliar disease presentation and particularly animals with congenital malformations, the clinician commonly considers the question, 'what genetic disorders occur in this age of animal and in this species and breed'. When faced with this situation, it is also important to remember that phenocopies of many disorders may exist with different genetic, toxic, or infectious causes. The deduction that a new disorder or syndrome is due to a genetic cause usually requires investigations to exclude toxic and infectious causes, often in circumstances in which a relatively simple pedigree analysis could have demonstrated heritability at a much earlier stage. Proper pedigree analysis to identify the closest common (maternal and paternal) ancestor is critical but is rarely well executed in practice. Accurate diagnosis of new genetic disorders is important for improving disease surveillance and breeding management, although it is also important to be careful not to suggest a genetic basis for a new disease entity without adequate evidence, as this can have serious reputational consequences for the producer and particularly the stud breeder.

The 'Founder Effect' and Artificial Breeding Risk

Due to the 'founder effect' in particular breeds, especially in cattle and dog breeds that have spread around the world from an initially limited numbers of animals and then more recently tended to be concentrated within a few families through the use of artificial breeding technologies, many recessively inherited defects are associated with both a particular breed and family within that breed. Each breed has a unique complement of recessively inherited defects (although similar defects can be observed in many breeds but are not necessarily all caused by the same mutation). Due to the restricted gene pools for many livestock breeds, we continue to see the emergence of new genetic disorders, often almost simultaneously in several countries sharing the same bovine gene pools. Public recognition of new defects is often delayed by a range of factors, including the genuine failure to diagnose the syndrome as a heritable disorder through to breeders choosing not to publicly disclose the presence of heritable disorders in their herds due to concerns of negative economic consequences as may have followed disclosure in the past. However, new developments in genetics allow for rapid development of tools to manage these disorders effectively. For the benefit of the breed, breeders, their organisations, and, importantly, their veterinarians should encourage early reporting and detailed investigation of suspected genetic disorders.

That newly recognised inherited disorders of cattle often present simultaneously on different continents is in part due to the efficient global distribution of the germplasm of elite individuals in the major breeds, combined with widespread use of artificial breeding. Some of the new disorders cause early embryonic death due to a lethal mutation and present as animals with reproductive failure. The early recognition of new and reemerging inherited diseases is important as it facilitates efficient control action by the various national cattle

VetBooks.ir

industries to minimise the future negative economic and animal welfare influences of these diseases, particularly through heterozygote detection to enable avoidance of 'carrier–carrier' matings. In addition to development of heterozygote detection, investigations of inherited diseases should include detailed clinic–pathological documentation and pedigree analysis verification to ensure that issues such as phenotypic variation and misinformation in the use of molecular diagnostic tests for detection of heterozygotes are managed for the benefit of the breed society and industry.

Examples of Recently Emerging Inherited Disorders in Ruminants

Published reviews describing a number of the more widely recognised inherited developmental disorders include: cattle (Jolly & Windsor 2010), sheep (Jolly et al. 2004), and skeletal disorders of sheep (Dittmer et al. 2015) and congenital and postnatal disorders of the nervous system of cattle and sheep (Windsor et al. 2011a, b). Although fewer genetic developmental disorders of sheep have been reported compared with cattle, there are an increasing number of publications describing diseases in which genetic factors have been demonstrated or are considered most likely to be involved in their aetiology, including an increasing long list of suspected inherited neurological syndromes of mainly Merino sheep in Australia (Windsor et al. 2011b).

Small Ruminants

Some recognised developmental disorders in small ruminants suggested as inherited include: *congenital holoprosencepahaly* (OMIA 000478) in Border Leicester lambs; *spina bifida* (OMIA 000933) in Poll Wiltshire sheep in Australia and Dorper sheep in New Zealand; *fetal hydrops* (OMIA 000493) in Poll Dorset and Dorset sheep in Australia, in Merino lambs in South Africa, in Awassi lambs in Jordan, and in Cheviot and Cheviot-cross lambs with pulmonary hypoplasia in the United States; *hereditary chondrodysplasia* or 'spider syndrome' (OMIA 001703) in Suffolk sheep associated with a single base deletion in fibroblast growth factor receptor 3 (FGFR3) in the United States, Australia, and New Zealand; and *beta-mannosidosis* (OMIA 000626) in Anglo Nubian goats caused by a single base deletion in the lysosomal mannosidase beta A gene (MANBA).

Brachygnathia, Cardiomegaly, and Renal Hypoplasia Syndrome

Brachygnathia, cardiomegaly, and renal hypoplasia syndrome in Poll Merino sheep was recently described in Australia, characterised by dwarfism (Fig. 9.6) and multiple defects in several organs, including skeleton, heart, liver, and kidneys (OMIA 001595). The disorder was reported as 'brachygnathia, cardiomegaly, and renal hypoplasia syndrome' (BCRHS), and the disorder appeared to be transmitted as an autosomal trait with a recessive mode of inheritance (Shariflou et al. 2011). An annual incidence of the disorder in the discovery flock of up to 2.5% was recorded, and the mutation was mapped to the distal end of chromosome OAR2 (Shariflou et al. 2013).

Cattle

The review papers also include several now historical bovine disorders (Table 9.1), including *citrullinaemia* (OMIA 000194), *congenital myoclonus* (CM; OMIA 000689), and *maple syrup urine disease* (MSUD; OMIA 000627) of cattle, where identification of these disorders was important initially in Australia then globally. Clarification of CM and MSUD as the previously confused entities of so-called neuraxial oedema enabled more accurate diagnoses and eventually heterozygote detection tests for both diseases. Further, identification of CM as a congenital failure of spinal glycine receptor function (Gundlach et al. 1988) led to this disease providing an animal model for human hyperekplexia (Dennis et al. 2004). MSUD has also served as an animal model for the disease in infants (Harper et al. 1991a). The discovery of citrullinaemia may have provided the first example of an inherited congenital disease that became economically important due to widespread global use of a particular bloodline (the bull Linmack Kriss King) in the Holstein–Friesian breed. Citrullinaemia was also likely to have been the first cattle disease controlled by molecular heterozygote detection and also provided a useful animal model of the disease in infants (Harper et al. 1991b, Windsor & Agerholm 2009). Readers seeking further information on these disorders and the now vast array of developmental disorders that is being accumulated from many species are referred to the cited reviews and the numerous publications listed in OMIA. With many of the more recently emerging bovine disorders having mutations identified enabling heterozygote detection and with others yet to be published or

• **Fig. 9.7** Polymelia in an Angus calf with an extra limb extending from the shoulders; likely to be developmental duplications defect, although image taken before discovery of the developmental duplications defect.

fully described, more detailed information is provided on some of these.

Developmental Duplication

Developmental duplication (DD; OMIA 002103) in Angus cattle emerged recently with initial recognition in Australia of neonatal calves with accessory limbs or polymelia in this breed (Fig. 9.7). This led to identification of a new mutation involving a single amino acid substitution in the NHLRC2 gene on Chromosome 26 (Table 9.1). Numerous pathological phenotypes have now been associated with the DD mutation that is transmitted with incomplete penetrance and variable expressivity. This includes DD homozygous animals present in the population as apparently normal individuals, although they may have subclinical lesions of DD (Denholm 2015). Sporadic cases of polymelia have been observed in other breeds, and these may involve the same or similar mutations, although it is possible that phenocopies of DD caused by other mechanisms may occur. DD causes losses from dystocia in calves with polymelia, costs of surgical amputations when performed, and the likelihood that significant embryonic mortality occurs, as suggested from genotyping information. A commercial molecular testing for the DD mutation is now available with these genotype nomenclatures adopted by the Angus breed societies:

- DDF Free: a noncarrier based on a DNA test result
- DDFU Free Untested: expected a noncarrier based on its recorded pedigree
- DDC Carrier: heterozygous for DD based on a DNA test result
- DDA Affected: homozygous for DD based on a DNA test result. Due to incomplete penetrance of the DD phenotype, a DDA animal may or may not express clinical signs of DD.
- DD__%: probability (%) that the animal is a DD carrier, calculated by 'GeneProb' software from the animal's BreedPlan recorded pedigree

DD appears to involve a fundamental neural tube defect, with both cranial and spinal dysraphism resulting from defective regulation of gene transcription in cell–cell signalling during transformation of the neural plate into the neural tube (neurulation). The wide range of abnormalities identified in DDA animals, either together in the same animal or in isolated phenotypes, has also been observed in dysraphic syndromes of other species. These include the following:

- *Polymelia:* Neonatal calves have one or more additional legs projecting from the body or head that originates close to the dorsal midline. This leg may appear relatively normal, have duplications of the digits including polydactyly or syndactyly, and the proximal bones may be vestigial, especially the scapula. The extra legs vary in size and dystocia is common.
- *Axial duplication:* Neonatal calves have an acephalic conjoined 'twin', with conjoined tissues having one or more projecting legs or resembling a mass attached to the posterior or flank of the host calf, with long bones usually within the tissue mass. Most present as dystocia and many die in the neonatal period.
- *Intradural teratomas:* A mature, well-differentiated, embryogenic teratoma is located within the dura of the CNS in the vicinity of the dorsal midline, usually in the occipital region or sacral area (where it may be associated with spina bifida).
- *Dermoid cysts and occipital skin flaps:* These may occur in similar locations to the teratomas and are small nodules of 0.5 to 1.5 cm in diameter, consisting of a fluid-filled cyst containing internally growing black hairs, with linkage to the midbrain or spinal cord. They are usually located within the dura, although may become extradural with subsequent development; some dermoids are located on the occipital bone at the base of a flap-like pouch of projecting skin.
- *Lipomas:* Some DDA cases have a fat tissue mass overlaying an embryogenic teratoma or dermoid cyst, sometimes located on the surface of the occipital bone near the midline and adjacent to an abnormal occipital foramen, although others may be intracranial.
- *Craniofacial dysmorphogenesis:* These are lesions of mild to severe facial defects, including maxillary brachygnathia and mandibular prognathia, cleft palate, defects of the muzzle, unilateral or bilateral micropthalmia, fusion of the eyelid or conjunctiva to the cornea, narrow palpebral fissures, hypoplasia of the oculomotor muscles, defects of the ocular lens, and hypoplasia of the optic foramen, sometimes with the retinal surface of the eye in proximity to the brain.
- *Craniofacial duplications:* Severe craniofacial dysmorphogenesis in DD results in diprosopus ('two faces') or possibly even dicephalon ('two heads').
- *Congenital arthrogryposis and hindlimb deformity:* Some DDA calves are born with deformed hindlegs, usually with arthrogryposis, but with no other signs of DD.
- *Postnatal ataxia:* Spinal cord tethering or compression may occur, although may not become clinically significant in DDA calves until the neonatal period or later, sometimes presenting with a postnatal onset of progressive hindlimb ataxia but no external signs of DD. Palpation of the spine may disclose a tumour along the spine or scoliosis associated with dysraphism and vertebral anomalies, although the cause of ataxia may only be detected by radiology or necropsy.
- *Embryonic deaths:* Dysraphic syndromes are associated with high rates of postimplantation embryonic death and resorption, with observations that much of the predicted mortality from genotyping information indicating mortalities occurred during embryogenesis.
- *Other presenting signs:* Other signs are expected in DD based on comparative pathological observations from human medicine and laboratory animals, and it is also expected that a proportion of congenital teratomas will become active later in life, with any expanding intracranial or intramedullary teratoma quickly becoming clinically significant. Dysgraphia has also been associated with thymic aplasia and aortic root anomalies.

• **Fig. 9.8** Inherited arthrogryposis multiplex in a newborn Angus calf; note the similarities to arthrogryposis induced by Akabane virus (see Fig. 9.5).

Arthrogryposis Multiplex

Arthrogryposis multiplex (AM; OMIA 001465) or 'curly calf syndrome' (although this term is often also applied to AKAV-induced arthrogryposis in Australia) emerged in Angus cattle in 2008 in Australia and the United States, with affected calves displaying congenital contracture and fixation of multiple joints at birth and presenting at term, but dying shortly before or during parturition (Fig. 9.8). Hydramnion is very common in cows carrying these calves. Despite a markedly reduced birth weight (15–25 kg), dystocia is common due to the congenital arthrogryposis, with forelimbs fixed in flexion and hindlimbs usually fixed in extension; this assists the diagnosis. Lateral deviation of the facial bones and severe scoliosis and torticollis, with rotational deviation of the cervical, thoracic, and lumbar vertebral column and deformation of the ribcage and sternum, are common. Mild hydrocephalus has been observed in a small proportion of cases and palatoschisis has also been noted. The mutation identified an extensive deletion that encompassed the entirety of the ISG15 ubiquitin-like modifier (ISG15) gene, one or both of the 5' regulatory region of the hairy and enhancer split 4 (HES4) and of the agrin (AGRN) gene, enabling development of commercial heterozygote detection (Table 9.1).

Neuropathic Hydrocephalus

Neuropathic hydrocephalus (NH; OMIA 000487) is a heritable recessive disorder that was initially called 'water-head' because of the extreme cardiomegaly that occurs from severe hydrocephalus. Although NH segregates independently from AM in the same Angus bloodline, more AM affected calves were born than NH affected calves, suggesting there is considerable (50%–70%) embryonic or fetal loss in NH. Although both AM and NH cause dystocia, the severity of hydrocephalus and cranial enlargement in NH (Fig. 9.9) may require that prior incision of the domed cranium, drainage of the excess CSF, and manual removal of the cranial bones from the collapsed cephalic vesicle occur to enable traction-assisted delivery. The causative mutation responsible for this extreme form of hydrocephalus in Angus cattle has been identified but remains unpublished as of December 2017, although heterozygote testing is available.

Congenital Contractural Arachnodactyly

Congenital contractural arachnodactyly (CA; OMIA 001511) or 'fawn calf syndrome' (FCS) is a recessive heritable 'marfanoid' syndrome in newborn Angus calves that first emerged in 1998 in Australia and is now recognised in the United States and elsewhere.

• **Fig. 9.9** A prominent meningocoele in an Angus calf with neuropathic hydrocephalus, requiring resection of the head to enable delivery.

• **Fig. 9.10** Congenital contractural arachnodactyly in a neonatal Angus calf.

CA is manifest at birth as an abnormal posture characterised by elongated limbs, congenital contractures of the spine (kyphosis), and proximal joints of the hindlimbs, with prominent hyperlaxity of the distal limb joints at birth that largely resolves within a few days (Fig. 9.10). Almost complete resolution of the contractures occurs within a few months of birth provided the affected calf is ambulatory. Muscular hypoplasia is prominent in CA and persists into adulthood, although clinical severity is variable and detection of the arachnodactyly in CA may require observation of the affected calf in comparison to normal siblings. The mutation has been located and sequenced with the function of the affected protein involved in the endomysial connective tissue, and commercial heterozygote detection is available through the Angus breed societies (Table 9.1).

Proportionate Dwarfism

Proportionate dwarfism (OMIA 001485) has been reported in so-called 'miniature' Angus calves in Australia, although further investigations are required to determine whether these animals are the same genotype as those reported from two commercial NSW herds in the 1990s, with birth weights as low as 6.5 kg. Calves with proportionate body conformation but birth weights <15 kg are suspect, and although intrauterine growth retardation can occur from a number of mechanisms, at least some of these

VetBooks.ir

• **Fig. 9.11** A miniature Angus–Jersey crossbred neonatal calf and normal sibling affected with Angus proportionate dwarfism.

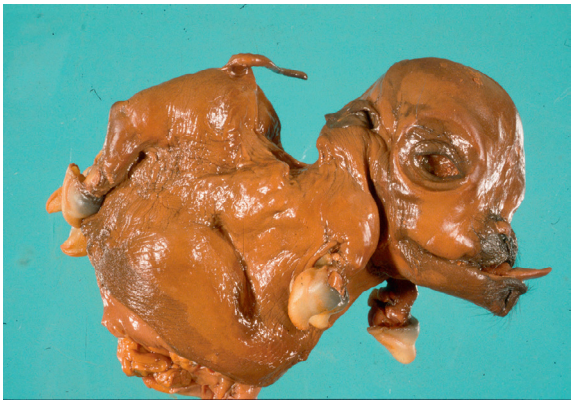
cases appear to be a form of primordial dwarfism, with affected calves being small for gestational age from conception. All these calves grow poorly (240 kg maximum), males are often cryptorchid, females are mostly infertile, and almost 30% of calves have some degree of scoliosis. Breeding experiments noted an average gestation length of only 8 months. The high frequency of occurrence of affected individuals (23/61 = 0.38 ± 0.06) among the progeny of matings of two clinically normal Angus sires to unrelated females of diverse breeding (Fig. 9.11) suggested the defect was transmitted by either an unstable mutant that changes at high frequency to the expressed dominant dwarfing allele during gametogenesis or a dominant allele with incomplete penetrance determined by an unlinked modifying locus (Latter et al. 2006). Other proportionate dwarfs in the Angus breed are reported to have normal birth weight but grow slowly after birth, typical of animals with reduced growth hormone function. With more than 200 forms of dwarfism reported in man, it is likely that many different forms of dwarfism are present in cattle, in addition to the proportionate and chondrodystrophic forms reported. Primordial dwarfism (associated with a higher than normal rate of failure of mitotic divisions and cell death in tissues throughout the body and consequent reduced life expectancy) will very likely be one of these.

Disproportionate Dwarfism

Disproportionate dwarfism (OMIA 001485) refers to one or more forms of dwarfism commonly and widely recognised in Angus cattle, in which mild chondrodysplasia is present, leading to aggressive culling practices in some herds for this suspected recessive genetic defect. Animals are typically smaller in stature than their cohorts with short legs and body, so the animal may appear to have a potbelly and a thick or blocky shape, and an elongated nose or shortened face (owner descriptions include a 'blocky conformation and a dished face with a long nose'). A recent molecular study sequenced four candidate genes and identified a nonsense R678X mutation in exon 15 of cGMP-dependant type II protein kinase (PRKG2) on Chromosome 6 that is involved in transcription of collagen 2 (COL2), consistent with the likelihood that this most common of phenotypes in Angus is a form of mild chondrodysplasia (Koltes et al. 2009).

Dexter Chondrodysplasia

Dexter chondrodysplasia (OMIA 001271) is a well-known defect in the Dexter breed in which, inadvertently, selection for a 'short legged phenotype' as the breed standard resulted in a high proportion of short-legged Dexters being heterozygous for the 'bulldog calf'



• **Fig. 9.12** Mummified Dexter fetus affected by chondrodysplasia, displaying the typical micromelia, shortened cranium, tongue protrusion, and shortened vertebral column and ribs.

• **Fig. 9.13** Chondrodysplasia in a Dexter fetus with micromelia, shortened cranium, tongue protrusion, and location of the abdominal viscera in a large umbilical hernia.

genotype. This is a nonviable fetus that may die *in utero* and be mummified (Fig. 9.12) or be aborted, although some calves survive until term, when fetal hydrops and hydramnios of the dam may also occur. Affected calves have severe chondrodysplasia manifest as micromelia, shortened cranium, palatoschisis, tongue protrusion, and shortened vertebral column and ribs (Fig. 9.13), resulting in multiple lobing of the lungs and eventration of the abdominal viscera through a large umbilical hernia (Harper et al. 1997). Two mutations on Chromosome 21 were identified in Australia involving two separate blood lines of Dexter cattle (Cavanagh et al. 2007), including a 4 bp insertion in exon 11 (2266_2267insGGCA) and

VetBooks.ir

a second, rarer transition in exon 1 (-198C>T) that cosegregates with the disorder (Tammen et al. 2007). In chondrocytes from cattle heterozygous for the insertion, mutant mRNA was subject to nonsense-mediated decay, showing only 7% of normal expression of aggrecan (ACAN), a protein enabling accumulation of fluid in cartilage matrix. These findings led to two PCR-based genotype tests that have helped to control the disorder worldwide.

Pulmonary Hypoplasia and Anasarca

Pulmonary hypoplasia and anasarca (PHA) (OMIA 001562) was diagnosed in Dexter cattle in Australia when breeders reported the occurrence of severe fetal dystocia due to a huge 'bulldog-like' calf from cows that were known not to be heterozygous for Dexter chondrodysplasia. At necropsy, the calf morphology was characterised by hydrops fetalis (or anasarca) accompanied by pulmonary aplasia or severe hypoplasia, manifesting as an absence of lung tissue or presence of only rudimentary lungs in a large thoracic cavity (Windsor et al. 2006). Pedigree analysis indicated the defect is transmitted in an autosomal recessive manner, and the mutation has recently been identified but has not been published as of December 2017. PHA was also diagnosed in a single Brahman stud, with extreme anasarca and minimal pulmonary tissue present (unpublished). The extremely swollen fetus could only be delivered by Caesarean surgery (Fig. 9.14). Similar entities have been observed in Shorthorn and Maine–Anjou cattle in the United States, a Belted Galloway in Denmark, and Cika cattle.

Complex Vertebral Malformation Syndrome

Complex vertebral malformation syndrome (CVM; OMIA 001340) is a congenital lethal malformation in Holstein–Friesian cattle causing extensive fetal mortality, with only about 23% of affected fetuses surviving until Day 260 of gestation. Those that survive to term are mostly stillborn and display growth retardation with bilateral flexion of the carpal and metacarpophalangeal joints and rotation of the digits accompanying vertebral malformation, malformed ribs, and arthrogryposis of the tarsal and metatarsophalangeal joints (Fig. 9.15). Diagnosis of CVM is based on detection of a single base mutation in the gene SLC35A3, which results in insufficient function of a nucleotide–sugar transporter needed for normal development of vertebrae. Genotyping of almost 1494 Australian Holstein–Friesian bulls born between 1955 and 2001 revealed a carrier frequency of 12.79%, suggesting that numerous affected calves would have occurred in Australia but were likely to have been undetected or unreported.

Brachyspina

Brachyspina (BS; OMIA 000151) is a congenital lethal malformation of Holstein–Friesian calves, originally reported in Denmark in 2006, then Italy, the Netherlands, Canada and the United States. BS is characterised by reduction of the birth weight to about 10 kg despite a gestation period of normal or slightly prolonged length, obvious shortening of the spine, long slender limbs, inferior brachygnathism or micrognathism, renal and gonadal dysplasia (Fig. 9.16), and, in some cases, additional internal malformations (Agerholm et al. 2006). BS is transmitted in an autosomal recessive manner, and the mutation identified in the FANCI gene (Fanconi anaemia complementation group 1) has enabled a molecular test based on genetic markers to be developed for genotyping (Charlier et al. 2012).

VetBooks.ir

Chromosomal Disorders

In Table 9.1 the chromosome on which the causative mutation(s) occurs is provided, reflecting the recent advances in molecular techniques that have enabled more rapid identification of the mechanisms that lead to inherited developmental disorders, including the disorders causing failures in gametogenesis and losses during blastogenesis, embryogenesis, or during fetal development, growth, parturition, and the early neonatal period. Although there are many thousands of genes, they are arranged in a limited number of chromosomes that can be visualised by karyotyping (Nicholas 2003). As some chromosomal abnormalities may have an important role in infertility in some species, where laboratory services are available, investigations of infertility should include cytogenetic examination of the karyotype to ensure major lesions of the chromosomes are absent.

Although chromosomes can be prepared from any dividing cell, peripheral blood lymphocytes collected in a heparinised blood sample is preferred, with short-term culture followed by addition of a spindle blocker to the medium, enabling the accumulation of cells at the mitotic metaphase for analysis of the chromosomes. Alternatively, chromosomes can be derived from fibroblast cultures established from skin subcutis samples. Simple staining enables chromosomes to be individually identified, the chromosomal number, morphology, and small abnormalities to be detected. Differential staining techniques identify either areas of highly repetitive DNA sequences (C banding) or bands of euchromatin and heterochromatin (G banding and R banding). Molecular genetic techniques, involving fluorescent in situ hybridisation (FISH), can also be used to identify specific DNA sequences or whole chromosomes. Chromosome spreads can be photographed, cut out, and arranged in an agreed order to construct a karyotype. Chromosome abnormalities may be numerical (e.g., aneuploidy or polyploidy) or structural, and may occur in the sex chromosomes (X or Y) or the nonsex chromosomes or autosomes. If an individual has more than one cell line it is referred to as mixaploid.

Numerical chromosome abnormalities include *aneuploidy* and *polyploidy. Aneuploidy* is when the chromosome number is almost diploid, but there are one or two chromosomes too many or too few, arising if there is nondisjunction during meiosis so that the chromosomes do not separate in a balanced fashion. X chromosome aneuploidy in females results in infertility because two X chromosomes are required for normal meiosis in the embryo, with a deviation resulting in oocyte atresia during embryonic development (i.e., XXX or triple-X syndrome, and XO or Turner's syndrome). An extra X chromosome in the male also results in infertility because the extra X chromosome interferes with spermatogenesis at puberty. Hence the phenotype is male but with small testes and azoospermia (i.e., XXY or Klinefelter's syndrome). Aneuploidy of the autosomes results in either too many (trisomy) or too few (monosomy) copies of a particular chromosome and its associated genes. The outcome of this depends on the genes involved, with either the individual displaying developmental abnormalities or, if these are not compatible with life, there is embryonic death. *Polyploidy* is when there are whole multiples of the haploid (i.e., half the diploid) chromosome number in excess and arises when there is a failure of the block to polyspermy or if there is retention of the first or second (or both) polar bodies during oogenesis.

Structural chromosomal abnormalities lead to outcomes that depend on whether genetic material has been lost (deletions) or simply rearranged (insertions, inversions, and translocations). When deletions have occurred, the developmental abnormalities depend on which genes have been lost and may be sufficiently serious to cause embryonic death. With rearrangements, balanced carriers of the anomaly are phenotypically normal, but problems may arise during meiotic prophase because the chromosomes have problems at pairing. This often results in nondisjunction and the production of chromosomally unbalanced gametes, producing unbalanced mostly unviable zygotes (trisomies or monosomies) if fertilisation occurs. Different abnormalities are found at different frequencies in the different species, with several of the more common anomalies in each species discussed.

Cattle

Centric Fusion Translocation

The most common chromosomal abnormality in cattle is a structural anomaly known as a centric fusion translocation in which two chromosomes fuse together near the centromere, resulting in a reduction in the chromosome number but little or no loss in genetic material. Over 30 different centric fusion translocations have been reported in cattle, of which the most common is the 1/29 translocation ('Robertsonian translocation'), which is found in a large number of breeds throughout the world. Heterozygosity (i.e., carrying one copy) for a centric fusion translocation results in a drop in fertility, the extent of which depends on which translocation is being carried. Animals heterozygous for the 1/29 translocation have a reduced fertility of the order of 5%. The drop in fertility is due to nondisjunction at meiosis, the production of chromosomally unbalanced gametes and embryos that undergo early embryonic death. The reduced fertility is manifested as a small increase in services per conception in the female and a lower nonreturn rate in the male. Carriers of some of the other centric fusion translocations have an even greater reduction in fertility, e.g., 46% with the 25/27 translocation in the Alpine Grey. Many countries will not allow the importation of animals carrying such translocations and artificial breeding agencies now often screen their bull populations and avoid using animals carrying translocations. Other less common chromosomal anomalies in cattle include phenotypically abnormal calves born with autosomal trisomies, cases of infertility in the bull due to the XXY Klinefelter's syndrome, and XXX infertile cows.

Freemartinism

Chromosomal analysis (see also Chapter 4) is also used in the diagnosis of *freemartins* because, in this condition, the fusion of the placental blood vessels not only allows Mullerian inhibition substance (MIS) and testosterone from the male to affect female development, but also allows the mixing of haemopoietic precursor cells, leading to the establishment of male and female cells in the blood of each twin. This can be detected by a simple chromosome analysis at any time after birth, enabling freemartinism to be predicted. No samples are required from the sire or dam. There is some debate as to the fertility of males born as a twin to a female. Although some surveys have shown reduced nonreturn rates, poor sperm freezability or poor sperm concentration and motility in the ejaculate of chimeric bulls, other surveys have shown no reduction in fertility and normal semen.

Sheep

Cases of infertility in the ram have been due to XXY Klinefelter's syndrome, with centric fusion translocations found in Romney, Perendale, and Drysdale sheep in New Zealand and in Romney Marsh sheep in the UK. However, unlike in cattle, centric fusion translocations have not been associated with a reduction in fertility

VetBooks.ir

in sheep. Reciprocal translocations have been reported in sheep with reduced fertility, but these are rare. In a survey of barren ewes, XX/XY (freemartinism) was the most common finding, and the XO (Turner's syndrome) has also been reported.

Goats

Centric fusion translocations have been found in Saanen and Toggenburg goats, although the effect on fertility is difficult to assess because of the confounding factor of the intersex gene associated with polledness in this species, nevertheless, it does seem that heterozygosity for a centric fusion translocation is associated with reduced fertility in the Saanen breed. The intersex gene is an autosomal recessive that is linked to the dominant gene for polledness, thus homozygous females for the polling gene are also homozygous for the intersex gene and are intersexes. Males that are homozygous for the polling gene are usually normal. However, 10% to 30% of these males may be infertile because of tubular blockage in the head of the epididymis.

Pigs

In the pig reciprocal translocations are the most common chromosome anomalies, with parts of chromosomes exchanged with little or no loss of genetic material. Carriers of reciprocal translocations are phenotypically normal but have problems at meiosis and produce unbalanced gametes, reducing litter size or even causing infertility. In Sweden 50% of boars culled for small litter sizes were found to be heterozygous for a reciprocal translocation, although most of these translocations appear to have arisen de novo and were not inherited, implying an environmental factor in induction of new translocations.

Horses

Chromosomal anomalies are an important cause of infertility in mares, with 50% to 60% of mares with gonadal dysgenesis having an abnormal chromosome complement. The most common chromosomal abnormality in mares is X chromosome aneuploidy (e.g., XO or XXX). Another common anomaly is XY sex reversal, with the animal presenting as a phenotypic female when it is in fact a genetic male. The incidence of such anomalies is uncertain, although in a study of 204 mares presented at stud for breeding, one mare was 65,XXX, one was 63,XO/64,XX, and one was a 64,XY sex-reversed male.

XO mares are usually small for their age, may have poor body conformation, usually fail to show oestrus, have small underdeveloped ovaries and a small 'infantile' uterus, and are infertile. XXX mares often present with the same clinical history as XO mares and, although some have shown irregular cyclic activity, all have been infertile. XY sex reversal is not uncommon in the horse, with most cases reported in Arabs and thoroughbreds. All are phenotypically female but are genetic males. The clinical signs are variable; some fail to show oestrus whereas others have irregular but strong oestrous behaviour. Some animals have had small, undifferentiated gonads, whereas others have had apparently normal ovaries with follicular activity. Most but not all are infertile. Mixaploid mares with normal as well as abnormal cells (e.g., XO/XX, XX/XXX, XO/XX/XXX or XO/XY) have been described, although diagnosis of the condition can be difficult. The fertility in mixaploid animals with a normal XX cell line is difficult to predict because, although most have been infertile, some have produced a foal. If the animal is actually showing oestrus and follicles are palpable on the ovary, it is probably advisable not to declare the animal infertile. Diagnosis of a chromosomal cause of a fertility problem cannot be made on the basis of the clinical history alone because animals with a normal karyotype present with the same history and clinical findings.

Few studies have been carried out on stallions with a fertility problem. Two colts have been reported with autosomal trisomies; one was a cryptorchid and the other had small testes. Structural abnormalities have also been found in Chromosome 1 in a stallion with a history of early embryonic death in mares that he covered.

Mules and Hinnies

The mule is a cross between a female horse and a male donkey, and the hinny is a cross between a female donkey and a male horse. The males of both crosses show abnormalities of chromosome pairing at the pachytene stage of meiotic prophase, and little or no mature spermatozoa are produced. Thus the males are infertile. Females are also affected during the fetal development of the germ cells, and most oogonia die as they are entering meiosis. However, sometimes a mature follicle is present in the adult, and, rarely, confirmed foalings have been reported in both mules and hinnies.

Dogs

Chromosomal abnormalities have not been associated with infertility in the dog except in one case of Klinefelter's syndrome and one case of prolonged prooestrus in a bitch with X chromosome monosomy (77,XO). Centric fusion translocations have been reported but there have been no consistent clinical findings. Their influence on fertility has not been investigated.

Cats

Chromosomal abnormalities are not common in the cat except in association with the tortoiseshell coat colour in the male. Many of these are XXY Klinefelter's syndrome cats, and they are always sterile. However, the mixaploid animals that have a normal XY male cell line may be fertile. Fertility presumably depends on whether the normal XY cell line is found in the testis. Fertile male tortoiseshell cats will breed as if they were normal XY toms and will transmit the coat colour genes by a Mendelian pattern of inheritance. Male tortoiseshell cats are considered uncommon, although in a survey of 9816 cats in the UK, of the 4598 males, 20 were male tortoiseshell cats. Because there is no reason to suppose that these chromosomal anomalies are only found in tortoiseshell cats, they are probably responsible for fertility failure in other cats but have gone undiagnosed because very few cats are examined cytogenetically. The XO condition has been reported and is therefore a possible cause of infertility in the female.

Abnormalities Due to Environmental Effects: Dietary and/or Toxic Disorders

Since the discovery of the teratogenic effects of hypovitaminosis A in pigs in 1933, the adverse influence of dietary factors on the development, growth, and survival of embryos have been regularly described. Teratogenic effects of vitamin, mineral, and trace element deficiencies and toxicities were demonstrated in experimental studies in rodents, and as these studies are informative for potential abnormalities in other species, they are briefly included here along with similar naturally occurring disorders of livestock populations. More detailed information is provided where there has been improved understanding in the teratogenic effects of deficiencies and toxicities.

VetBooks.ir

Undernutrition of both food (and water) is very likely to be important in adverse prenatal development, with increasing interest in the role of restricted protein and energy nutrition in induction of intrauterine growth retardation (IUGR) in livestock production (Long et al. 2009). IUGR adversely affects neonatal survival, postnatal growth performance, efficiency of feed utilisation, tissue composition (including protein, fat, and minerals), meat quality, long-term health of offspring, and adult onset of disease. IUGR involves genetic, epigenetic, and environmental factors including nutrition, as well as maternal maturity effect on the size and functional capacity of the placenta, placental vascular growth, utero–placental blood flows, transfer of nutrients from mother to fetus, the endocrine milieu, as well as embryonic development of myocytes, adipocytes, and other cell types. Growing evidence suggests that arginine-derived signalling molecules (nitric oxide and polyamines) play an important role in regulating these key physiological and biochemical processes. Potentially, modulating arginine-metabolic pathways that can enhance embryonic/fetal survival and growth may provide a useful approach to prevent and treat IUGR, although in many parts of the world, improving nutritional quality and quantity by improving feed resources for pregnant and lactating animals is a major challenge for improving livestock production efficiency. Maternal malnutrition was studied in mice deprived of food for limited periods before or during pregnancy, resulting in malformed offspring with the brain, ribs, and vertebrae affected.

Suspected nutritional chondrodysplasia of cattle refers to various syndromes of neonatal skeletal deformity reported in both free range and housed beef cattle in Europe, North America, South Africa, New Zealand, and Australia. Several descriptors have been used to identify affected calves including 'acorn calves, bulldog calves, congenital joint laxity, and dwarfism with congenital spinal stenosis' and, more recently, *congenital chondrodystrophy of unknown origin* (CCUO) associated with drought (White & Windsor 2012). Based on similarities of phenotypic appearance, affected calves display signs of disproportionate dwarfism (frequently with superior brachygnathia), shortened limbs (Fig. 9.17) and spinal deformities, with histopathology displaying disruption to normal endochondral ossification of long bones. Investigations including genetic, infectious, toxic, and nutritional aetiologies have been inconclusive with a common hypothesis promoted that the condition may result from a maternal nutritional deficiency. Recent investigations in Australia have shown the condition is associated with drought and with poor quality maternal nutrition (White & Windsor 2012). It is possible that CCUO calves result from multiple aberrant nutritional factors, with the epidemiological evidence suggesting manganese deficiency not strong, although the evidence for zinc deficiency appears stronger as a cause of CCUO. It was suggested that studies into short-term zinc deficiency in ruminants may prove helpful in future investigations.

• **Fig. 9.17** Weaner crossbred calf affected from birth with congenital chondrodystrophy of unknown origin (CCUO) associated with drought in southeastern Australia, displaying disproportionate dwarfism with shortened limbs from disruption of endochondral ossification.

Abnormalities From Deficiencies and Toxicities of Vitamins

Vitamin A

Vitamin A deficiency in the maternal diet causes ocular and facial malformations in pigs, commonly presenting as anophthalmia or microphthalmia, although malformations of the brain, the spinal cord, and other organs including the mouth and urogenital systems occurred, prevented by supplementation of the maternal diet by cod liver oil. In cattle, hypovitaminosis A during gestation causes abortion, resorption, stillbirth, or fetal malformations, with profound ocular changes and even blindness frequent in vitamin A-deficient calves. Primary vitamin A deficiency in growing cattle occurs most commonly from a lack of green feed during periods of grain-feeding in drought or in feedlots where carotene is excluded from the diet. Secondary deficiency may occur with a combination of chronic hepatic and intestinal disease as the liver is the principal storage site, and conversion of carotene to vitamin A occurs in the alimentary tract. Because vitamin A is required for osteoclast function and deficiency causes failure of bone remodelling, excessive bone is produced from where resorption should be occurring and may cause asynchrony between development of the CNS and bones in the skull, particularly in the lining of the optic canals through squamous metaplasia, reducing the space for the optic nerves.

Vitamin A toxicity during pregnancy can also produce malformations, with oral administration of 35,000 IU of vitamin A to pregnant rats producing various CNS abnormalities including exencephaly, with anophthalmia, microphthalmia, exophthalmos, cataracts, retinal defects, and open eyelids also described. Retinoic acid is the most teratogenic form of vitamin A and, in excess, can impair the normal development of many organ systems, inducing craniofacial and fetal limb abnormalities.

Vitamin B

Vitamin B complex deficiencies during pregnancy may adversely affect embryonic development and survival. The detrimental effect of chronic dietary deficiency of **thiamine** on embryonic growth and survival was established in rats and pigs, although no malformations were identified. Maternal **riboflavin** deficiency in pigs may result in anomalous limb development, with a deficiency in the diet of pregnant rats altering the development of the mandibles, long bones, and digits; thus a relatively mild degree of maternal riboflavin deficiency is considered teratogenic. **Niacin** (nicotinic acid) deficiency during pregnancy, produced by the incorporation of the antimetabolite, 6-aminonicotinamide, into the diet of rats, resulted in brain malformations, mainly exencephaly and hydrocephalus, although other brain malformations and ocular, urogenital, skeletal, and vascular abnormalities were induced by a single injection of this antimetabolite. Although **pyridoxine** (vitamin B6) deficiency during pregnancy may adversely affect perinatal development and survival, no definite evidence of teratogenicity has been noted, although the additional use of the antagonist (4-desoxypyridoxine) has been shown to be teratogenic to rat fetuses. **Folic acid** deficiency in pregnancy is also detrimental to

VetBooks.ir

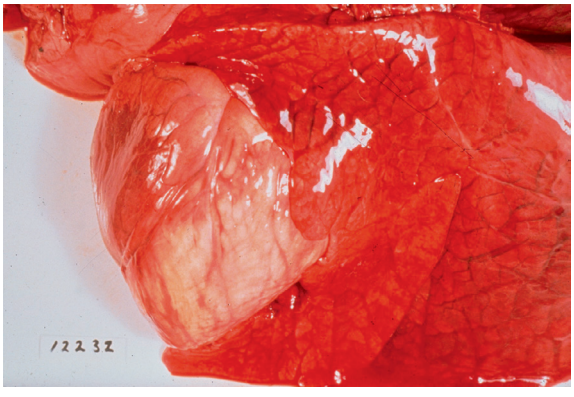
the development of rodent embryos, with teratogenicity increased by the addition of the folic acid antagonist pyrimethamine. Maternal folic acid supplementation in humans is associated with protection against deficits of neurulation; in rats, a deficiency of folic acid lasting only a few days during the early stages of embryogenesis produced a high rate of malformations, with hydrocephalus evident in the postnatal period and malformations of the brain, face, and mouth, as well as of the ocular, cardiovascular, urogenital, and skeletal systems observed. A diet insufficient in **pantothenic acid** fed to rats before and during pregnancy caused eye and brain abnormalities in the offspring, with exencephaly predominant. In pigs, reduced dietary levels of pantothenic acid resulted in fetal deaths and locomotor incoordination of the young. Maternal dietary deficiency of **vitamin B12** caused hydrocephalus in rat young, and even a marginal reduction in vitamin B12 intake of pregnant rats adversely influenced birth weight and postnatal growth.

Other Vitamins

Vitamin C has been shown to have no teratogenic affects in pregnant mice or rats, even at doses as high as 1000 mg/kg.

Vitamin D deficiency during pregnancy is harmful to the fetus, with skeletal abnormalities resulting from maternal rachitogenic diets occurring in rodents, pigs, and calves. Maternal **hypervitaminosis D** in mice and rats adversely altered osteogenesis of the long bones and ossification of the digits, with defects of the extremities increasing in degree of severity with advancing postnatal age.

Vitamin E deficient diets have also been shown to have a detrimental effect on maintenance of pregnancy, development, survival, and growth of rodent offspring, with severe maternal deficiency of vitamin E resulting in complete embryonic resorption. Supplementation with alpha-tocopherol enabled some embryo survival, with the incidence of malformations depending on the degree of vitamin E deficiency, including exencephaly, hydrocephalus, cleft palate, umbilical hernia, syndactyly, and tail deformities. Maternal vitamin E deficiency resulted in stillbirths in the dog, and neonatal deaths and incoordination of the hind legs in piglets, with grossly visible lesions of myodegeneration in congenital white muscle disease (WMD), including the heart (Fig. 9.18), observed in neonatal lambs, calves, and foals. Investigations of WMD should examine whether the issue is caused by vitamin E, selenium deficiency, or both, particularly as vitamin E and selenium supplementation reduces the incidence of these conditions. **Vitamin E excess** given orally at doses of 590 IU to mice during Days 7 to 11 of gestation produced neither embryotoxicity nor teratogenicity.



• **Fig. 9.18** Congenital cardiac white muscle disease in a neonatal calf due to vitamin E deficiency; note the lesions of extensive pallor of the myocardium due to myodegeneration.

Vitamin K deficient diets fed to pregnant rats caused cerebral haemorrhage in about one-third of the young, and abortions in pregnant rabbits. In cattle the ingestion of sweet clover hay or ensilage containing dicoumarol may result in death of newborn calves, especially when the dietary intake of dicoumarol exceeds 2 mg/kg body weight. Lambs are less susceptible than calves to the detrimental effect of dicoumarol ingestion by the mother.

Abnormalities From Mineral and Trace Element Deficiencies and Toxicities

Copper

Copper deficiency occurring during gestation in sheep may manifest as *congenital enzootic ataxia,* or 'swayback', and may be due to a primary deficiency due to low soil copper levels (as occurs on volcanic red soils after rain), or secondary to impaired gut absorption, usually from the presence of antagonists such as molybdenum. Copper is important for coenzyme for metabolic functions, and inadequate levels impede cellular respiration leading to energy deprivation. Affected lambs with swayback present from birth with motor dysfunction, including staggering, ataxia, recumbency, and occasionally blindness. They display bilaterally-symmetrical malacia (softening) of the cerebral white matter and defective myelinogenesis, leading to cerebral cavitation. A delayed form may also occur after several weeks of the postnatal period. In goat kids, copper deficiency is expressed mainly as the delayed form with lesions of cerebellar degeneration.

Copper toxicity is well described in grazing animals, particularly in Australia where exposure to pyrrolozidine alkaloid containing plants (particularly *Heliotropium europaeum, Echium plantagineum, Senecio* spp., *Amsinckia* spp., *Crotalaria* spp., and *Cynoglossus* spp.) is common and results in accumulation of hepatic copper until a precipitous release occurs, causing a hemolytic crisis and, often, mortality outbreaks. The potential teratogenic effects of these copper-accumulating situations is worthy of more detailed investigation.

Selenium

Selenium deficiency in neonatal lambs is typically manifest as ***congenital muscular dystrophy*** (white muscle disease/WMD) that can occur in newborn lambs, although is more commonly seen in lambs up to 3 months of age (subacute enzootic muscular dystrophy or 'stiff lamb' disease). Selenium is essential for a variety of roles, including: antioxidant actions in conjunction with vitamin E to prevent and repair cell damage; immune functions; and growth and fertility. In Australia, factors predisposing sheep to selenium deficiency include: acidic basalt/granite soils and sandy soils; annual rainfall over 450 mm; clover dominant pastures; and heavy or long-term fertiliser application, particularly with sulphur-fortified superphosphate or gypsum. Outbreaks of WMD and responses to selenium supplementation are more likely in lambs from ewes grazing in lush seasons on heavily fertilised, clover dominant pastures on granite soils. Similarly, weaner ill-thrift and scouring due to selenium deficiency will occur in 'the good years' but is less likely in dry years or under drought conditions. Selenium deficiency causing clinical WMD has also been observed in young lambs born to ewes that had been fed on wheat for most of their pregnancy, as some grains may be low in selenium, depending on the selenium availability in areas in which the crops were grown. As several disorders can cause similar clinical signs to WMD, clarification of the levels of both selenium (usually as plasma glutathione peroxidase) and vitamin E is advised, particularly as selenium therapy can be toxic if given excessively.

VetBooks.ir

Selenium toxicity is of potential concern where exposure to industrial contamination, grazing of seleniferous pastures, or where administration of excessive selenium supplementation to address deficiency concerns has been occurring (an increasing risk with promotion of selenium-fortified anthelmintic preparations). An overdose of selenium can be toxic, with an oral dose of 10 to 15 mg of selenium known to kill lambs, and an injection of 5 mg selenium potentially lethal to lambs. Selenium toxicity may be acute or chronic. Signs of selenium toxicity include: respiratory distress, blindness, staggering, head pressing, anorexia, salivation, abdominal pain, watery diarrhoea, convulsions, paralysis, and death. Administration of selenium (3 ppm) in the drinking water to mice during pregnancy caused an increase in the number of runts, with subcutaneous injection (40 µmol/kg of sodium selenite) to mice on Day 12 of pregnancy causing fetal mortalities and abortion. Interestingly, pretreatment with vitamin E (50 mg/kg) prevented abortion and maternal death but not fetal loss. Excessive selenium intake during gestation has been reported to have adverse effects on development and survival of the offspring in farm animals, with lambs born from ewes grazing on a seleniferous range displaying multiple malformations of the eyes (e.g., microphthalmia) and extremities (e.g., thickened joints, twisted and malformed phalanges), and hypoplasia of the reproductive organs, with almost 75% of 250 malformed lambs stillborn or dying shortly after birth. Hoof deformities occurred in calves and foals from dams receiving excessive amounts of selenium in their diet during gestation. Sows fed 10 ppm sodium selenite during gestation farrowed many dead piglets, with the survivors small and weak at birth.

Iodine

Iodine deficiency manifests as ***congenital goitre*** (CG), with clinical sign of hypothyroidism recognised when a neonatal lamb, kid, or calf has an enlarged thyroid gland at birth, increasing the risk of dystocia (Fig. 9.19). Neonatal goitre may be caused by an absolute deficiency of iodine when the pregnant females are grazing pastures grown on iodine deficient soils or be induced when ingested goitrogenic compounds in plants interfere with the uptake of iodine by the thyroid gland, causing iodine deficiency despite the females having normal plasma iodine levels. Hypothyroidism causes a reduction in metabolic rate, and the lambs and kids have reduced suckling behaviour and increased susceptibility to hypothermia, particularly in lambs with compromised development of wool follicles. Affected flocks and herds have reduced birth rates, increased stillbirths and neonatal mortality, with smaller birth weights and increased prevalence of 'wool break' within the flock (Robertson et al. 2008) and hypotrichosis in calves (Fig. 9.19). Goitrogens are found in *Brassica spp.* (canola, broccoli, cauliflower, Brussels sprouts, or cabbage), plus soy, pine nuts, millet, peanuts, and *Trifolium repens* (white clover). In *Brassica napus* (canola), the goitrogenic glucosinolates and S-methyl cysteine sulfoxide are released as isothiocyanates during digestion, interfering with the thyroidal uptake of inorganic iodine from the blood through the thyroid blood vessels, causing thyroid hypertrophy as a physiological response to the induced iodine deficiency.

• **Fig. 9.19** Marked enlargement of the thyroid due to colloid goitre in a stillborn crossbred calf with hypotrichosis; the producer is now supplementing with iodised salt.

Calcium deficiency is commonly occurs in adult cattle with postnatal hypocalcaemia (milk fever), causing flaccidity and paresis, reflecting the important role of calcium in controlling the release of the neurotransmitter acetylcholine that gates neuromuscular function. Hypocalcaemia syndromes also occur in feed-deprived sheep and in sheep consuming high-oxalate-containing pastures. However, as calcium is also critical for calcification and ossification processes, there is teratogenic potential of calcium deficiency when severe prolonged maternal deficiency during pregnancy adversely affects fetal skeletal development. Severe calcium deficiency of the mother may result in stillborn offspring or nonviable young in rats, cattle, and sheep; however, if the deficiency is mild or of short duration, fetal skeletal development remains unaffected due to mobilisation of maternal reserves from bone. **Calcium toxicity** from excessive calcium intake in the diet during pregnancy was shown to be detrimental to the developing fetus and young of pregnant rats, causing increased intrauterine mortality, reduced birth weights and postnatal growth rate, plus alopecia.

Magnesium deficiency is also common in grazing ruminants, particularly in lactating cattle sensitive to either low dietary magnesium or high potassium in lush green pasture, inhibiting rumenal magnesium absorption. Magnesium is important for neuromuscular function and deficiencies manifest as spasticity, convulsions, tremor, and tetanic spasms (grass tetany). Dietary magnesium deficiency during pregnancy may adversely affect survival and development of the fetus, with severe deficiencies in rats (0.2 mg magnesium/100 g diet) fed from Day 6 to 14 of pregnancy, resulting in very high (90%) rates of fetal resorption. When the deficient diet was fed only from Days 6 to 12, about 70% of the embryos survived, although malformations were common, including cleft lip, clubfoot, hydrocephalus, micrognathia, polydactyly, syndactyly, and heart, lung, and urogenital anomalies. An increase in the incidence of resorptions, malformations, and stillbirths was noted even with a relatively mild deficiency of magnesium (2.5–5 mg/100 g diet).

Iron deficiency in the diet before and during pregnancy causes anaemia in rat offspring with severe deficiency of iron resulting in very high neonatal mortality, with a few cases of ocular defects occurring in the offspring of rats deficient in iron during pregnancy. Inhibition of mitochondrial oxidative enzymes during fetal development is likely responsible for the high rate of fetal resorption and small fetal size observed in the rat in iron deficiency. Although this is not described in other species, the requirement for intensively housed neonatal pigs to receive iron supplementation in the immediate postnatal period is well known.

Manganese deficiency during pregnancy in rats and mice causes ataxia from absent or defective otoliths resulting in loss of equilibrium in the offspring, with severe shortening of the radius, ulna, tibia, fibula, and cranial bones. Supplementation with manganese prevented the neonatal ataxia, and studies suggested the possibility that aberrant development of the inner ear and the skeleton was

VetBooks.ir

caused by impaired synthesis of mucopolysaccharides. Ataxia of the young, as a consequence of maternal manganese deficiency, was also noted in pigs, and defects of the skeleton involving the limbs and vertebrae were attributed to maternal manganese deficiency in newborn rabbits and calves. Syndromes of drought-associated nonhereditary congenital chondrodysplasia in cattle in Australia (and elsewhere) have been commonly reported that likely involve environmental factors other than manganese deficiency, particularly as supplementation failed to ameliorate the disorder (White & Windsor 2012). **Excessive manganese** failed to produce teratogenicity in pregnant hamsters.

Phosphorus deficiency is common in many of the ancient soils of Australia, with grazing cattle often adversely affected, displaying signs of bone fragility and pica that increases the risk of botulism from consumption of decaying bones. As normal fetal growth and calcification of the skeleton depends on an adequate ratio of calcium to phosphorus in the diet of pregnant animals, studies of rats fed diets deficient in phosphorus noted in an increased occurrence of resorption of embryos; similarly, unmanaged phosphorus deficiency may potentially affect deleteriously the reproductive performance of grazing ruminants.

Zinc deficiency has deleterious effects on development and survival of embryos, with maternal dietary deficiency of zinc in rats fed an almost zinc-free diet (0.3–0.5 ppm of zinc) resulting in embryonic death or malformations, with 40% to 50% of the implantation sites resorbed and nearly all survivors displaying malformations affecting almost every organ system. Malformations included anencephaly, hydrocephalus, exencephaly, and, less commonly, defects of the eye, lip, palate, heart, lung, spine, urogenital organs, and pituitary and pineal glands. Zinc deficiency in early pregnancy in rats causes abnormal cleavage and blastulation in preimplantation embryos, suggesting the malformations result from impaired nucleic acid synthesis. Zinc deficiency in sows during the last trimester of pregnancy resulted in a moderate degree of hydrocephalus in some piglets and irregular ossification centres and hypoplasia in the developing skeleton, with excessive umbilical haemorrhage causing reduced neonatal survival. Excessive amounts of zinc in otherwise adequate diets seem to have little adverse effect on embryonic development and survival in hamsters and rats.

Abnormalities From Industrial Pollutant and Agricultural Chemical Toxicities

With exception of a limited number of pharmaceutical agents that are of large molecular size, or biotransformed into inactive metabolites, or firmly bound to maternal tissue, most chemicals used in industry and agriculture readily cross the placental barrier and enter the embryonic milieu where they may interfere with the various processes of prenatal development and growth, including embryonic death, intrauterine growth retardation, and malformation (Szabo 1989). These effects on prenatal development may depend on the specificity and embryotoxic or teratogenic potentials of the agent, on the time of exposure during pregnancy, and on the susceptibility of the species. A few of the various classes of chemicals, drugs, and pharmaceutical agents that have been found to cause teratogenic effects in domestic animals are discussed in this section. As the literature is vast on the many drugs that are known to adversely influence prenatal development in experimental animals if given at sufficient dosage by the appropriate route to a susceptible animal species at the sensitive stage of embryogenesis, the reader is advised to seek more detailed information from other sources (McGeady et al. 2017).

Atrazine is a synthetic triazine insecticide, herbicide, and stabilising compound used in plastics. It is capable of causing altered gene expression and disruption of endocrine function even at low concentrations. It is of particular concern as a pollutant of wildlife populations as it causes abnormities of the gonads in fogs and male rats. Atrazine induces production of aromatase that converts testosterone to oestradiol, adversely affecting male fish and amphibians with immunosuppression increasing the susceptibility to infectious agents in aquatic environments.

Bisphenol A is also a stabilising compound used in plastics but can leach into water at levels that can affect gonadal development in rodents through oestrogenic activity. In addition, *in utero* exposure in rodents induces cellular changes that lead to tumour formation on exposure to oestrogens or carcinogens later in life. There are concerns that accumulation of bispenhol A in children from widespread use of such compounds and their persistence in the environment may create future toxicity problems in populations of wildlife, domestic animals, and humans.

Cadmium toxicity is of potential concern in grazing animals and is a known teratogen in rodents with intravenous injection of 2 mg/kg cadmium on Day 8 of pregnancy producing severe facial deformities, including mandibular defects and cleft palate in hamsters. Combined treatment with cadmium and lead resulted in synergistic effects with malformations differing from those produced by either of these two agents given alone. Intraperitoneal injection of cadmium sulphate on Day 7 of pregnancy in mice caused fetal exencephaly, with cellular changes in the embryonic nervous tissues detected relatively soon after cadmium injection and haemorrhages a few days later.

Dioxin is a halogenated hydrocarbon used widely as an herbicide, linked to congenital anomalies in human populations when used as a defoliant in the Vietnam War. Exposure of pregnant mice to dioxin induces defects of the palate (cleft), brain, kidney, and other organs, with teratogenic effects suggested due to interference with epidermal growth factor or transforming growth factor.

Lead toxicity occurs commonly in grazing ruminants, particularly cattle exposed to lead in paint or batteries. Moreover, high levels of lead in drinking water, vegetables, and air, are considered as risk factors for toxicity in children. However, the teratogenic effects of lead toxicity in ruminants is not well known, although it is of potential concern as embryotoxic and teratogenic effects have been demonstrated with lead exposure in mice, rats, and hamsters causing skeletal, vertebral, and urorectal defects. The teratogenic effect of lead in the mouse was markedly enhanced when the pregnant animals were kept on a diet low in calcium. Lead accumulates in fetal tissues and, as in children born to mothers exposed to subclinical levels of lead had behavioural disturbances, lead pollution in humans and other animals is of serious concern in a number of environments.

Mercury as methyl mercury ingested during pregnancy causes damage to the fetal CNS of humans, with cerebral palsy, blindness, mental retardation associated with lesions of microcephaly, and cerebral atrophy.

Organochlorines, or chlorinated hydrocarbons, are environmentally polluting chemicals including DDT (dichlorodiphenyltrichlorethane), Heptachlor, and Dieldrin, used widely as pesticides until they were banned in the mid-1970s. These compounds were notorious for accumulating in the soil on farms and in the fat of predated animals, leading to a concern of pollution of the human food chain, and a precipitous decline in the populations of predatory birds, especially condors, eagles, and falcons, due to egg shell fragility. The metabolic product of DDT is DDE, reported to mimic

VetBooks.ir

oestrogenic activity or inhibit androgen effectiveness. Feminisation of fish populations, declining human sperm counts, and increased frequency of breast cancer are commonly attributed to DDE. DDT fed to animals can cause toxicity of the embryo and fetus.

Polychlorinated biphenyls (PCBs) are halogenated aromatic hydrocarbons used widely for industrial purposes until they were banned in the 1970s due to toxicity and pollution concerns. PCBs are teratogens, carcinogens, neurotoxic, and immunosuppressive, with indications they caused decline in reproduction of otters, seals, mink, and fish. High doses in pregnant women caused reduced fetal growth rates and skull abnormalities, plus deformed nails and hyperpigmentation of gums and other tissues, with deficient cochlear development and deafness in rats. As some PCBs structurally resemble oestrogens and thyroid hormone, they likely exert teratogenic effects through disruption of endocrine functions.

Abnormalities From Veterinary Therapeutic Toxicities

Azoles (e.g., fluconazole) are used for fungal therapy but contraindicated in pregnancy as they have been shown as teratogenic in rodents and caused skeletal and cardiac anomalies in babies born to mothers administered high doses in gestation.

Angiotension–tension converting enzyme inhibitors administered in mid- to late gestation to pregnant humans have caused pulmonary hypoplasia, IUGR, and skull and renal abnormalities, with fetal and neonatal mortalities from severe fetal hypotension.

Benzodiazepines (e.g., diazepam) are commonly used as sedatives in humans and occasionally animals, but readily cross the placental barrier where, in the first trimester, they may cause fetal craniofacial abnormalities in babies.

Benzimidazoles are widely used as anthelmintics in livestock production, and some earlier preparations (e.g., parbendazole, cambedazole) produced embryonic abnormalities, including skeletal, renal, and vascular anomalies, when administered to pregnant ewes between Days 14 and 24 of gestation.

Doxycycline is used commonly in companion animals and caution is advised as it presents embryotoxic risks when administered to humans in the first trimester of pregnancy.

Griseofulvin is commonly used for oral antifungal therapy in companion animals, although there are risks of teratogenicity in pregnant cats and horses.

Methallibure has been used to control oestrus in sows but causes cranial and limb deformities when administered in early gestation.

Streptomycin has long been associated with deafness in babies from deleterious effects on cranial nerve VIII.

Abnormalities From Plant and Fungal Toxicities

Dysphania glomerulifera is an Australian native chenopod that is the likely cause of outbreaks of *congenital biliary atresia* (BA) in neonatal lambs (and two calves) born to mothers restricted to grazing the plant during gestation after droughts in Australia in 1964, 1988, 2007, and 2013. BA is a rapidly progressive and destructive fibrotic disorder of undetermined aetiology, affecting the extrahepatic biliary tree of neonates in many species but particularly in humans, being the most important cause of infantile liver transplantation. The Australian outbreaks affected between 14% and 100% of neonatal lambs born to ewes grazing the banks of two large water reservoirs during gestation in which abundant *Dysphania sp.* had been growing when water levels were low. Affected lambs displayed white faeces and failed to thrive, with necropsy confirming the dysgenesis of the gall bladder (see Fig. 9.1) and microscopic lesions suggesting a toxic hepatopathy associated with choledysgenesis (Harper et al. 1990). The ewes and other adult animals were unaffected. Recently, a new isoflavonoid compound 'biliatresone' was isolated from *Dysphania sp.* recovered from the vicinity of an outbreak of BA in sheep, causing selective destruction of the extrahepatic biliary system of larval zebra fish (Koo et al. 2016). Further, as a mutation that enhanced biliatresone toxicity was mapped to a region of the zebra fish genome that has conserved synteny with an established human BA susceptibility locus and the toxin also caused lesions in neonatal mouse extrahepatic cholangiocytes in cell culture, it was proposed that congenital BA could be due to exposure to an environmental toxin during gestation (Lorent et al. 2015).

Veratrum californicum (western false hellebore or skunk cabbage) consumed by pregnant ewes early in gestation can produce craniofacial and skeletal defects, including cyclops, in up to 25% of lambs born. Studies identified that embryonic death occurred in ewes exposed at high doses on Day 14, whereas the facial and limb deformities occurred in lambs from ewes exposed to less toxic levels. When pregnant ewes were gavaged with root–rhisome material for 3 days near Day 29 of gestation, lesions of shortened fetal metacarpal, metatarsal, and tibial bones were identified in the lambs, and some displayed arthrogryposis (Keeler & Stuart 1987). These findings confirmed that the severity of defects varied with level of toxicity and gestational stage, and identification of the toxins cyclopamine and veratramine enabled studies on craniofacial defects in humans and other species.

Theories explaining the pathogenesis of craniofacial malformations have included: a defect in the prechordal mesoderm; failure of the prosencephalic organising centre to induce development of the anterior part of the neural tube; abnormal position of the notochord; a defect in the neural plate or the neural tube; and an abnormality in the hyaluronate-rich extracellular matrix through which the neural crest cells migrate. However, more recent discoveries of the role of the soluble morphogen Sonic hedgehog *(Shh),* a vertebrate orthologue of Drosophila hedgehog, as a key signalling factor in the regulation of craniofacial skeleton development in vertebrates, may offer more fundamental understanding of how CFDs occur. First identified in 1993, *Shh* now has multiple roles in development and disease (Dwokin et al. 2016). The *Shh* gene is expressed in the notochord, the floor plate of the neural tube, the posterior limb buds, and the developing gut. However, mutations in *Shh* classically lead to defects in midline structures, particularly the face and eyes and brain, such as holoprosencephaly, plus numerous defects of nonneural tube origin, including ocular hypertelorism, midface hypoplasia, and cleft lip only or cleft lip/palate defects. *Shh* mutations also cause defects of the eye, including coloboma (missing eye tissue) and micropthalmia (abnormally small eyes). As *Shh*-mediated craniofacial defects are largely caused by a loss of neural crest cell fidelity and survival within the pharyngeal arches, a holistic role for *Shh* genes in craniofacial development is likely, and mutations in *Shh* may yet prove to be also clinically relevant in the aetiology of CFDs in animals, particularly sheep.

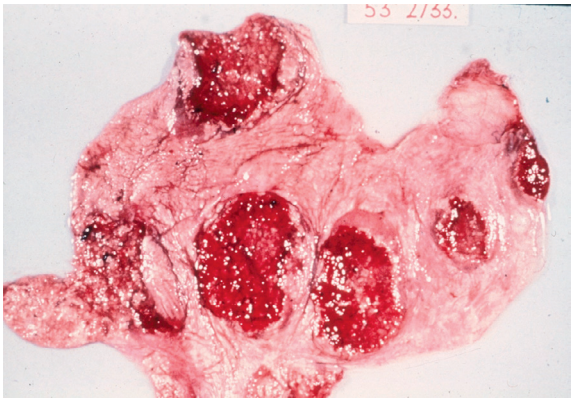
Lupinus spp. caused bovine skeletal deformities and cleft palate in the United States in the late 1950s when newborn calves affected by 'crooked calf disease' (arthrogryposis) were attributed to maternal ingestion of *Lupinus* spp. Then in the late 1960s and early 1970s in the United States, epidemics of skeletal malformations in pigs were recorded, associated with ingestion of poison hemlock (*Conium maculatum*) and burley tobacco (*Nicotiana tabacum*). The malformations in newborn pigs appeared similar to those in

VetBooks.ir

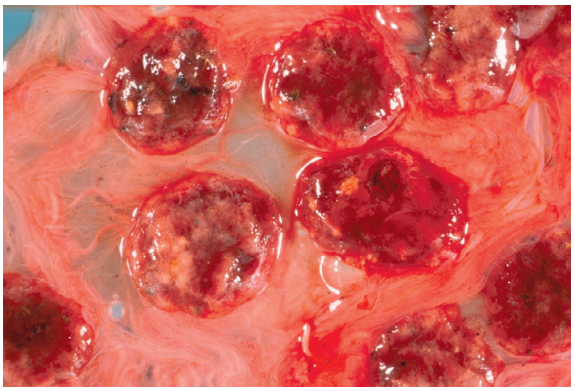
crooked calf disease, with the proposed mechanism of action for *Lupinus*-induced malformations and cleft palate attributed to reduction in fetal movement, with the teratogenic effects of *Lupinus, Conium,* and *Nicotiana* spp. believed to be identical (Welch et al. 2012). Ultrasonography demonstrated a direct relationship between reduced fetal activity and severity of contracture-induced skeletal defects and cleft palate in sheep and goats. *In utero* positioning and/or abnormal tendon and ligament development resulting from lack of movement and the cleft palate is believed to result from mechanical interference by the tongue between the palatal shelves at the programmed time of closure (Panter et al. 1990). A goat model was developed for the study of cleft palate in humans, with research focused on the privileged period of fetal scarless healing after *in utero* surgery to repair cleft palates early in gestation.

Mycotoxins are metabolites produced by fungi (e.g., aflatoxin from *Aspergillus flavus*) and, when ingested, often through spoiled feed, have produced teratogenic, carcinogenic, mutagenic, and immunosuppressive effects in farm animals. *Aspergillus fumigatus* and *Mortiarella wolfii* are fungi that are capable of causing sporadic abortions from infections of the bovine placenta and fetus in late gestation, with lesions often grossly visible on the epidermis of aborted calves (see also Chapter 26).

Other toxic plants are very likely to cause developmental abnormalities as there are many plant species throughout the world that containing toxins that are structurally similar to the alkaloids known to be teratogenic. Although these plants may appear in the diets of humans and other animals, toxicity and teratogenicity are a matter of dose, rate of ingestion, time of insult, and alkaloid concentration and composition in the plant; thus toxicity/teratogenicity may not always be readily correlated with ingestion. For example, there is circumstantial evidence that the alkaloids in *Lathyrus latifolius* may have been the cause of arm and hand deformities in a baby boy, via maternal ingestion of goat's milk (Welch et al. 2012).



• **Fig. 9.20** Diffuse severe necrotising placentitis accompanying fetal infection in cattle due to infection with *Brucella abortus.*



• **Fig. 9.21** Multifocal moderate hypertrophic placentitis with enlarged cotyledons of an ovine placenta accompanying fetal infection in sheep due to infection with *Toxoplasma gondii.*

Abnormal Development Due to Infections

Congenital malformations of animals caused by viral infections with pathogenicity for developing organs of the fetus (see also Chapter 26) are extremely important in livestock production in many parts of the world, and there is recent renewed interest in these infections because of the occurrence of Zika virus in humans (Kim & Shresta 2016). Outcomes of teratogenic virus infections reflect the often complex interactions between the host–pathogen–environment (HPE) factors including virulence and transmission potential of the infecting viral strain, host factors including species, breed, age, and immune status, plus, in arthropod-borne infections, vector survival and spread as determined by dynamic environmental influences including climate change. Further, the pathogenesis of the lesions produced by teratogenic viruses reflects the gestational stage of the fetus when infected. Typically, the cells of the CNS and sometimes other organs become susceptible to tissue damage after the onset of early immunocompetence (usually after 80 days of gestation), indicating that the disease is a consequence of cellular damage from both viral and inflammatory mechanisms. After development of more complete immunocompetence (usually after 160 days of gestation), these viral infections are usually cleared adequately by immune mechanisms and infected animals are largely spared from congenital malformations.

Intrauterine infections by bacterial and protozoan parasites are also common in ruminants, with the invasion of the placenta and fetal tissues causing abortion, stillbirth, and neonatal disorders, although the extreme deformities as caused by the teratogenic viruses are rarely observed by these pathogens. Bacterial infections that cross the placenta, causing placentitis (Fig. 9.20) and fetal infection that cause abortions and neonatal mortalities, include *Listeria* spp., *Brucella* spp., *Leptospira* spp., *Chlamydiophila* spp., and others and are discussed elsewhere in this book. Similarly, the common Apicomplexan protozoal infections *Neospora caninum, Toxoplasma gondii,* and several of the *Sarcocystis* spp., with sexual reproductive life cycles in the alimentary tract of carnivores, regularly invade in tachyzoite form the nervous systems, and other organs of ruminants during gestation. Congenital infection of both clinically diseased and normal calves by *N. caninum* is well described (Kessell et al. 2011), with neosporosis mainly a disease of cattle (Boulton et al. 1995, Atkinson et al. 2000), although sheep and goats have been infected (Bishop et al. 2010). The primary host for *N. caninum* is the dog, including dingoes in Australia (King et al. 2010), whereas the primary host for *T. gondii* is the cat. Toxoplasmosis commonly infects the fetus in many species, with congenital infection recorded in dogs (Al-Qassab et al. 2009), and severe lesions in the CNS have been observed in aborted lambs, with hypertrophic lesions observed in the placentomes (Fig. 9.21). Cattle appear rarely infected. The protozoan *Babesia argentina* infection in parasitemic cattle has also been observed to cause congenital infections. As the nonviral infections of ruminants only occasionally produce congenital deformities, usually involving the neuromuscular system as a consequence of CNS infection compromising lower motor neuron function, readers are referred to further discussion elsewhere in this book or recent reviews of the subject (Kessell et al. 2011).

Cattle and Small Ruminants

Bovine Viral Diarrhoea Virus

Bovine Viral Diarrhoea virus (BVDV), in the genus *Pestivirus* of family *Flaviviridae,* exists as two genotypes, BVDV-1 and BVDV-2, with each genotype containing the two biotypes characterised by their capacity to affect the cells in laboratory cultures, i.e., cytopathogenic (cp) and noncytopathogenic (ncp) biotypes (Agerholm et al. 2015). Although both BVDV genotypes are likely to be distributed globally and cause similar disease manifestations, BVDV-1 strains occur more commonly, and BVDV-2 strains are considered more virulent. BVDV infection with the ncp biotype of either genotype 1 or 2, occurring before and during gestation, may result in a variety of clinical–pathological outcomes, depending on the immunity of the dam, gestational stage, fetal immunocompetence, virus biotype, and strain virulence. Fetal infection with ncp BVDV before 79 days of gestation usually results in embryonic death or persistence infection due to immune incompetence, although infection up to 6 months of gestation may result in mummification, abortion, premature birth of a live, weak, undersized or apparently normal calf, and various congenital malformations. Fetal infections with ncp BVDV between Days 79 and 150 of gestation, when the CNS is most vulnerable to cellular damage and fetal inflammation, may cause lesions of cavitation of the cerebrum (i.e., hydranencephaly and porencephaly) and, more commonly, the cerebellum, causing various degrees of dysplasia, most commonly cerebellar hypoplasia of varying degrees (see Fig. 9.4). Congenital malformations of BVDV may also include ocular lesions (i.e., micropthalmia) and alterations of thymus (i.e., thymic hypoplasia), bones (i.e., brachygnathia inferior, growth retardation), hair coat (i.e., hyotrichosis or alopecia), lung (pulmonary hypoplasia), kidneys (i.e., renal hypoplasia), and changes of the hair coat (hypotrichosis/alopecia, curly hair). As BVDV infections causing lesions resulting in malformations usually follow commencement of immunocompetence, affected calves will generally be seropositive. A recent review of the lesions in BVDV-induced congenital malformations includes detailed description of the CNS lesions (Agerholm et al. 2015).

Akabane and Aino Viruses

Akabane and Aino viruses are closely related arboviruses of the genus *Orthobunyavirus,* within the Simbu serogroup in the family *Bunyaviridae.* Akabane virus (AKAV) was first suspected of causing the congenital bovine abnormalities of hydranencephaly and arthrogryposis in 1974 in Japan and a few years later in Australia. As outbreaks of AKAV have also sometimes been accompanied by other abnormalities, including abortion, stillbirth, polioencephalomyelitis, and possibly microencephaly, it is generally considered the most pathogenical of the Simbu serogroup viruses. AKAV is readily transmitted to cattle by the insect vector, the biting midge *Culicoides brevitarsis* in tropical and subtropical 'endemic' regions of Australia, with outbreaks or sporadic cases of hydranencephaly (see Fig. 9.2) and arthrogryposis (see Fig. 9.5) reflecting the distribution of the vector to areas where naïve cattle are located or movement of naïve pregnant animals into the endemic zone. In these areas AKAV regularly infects young female cattle before gestation, enabling immune protection of the fetus in subsequent pregnancies. Clinical signs are rarely observed in these endemic zone above the so-called 'brevitarsis line', although movement of naïve pregnant cattle into the endemic zone during periods when the fetal CNS is vulnerable to damage from the virus and inflammation has caused extreme financial losses and welfare concerns (Jago et al. 1993). In cattle, infection between Days 79 and 104 of gestation results in hydranencephaly due to cavitation of cerebral tissue, whereas exposure at Days 103 to 174 causes arthrogryposis, resulting from lesions of dysplasia and loss of lower motor neurons in the spinal cord, occasionally accompanied by focal Wallerian-type degeneration in the CNS. Because arthrogryposis occurs later in gestation, it is usually observed before the occurrence of hydranencephaly in herds with a relatively prolonged parturition period. Clinical signs of AKAV infection are not usually observed during the postnatal viraemic period in cattle in Australia, although encephalomyelitis has been suspected and has occasionally been reported in calves and adult cattle infected postnatally in Japan. Placentitis is not a feature of transplacental transmission of AKAV, with calves affected by hydranencephaly frequently born alive with behavioural abnormalities, described as 'dummy calves'. Lesions in the brain produce cerebral defects, from mild porencephaly to severe hydranencephaly with only a small rim of cortical tissue remaining, although hydrocephalus and, in rare cases, mild cerebellar hypoplasia have been observed. Calves with arthrogryposis frequently cause dystocia. As AKAV infections cause lesions after commencement of immunocompetence, affected calves will be seropositive. Although an efficacious, commercially available vaccine was developed for use in Australia in the 1980s, it was withdrawn after a short period due to market failure. A recent review of the lesions in AKAV-induced congenital malformations includes detailed description of the CNS lesions (Agerholm et al. 2015).

Schmallenberg Virus

Schmallenberg virus (SBV) is also a member of the genus *Orthobunyavirus* within the Simbu serogroup of the family *Bunyaviridae* and was identified in 2011 as the first pathogenical orthobunyavirus of ruminants to be recognised in Europe. As with other orthobunyaviruses, SBV is transmitted by biting midges, the *Culicoides* spp. Although the origin of SBV remains undetermined, it was first detected in the vicinity of the German rural town of Schmallenberg near the Dutch border, and then identified in 27 European countries within 2 years, indicating efficient transmission by the insect vector. Infection of naïve cattle during the vulnerable period of the fetal CNS between gestational days 60 and 180 results in lesions of the CNS producing syndromes of congenital hydranencephaly or arthrogryposis. The severity of lesions in the brain and spinal cord reflects an interaction between the developing fetal CNS tissue and developing immunocompetence, plus the virulence of the SBV strain. As with AKAV, infection during early gestation results in moderate to severe dysplasia of the brain and spinal cord, with infections in later gestation resulting in encephalomyelitis. Placentitis is not a feature of transplacental transmission of SBV, although unlike in AKAV in which calves with hydranencephaly are frequently born alive, most SBV-malformed calves are stillborn with a significantly lower body mass than unaffected calves. Lesions in the brain produce cerebral defects, ranging from microencephaly or porencephaly in combination with hydrocephalus and lissencephaly to severe hydranencephaly with only a small rim of cortical tissue remaining, although cerebellar hypoplasia may also be observed. Lesions of the spinal cord cause varying degrees of athrogryposis and are often associated with scoliosis and/or kyphosis of the thoracic part of the vertebral column. As SBV infection causes lesions after commencement of immunocompetence, affected calves will be seropositive. A recent review of the lesions in SBV-induced congenital malformations includes detailed description of the CNS lesions (Agerholm et al. 2015).

VetBooks.ir

Blue Tongue Virus

Blue tongue virus (BTV), the cause of blue tongue (BT) disease in mainly small ruminants, is a member of the genus *Orbivirus* within the *Reoviridae* family; currently, 26 serotypes are distinguished, most commonly occurring in tropical and subtropical areas. A large scale epizootic of BTV infection, causing high morbidity and mortality on a number of the Mediterranean islands and later in most countries bordering the northern Mediterranean coast, occurred between 1999 and 2002, with over 0.5 million sheep affected in Italy and Sicily alone. BT disease is mostly confined to sheep, although some highly virulent strains occasionally cause disease in goats; there was no evidence of disease in cattle until the emergence of an unusual strain of BTV serotype 8 (BTV-8) in The Netherlands and Germany in 2006, with subsequent spread through most of Western Europe and into England and southern parts of the Scandinavian countries. BTV-8 can cross the placenta in ruminants causing congenital defects, is excreted in semen, and can cause mild disease in a very small proportion of infected cattle. However, cattle are generally considered to be the amplifying mammalian host and can carry infectious virus for many weeks, long after the development of an antibody response.

The clinical outcome of a BTV infection, as with other arthropod-borne viral entities, is dependent on numerous HPE interactions. Seasonal outbreaks of BT due to BTV serotypes 1, 2, 4, 9, and 16 have appeared regularly in Mediterranean regions since 1998. When BTV-8 emerged unexpectedly in northwestern Europe in 2006, initially there were moderate morbidity and mortality rates in sheep and cattle, increasing in severity in the next 2 years, necessitating widespread vaccination programmes. Clinical signs in cattle with BTV-8 included fever, salivation, facial oedema, buccal and nasal mucosal lesions with ulceration, plus coronitis. BTV-8 also transmitted to the fetus via the placenta between 70 to 130 days of gestation at rates of 16% to 35%, resulting in hydranencephaly, occasionally accompanied by cerebellar dysplasia; porencephaly and hydrocephalus occurred. Surviving calves with hydranencephaly may show behavioural abnormalities, with dullness, inability to stand and suckle, disorientation, and impaired vision, similar to the 'dummy calves' observed in Australia due to AKAV infection. With increasing immunocompetence, fetal infection after 145 days of gestation results in viral clearance and a seropositive live calf. A recent review of the lesions in BTV-8 induced congenital malformations includes detailed description of the CNS lesions (Agerholm et al. 2015). Of note is that, as BTV-8 infections do not cause significant lesions to the brainstem and spinal cord, arthrogryposis and vertebral column malformations are not recorded. Australia currently has 10 serotypes of BTV (1, 2, 3, 7, 9, 15, 16, 20, 21, and 23) of low pathogenicity and occurring in cattle in tropical areas above the 'brevitarsis line' where sheep are rarely grazed. Mild clinical signs of BT in Australia have only been observed in sheep after experimental infections with some serotypes (e.g., 16 and 23) after movement of sheep to the northern endemic area.

Other Viruses

Rift Valley fever virus is an arbovirus in Africa that causes abortion in cattle, sheep, and goats after replication in the placentomes. A live attenuated vaccine used in endemic areas during outbreaks can cause congenital defects, including hydranencephaly, cerebellar hypoplasia, microcephaly, and arthrogryposis.

Wesselsbron virus, also in Africa, causes abortions and neonatal mortalities in lambs and kids with congenital malformations, including hydranencephaly and arthrogryposis.

Pigs

Japanese B encephalitis virus is a Flavivirus, and infection in midgestation of sows may cause abortion, mummification, stillbirths, and neonatal losses with CNS signs, although experimental infections have produced hydrocephalus, cerebellar hypoplasia, and hypomyelinogenesis.

Porcine herpesvirus 1 causes Aujesky's disease. When sows are infected in early gestation, embryonic resorption occurs, whereas in later gestation, abortion, stillbirth, mummification, and neonatal mortalities may occur.

Porcine parvovirus infection *in utero* produces different outcomes, depending on the stage of gestation. Embryonic mortality and resorption occurs from infection within the first month of gestation, whereas fetal death and mummification occurs from infections between days 30 to 70. Later infections may cause stillbirths.

Porcine respiratory and reproductive syndrome is caused by an Aterivirus that appears only able to cross the placenta in late gestation, causing abortions, stillbirths, mummification and neonatal losses.

Cats

Feline panleucopenia virus is a Parvovirus inducing fetal lesions dependent on the time of infection in gestation, ranging from embryonic death and resorption in early gestation, with cerebellar hypoplasia, retinal dysplasia, fetal death, and stillbirths from infections later in gestation.

Abnormalities Due to Uncertain Aetiologies, Including Fetal Monsters, Dropsies, Abortion, Maceration, and Mummification

Fetal Monsters

A fetal monster describes the abnormal presentation of a fetus in which the lesions displayed are considered sufficiently extreme for the fetus to be considered as 'monstrous'. The term is increasingly historical, having been considered in humans in biblical and medieval contexts, as resulting from 'unclean' practices. Interestingly, in animals a misshapen 'monk calf' born in Freiberg, Germany, in 1522 with limbs in extension and a fold of skin over the head (suggestive of arthrogryposis and a meningocoele) was compared with a monk and used to criticise Martin Luther, who responded that it represented the monstrosity of the Catholic church (Szabari 2006). However, with increasing scientific knowledge of the causes of congenital abnormalities and now elaboration of the pathological pathways that lead to the more extreme lesions occurring during development in humans and other animals, the term 'monster' is less commonly used as deformed animals are increasingly presented to veterinarians from owners seeking more rational explanations than the mystical or theological explanations of history. Unfortunately, many veterinarians have frequently dismissed congenital 'monsters' as idiopathic errors of development, contributing to the causes of dystocia or perinatal mortality, and rarely conducted the detailed investigations required to define the nature of the lesions presented.

However, as a number of these 'monster' entities have recently been found to be caused by inherited mutations, including several of the more common bovine fetal monsters recognised for over 100 years, there is emerging enthusiasm to better characterise them.

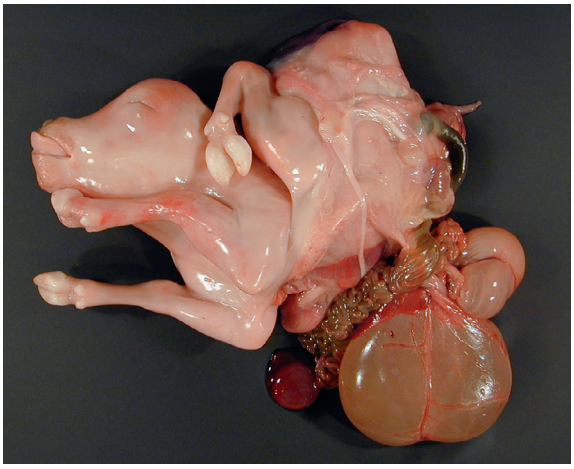
VetBooks.ir

In recent years, the commonly recognised 'bulldog calves' affected with chondrodysplasia (OMIA 001271) and 'dropsy calves' affected with fetal hydrops or anasarca (OMIA 001562) have been characterised in Dexter and other breeds of cattle. 'Spinal deformity' calves characterised by shortening of the spine (see Fig. 9.16) and arthrogryposis (see Fig. 9.15) due to brachyspina (OMIA 000151) or congenital vertebral malformation (OMIA 001340) have been reported in Holstein–Friesian cattle. 'Curly calves' (see Fig. 9.8) with arthrogryposis multiplex (OMIA 001465), 'water head' calves with neuropathic hydrocephalus (OMIA 000487) causing a protruding encephalomeningocoele (see Fig. 9.9), and most recently, polymelia (see Fig. 9.7), or 'accessory limbs', with a variety of limb and other tissue developmental duplications (OMIA 002103) have been reported in Angus cattle. Similar descriptions of these disorders are increasingly recognised in other breeds and shown to be or suspected of being due to inherited disorders. Detailed description of these 'monsters' is provided in the inherited disorders section, and it is of great interest to investigators of congenital abnormalities, whether we will continue to see so-called 'idiopathic' fetal monsters in cattle and other species, ultimately determined to be mainly due to previously unrecognised inherited conditions. Already some forms of the spinal shortening deformity perosomus elumbis (OMIA 000789), the vertebral arch deformity spina bifida (OMIA 000933), and the spectacular deformity that almost invariably causes dystocia in cattle known as schistosomus reflexus (OMIA 000890) are considered more than likely to be caused by or associated with genetic factors, and thus provided with an OMIA number.

However, it is also plausible that other pathogenical pathways could also produce 'phenocopies' of these disorders should it be determined that they are inherited in certain breeds. Similar metabolic errors caused by different mechanisms of pathogenesis are well recognised in veterinary medicine. For example, alpha-mannosidosis in Angus cattle (OMIA 000625) and ingestion of the toxic plant *Swainsona glomerulifera* both inhibit cellular mannose metabolism, resulting in pathological accumulation of lysosomal storage material. Congenital deformities may arise from very different aetiological mechanisms, causing errors in the same or similar metabolic pathways, meaning both inherited and noninherited forms of these disorders may well be observed and need to be properly described. The following disorders are examples of deformities in cattle in which the evidence for their being transmitted by inheritance remains inconclusive.

Perosomus elumbis (PE; OMIA 000789) is a lethal congenital defect characterised by absence of the lumbar, sacral, and coccygeal spinal segments and spinal cord, associated with musculoskeletal malformations of the hindquarters. Bovine PE was first reported in the veterinary literature in 1832, and although there have been a number of recent case reports of the disorder in the Holstein–Friesian breed worldwide, investigations into a possible genetic aetiology of PE in cattle remain unreported (Agerholm et al. 2014). PE has also been reported in other animal species, including sheep, pigs, dogs, and horses, and although a recent publication suggested that fetal infection with bovine virus diarrhoea virus (BVDV) may have contributed to PE, plus an ovine PE case after feeding of pregnant sheep with *Veratrum californicum* on Days 16 and 17 of gestation. That teratogens should cause PE remains speculative and research into the aetiology of this disorder is required.

Spina bifida (SB; OMIA 000933) is a congenital defect characterised by defective closure of the two halves of the vertebral arch through which the spinal cord and meninges may or may not protrude. It is observed occasionally in cattle and not uncommonly in sheep, with inherited forms suspected in Poll Wiltshire and other breeds in Australia (Windsor et al. 2011a).



• **Fig. 9.22** Schistosomus reflexus of a fetus displaying spinal inversion, exposure of the abdominal viscera through a fissure of the ventral abdominal wall, and abnormal positioning of the limbs adjacent to the skull, with pulmonary and diaphragmatic hypoplasia.

Schistosomus reflexus (SR; OMIA 000890) is a fatal congenital disorder mostly observed in ruminants, characterised by spinal inversion, exposure of the abdominal viscera through a fissure of the ventral abdominal wall, limb ankylosis, abnormal positioning of the limbs adjacent to the skull, and pulmonary and diaphragmatic hypoplasia (Fig. 9.22). Variable components of SR include scoliosis, cleft sternum, exposure of thoracic viscera, and abnormalities of the digestive and urogenital systems. A 2005 report of a female Holstein SR calf with thoracoschisis, scoliosis, and anomalies of the appendicular skeleton also had abnormalities of the cardiovascular, respiratory, digestive, and urogenital systems. It was suggested that the SR occurred as early as the postgastrulation embryo and involved the intermediate mesoderm, with preliminary pedigree analysis indicating a possible genetic aetiology (Laughton et al. 2005).

Amorphous globosus, or acardiac monster, or fetal mole, is a spherical body attached to the fetal membranes of a normal fetus in the bovine (Fig. 9.23). They are formed from connective tissue surrounded by skin and may be of a different sex from that of the normal twin; although as there is not usually any gonadal development, they do not pose a threat of freemartinism (Long 2001).

Craniofacial deformities (CFDs) are relatively uncommon in animals, occurring sporadically, although with an interesting regularity in Australian sheep flocks. However, CFDs are widely prevalent in humans, accounting for approximately 75% of human birth defects, affecting 0.1% to 0.3% of all births and ranging from minor cosmetic irregularities to considerable structural malformations that can lead to problems in breathing and feeding, compromised social and mental development, and in extreme cases, death (Dwokin et al. 2016). As surgical reconstruction of CFDs is complex and often requires multiple procedures, understanding the mechanisms and aetiology of CFDs in animals is of potential importance in improving human CFD surgery. The most consistent denominator of this group is aplasia of the olfactory system and other cerebral hemispheric organisations (Szabo 1989). Lambs often present with agnathia (absence of the mandible) and misplaced ears (Fig. 9.24). Craniofacial defects include the following:

- ***Arhinencephaly*** characterised by marked reduction or complete absence of the olfactory organs, often involving ocular, nasal, and palatal defects. Where the cerebral hemispheres and lateral and

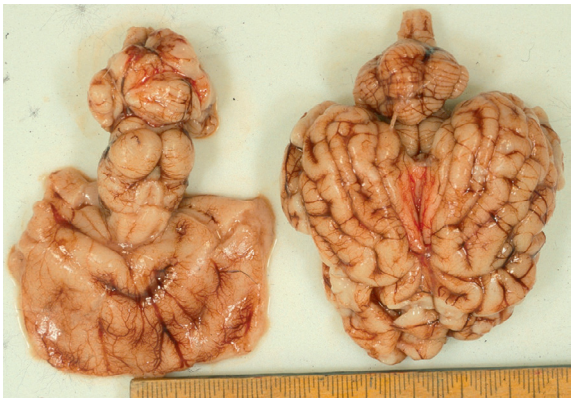
third ventricles are reduced to a single structure with absence of the corpus callosum, the defect is termed *holoproencephaly.*

- ***Cebocephaly*** ('ape head') represents a transition between arhinencephaly and cyclopia, with two rudimentary eyes located in closely situated orbits, a flattened nose, frequently rudimentary and often with a single nostril, and brain malformations similar to cyclopia, sparing the cerebellum and brainstem.



• **Fig. 9.25** Congenital holoprosencephaly affecting the brain of a Border Leicester lamb with craniofacial deformities; note the single dysplastic cerebral hemisphere *(left)* compared with a normal brain *(right)*.

- ***Cyclopia*** is the most severe of these malformations, involving the orbits, brain, and nose, characterised by fusion of the eyes in a single orbital cavity with a proboscis above a rudimentary nose. The eyeballs may be normal in size, but anophthalmia and microphthalmia are common, and eyelids and lashes are usually absent. The anterior regions of the cerebrum, the septum pellucidum, the corpus callosum, and the cranial bones and nerves are either partially or completely absent. The cerebral hemispheres are completely fused and flattened. The thalamus and hypothalamus can be identified, but the third ventricle is usually absent, as are the olfactory bulbs, nerves, and the pituitary gland. Cyclopia is frequently accompanied by micrognathia or agnathia, cleft palate and harelip, spina bifida, polydactyly, sirenomelia, and defects of the heart and great vessels, kidneys, and adrenals.
- ***Otocephaly*** ('ear head') is related to cyclopia and arhinencephaly, occurring in varying grades of severity. In severe cases the forebrain and midbrain are usually affected and the third and lateral ventricles form a single cavity. The olfactory tracts are usually absent, the mouth and mandible are rudimentary, and the development of the tongue is incomplete. The eyes and ears are low set and fused or absent. In lower grades of otocephaly the brain may be normal but the eyes, ears, jaws, and nose are defective.

There is a particular interest in this group of congenital abnormalities in sheep, particularly because a necropsy study of 4408 newborn dead lambs in Australia from 79 predominantly Merino flocks found otocephaly in 25 lambs (Hughes et al. 1972), and a survey of congenital defects of sheep in Western Australia found that about 5% of the farmers had seen cyclopia in a large, predominantly Merino population of lambs (Dennis 1993). As mentioned, an inherited form of CFD has been described in Border Leicester sheep in Australia, with facial deformities (see Fig. 9.24) associated with holoprosencephaly (Fig. 9.25) of the cerebrum (OMIA 000478) and breeding studies suggesting autosomal recessive inheritance (Roth et al. 1987). Further, as previously discussed, in lambs born to ewes exposed to the teratogenic plant *Veratrum californicum,* CFDs and skeletal defects occurred with studies confirming embryonic vulnerability from Day 14. Findings confirmed that the severity of defects varied with level of toxicity and gestational stage, and identification of the toxins cyclopamine, cycloposine, and jervine enabled studies on CFDs in humans and other species with these alkaloids now known to interfere with Sonic hedgehog signalling.

VetBooks.ir

• **Fig. 9.26** Craniofacial deformities in a lamb from Australia characterised by otocephaly, with mandibular agnathia, ventral displacement of the ears, and an open trachea.

However, it would appear from the limited investigations possible thus far that neither inheritance nor exposure to known toxic plants or chemicals is able to explain the majority of sporadic yet persistent occurrence of CFDs in the Australian ovine population, usually characterised by otocephaly, with agnathia and ventral displacement of the ears commonly observed (Fig. 9.26). The possibility that at least some outbreaks of CFDs in Australian sheep may be due to arbovirus infections has been suggested (Ball 2011), although systematic studies are required to address a problem that could prove to be complicated by gene–environment interactions.

Numerous environmental factors are associated with the aetiology of CFDs in humans, including exposure to ionising radiation, vitamin deficiency, tobacco smoke, and maternal alcohol intake. However, it seems likely that human embryos exist with a genetic predisposition to CFDs due to sensitising mutations, such as the *Shh* genes that regulate craniofacial development, yet are influenced by environmental factors (Dwokin et al. 2016). Characterising these gene–environment interactions (GEI) could prove beneficial, particularly as identifying genetic mutations could provide prenatal diagnostic tools to limit the severity of human birth defects. With very few animal models of CFD susceptibility to environmental insult currently in existence, the identification of genes such as *Shh* in humans and other animals is important as it may influence future therapies of severe prenatal defects of human development and help ameliorate developmental defects in animal populations. That CFDs in Australian sheep frequently involve abnormalities of the jaw such as agnathia, and the *Shh* genes have an important role in craniofacial development, including the development of the jaws, suggests ovine CFDs offer a potentially important area for future study.

Dropsies

Dropsy is an old term for the swelling of soft tissues due to excessive accumulation of fluid, although similar to 'monster', the term is declining in use as the causes of these disorders are increasingly recognised. The three dropsical conditions of the conceptus commonly observed in veterinary obstetrics include oedema of the maternal placenta, the fetal placenta, and of the fetus. They may occur separately or in combination.

Oedema of the Fetal Membranes and Placenta

Placentitis caused by infections of the reproductive tissues often results in oedema of placenta, although this depends on the severity and distribution of the infection. The site of oedema may assist in characterising the nature of the infection. For example, in brucellosis in cattle caused by *Brucella abortus* infection, bacterial infection of the reproductive tissues may cause a severe necrotising placentitis and abortion, with oedema accompanying the necrosis causing partial destruction of the integrity of the caruncles, then spreading to the cotyledons and eventually to the intercotyledonary tissue of the fetal placenta (see Fig. 9.20), accompanying abortion. In contrast, in toxoplasmosis of sheep caused by the Apicomplexan protozoan *Toxoplasma gondii,* lesions are confined to the caruncles and cotyledons, with tissue hypertrophy (see Fig. 9.21) observed accompanying the proliferation of tachyzoites in endometrial cells and a higher chance of survival of the fetus to term.

Excessive quantities of fluid in the amnion or allantois, is referred to as hydramnios or hydrallantois, respectively. Hydrallantois appears more common than hydramnios, although fetal abnormalities are more likely to be associated with fluid accumulation in the amnion, as commonly occurs in chondrodysplasia (OMIA 001271) and 'dropsy calves' affected with fetal hydrops or anasarca associated with pulmonary hypoplasia (OMIA 001562) in Dexter calves. Although dropsy of the fetal sacs is more common in cattle and may be caused by a number of pathogenical pathways, including twinning (Harper et al. 1995, Windsor et al. 2006), it has also been observed in horses in pluriparous mares of 10 to 20 years of age between 7 to 9 months of gestation, in a dog litter, and on a number of occasions in sheep associated with twins or triplets, with up to 18.5 litres of fluid in the amniotic sac (Long 2001).

Apart from the hereditary cases of hydramnios that accompany the Dexter disorders and observed in other breeds from early to midgestation, hydrallantois of cattle is more likely to be seen in the last 3 months of gestation when there is a markedly accelerated production of allantoic fluid from 6 months of gestation. When placental dysfunction exists, as in abnormal placentation or placental circulation, the increase in fluid may become uncontrolled and lead to massive fluid accumulation. Hydrallantois has been associated with twinning in cattle, with a report of the birth of a single occurrence of hydrops fetalis that was accompanied by hydrops of the fetal sacs from a total of 514 twin calves born in the studies, suggesting a prevalence of 0.2% for bovine hydrops in experimental bovine twinning (Harper et al. 1995).

Hydrallantois cows present with progressive distension of the abdomen by the excessive fetal fluid. The volume of allantoic fluid may vary, with up to 273 litres imposing a serious strain on the cow, restricting respiration and impeding prehension and locomotion, with a gradual loss of condition leading to recumbency and death. Occasionally, affected animals may abort, with less severely affected cows achieving term in poor condition and presenting with dystocia from uterine inertia, often accompanied by incomplete dilation of the cervix. The diagnosis of bovine hydrallantois is based on the readily observed fluid distension of the abdomen in the last third of pregnancy, with confirmation obtained by the rectal palpation of the markedly swollen uterus and by the failure to palpate the fetus either per rectum or externally. The management of these cases depends on the viability of the cow, and moribund animals should be slaughtered. If the animal is viable and near term, Caesarean surgery is advised, performed with care to enable the fluid to escape slowly and prevent hypovolaemic shock. As hydrallantois is frequently seen in twin pregnancies in cows, it is important to search the grossly distended uterus for the

VetBooks.ir

second calf. Cases of hydrallantois that calve or are delivered by Caesarean surgery frequently retain the placenta and are at risk of metritis, with protracted convalescence and delayed conception. Use of a synthetic corticosteroid (20 mg dexamethasone) followed 4 to 5 days later by oxytocin administered by intravenous drip for 30 minutes is advised therapy (Long 2001). As the placenta is markedly oedematous, gross and microscopical examination of cotyledons and caruncles to identify if lesions of the endometrium are present is advised.

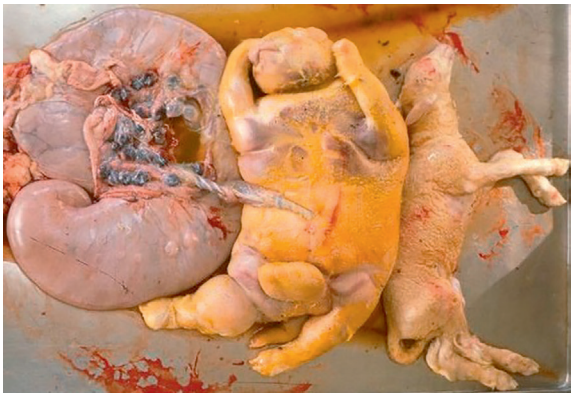
Dropsy of the Fetus

In humans massive oedema of the newborn infant has been recognised for at least three centuries, and a causal relationship with maternal–fetal blood group incompatibilities was recognised soon after red cell antigens were identified. Fetal hydrops was, historically, mostly attributed to severe maternal isoimmunisation to fetal blood group antigens foreign to the mother. However, in the majority of current human cases, the diagnosis of hydrops fetalis is now made prenatally, with few due to immune mechanisms and many causes for nonimmune hydrops now recognised, including: haematological disorders; infections; chromosomal abnormalities; tumours; and congenital anomalies, including pulmonary hypoplasia. The pathophysiological events in fetal hydrops were poorly understood until recent studies in sheep models of fetal hydrops induced by occlusion of lymphatic drainage, obstruction of cardiac venous return, and induced fetal anaemia or tachycardia (Andres & Brace 1990). However, of the numerous physiological disturbances noted in human fetal hydrops, a three- to fivefold increase in atrial natriuretic peptide (ANP) has been noted to accompany both human fetal hydrops with cardiac anomalies or isoimmunisation, as well as ovine hydrops induced by obstruction of venous return, sustained tachycardia, or induced anaemia. As vascular permeation of albumin is enhanced and cardiovascular and renal homeostatic adaptations are influenced by ANP, a key role for ANP in fetal hydrops has been suggested, particularly as ANP levels return to normal with resolution of the hydrops (Shinbane et al. 1997).

In animals, there are also several types of fetal dropsy of obstetrical importance, including fluid accumulation in the fetal brain (hydrocephalus and hydranencephaly that may require intervention, as previously described), in the abdomen (ascites), and in body cavities and subcutis (anasarca). The form of the fetus and the degree of obstetrical hazard are determined by the location and amount of the excess of fluid, with dystocia risk due to the increased diameter of the fetus.

Fetal ascites involves excessive fluid in the peritoneal cavity and frequently accompanies fetuses that have died preterm as a result of decomposition and may cause dystocia, infectious disease of the fetus, and some developmental defects where there is compression of the peritoneal cavity. For example, fetal ascites and hydramnion commonly occur in chondrodysplasia in the Dexter and other breeds of bulldog calf, when there is insufficient space to accommodate the viscera, and the calf presents with a large ventral hernia (see Fig. 9.13). Fetal ascites as a cause of dystocia is usually assisted by incising the fetal abdomen with a fetotomy knife.

Fetal anasarca is a common event when the fetus is carried to term but there is lack of progress in second stage parturition, leading to an increase in fetal volume from excessive fluid in the subcutaneous tissues, particularly of the head and hindlimbs. Tissue swelling can be extreme, and there is frequently excessive fluid in the peritoneal and pleural cavities with dilatation of the umbilical and inguinal rings as well as hydrocele. Hydramnios can also be extreme, and there may also be some hydrallantois present.



• **Fig. 9.27** Hydrops fetalis in a lamb displaying severe oedema of subcutaneous tissues, fluid accumulation in the serous cavities, and oedema of the placenta, accompanying a normal twin lamb *(on right)*; hepatic extramedullary haemopoiesis suggested fetal anaemia.

Animals with fetal anasarca should be necropsied as the anasarca may be attributed to developmental lesions. Fetal anasarca associated with pulmonary dysplasia resulting in severe *cor pulmonale* is now well recognised in Dexter calves (OMIA 001562) and some other breeds at term (Windsor et al. 2006). The fetal hydrops in the Dexter calves with pulmonary hypoplasia appears to have been a progressive development *in utero* in late gestation, leading to fetal dystocia and associated with development of hydramnion, resulting in death of the calves at the onset of parturition, unlike in Dexter 'bulldog' fetuses that are often spontaneously aborted in midgestation. Further, an outbreak of fetal anasarca in Poll Dorset and Dorset sheep from ewes with hydramnion was reported in association with suspected fetal anaemia (Plant et al. 1987). Ewes showed marked abdominal distension, and most died at parturition and were unable to deliver the large affected fetuses weighing up to 18 kg and displaying severe oedema of subcutaneous tissues (Fig. 9.27), fluid accumulation in the serous cavities, and oedema of the placenta (OMIA 000493). As hepatic tissue from affected lambs displayed generalised extramedullary haemopoiesis and oedema on microscopical examination, the findings were hypothesised to resemble those of the homozygous a-thalassaemia in infants associated with haemoglobin Barts. Ovine fetal hydrops has also been reported in Awassi and Beulah Speckle Face and Cheviot sheep, with five Cheviot and Cheviot–Texel crossbred lambs born with pulmonary hypoplasia (Alleaume et al. 2012).

Abortion, Maceration, and Mummification

Fetal death may be followed by abortion, maceration, or mummification, with abortion and maceration occurring when endocrine support of pregnancy is lost. Abortions may be recognised by the presence of the fetus(es) or/and an abnormal vaginal discharge from the dam. Maceration occurs when the fetus fails to abort, and decomposition *in utero* occurs, resulting in retention of the fetal skeleton in the reproductive tract compromising future breeding. Palpation and/or ultrasound will usually result in a positive diagnosis.

In fetal mummification, the fetal death is rarely apparent, and there is no discharge or signs of return to oestrus, with owners recognising that the animal is failing to develop the expected external signs of late pregnancy. Fetal mummification occurs occasionally in most domestic species, although it is considered more common in multiparous and polytocous species such as pigs. It is likely that many different pathogenical mechanisms are responsible for early

VetBooks.ir

fetal mortality as this outcome is unpredictable and influenced by several factors, including: the cause of fetal mortality; differences in pregnancy between species; stage of gestation at fetal death; and the number of fetuses, as reviewed recently (Lefebvre 2015). In cattle fetal mummification has an incidence of less than 2%, with breed and previous occurrence as risk factors; there is a higher incidence of fetal mummification in Guernsey and Jersey cattle and a higher risk of recurrence (30%) in cows that have experienced a similar event in a previous gestation. Mummification occurs most often in cattle between the third and eighth month of gestation, without any concomitant luteolysis of the corpus luteum (CL) or opening of the cervix. Fetal mummification associated with a persistent CL is observed mainly in cattle and goats, as both species are dependent on progesterone (P4) produced by the CL for the maintenance of pregnancy. However, in cattle the placenta can produce sufficient P4 to maintain pregnancy between Days 150 to 200 of gestation. After fetal death, the amniotic and allantoic fluids are resorbed, fetal tissues and annex membranes dehydrate, and, eventually, the caruncles disappear. The longer the mummified fetus is retained, the dryer, firmer, and more leathery the tissues of the fetus become.

Potential causes for bovine fetal mummification include: infections (BVDV, leptospirosis, *Neospora caninum,* fungal infections); mechanical factors (compression and/or torsion of the umbilical cord); uterine torsion; defective placentation; some genetic abnormalities causing fetal loss; abnormal hormonal profiles; and chromosomal abnormalities. In practice, a definitive aetiology is rarely established with tissue decomposition and autolytic changes compromising histological, microbiological, and chromosomal analyses, although development of molecular tests is increasing the opportunity for some diagnoses to be established if DNA extraction occurs.

The majority of diagnoses of suspected fetal mummification (63%) are established by veterinarians after the owner notices that the cow's abdomen is unusually small for the given stage of pregnancy and that no significant systemic or other illness is observed in cows except for spontaneous abortion, which may or may not occur. The diagnosis of fetal mummification is generally uncomplicated, by transrectal palpation and ultrasonographic examination revealing that the mummified fetus is a compact, firm, and immobile mass without placental fluid or placentomes. Ultrasound reveals the absence of a heartbeat, and the general physical examination of the dam usually indicates other systems appear normal. A systematic approach to treating pregnant cows diagnosed with fetal mummification is suggested (Lefebvre 2015), with prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) considered most effective in expelling the fetus. After expulsion of the fetus, a uterine lavage may be performed to remove fetal and placental debris, and the cow can be rapidly induced into oestrus and inseminated. In the absence of a treatment response, the most cost effective option is then to proceed with a second injection of $PGF_{2\alpha}$.

Further information on fetal mummification in the major domestic species, including common aetiologies, and treatment options for restoring future pregnancy and herd fertility can be found in the recent review (Lefebvre 2015).

Prolapse of the Cervix and Vagina

DAVID E. NOAKES

Typically, prolapse of the cervix and vagina (CVP) is a disorder of ruminants, normally in late gestation. Occasionally, it is seen after parturition and rarely occurs unconnected with pregnancy or parturition. It less frequently occurs in pigs. It can be recognised by the protrusion of varying parts of the vaginal wall and sometimes the cervix through the vulva, so that the vaginal mucosa is exposed. In some bitches, hyperplasia of the vaginal mucosa occurs at prooestrus/oestrus, which may protrude through the vulva. This is sometimes referred to as vaginal prolapse, although such a description is incorrect and is not comparable with the condition in other species (see Chapter 33).

Sheep

Incidence and Cost

The disorder is much more common in sheep than in other species and is thus of real economic importance. Average incidences are 0.53% (Edgar 1952), 0.46% (Bossé et al. 1989), 0.98% (Low & Sutherland 1987), and 1.05% over 2 years (Jackson et al. 2014), which may rise to 20% and 46% in some flocks. In any 1 year there can be considerable between-farm variations; studies involving 113 and 88 farms in the years 2000 and 2001 in the Southland (S) and Hawkes Bay (HB) regions of New Zealand showed the annual incidence for both years was 0% to 3.9% for the HB farms and was 0% to 5.9% for the S farms. The financial cost of CVP is substantial. For example, Hosie (1989) calculated that in the United Kingdom each case cost £41, based on the average cost of replacing a breeding ewe minus the value of a culled affected ewe, lamb mortality, and the cost of treatment. In addition, there are the unquantifiable welfare implications. The financial costs of the disorder are based on these assumptions:

- Some affected ewes will die.
- If not treated, some will abort.
- Some will have reduced fertility.
- Ewes may be culled because of the possibility that prolapse may recur.
- The stillbirth rate and neonatal mortality are increased.
- There is a greater chance of dystocia in affected ewes.

Classification of Severity

The disorder is normally easily recognised, although sometimes the prolapsed organ can be confused with the allantochorion as it protrudes from the vulva before it ruptures. The severity of the disorder varies, and a number of different classifications have been used. Probably the simplest is that used by Bosse et al. (1989), as illustrated in Figs 10.1 and 10.2 which is:

- Stage 1, in which the vaginal mucosa protrudes from the vulva when the ewe is recumbent but disappears when she stands;
- Stage 2, in which the protruding vaginal mucosa remains visible even when the ewe stands; the cervix is not visible; and
- Stage 3, in which the vagina protrudes and the cervix is visible.

Other systems of classification have been used that also take into account the duration of the prolapse, its size, and the other organs contained within the prolapsed organ. Cox (1987) uses the terms mild, moderate, and severe. The bladder is most frequently involved, as it becomes reflected to occupy the vesicogenital peritoneal pouch. This can be followed by complete or partial constriction of the urethra, causing urinary retention; the uterine horns and intestines can also be involved. Real-time ultrasonography can be used to diagnose the contents of the prolapse (Scott & Gessert 1998).

Causes and Pathogenesis

Much of the evidence relating to the cause of the disorder is anecdotal and often contradictory. In the New Zealand study by Jackson et al. (2014), the crude relative risk of a prolapse occurring was 5.3 times higher in ewes carrying twins and 11.3 times higher in those carrying triplets than with singletons. It was less common in pure or crossbred Perendale ewes, which is evidence of a breed predisposition, whereas it was more prevalent in farms with a moderate to steep terrain compared with a flat terrain. There are probably a number of predisposing factors, some of which may interact, although for the prolapse to occur, there must be some inherent defect in the structure of the vaginal wall. Predisposing factors include:

- Hormonal excesses and imbalances,
- Hypocalcaemia,
- Large fetal load (twins or triplets),
- Fat condition,
- Thin condition,
- Inadequate exercise,
- Short tail docking,
- Bulky food (root crops),
- Excess dietary fibre,
- Dietary oestrogens and their precursors,
- Sloping terrain,
- Vaginal irritation,

VetBooks.ir

- Previous dystocia,
- Inherited (breed) predisposition.

Irrespective of the alleged predisposing factors, there are three requirements for CVP to occur (McLean 1956). They are the following:

- The vaginal wall must be in a state in which it can be readily everted, and the vaginal lumen must be large.
- The vulva and vestibular wall must be relaxed.
- There must be a force that can displace the vaginal wall, causing it to become everted.

Studies by Ayen et al. (1998) have attempted to measure the changes in the compliance of the vaginal wall (which will be related to the ease with which the wall can be everted) and the size of the vaginal lumen, the capacity of the vagina (which will assess the ease with which the everted vagina can be expelled to the exterior). There are considerable between-animal variations in these parameters, which explain why CVP occurs in some ewes but not others. The compliance of the vaginal wall was greater during the second than the first pregnancy, and this supports the observation that CVP is less frequently identified in primigravid than in plurigravid ewes. Both endogenous and exogenous estradiol and progesterone can influence the compliance of the vaginal wall and the capacity of the vagina. Ennen et al. (2011) found that peripheral plasma progesterone concentrations of ewes with vaginal prolapse were higher than in unaffected controls (19.35 vs 10.44 ng/mL), whereas oestradiol values were not statically different. The vaginal wall is comprised of collagen and smooth muscle, so both parameters will be influenced by either the amount, the distribution, or the type of collagen present (Ayen & Noakes 1998). There is evidence that there are changes in the tissue composition of the vaginal wall that influence its function, as assessed by in vitro tensiometry (Ulrich et al. 2014). The vaginal wall of pregnant ewes was the most extensible but the weakest, whereas tissues from both nulliparous and parous nonpregnant ewes were strong and elastic. Extrapolation from work relating to genitourinary prolapse in humans suggests that it may well be a change in the collagen type that reduces the mechanical strength of the vaginal wall (Jackson et al. 1996). Studies of human patients with prolapse showed that the vaginal wall had more total collagen, particularly subtype III, as well as greater active expression of the matrix metalloproteinases 9, compared with normal controls (Moalli et al. 2005). This, the authors considered, was an indication of active tissue remodelling occurring. Furthermore, the influence of oestrogens on vaginal collagen metabolism was shown in a human study in which estradiol valerate therapy in menopausal women caused a significant reduction in total aged collagen but an increase in new collagen (Jackson et al. 2002). In prolapsed tissue, the alpha chain of collagen 1 showed a decrease expression compared with unaffected ewes in late pregnancy. Biomolecular analysis shows that ewes suffering from vaginal prolapse have periparturient changes in metabolism of vaginal connective tissue, for example, collagen (Ennen et al. 2011).

Clinical Signs and Progression of the Disease

The clinical signs are obvious that the only possible confusion might be the protruding allantochorion. Prolapse occurs most frequently in the last 2 to 3 weeks of gestation. The only distinction that needs to be made is the severity. In sheep a severe prolapse with heavy straining is not well tolerated, and death from shock, exhaustion, and anaerobic infection is common. Abortion or premature delivery, often of a dead fetus, may be followed by rapid maternal recovery. In a study involving 129 ewes with CVP, spontaneous parturition occurred in 26%, with dystocia in 58%, of which 70% suffered from incomplete cervical dilatation ('ring womb') (Kloss et al. 2002).

White (1961) first described a fatal condition of heavily pregnant ewes in which the intestines become prolapsed through a spontaneous rupture of the dorsal or lateral wall of the vagina. This has been shown to be associated with vaginal prolapse, although why it should occur is not entirely clear (Knottenbelt 1988). A study involving the Norwegian Dala breed has questioned this theory and has presented information suggesting that it might be due to a number of reasons, including uterine torsion (Mosdol 1999).

Treatment

The early replacement and retention of the prolapse is very important to prevent trauma and to ensure that the ewe maintains pregnancy to term. Hosie (1989) reported on the consequences of such a prolapse on the health and viability of both ewes and lambs. Of the 183 ewes, 9.2% suffered from vaginal rupture, and a similar number had other unspecified complications, whereas 14.6% of the 253 lambs were either stillborn or died soon after birth.

Treatment of ewes with CVP is often carried out without any consideration for the welfare of the animal. It is relatively easy for veterinarians to reduce pain and discomfort during replacement by using caudal epidural anaesthesia. The technique, which is described in Chapter 13, should be used for all but the mildest prolapse; it also makes the replacement much easier to perform.

In sheep the perineal wool or string fastened to it may be tied across the vulva; large safety pins have sometimes been used. For retaining the prolapsed vagina of ewes, Fowler and Evans (1957) and Jones (1958) first described the use of a stainless steel stay in the form of the letter U, which is placed in the vagina. The emerging ends are bent at right angles and fitted with eyes that are securely fastened with string on either side to the wool of the gluteal region. This type of prolapse retainer has been improved by the development of a plastic spoon, which is fastened in the same way as the U-shaped device, or by combining it with a harness made from baling twine or nylon strapping (Fig. 10.3). Buhner's method, which is described in detail in the section on cattle later in this chapter, is equally applicable to ewes with a prolapsed vagina; it involves the laying of a suture of tape subcutaneously, using a large half-curved cutting suture needle; the smaller (15 cm long Buhner's needle) which is a smaller version of the one used in cows is preferable (see Fig. 10.6).

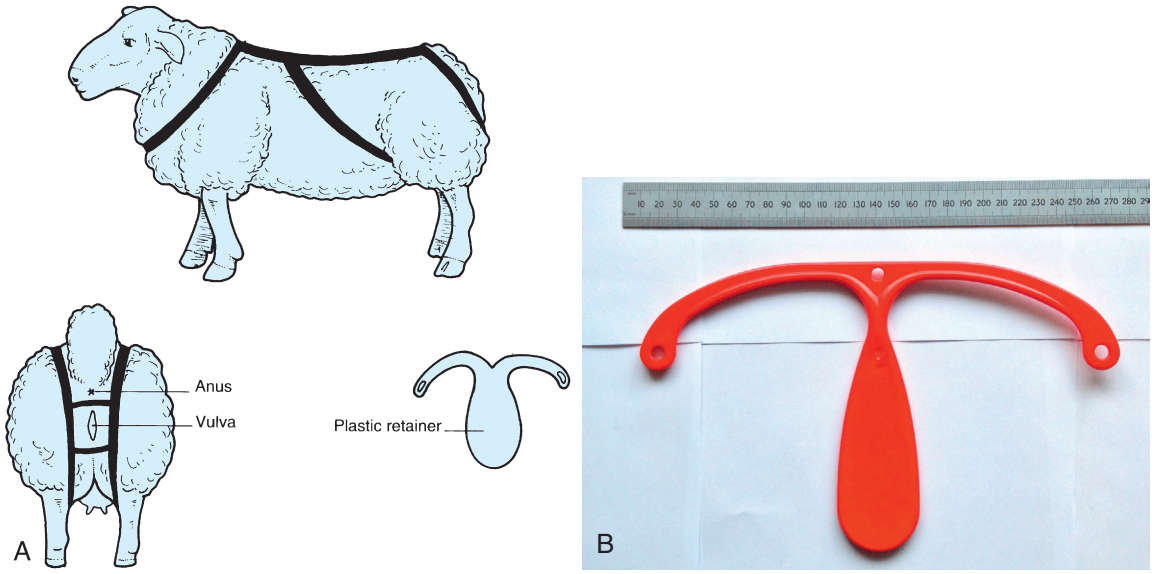
Insofar as it is possible that there may be a genetic predisposition to the disorder, it would seem unwise to breed from animals that have previously suffered from vaginal prolapse. There is little doubt that by adopting this culling policy over the years, stock owners have exerted a large measure of control over the condition. Although the recurrence rate is variable, Piorowicz (1987) and Hosie (1989) quoted recurrence rates of 72% and 40% respectively; an 18% rate in a small study involving 11 ewes was reported by Ayen and Noakes (1997).

Cattle

Causes and Pathogenesis

The exact cause of the disorder has not been ascertained but several factors are generally believed to play a part. Cattle of the beef breeds, particularly Herefords, Simmentals, and Charolais, are

VetBooks.ir



• **Fig. 10.3** (A) The positioning of a harness (constructed of baling twine or nylon strapping) in a ewe together with a plastic retainer. The latter is not always used if pressure from the harness on the perineum is sufficient to retain the prolapse. (B) The plastic retainer. Plastic prolapsed retainer normally used with harness but can be used with cotton tape tied to wool. (Courtesy Will Douglas, 'Nettex'.)

most commonly affected. Woodward and Queensberry (1956) recorded 1.1% of vaginal prolapses in 7859 pregnancies in Hereford cattle in the United States, and it has been suggested that in this breed the anatomical anchorage of the genital tract is less efficient than in other animals. An excessive deposition of fat in the perivaginal connective tissue and ligamentous relaxation may increase the mobility of the vagina. Both these effects might be due to a state of endocrine imbalance, in which oestrogenic hormones predominate; the administration of diethylstilbestrol has been shown to soften the suspensory ligaments of the genital tract. When oestrogenic substances are present in inordinate amounts in the diet, as in subterranean clover pastures of Western Australia (Bennetts 1944) or in mouldy maize and barley, which are considered to have a high oestrogen content, this can result in a high incidence of prolapse. When heifers are fed these in their diet, they may show vulvovaginitis, with oedema of the vulva, relaxation of the pelvic ligaments, tenesmus, and vaginal prolapse (Koen & Smith 1945, McErlean 1952). Predisposition to CVP is inherited, as shown by its greater frequency of occurrence in beef cattle. Mechanical factors, such as the increasing intraabdominal pressure of late pregnancy and gravity acting through the medium of a sloping byre floor when cattle are tethered, are considered to be significant (McLean & Claxton 1960).

Postparturient prolapse of the vagina of cattle is usually due to severe straining in response to vaginal trauma or infection after a serious dystocia. Vaginal contusion at parturition, followed by *Fusobacterium necrophorum* infection, exerts a high degree of irritation with frequent exhausting expulsive efforts.

Clinical Signs and Progression of the Disease

Initially, the lesion involves a protrusion of the mucous membrane, more frequently the floor of that part of the vagina that lies just cranial to the urethral opening. In severe cases the whole of the anterior vagina and cervix may protrude. The earlier in pregnancy the disease develops, the more severe it is likely to become because advancing pregnancy tends to accentuate the condition. Most cases occur in the last 2 months of gestation. In the mildest form the prolapse appears only when the cow is recumbent, and when the animal rises, it recedes. However, the tendency is for the prolapse to become more severe so that, in time, a large tissue mass protrudes and does not disappear in the standing position. The protruding tissues, with their circulation impaired, are prone to injury and infection. The resultant irritation causes expulsive straining efforts. This increases the severity of the prolapse, and a vicious circle is established. Eventually, the whole of the vagina, cervix, and even the rectum may become everted (Figs 10.4 and 10.5). Thrombosis, ulceration, and necrosis of the prolapsed organ, accompanied by toxaemia and severe straining, lead to anorexia, rapid deterioration in bodily condition, and occasionally death.

Treatment

If prompt attention is given, simple measures often succeed. The aim is to arrest the process by early replacement and retention of the prolapsed portion. Caudal epidural anaesthesia (see Chapter 13) is indicated both to obviate straining and to desensitise the perineum for suturing. The everted mass is cleaned, using plain water or a mild nonirritant antiseptic, and replaced gently with the palm of the hand, being careful not to cause trauma to the inflamed and sometimes fragile tissue. It is retained by tape or stout nylon sutures that cross the vulva and are inserted in the perineal skin. Quill sutures tied over rubber tubing are best. In cases in which the vagina has suffered little damage and especially in which parturition is imminent, such measures are usually sufficient. However, when irritation from trauma and infection causes vigorous straining, or even the trauma caused by the insertion of the sutures themselves, the retaining sutures may tear through the tissue, become displaced, and prolapse recurs. Although straining may be controlled by caudal epidural anaesthesia in the short term and although xylazine will prolong its effect (see Chapter 13), it is not practical to provide continuous anaesthesia by this means. Perineural injection of the pudic nerves has the same effect and the same disadvantage. Tenesmus has been prevented for several

days and for up to a week or more by the induction of an artificial pneumoperitoneum.

Because of the deficiencies of the simple suture methods of retention, in the author's experience the best means of retaining the replaced vagina is the technique described by Buhner (1958) (Fig. 10.6). It entails the placing, by use of a special needle, of a subcutaneous suture of nylon tape around the vulva. To facilitate introduction of the large needle, two stab incisions are made (under epidural anaesthesia previously induced to aid replacement of the vagina) in the midline; the upper one is midway between the dorsal commissure of the vulva and the anus, and the lower one is immediately beneath the ventral vulvar commissure. The needle is inserted into the lower incision and gradually passed subcutaneously up the right side of the vulva until its point emerges through the

VetBooks.ir

• **Fig. 10.7** Chronic prolapse of the cervix, treated by using Robert's modification of Caslick's operation.

upper incision, whereupon the needle is threaded with a double length of nylon tape. While one end of the tape is firmly held, the loaded needle is pulled downwards until free of the lower incision, when it is unthreaded, thus leaving a length of tape protruding from each incision. The needle is now inserted again into the lower incision and passed subcutaneously up the left vulvar labium. When its point emerges the needle is threaded, then pulled backwards and outwards from the lower aperture and unthreaded. The tape now encircles the vulva subcutaneously, and its two ends hang from the lower incision. These ends are tied with a simple knot with such a degree of tightness that four fingers can be inserted flatwise up to their second joints into the vulva. The upper incision is closed with a couple of sutures of fine monofilament nylon, and the lower incision can be either left open or sutured according to the cow's proximity to parturition. The suture causes practically no tissue reaction, the vulvar labia are not damaged by it, and it can remain in situ for months until the cow is on the point of calving, when the knot should be cut so as to release the thread and allow the vulva to dilate for the birth of the calf.

For cows showing recurrent prolapse that are remote from parturition and also for postpartum cases, Roberts (1949) suggested a method of almost complete surgical occlusion of the vulva by a technique that is really an extension of Caslick's vulvoplasty operation for preventing vaginal aspiration in mares (Fig. 10.7). Under caudal epidural or local infiltration anaesthesia, strips of mucous membrane, 1.2 cm wide, are dissected from the upper three-fourths of each vulvar lip. The denuded areas are then approximated by means of fine, nonabsorbable sutures, and a few mattress sutures of tape or stout nylon are deeply placed across the vulva to protect the coapted lips from the effects of straining. First intention healing should occur, and the suture line must be incised when parturition is imminent.

Farquharson (1949), who saw hundreds of cases of vaginal prolapse in Hereford range cattle in Colorado, successfully applied a technique of submucous resection, or 'reefing' operation, on the prolapsed organ. The object of the operation, which should not be performed later than 3 to 4 weeks from term, is to excise the protruding mucosa, which forms the bulk of the everted mass, and then approximate the cut edges. The operation is performed under caudal epidural anaesthesia. Subsequent parturition and conception are not affected, and the cure is permanent. An alternative approach is to prevent displacement of the cervix caudally by anchoring it, using nonabsorbable sutures or nylon tape, to the prepubic tendon or the sacrosciatic ligaments (Winkler 1966). Although Winkler describes the technique as being done under caudal epidural anaesthesia, in the author's experience, although the approach to the sacrosciatic ligament is possible using this approach, attachment to the prepubic tendon requires general anaesthesia, with the cow in dorsal recumbency, and a caudal midline laparotomy between the two udder halves.

Pigs

Vaginal prolapse (Fig. 10.8) occurs in gilts at oestrus, but more frequently in housed pregnant older sows (> 5 pregnancies) that are in fat bodily condition, carrying large litters and with high levels of

VetBooks.ir

feed intake; anecdotally, the feeding of mouldy cereals, supposedly because of their high oestrogen content, has been implicated. An incidence of 0.5% has been quoted. In mild cases the prolapse is often intermittent, with it protruding only when the sow is recumbent and disappearing from view when she stands. However, if it continues to protrude, a simple tape or Buhner's suture (as described in Fig. 10.6) can be used but obviously must be cut as farrowing approaches. Affected sows/gilts should be culled. Vaginal prolapse in pigs is discussed in greater detail in Chapter 17.

Dogs

Vaginal hyperplasia occurs in bitches around the time of oestrus, and when there is excessive oedema of the vaginal mucosa cranial to the urethral orifice, it can protrude from the vulva appearing as if the vaginal wall has prolapsed (Johnston et al. 2001); thus this is sometimes incorrectly referred to as vaginal prolapse (see Chapter 34). A few cases of true vaginal prolapse have been reported, both single case reports (Memon et al. 1993, Alan et al. 2007). One case was first seen around the time of oestrus and recurred during pregnancy, whereas the other first appeared in late gestation and resulted in dystocia. Chronic prolapse during pregnancy in the bitch has been reported (Memon et al. 1993, Alan et al. 2007) that was treated by hysteropexy, and subsequent caesarean followed by ovariohysterectomy, respectively. Long-term, chronic vaginal prolapse in the absence of pregnancy involving herniation of abdominal viscera has also been described (McNamara et al. 1997).

Approach to an Obstetrical Case

TIMOTHY J. PARKINSON, JOS J. VERMUNT AND DAVID E. NOAKES

Each case of dystocia is a clinical problem that may be solved if a correct procedure is followed. The successful management of the case requires obtaining a history from the owner or attendant, a focused clinical examination, and specific examination of the reproductive tract. There should be careful differentiation between a labour that is not fully established from one that has become interrupted, and a careful diagnosis should be made of any faulty fetal disposition before attempting any correction. There should also be a differentiation between whether the labour has been interrupted due to a problem with the birth process per se, and whether other disease processes are interfering with it.

Causes and Classification of Dystocia

A normal birth occurs when the **expulsive forces** are sufficient to propel a **fetus of normal size and disposition** through a **birth canal of adequate size**. Dystocia occurs when any of these are abnormal or insufficient. Thus the causes of dystocia can be considered in terms of the:

- Expulsive forces
- Adequacy of the birth canal
- Size and disposition of the fetus

Difficult birth will occur when the expulsive forces are insufficient, when the birth canal is of inadequate size and shape, or when the presenting diameter of the fetus is unable to pass through the normal birth canal because it is too large or its disposition prevents it from doing so. An overview of the types and causes of dystocia are given in Fig. 11.1.

Defects of the expulsive forces and of the adequacy of the birth canal are commonly referred to as **maternal dystocia**, whereas those due to defects of the presentation of the fetus or to its disproportion (i.e., with respect to the size of its dam) are known as **fetal dystocia**. However, there will be times when it can be difficult to identify the primary cause and others when there will be a change in the dominant cause during the course of the dystocia.

Defects of Expulsive Forces

Defects of expulsive forces generally refer to intrinsic defects of uterine contractility, nervous voluntary inhibition of labour, or failure of contraction due to mineral/hormonal imbalances (**primary inertia**), or to exhaustion of either the uterine muscle itself or depletion of pituitary oxytocin stores (**secondary inertia**). Failure of contraction of abdominal muscles during second stage labour can also occur.

Defects of the Adequacy of the Birth Canal

The birth canal consists of the internal tubular organs of the reproductive tract from the uterine horns and body to the vulva. Abnormalities of any part of these structures can lead to dystocia.

Such abnormalities include function disturbances of the genitalia (e.g., incomplete cervical dilation; torsion of the uterus), obstructions (e.g., neoplasia), or mechanical abnormalities (e.g., double cervix; remnants of the paramesonephric ducts). Rarely, the uterus can be displaced into a subpubic position or through a hernia in the abdominal wall.

Abnormalities of the surrounding tissues can, likewise, lead to dystocia. Such tissues include the pelvis (e.g., heritable pelvic malconformation such as occurs in Belgian Blue cattle and brachycephalic dog breeds; fractures of the pelvic bones; sacroiliac dislocation), the bladder (e.g., prolapse into the vagina), or excess intrapelvic fat,

Faulty Fetal Disposition

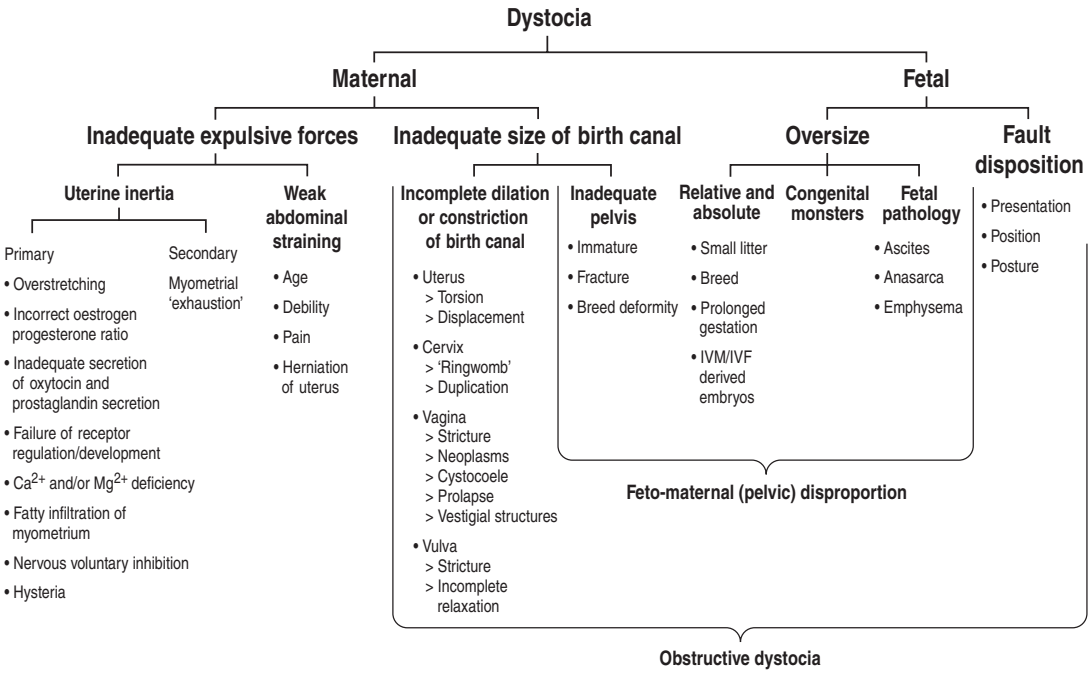
During pregnancy, particularly in monotocous species such as cattle, horses, sheep, and goats, the fetus assumes a disposition within the uterus which is such that the space occupied is as little as possible: for example, the vertebral column and limbs will be flexed to varying degrees. In order to negotiate the birth canal unaided, these joints need to be extended. The term 'faulty' or 'abnormal fetal disposition' is used to describe the situation in which the fetus has failed to assume the disposition that enables it to be expelled unaided *per vaginam.* The universally accepted terminology to describe these abnormalities is that first defined by Benesch. This involves the use of the terms presentation, position, and posture, each of which has a specific meaning in relation to veterinary obstetrics (Fig. 11.2).

Presentation signifies the relationship between the longitudinal axis of the fetus and the maternal birth canal. These may be:

- **Longitudina**l presentation, which can be **anterior** or **posterior**, depending on which fetal extremity is entering the pelvis;
- **Transverse** presentation; **ventra**l or **dorsal**, according to whether the dorsal or ventral aspect of the trunk is presented; and
- **Vertical** presentation; **ventral** or **dorsal**. Vertical presentations are very rare, and only the obliquely vertical 'dog-sitting' presentation in the horse needs to be considered in detail.

Position indicates the surface of the maternal birth canal to which the fetal vertebral column is applied. It can be **dorsal**, **ventral,** and **left or right lateral**.

VetBooks.ir



• **Fig. 11.1** The causes of dystocia.

Posture refers to the disposition of the movable appendages of the fetus and involves flexion or extension of the **neck or limb joints**, for example, lateral flexion of the neck or hock flexion posture.

Disproportion: Fetomaternal disproportion occurs when the fetus is larger than the capacity of the pelvis through which it has to pass. Disproportion may occur if the fetus is larger than normal, either in terms of its absolute size or of the size of particular parts of its body (notably shoulders and/or pelvis), or if the pelvic canal of the dam is too small or is of incorrect shape.

History and General Examination

History

Before examining the animal, an effort should be made to obtain a pertinent history of the case from the owner/attendant. Key points to be elicited from the history are summarized in Fig. 11.3.

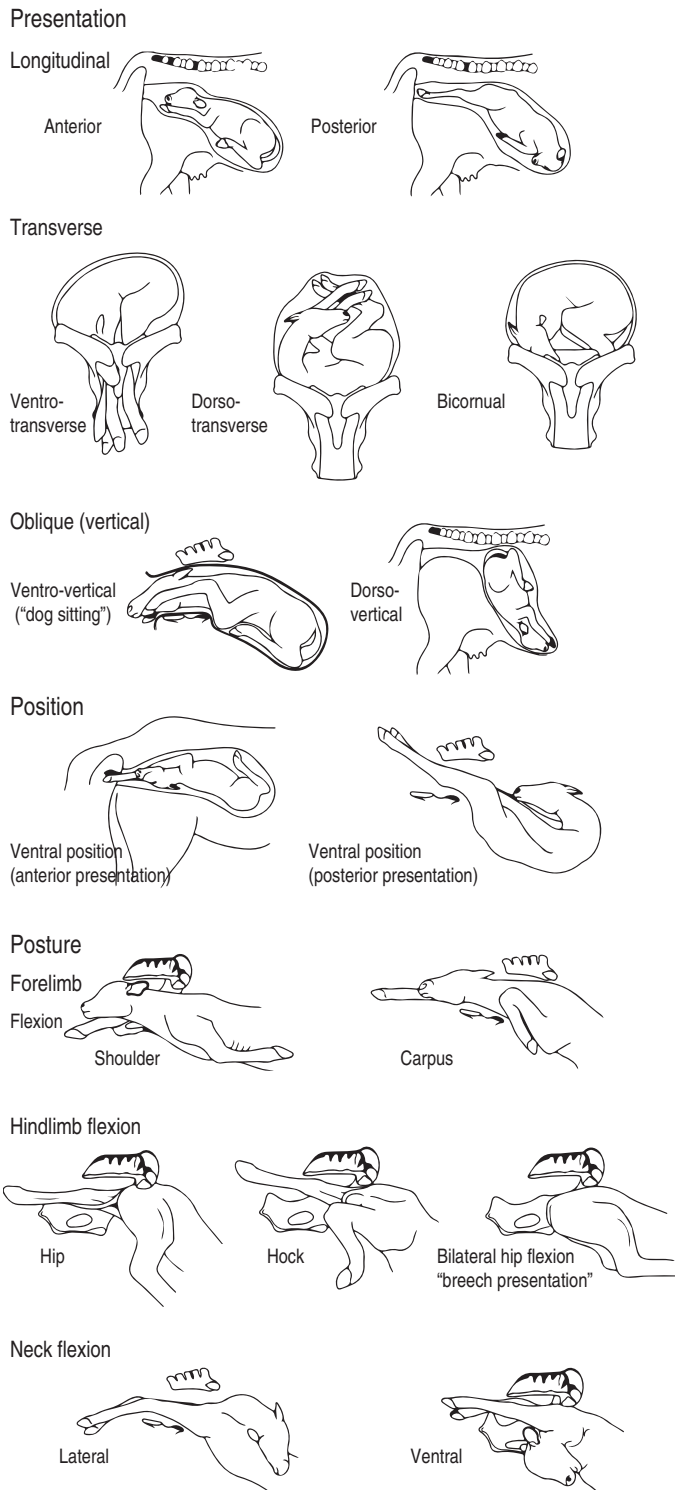
Perhaps the most important aspects of the history are (i) the duration of labour and (ii) attempts that have already been made to assist the birth. The parity of the animal is the third key aspect because the incidence of different types of dystocia varies markedly with parity. For livestock, it is generally obvious whether the animal is primigravida or multigravida, but this can be rather less obvious in other species.

The duration of labour is important inasmuch as it is one of the key determinants of outcome for mother and fetus and often constrains the options available to the obstetrician for managing the case. Calculating the time the start of labour is often difficult because the signs of the onset of first stage labour are sufficiently vague and indistinct to easily escape the attention of an attendant. The onset of second stage labour, which is typified by vigorous and frequent straining, appearance of the amnion, expulsion of fetal fluids, appearance of a fetal extremity, and/or recumbency of the animal, are easier to recognize; this will typically be identified by an attendant as the 'start of labour'. Even so, in intensively managed livestock, it is by no means uncommon for the onset of even second stage labour to pass unnoticed and for the animal to be presented once a dystocia is obviously present, but with little indication of its duration.

As a generalization, it is reasonably certain that some form of obstructive dystocia exists if several hours have elapsed since the onset of second stage labour. The fetus can survive a moderate period of dystocia in most species, but this depends on the extent to which the fetus has traversed the birth canal before the labour is arrested. Thus, if the cause of the dystocia is relatively simple, such as slight fetomaternal disproportion or a minor limb malposture, and the case has not been neglected, fetal and maternal survival are often good. On the other hand, fetal survival of dystocia in the mare is short, as the normal course of delivery is so rapid and separation of the placenta occurs so quickly once second stage has commenced that any delay generally results in the death of the foal. If the dystocia has not been noticed until 24 or more hours after the start of second stage labour has started, the fetus is likely to have died and will often have started to become putrefied and decompose. Managing these cases is difficult because straining efforts have commonly ceased, fetal fluids have been entirely lost, and the uterus has started to contract down onto the retained fetus. In polytocous species, fetuses may survive for some time behind a point of obstruction, but eventually they will also die and/or start to decompose.

It is valuable to discover whether an attempt has already been made to assist the delivery. This may not only provide useful information about the type of dystocia that is (or is not) present, but may also provide evidence of whether injury has been caused either to the genital tract or to the musculoskeletal system of the animal. All of this information helps the obstetrician to provide a prognosis for mother and fetus for the outcome of the birth. It is particularly important to determine whether any drugs (commonly calcium, antibiotics, or oxytocin) have been given before assistance is requested, as this may affect the subsequent management of the case and will undoubtedly affect meat or milk withholding times for livestock.

VetBooks.ir



• **Fig. 11.2** Abnormalities of fetal presentation, position, and posture.

General Examination

The animal's physical and general condition should be noted. If recumbent, is she merely resting, is she exhausted, or is she suffering from a metabolic disease? Body temperature and pulse rate should be noted and the significance of abnormalities considered. Cattle should be routinely assessed for the presence of hypocalcaemia, and the possibility of toxic mastitis should not be overlooked.

The vulva should next be inspected. Parts of a fetus may be protruding, and it may be possible to assess the nature of the dystocia from these. Are exposed fetal parts moist or dry, or swollen emphysematous or oedematous? Such evidence serves not only as a guide to the duration of the condition but also to the effort that will be necessary to correct it. If parts of the amnion protrude, what is their condition? Are they moist and glistening with fluid caught up in their folds? If so, their exposure is recent, and the case is an early one. If, however, the membranes are dry and dark in colour, it may be taken that the case is protracted. Attention should also be paid to the nature of the discharge from the vulva, especially if neither fetus nor membranes are presented. Fresh blood, especially if profuse, generally indicates recent injury to the birth canal. A dark brown, fetid discharge indicates a grossly delayed case.

When dealing with the bitch and cat, the degree of abdominal distension should be observed, for it may be possible to make an estimate of the number of fetuses that occupy the uterus. The onset of vomiting, together with a great increase in thirst, should be regarded as grave signs in the bitch.

Detailed Examination of the Animal

Large Animal Species

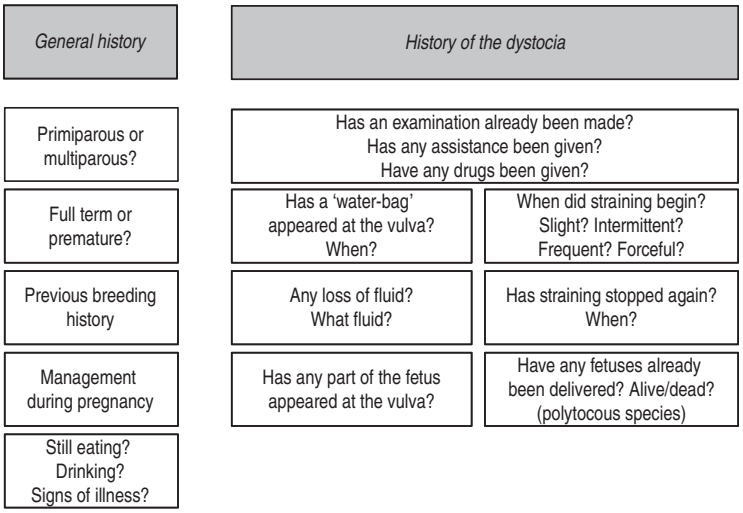
The animal should be effectively restrained in a clean environment, for the safety of the veterinarian, any assistants, and the animal concerned. In the case of the mare (Fig. 11.4), cow, ewe, and doe goat, it is usually easier if they remain standing; the sow is best examined in lateral recumbency. One should never forget that large animals can collapse suddenly during examination, so it is important to ensure that (i) the animal can be easily extracted from the restraint if it does collapse and (ii) the obstetrician's hand/arm does not become trapped inside the animal when it collapses.

It may be necessary to sedate the animal before examining her – ideally, at a sufficiently early stage in the proceedings that she does not become fractious, but to a level that does not result in unplanned collapsing/recumbency. A decision whether to use epidural anaesthesia should likewise be made as early as possible. If the fetus is dead and/or the uterus is grossly contaminated, the epidural should be given before a vaginal examination is performed in order to minimize the risk of infecting the neural canal.

It is impossible to perform obstetrical procedures aseptically in any animal species, but the amount of contamination of the genital tract should be kept as low as possible. To this end, plentiful supplies of clean hot water with soap or surgical scrub should be available, as well as a table or bench covered with a sterile cloth on which instruments may be placed. Making sure that any bedding is clean (e.g., clean straw placed behind the animal) is also helpful. Because the floor is often wet and slippery, application of sand or grit is a worthwhile precaution.

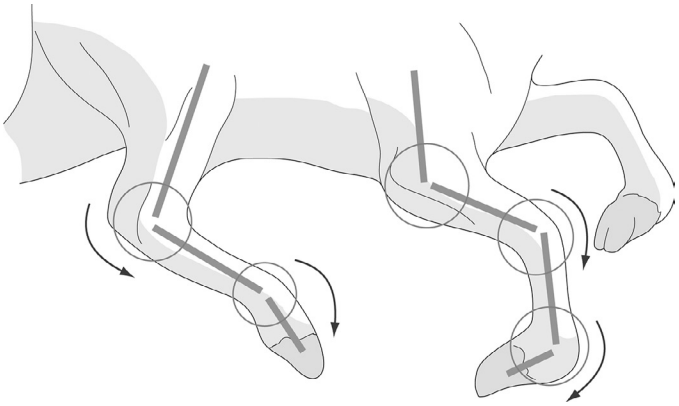
The external genitalia and surrounding parts are thoroughly washed, and the tail is held or tied to one side. The obstetrician's hand and arms should be cleaned in water from a different bucket. The first vaginal examination usually provokes reflex defecation: more washing of animal and obstetrician is required. Some obstetricians prefer to wear a disposable plastic sleeve during examination of the animal: certainly this reduces the need for repeated rewashing of the obstetrician's arms, but some find it more difficult to differentiate tissues within the uterus when wearing a sleeve. When gross contamination of the uterus is present (e.g., in cases of bacterial abortions or when a putrefying fetus is present), it is very strongly advised that a sleeve should be worn. In the mare a

VetBooks.ir



• **Fig. 11.3** Key points in the obstetrical history of a case.

• **Fig. 11.4** Mare with dystocia, restrained in stocks for vaginal examination and correction of dystocia.



• **Fig. 11.5** Determining whether presented limbs are fore- or hindlimbs. The olecranon and hock are easy to confuse during vaginal examination: however, in the forelimb, the first two movable joints (fetlock and carpus) flex in the same direction, whereas in the hindlimb, the first two movable joints (fetlock and hock) flex in the opposite directions.

clean tail bandage is applied because the tail hairs are frequently introduced into the vulva and vagina which can cause quite severe lacerations. Without the previous induction of epidural anaesthesia and the resultant paralysis of the rectum, it is almost impossible to make a vaginal examination in the cow without introducing some faecal contamination. There is little serious consequence of mild contamination, fortunately; but the greater the contamination that occurs, the greater the risk of postpartum uterine infection.

The next stage is to perform a vaginal examination in order to establish the patency of the birth canal, the orientation of the fetus, and the position of its movable parts (i.e., head, limbs, tail). Copious lubrication should be introduced to the birth canal at the start of the vaginal examination.

In the majority of cases, some part of the fetus occupies the vagina – the head, a limb, or limbs. Some difficulty can initially be experienced in recognizing the fetal parts being palpated if they are covered by amnion. To overcome this, the torn edges of the amniotic sac should be identified and opened, and the hand inserted so that the fingers come into direct contact with the fetus. It is often necessary to repel the fetus back into the uterus to ascertain the nature and direction of displaced parts. If continued straining makes this difficult, the induction of epidural anaesthesia should be considered at once, but it should be remembered that the dam's expulsive effort may be required after any corrective procedure has been performed.

Recognition of the head is not difficult; the mouth and tongue, the orbits, and the ears are generally obvious. In the case of limbs, the first requirement is to ascertain whether it is a forelimb or hindlimb. There are two main ways of assessing this: the orientation of the feet and the flexion of the joints of the limb. If the plantar aspect of the digit is downwards, it is most likely to be a forelimb; if the plantar aspect is upwards, it is most likely to be a hindlimb. This 'rule of thumb' nearly always holds true for the cow/ewe/doe, but in the mare, it is not uncommon for the fetus to be in the ventral position, so more caution is needed. The direction of flexion of the limb joints differs between forelimb and hindlimb: if the fetlock and the joint immediately above it flex in the same direction, it is a forelimb. Conversely, if the fetlock and joint above it flex in the opposite direction, it is a hindlimb (Fig. 11.5). If more than one limb is present, it must be established that they are either fore or hind and if they are from the same fetus.

If nothing is present in the vagina, the cervix should next be examined. First, it should be determined whether the cervix is completely dilated. If the cervix is largely, but not fully, dilated, a 'lip' of tissue will be evident, usually at the caudal end of the cervix. If less dilated, the cervical structure will be obvious, and there may even still be mucous within it. In the latter case the

VetBooks.ir

first thing to consider is whether the first stage of labour is not yet complete; i.e., the second stage of labour has not yet begun, and the animal requires more time. On the other hand, failure of cervical dilation can be a sign of dystocia. For example, the cervix usually fails to fully dilate in cases of uterine torsion, and failure of the fetus to impact the internal os of the cervix (i.e., through some form of faulty disposition) can also lead to partial failure of cervical dilation. Finally, it should be ascertained whether the cervix is incompletely dilated as the dystocia has been neglected, and the cervix has started to close again. This will usually be accompanied by complete loss of fetal fluids and often by obvious signs that the fetus has died and is starting to decompose.

When the fetus has not fully entered the birth canal, deeper palpation is needed to determine what parts are presented. For example, palpating the fetal tail and perineum means that there is a high likelihood that the fetus is in 'breech' presentation. Likewise, if a flexed neck is palpated and a search on one or other side reveals ears and occiput, the case is one of lateral deviation of the head. Similarly, presentation of the head but not of forelimbs can indicate flexion of the carpi or of the shoulders. In the mare (and sometimes in ruminants), it may indicate that the fetus is in a dorsotransverse presentation, or perhaps occupying both horns (bicornual gestation). Finally, the presentation of a plethora of limbs may indicate simultaneous presentation of twins, fetal abnormalities such as schistosoma reflexa or limb duplication, or a ventrotransverse or vertical presentation.

It may be worthwhile trying to assess the viability of the fetus, inasmuch as this can influence the options for management of the case. For cattle, however, it should be noted that, with increasing herd sizes and the associated improvements of the skills and knowledge of farm staff, it is increasingly unusual for the calf to be alive at the time when obstetrical assistance is requested. Viability can be assessed by attempting to elicit reflexes such as corneal/palpebral, suck, anal (if in posterior presentation), and limb withdrawal. Palpation for the presence of a pulse in the umbilicus may be feasible when the fetus is in posterior longitudinal presentation.

In the neglected or protracted case, assessment of the exact nature of the dystocia and methods of correction may be more difficult. The vaginal wall becomes progressively more oedematous, so that even the insertion of a hand and arm becomes difficult, and there is no room in which to carry out manipulations. Loss of fluid results in the dam's mucous membranes and fetal parts becoming dry. Contraction of the uterus directly on the irregular contour of the fetus makes retropulsion difficult or even impossible. In general, these cases have to be managed by relaxing the uterine muscle with a spasmolytic, such as clenbuterol, and/or by infusing replacement fluids into the uterus, and always by the use of large quantities of obstetrical lubricant. In such cases, it may be necessary to estimate the time interval since the fetus died. Fetal emphysema and detachment of hair means that the fetus has been dead for at least 24 to 48 hours. If there is no emphysema and the cornea is cloudy and grey, then it will have been dead for 6 to 12 hours.

Dog and Cat

The bitch, unless an exceptionally large one, should be placed standing on a table. It is preferable that a person with whom the animal is familiar should hold its head and be warned that even some quiet stoical bitches may resent a vaginal examination. Fetal numbers may be assessed in some bitches by gentle abdominal palpation or, more commonly, by the use of transabdominal ultrasonography. Ultrasonography has the added advantage of being able to determine whether the pups are alive by identifying the beating fetal heart. At a later stage in the examination, it might also be necessary to take radiographs.

As a general rule, the operator will proceed to make a digital examination *per vaginam,* especially in early cases in which it is likely that obstruction is the cause of the delay and also in protracted ones in which it is estimated that a single fetus only remains unborn. Nevertheless, cases will be met in which it is obvious that inertia has supervened, and there are several fetuses to be delivered, in which case immediate Caesarean surgery or hysterectomy is indicated.

Whether or not the hair is clipped from the area around the vulva before making a vaginal examination will depend on the length of the coat. In long-coated animals, it is a great convenience to do so; although it is impossible to render the area sterile, it should be thoroughly cleansed beforehand.

Sometimes on raising the tail it is seen that part of a fetus, a head or hind parts, is protruding from the vulva. Such a finding is more common in the cat than the bitch. The case is a simple one; traction on the exposed parts effects delivery without difficulty and, provided this assistance has been forthcoming early, it is probable that parturition will proceed normally. Occasionally, it is found that the vagina is occupied by a fetal head or buttocks which have become impacted. In the majority, however, the pelvic canal is unoccupied and obstruction occurs at the inlet.

The fetal disposition should then be determined. If the head is present, but the occiput and ears are palpated rather than the mouth, it is likely to be a case of vertex presentation. If a single limb is felt, but there is no sign of the head, the case is probably one of lateral deviation of the head. If the presentation is posterior, the tail may be recognized (although sometimes it is directed forwards over the fetal back). The hindlimbs may have entered the pelvis or they may be retained (flexed). The fetus may have rotated into ventral or lateral position.

Determination of fetal viability by attempting to elicit reflexes is unreliable.

Obstetrical Equipment

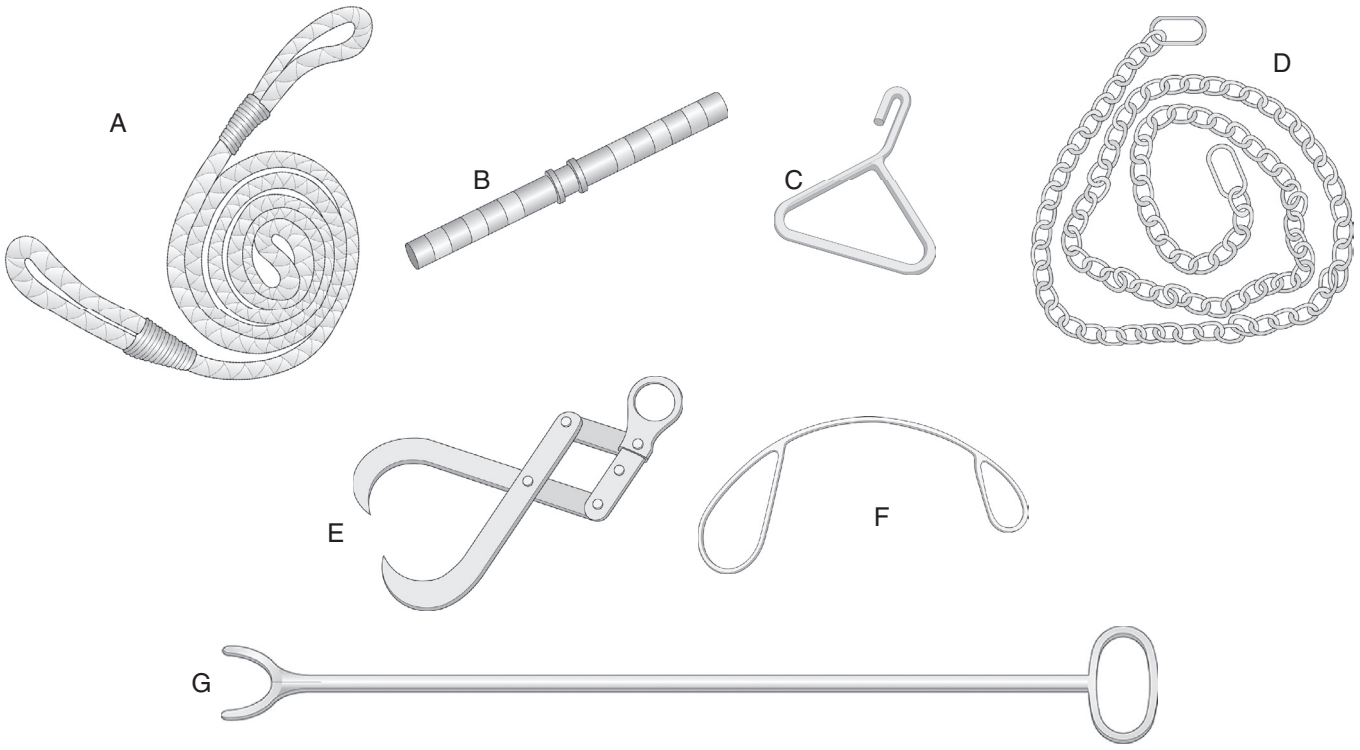
Manipulative Deliveries *per vaginam* in Large Animals

The most important obstetrical instruments are the clean and gentle hands and arms of the obstetrician.

There is, however, an array of equipment that can be used to assist in obstetrical procedures; arguably, the obstetrician should aim to possess a minimum of essential equipment and to be thoroughly conversant with the use of each item. For the veterinarian doing ambulatory visits to farms, studs, and other livestock units where parturient animals are kept, it is advisable to have a dedicated collection of **core obstetrical instruments** and other equipment that is always available in an emergency; in addition, a dedicated **Caesarean surgery kit** is also important (see Chapter 16 and, when working with cattle, a **fetotomy kit** (Chapter 15) should be carried.

Simple instruments that are easy to handle and convenient to sterilize are best. More complex equipment is occasionally required, and the important consideration is to know when the use of such complicated instruments is indicated. With the availability of better sedatives and anaesthetic agents and improved methods for fetotomy and Caesarean surgery, many of the long-established items of obstetrical instrumentation have become obsolete, and veterinarians have lost the skills to use them effectively. Despite this, many of

VetBooks.ir



• **Fig. 11.6** Essential obstetrical equipment for use in cattle and horses. (A) Obstetrical snares made of cotton rope, nylon, or webbing. The snares have loops in both ends. (F) Snare introducer for use with cord or chain snares. (G) Kühn's obstetrical crutch.

them can be very helpful at times and, for completeness, some of the more useful ones in cattle, and to a very much lesser extent in horses, are shown in Fig. 11.6. The most essential instruments are:

Obstetrical Snares

- Obstetrical snares are essential. Snares can be cord or chains.
- **Cord snares** are ~1 m lengths, with loops, of cotton rope (clothes line), nylon cord, or webbing (see Fig. 11.6A) (a finer cord for snaring the mandible is essential) and traction bars (see Fig. 11.6B). If cord snares are used, it is advisable to have at least two sets; they can be sterilized between uses.
- An alternative to snares that many veterinarians prefer to use is Moore's **obstetrical chains** (see Fig. 11.6D) with handles (see Fig. 11.6C). Many veterinarians find these easier to use than rope snares. Their main advantage is that they are heavier and do not move so readily when they are repositioned during intrauterine or intravaginal manipulation. It is also easier to clean them after use than cord snares.
- A **snare introducer** (see Fig. 11.6F) is also valuable for placing snares in tight spaces. It can be used with ropes as well as chains. A bull ring is an effective substitute

Traction

- A means of applying traction is also essential. Traction may be applied using a block and tackle or a calving aid such as an HK calf puller or Vink calving jack (Fig. 11.7).

Additional Equipment

- **Obstetrical hooks and crutches**. The main use of these is in fetotomy, and their use is described more fully in Chapter 14. Of these, probably the most useful is the Krey double-jointed hooks (see Fig. 11.6D). Less widely used are Obermeyer's anal hook, Harms's sharp or blunt paired hooks on a fine chain, and Blanchard's long, flexible cane hook. These are useful when performing fetotomy to enable traction to be applied to various fetal segments. Kühn's obstetrical crutch (see Fig. 11.6G) can also be useful for repelling the fetus in a tight space.
- **Detorsion rods and bar** are valuable aids to managing uterine torsion in the cow, and many veterinarians in cattle practice choose to have these as a part of their core kit.

Equipment for manipulative delivery of small animal fetuses is described in Chapter 18.

Specialised Equipment

Fetotomy is arguably the best alternative to the Caesarean surgery for delivering a dead, decaying, or emphysematous calf, so carrying a fetotomy kit is recommended. The kit includes a wire saw fetotome, cutting wire, handles and wire cutters, a fetotome threader, an introducer for positioning the cutting wire, and a set of Krey's hooks.

General Equipment

A general kit should be readily at hand alongside the obstetrical equipment. This consists of the following:

- Casting rope, halter, a 'general purpose' rope
- Buckets for washing water, antiseptic detergent
- A source of light (e.g., powerful torch and spare batteries)
- Core drugs: antibiotic, oxytocin, clenbuterol, local anaesthetic, analgesic (i.e., NSAID), injectable calcium (for cattle), sedatives; plus needles and syringes that are appropriate for the drug and its route of administration

Consideration of Treatment

General

The ideal outcome for any obstetrical procedure is the delivery of live and viable young without compromising the health or future fertility of the dam. When both fetus and dam are alive at the start of the procedure, this is indeed the primary measure of success. Nonetheless, there are situations in which the fetus is not viable or is dead at the start of the procedure. There are also situations in which the fetus is not viable, but the way in which that fetus is delivered will have a significant effect upon whether or not the dam survives (and/or is healthy and fertile). Finally, there are occasions when neither the fetus nor the dam are viable, in which case euthanasia may be the most humane and most cost effective way of resolving the situation. Hence a cascade of decisions has to be made (Fig. 11.8). If neither dam nor fetus will survive, euthanasia is appropriate. If the dam may survive, but the fetus will not, a decision regarding the most appropriate obstetrical method to extract the fetus while minimizing the risk to the dam has to be made. Rarely, the fetus may be viable but the dam not, in which case euthanasia of the dam/post mortem Caesarean may be a way of salvaging the fetus. Finally, if both dam and fetus are viable, different decisions have to be made about the best way of separating them.

No less important than this decision process is an assessment of the duration of the dystocia and the attempts that have been made to deliver the fetus. For example, a carpal flexion is a very simple dystocia to correct if the case is presented soon after the onset of second stage labour. If the dystocia has been neglected for a significant period of time, the fetal fluids will have been lost, the uterus may be contracting down on the fetus, and the fetus may be severely impacted in the birth canal. In such circumstances, manipulative correction of even such a simple faulty posture may not be feasible. If the dystocia has been neglected for even longer, the

VetBooks.ir

fetus may have started to decompose and become emphysematous, so that vaginal delivery of the intact fetus is no longer possible.

In cattle the duration and degree of traction to which the cow has been subjected is a major determinant of the outcome of subsequent Caesarean surgery. Similarly, in horses the duration of dystocia and the degree of trauma to the uterus significantly affect the outcome of subsequent interventions. However, with the advent of new and safer anaesthetic agents, Caesarean surgery should not be considered as 'the last resort' but as an effective method of treatment when used appropriately. Moreover, fetotomy should not be disregarded as a method of treating dystocia: in cattle, it probably remains the treatment of choice for grossly neglected cases in which the calf is decomposing and emphysematous or if the uterus is grossly contaminated.

Taken together, therefore, there should be an early commitment in the management of an obstetrical case as to whether it should be managed by manipulation plus or minus traction, by fetotomy, or by Caesarean surgery. As a general rule, failure to make progress by manipulation and/or traction within a reasonable period of time means that the original decision about the management of the case should be review, and the decision to proceed to an alternative method (Caesarean, fetotomy) should be made before either the veterinarian or patient become exhausted. The adverse consequence of traction that is either excessive in force or duration (such as laceration and contusion of maternal soft tissues, perineal laceration, rectovaginal fistula, pelvic nerve damage, hindlimb paralysis, or sacroiliac dislocation) are so well-known that there is no merit in persisting with traction beyond a point when it has ceased to result in progress towards the delivery of the fetus.

Of course, veterinarians will sometimes be pressurized by owners into performing Caesarean surgery when it is not necessary, particularly in cows with muscular hypertrophic calves or brachycephalic/achondroplastic bitches, purely because owners want to ensure the birth of live offspring. Likewise, owners will sometimes request the use of severe and prolonged traction rather than pay for the cost of Caesarean surgery. An ethical dilemma can then ensue as the veterinarian tries to balance the welfare of the patient with the expectations of its owner.

Horse

The first consideration is whether attempts at correction should be made with the animal standing or recumbent, or restrained and sedated, or under caudal epidural or general anaesthesia. The decision will be influenced in part by the size and temperament of the mare, by the type of dystocia, by the personnel to assist with the delivery, and by the accessibility of faculties for general anaesthesia and surgery (Miller 2010). Not infrequently, the operator begins manipulative correction with the mare unsedated and standing but soon realizes that, for success, restraint and/or sedation will be required. It is important in such cases that this decision be made early so that neither obstetrician nor mare becomes exhausted as the result of prolonged, futile efforts. In all severe cases the operator should consider the advisability of seeking the assistance of a colleague, for it is always possible that the combined efforts of two will succeed where those of one alone fail.

Relatively simple abnormalities, such as carpal flexion or lateral or downwards deviation of the head, can often be corrected using the hand alone, particularly when the mare is comparatively small and straining has been eliminated. However, it must be remembered that the limbs of the thoroughbred newborn foal are very long (70% of their adult length), which requires a substantial amount of space to facilitate flexion and extension. When, however, one of the more difficult forms is present, such as transverse presentation, ventral position, or impaction of the fetus in the pelvis, or when there is laceration of the vagina or vulva, it is generally best to anaesthetize the animal at the outset, particularly in a hospital environment. One of the advantages of general anaesthesia is that by changing the position of the mare – for example, so that she is in dorsal or lateral recumbency or even suspended by her hindlimbs (the anaesthetists will not be very enthusiastic about this approach because of pressure on the diaphragm!) – the change in the pressures on the fetus within the uterus can be utilised to facilitate correction. Whenever fetotomy is required, both sedation and caudal epidural anaesthesia should be used. In veterinary hospitals, general anaesthesia is preferable because the foal is almost always already dead and will not be affected by transplacental transfer of anaesthetic agents.

The value of partial fetotomy as a treatment of equine dystocia in which the fetus is dead or deformed has long been recognized. Vandeplassche (1980) considered partial fetotomy to be the method of choice for rapid, safe correction of dystocia that cannot be resolved by manipulation. However, Frazer (2001) noted that fetotomy should be avoided when the reproductive tract of the mare is already traumatized by failed attempts at manual correction. Carluccio et al. (2007) described that deliveries could commonly be made with just two cuts. The indications for partial fetotomy are shown in Table 11.1. Sequelae of fetotomy have remained surprisingly consistent over many years: the survival rate is between 85% and 90%, around 25% to 35% of mares have retained fetal membranes and/or postpartum endometritis, and fertility in the first season after fetotomy is around 30% to 40% (Vandeplassche 1980, Ras et al. 2014).

With improved methods of general anaesthesia and aseptic surgery, Caesarean surgery has a definite place in equine obstetrics, particular indications being maternal dystocia due to bicornual gestation, uterine torsion, and narrow or deformed pelvis, as well as those cases of fetal dystocia in which there is oversize or faulty fetal disposition combined with maternal injury or when the uterus has contracted on to a dead, emphysematous foal. In the series of Caesarean cases reported by Abernathy-Young et al. (2012), 75% were due to dystocia, with most of the remainder due to concurrent maternal disease (i.e., colic) that compromised the fetus. Interestingly, 16% of the Caesarean were performed after a failure of partial fetotomy. Survival rates have not changed much over the years, however: Vandeplassche (1980) recorded 81% survival whereas the figure achieved by Abernathy-Young et al. (2012) was 84%. Hodder et al. (2012) noted that survival of emergency Caesareans was lower than that for elective surgery (75% vs 100%). Foal survival is poor for emergency Caesareans, as most foals were dead or severely compromised before the onset of surgery.

Cattle

The most common cause of dystocia in cattle is fetomaternal disproportion, with faulty disposition of the fetus being the next most common in both beef and dairy cattle (Meijering 1984, Citek et al. 2011). In principle, these dystocias can be delivered by correction of the fetal disposition or delivery by traction. However, the most important factor in determining the course of action in

VetBooks.ir

TABLE 11.1 Prevalence of different forms of dystocia in mares undergoing fetotomy

Cause of Dystocia	Vandeplassche	Carluccio	Total	(%)
Anterior presentation: lateral or ventral deviation of the head	72	31	103	(50.5%)
Anterior presentation: hydrocephalus or two heads	6	1	7	(3.4%)
Anterior presentation: flexion, deformity, or ankylosis of forelegs	12	18	30	(14.7%)
Breech presentation with ankylosis	17	5	22	(10.8%)
Posterior presentation, hock flexion		8	8	(3.9%)
Transverse presentation	25	5	30	(14.7%)
'Dog-sitting' position		1	1	(0.5%)
Others		3	3	(1.5%)
Total	132	72	204	

Derived from Vandeplassche (1972, 1980) and Carluccio et al. (2007).

bovine dystocias is not (usually) the cause of the dystocia, but the interval that has elapsed between its onset and the presentation of the case for examination.

In neglected or protracted cases, there is often severe impaction of parts of the fetus in the pelvis; the greater part of the fetal fluids has often been lost, and there is insufficient space to repel the fetus; the fetal skin and the vaginal mucosa have lost their natural lubrication, whereas the vagina and vulva are often swollen, and manipulation is rendered difficult. Correction of the dystocia, whether due to faulty disposition or fetomaternal disproportion, in such cases may prove very difficult and may necessitate an early decision to undertake fetotomy or Caesarean surgery in preference to attempting vaginal delivery.

Fetomaternal disproportion is more common in heifers than in multigravida cows (Zaborski et al. 2009). Traction is the first method of delivery that should be attempted in most cases of fetomaternal disproportion. Before traction is applied, the vagina and those parts of the fetus occupying it must be thoroughly lubricated with copious application of several litres of a proprietary cellulose-based obstetrical lubricant. In cases in which the fetal disposition is normal and the disproportion is slight, it is a comparatively simple matter to apply snares to the fetal extremities (i.e., the limbs and head) and, adhering to the principles described in Chapter 14, the fetus is delivered by traction. As a rule, the animal remains standing during the application of snares but often goes down during the passage of the calf's head through the vulva. More severe disproportion requires more careful assessment and, as described previously, an early decision to use an alternative to traction when this is unlikely to be successful. Traction, however, must be employed with care because excessive traction can not only cause damage to the dam, but can also cause the fetus to become so tightly impacted in the birth canal that its subsequent delivery by Caesarean surgery or fetotomy can become difficult or impossible. Hence the amount of traction must be limited to that of three persons or a calving aid and the progress of the operation must be very closely scrutinized by the veterinarian. If no progress is made after 5 minutes or if the fetus becomes lodged and fails to yield to 5 minutes of further traction, then partial or total fetotomy or Caesarean surgery should be performed (Chapters 15 and 16).

Faulty fetal disposition is more common in parous cows than in primigravida. When faulty disposition is the cause of the dystocia, an assessment needs to be made of the measures that will be needed to correct it. Sometimes the space required for correction is lost due to the effects of continual straining or the contracted uterus. If so, one or all of caudal epidural anaesthesia, clenbuterol, and/or infusion of replacement fetal fluids should be given without delay. Occasionally, inducing epidural anaesthesia will allow an animal that has become recumbent to rise, which makes any manipulative procedures easier because the veterinarian can stand and the intraabdominal pressure is reduced.

Management of dystocia due to fetal 'monsters' again requires an early assessment of the best means of delivering the calf. Many 'fetal monsters' cannot be delivered intact *per vaginam* and will require either fetotomy (usually) or Caesarean surgery (sometimes). It should, however, be noted that for fetal monsters for which Caesarean surgery is the method of choice (e.g., schistosoma reflexus in which the head and limbs are directed towards the pelvic inlet), fetotomy is contraindicated.

Sheep and Goat

The ability of a veterinarian to resolve dystocia in the ewe or doe largely depends on the operator's ability to pass a hand through the pelvis into the uterus. Primigravid animals of the smaller breeds sometimes foil attempts of even the smallest hand to traverse their birth canal, making delivery by Caesarean surgery the best option for success.

Cases of fetomaternal disproportion are relatively uncommon, except in ewes carrying a singleton fetus. Most cases have normal fetal disposition, so once the head has been repelled from the pelvic inlet, gentle traction upon the limbs effects delivery. Use of a lambing snare (Fig. 11.9) to control the direction of the head is often helpful in cases of fetomaternal disproportion. When there is malposture of the limbs or head, repositioning after retropulsion is, as a rule, relatively easy. Retropulsion, replacement of lost fetal fluids, and correction of a faulty disposition are made much easier by, first, giving causal epidural anaesthesia and, second, elevating the hindquarters of the ewe. This can be done by rolling her on to her back and having an assistant pull both hind legs upwards and

VetBooks.ir

• **Fig. 11.9** Lambing snare.

forwards. It is especially important to ensure that the presented parts all belong to the same fetus. The young, in cases of twins and triplets, are small and retropulsion and reposition are seldom difficult. Gentleness is critical in handling dystocias of the ewe and doe, as it extremely easy to damage the birth canal, pelvis or obturator nerve. Likewise, great care must be taken during intravaginal manipulations that the mucous membrane at the pelvic inlet is not lacerated. It is an accident that may occur quite simply, particularly when a finger is being used to lever a head or limb upwards. Such lacerations are usually followed by infection and possibly death.

In most cases in which manipulation and delivery *per vaginam* is not possible, delivery by Caesarean surgery is usually the best option.

Pig

In the sow, the ease with which obstructive dystocia can be relieved depends almost entirely on the operator's ability to pass a hand through the pelvic inlet. Provided this is possible, it is usually a relatively easy matter to grip the head or hind parts and withdraw the fetus. In small gilts and in sows of breeds such as the Vietnamese pot-bellied breed, the use of a lambing snare (see Fig. 11.9) may be useful to apply traction to the head. The disposition of the limbs is seldom of much consequence. When assistance is given early in the dystocia (i.e., within an hour or two of the onset of second stage labour), removal of the obstructing fetus is often followed by the normal expulsion of the remainder. Assistance in the sow is frequently delayed, however; in these cases the obstetrician will be well advised to remove as many piglets from the uterine body and cornua as are within reach. The subsequent course will depend chiefly on the measure of delay and thus the degree of inertia which has supervened. It may be found in an hour or so that normal expulsion has recommenced or that on further examination more fetuses are accessible to manual extraction, and by continued attention to the sow in this manner the whole litter can be removed. It is worth remembering that intravaginal and intrauterine manipulations will stimulate the release of endogenous oxytocin and thus stimulate myometrial contractions. Quite often, however, complete inertia has developed and no further progress follows the removal of the accessible fetuses. In these, Caesarean surgery is the only means of saving the sow.

The strategic use of oxytocin to induce myometrial contractions can be used to treat overt cases of dystocia and also to hasten the expulsion of piglets if there is an extended time interval before the arrival of the next, thus preventing stillbirth. It is important to give low doses of oxytocin because it is a potent ecbolic, and large dose rates will cause spasm of the myometrium rather than rhythmical peristaltic-like contractions. In addition, the myometrium will become refractory to its effect, and it may be necessary to increase the dose rate in order to obtain a response. The dose of oxytocin is therefore critical to its successful use in farrowing. Mota-Rojas et al. (2006) noted that too high of a dose (or too rapid elevation of blood concentrations, particularly by IV administration) was associated with higher rates of fetal asphyxia/fetal distress, but that a low dose of oxytocin (0.083 IU/kg) gave a useful acceleration of parturition without causing fetal distress (Mota-Rojas et al. (2005) and improved survival of piglets experiencing dystocia (González-Lozano et al. 2009). Jackson (1996) observed that the greatest problem in porcine obstetrics was to know when a parturient sow had expelled all her piglets. Good, but not infallible, indications of the end of labour are that the sow rises, passes a large volume of urine, and then resumes recumbency in an attitude of contentment.

When it is suspected that parturition is incomplete, the clinician should pass a hand as far as possible into the uterus and sweep it gently about the abdomen in the hope of balloting indirectly a piglet in an adjacent segment of the long uterine horn. Transabdominal ultrasonography can potentially be used to locate a retained fetus (see Chapter 17). The presence of retained fetal membranes is even more difficult to determine. When the clinical manifestations suggest that a fetus (or fetuses) is still retained and there has been no response to the administration of ecbolics, the only approach would be an exploratory laparotomy. Sows and gilts will often survive the presence of retained piglets, which sometimes become mummified (see Chapter 17). Because they are occasionally seen in the uteri of culled sows and gilts at the abattoir, it is likely that, although the mothers survived, they were infertile.

Dog and Cat

The primary consideration in the management of a case of dystocia in the bitch or queen is whether one should attempt delivery *per vaginam* or immediately resort to Caesarean surgery. Factors that will influence the decision are:

- The cause of dystocia, whether obstruction or primary inertia;
- The duration of second stage labour and hence the condition of the fetuses and the uterine muscle; and
- The number of fetuses retained and their viability.

When the case is recent (i.e., a few hours only), attempting vaginal delivery may be appropriate. A modest degree of fetomaternal disproportion with the fetus in anterior or posterior presentation may be resolved by traction using the fingers only (see Figs 18.1 and 18.4), or finger and vectis, or forceps (these should be used with great care to prevent trauma to both dam and offspring); this traction will succeed in effecting delivery, and parturition will then proceed normally. Similarly, in cases of faulty fetal disposition, such as vertex posture or breech, traction may succeed after correction of the abnormal posture.

Increasingly commonly, however, the decision is likely to proceed directly to Caesarean surgery. Certainly, in cases of gross fetomaternal disproportion (which is very common with litters of

VetBooks.ir

one or two) or in cases in which the dystocia is of more than a few hours duration, Caesarean surgery is indicated. The obstetrical justification for this decision is that it is very likely that secondary inertia has supervened and removal of the obstructed fetus will not alter the ultimate outcome. This decision is often, however, subordinate to an economic justification: Caesarean surgery is used to minimize the risk of death of the dam and litter of pups or kittens – both of which may be valuable. The question sometimes arises of whether one should first attempt to remove the presented fetus *per vaginam* before performing surgery. It is highly likely that this fetus is contaminated, and withdrawing it through an abdominal wound may predispose to development of peritonitis. There is also, of course, the possibility that forceps interference will subject the bitch or queen to greater risk. Many veterinarians are of the view that the risk to the dam and the rest of the litter is minimized if the presented fetus is removed during the Caesarean surgery unless there is a very clear indication indeed for its removal *per vaginam.*

The length of time for which the fetus will remain alive after the onset of second stage labour also has to be considered. It is very improbable that the presented fetus will live longer than 6 to 8 hours, for by that time its placenta will have completely separated. The remaining fetuses, however, may be alive for much longer periods. Thus it is possible that after 36 hours' delay, the presented fetus may be dead with early signs of emphysema, yet those occupying the anterior parts of the cornua may be alive. After a delay of 48 hours, this is highly unlikely to occur.

Hysterectomy may be chosen as an alternative to Caesarean surgery (see Chapter 19). Robbins and Mullen (1994) showed that newborn survival rates of 75% for dogs and 42% for cats are comparable to the outcomes of Caesarean surgery to treat dystocia.

Prevalence, Causes and Consequences of Dystocia

TIMOTHY J. PARKINSON, JOS J. VERMUNT AND DAVID E. NOAKES

Introduction

The diagnosis and treatment of dystocia requires a good understanding of normal parturition, sensitivity to the welfare of both dam and offspring, and good practical competences.

Developing an adequate definition of dystocia that can be applied to scientific study of the causes, efficacy of treatment, and consequences of dystocia has not proved to be an easy task. Although a simple binary classification into 'dystocia' (i.e., a difficult birth) and 'eutocia' (i.e., a normal birth) may seem straightforward, the diagnosis of dystocia is actually highly subjective, inasmuch as situations that one person will consider to be normal will be considered as difficult by another. Attempts have been made to increase the objectivity of the diagnosis of dystocia by, for example, at one end of the spectrum creating a hierarchical classification of dystocia according to the level of intervention that is required (Dematawewa & Berger 1997) or, at the other, through a binary classification into 'assisted' or 'not assisted' births (Morton 2000).

In principle, dystocia occurs when there is a failure of either the expulsive forces or the adequacy of the birth canal, or the disposition of the fetus. These failures relate, ultimately, to genetic factors derived from the sire and dam and management factors relating to the dam during and before pregnancy. Taking this concept further, Mee et al. (2011) identified proximal ('immediate'), intermediate, and ultimate causes of bovine dystocia. Proximal causes are those problems that one identifies at the time of an obstetrical intervention – such as fetomaternal disproportion, fetal maldisposition, uterine inertia, or uterine torsion (Fig. 12.1). In the example of fetomaternal disproportion, intermediate causes are calf birth weight and maternal pelvic size. The ultimate causes for these intermediate factors include the gender and breed of sire of the calf, as well as the parity, weight, age, and condition score of the dam. In fact, fetomaternal disproportion very nicely illustrates the interplay of factors that cause dystocia, as it is neither strictly fetal in origin nor is it strictly maternal. Sometimes it is indeed due to an absolute 'oversize' of the fetus, but it can equally be due to an absolute 'undersize' of the birth canal or pelvis of the dam, or, in most cases, the fetus is relatively too large and the dam relatively too small so these two are disproportioned to each other. Regardless, the condition represents a complex interplay between sire, dam, and environmental factors that can need to be carefully teased apart to understand the ultimate cause of the dystocia. Only when the ultimate causes have been identified can effective preventative measures be instituted.

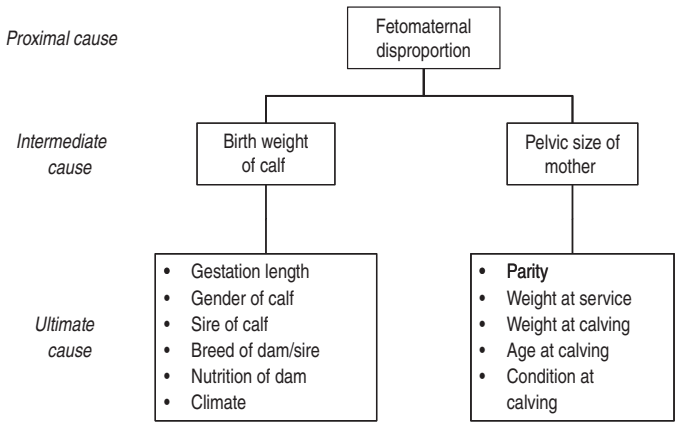
Prevalence

Cattle

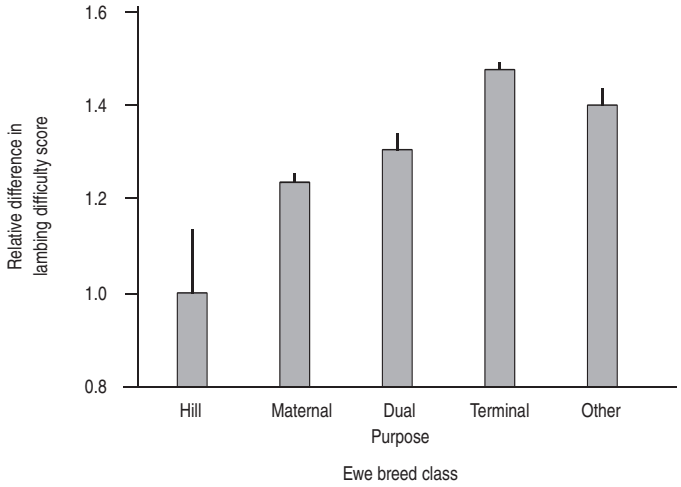
Obtaining a generalised figure for the prevalence of dystocia is beset by the difficulties of classification of the severity of dystocia that have been mentioned. Adopting the convention that a 'hard pull', surgery/fetotomy, or stillbirth is a 'dystocia', whereas lesser interventions are an 'assisted calving' (Lopez Helguera et al. 2016), an overall figure of 4% to 6% of births appears to be remarkably consistent across time, farming systems, and country. Thus Mee (2008) reviewed recent literature that showed the overall prevalence of dystocia in dairy cattle to range from 1–5% to 6.6%, although the proportion of calvings that were assisted was very much higher (varying between 10% and 50%) (Hansen et al. 2004, Heringstad et al. 2007). The risk of dystocia is consistently higher in primiparous than multiparous cows. Edwards (1979) found that dystocia was more common in heifers than multiparous cows, such that there were 66.5%, 23.1%, and 14.3% assisted deliveries in first, second, and third calvings respectively. Many subsequent studies have confirmed this trend (Sieber et al. 1989, McDermott et al. 1992, Mee et al. 2011). Citek et al. (2011) reported a prevalence of 4.1% across a range of beef breeds, and McDermott et al. (1992) reported that of the 8.7% of beef breed calvings that required assistance, only 3.4% were regarded as 'difficult'. Some breeds are more at risk of dystocia than others: large, or 'double muscled' beef breeds are at greater risk than other beef breeds. Among dairy breeds, the prevalence of dystocia in Holstein heifers is worryingly high, with figures of 17%, 21%, 22%, and 40% of all primiparous births requiring assistance (Meyer et al. 2001, Mee 2008, Mee et al. 2011). Lopez-Helguera et al. (2016) similarly recorded a figure of 40% Holstein–Friesian heifers requiring assistance, 9% of which were also classed as having dystocia.

Fetomaternal disproportion is the most common overall cause of dystocia in cattle, with a relative frequency of about 50% of all dystocias (3.5% of all births). It is much more common in primiparous than multiparous animals, whereas dystocia due to faulty disposition of the fetus is relatively more common in multiparous than primiparous animals (Meijering 1984). Some studies have attempted to provide separate prevalences for the 'maternal' and the 'fetal' components of fetomaternal disproportion. For example, Citek et al. (2011) reported that 53% of dystocias in beef cattle was due to fetomaternal disproportion, of which 24.5% was due to fetal oversize and 28.5% due to narrowness of the maternal pelvis.

VetBooks.ir



• **Fig. 12.1** Intermediate and ultimate causes of dystocia due to fetopelvic disproportion in dairy cattle. (Based upon Mee 2008.)



• **Fig. 12.2** Mean (SE) lambing difficulty score for ewe breed class relative to the hill ewe breed. (Derived from McHugh et al. 2016.)

Dystocia due to faulty disposition of the fetus is less common, variously estimated at 17% to 30% of dystocias (2%–4% of all births). Citek et al. (2011) estimated that faulty posture, position, and presentation accounted for 7.8%, 2.3%, and 8.2% of dystocias, respectively. Many of these dystocias due to 'faulty' disposition are, in fact, uncomplicated posterior presentations, which occur in about 5% of all births and which results in dystocia in up to 50% of such births. Departures from longitudinal presentation are uncommon because the anatomical arrangement of the uterine cornua and the absence of a distinct uterine body in the cow do not favour transverse presentation. Postural irregularities of the head and limbs are relatively common, particularly carpal flexion, lateral deviation of the head, and 'breech presentation'. Thus Holland et al. (1993), who recorded the prevalence of faulty disposition of the fetus over a 21-year period in Colorado, United States, found that abnormal disposition of the fetus occurred in 4% of calvings. Of these, 73% were uncomplicated posterior presentations, 8% were in breech position, and 1% was in posterior longitudinal presentation and ventral position. Of those in anterior presentation, 11% had unilateral carpal or shoulder flexion, 2% had incomplete extension of the elbow, and 2.5% had lateral deviation of the head. Transverse presentation and oblique ventrovertical presentation/position were present in 1.4% and 0.6% of cases, respectively.

Twin calvings, which occur in 2.5% of births, have about a 2.5 times greater risk of dystocia than do singleton births, although Correa et al. (1993) estimated that, in Holstein cows, the risk of dystocia in multiple births was 10 times higher than in singleton births. Simultaneous presentation of twins is a well-recognised cause of bovine dystocia, and one of the first duties of the obstetrician when proceeding to manipulative delivery is to ensure that the presenting limbs belong to the same fetus.

The prevalence of dystocia due to anatomical defects of the dam is relatively low: the prevalence of uterine torsion has been estimated at around 7% to 10% of dystocias requiring veterinary attention (0.25% of all births) and incomplete cervical dilation at around 2% to 5% of cases requiring veterinary attention (see Ben-David [1961], Meijering [1984], Colnar et al. [2008], Mee et al. [2011], Purohit et al. [2011], Lyons et al. [2013], Uematsu et al. [2013]). Uterine inertia, often associated with hypocalcaemia, is well known, particularly in pluriparous cows (>5 years of age).

The prevalence of fetal monsters is relatively high in the cow. They are generally of the distorted and celosomian types, schistosoma reflexus and perosomus elumbis being the most common (see Chapter 9). Knight (1996) reported a prevalence of 1.3% of the dystocias attended by veterinarians in Victoria, Australia, were due to schistosoma reflexus. Likewise, in a survey of calvings in Poland from 1970 to 1974, 13% of fetuses or newborn calves with developmental congenital abnormalities were also due to this abnormality (Cawlikowski 1993).

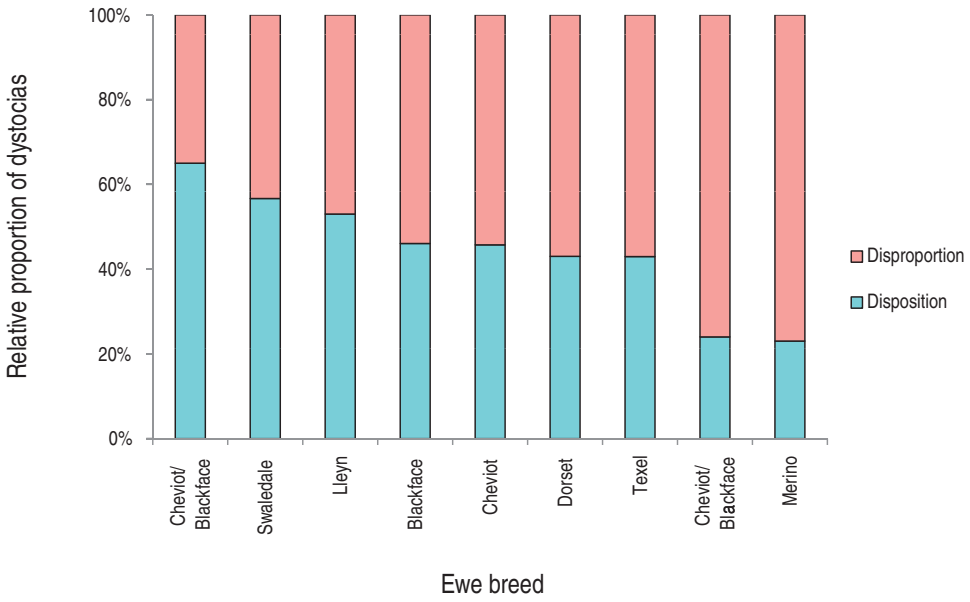
Sheep and Goats

Ewes. The prevalence of dystocia in sheep is influenced by breed, parity, and litter size. Estimates of prevalence vary greatly between breed, such that hill breeds tend to have lower dystocia scores than other breeds, particularly terminal breeds (Fig. 12.2). Among UK hill sheep, dystocia rates reported for the Scottish Blackface, Cheviots, and Welsh Mountain breeds vary between 1% and 6% (Gunn 1968, Whitelaw & Watchorn 1975, Woolliams et al. 1983, Speijers et al. 2010), whereas among the terminal breeds, rates of 34% (Dorset Horn), 31% (Suffolk), and 56% (Texel) have been reported (George 1976, Grommers 1977, Dwyer & Bunger 2012). It is, however, important to recognise that variation in the definition of dystocia between studies makes it exceedingly difficult to make comparisons between trials of absolute rates for dystocia in different breeds.

Fetomaternal disproportion and faulty disposition of the fetus are the two most common causes of dystocia in sheep (Fig. 12.3). Fetomaternal disproportion is related to particular breeds, and the risk for development of the condition is high when there is crossing of disparate breeds for commercial lamb production. Although lamb birth weight is an important contributor to fetomaternal disproportion, such that the risk of dystocia rises markedly >6 kg birth weight, *lamb mortality* increases when birth weight falls <3 to 4 kg (Refshauge et al. 2007, Speijers et al. 2010).

The relative risk of faulty fetal disposition as a cause of dystocia is higher in ewes than in cows but, although the relative proportions of disproportion *versus* faulty disposition varies among studies, this appears to be largely unrelated to breed. Maldisposition of the fetus is more common with multiple than singleton births (Gunn 1968). Pluriparous ewes are relatively more likely to experience dystocia due to faulty fetal disposition than are primiparous animals, and

VetBooks.ir



• **Fig. 12.3** Relative contribution of fetomaternal disproportion and faulty fetal disposition as causes of dystocia in ewes. (Data from Gunn 1968, Whitelaw & Watchorn 1975, George 1975, 1976, Speijers et al. 2010.)

primiparous ewes are more likely to experience dystocia due to disproportion than are pluriparous ewes. Grommers et al. (1985) noted that 5.7% of lambs were in posterior presentation – a figure that was remarkably similar to the 3.6% recorded by Wallace (1949) many years earlier. Difficult parturition occurred in nearly 65% of births in which the lamb was in posterior presentation (Grommers et al. 1985). In the study of Dwyer & Bunger (2012), nearly 20% of all malpresentations were of a posterior nature, but, of these, there were more lambs in breech position (11.6%) than in uncomplicated posterior presentation (9.6%). Overall, flexions of the forelimb (carpal, shoulder) are the most common type of malpresentation (46%–55% of all malpresentations; Grommers et al. (1985), Dwyer & Bunger (2012)), although noting that ewes with unilateral shoulder flexion can often lamb spontaneously. Grommers et al. (1985) noted that only 37% of such presentations were associated with dystocia. The prevalence of deviation of the head varies from 2% (Wallace 1949) to 6% (Dwyer & Bunger 2012). Dystocia due to congenital defects of the fetus ('fetal monsters') occurred in 2% of births in the study of Woolliams et al. (1983), with arthrogryposis accounting for 1% (i.e., half) of these defects.

The most important maternal cause of dystocia in ewes is nondilation of the cervix (ringwomb): studies reviewed by Purohit (2006) show that 25% to 50% of cases of dystocia in ewes are due to cervical nondilation. Such figures may, however, overrepresent the true prevalence of the condition inasmuch as such dystocias cannot be relieved without veterinary intervention. Consequently, studies from veterinary schools' clinics show incomplete cervical dilatation as a major cause of dystocia, whose prevalence ranges from 35% to 70% of cases of dystocia presented for veterinary assistance (Thomas 1990, Sobiraj 1994, Kloss et al. 2002). It is difficult to compare results from different studies, because there were differences in the criteria used to diagnose this disorder. However, there is an impression that incomplete dilatation of the cervix in sheep is more prevalent now than it was 30 or 40 years ago. Other maternal causes are relatively uncommon.

Does. The prevalence of dystocia in does is difficult to ascertain, as most published series are of relatively small numbers of animals. However, the prevalence is generally held to be relatively low: for example, Palanivel and Gajendran (2006) estimated it at 2.5%. Sobiraj (1994) noted that the main indication for manual assistance with kidding was abnormal fetal presentation, whereas the main indication for Caesarean surgery was fetomaternal disproportion. Cervical nondilation is a significant cause of dystocia in does: a study by Majeed and Taha (1989) found that cervical nondilation accounted for 25% of cases of dystocia, whereas Anusha et al. (2016) reported that it was the cause of 80% of maternal dystocia. Uterine torsion is generally considered to be relatively rare in the doe (Purohit 2006), although Philip et al. (1985) recorded it as the most common indication for Caesarean surgery in their series of cases. Faulty disposition of the fetus is the most common cause of fetal dystocia, accounting for between 60% (Purohit 2006) and 75% (Anusha et al. 2016) of such cases. In the study of Bhattacharyya et al. (2015), fetal dystocia (54%) was more common than maternal dystocia (37%). Head deviation, flexion of the forelimb, breech presentation, dog-sitting position, and fetal monstrosities were the common fetal causes, whereas cervical nondilation was the most common maternal cause.

Pig

Dystocia is generally considered to be less common in the pig than in monotocous animal species. Figures of 0.25%, 1% (Jones 1966, Jackson 1995), and 3% (Randall, 1972) have been reported in the literature. However, dystocia per se is of far less importance than is piglet survival through the perinatal period, so there is a limited focus upon dystocia as an entity.

In common with other polytocous species, maternal forms of dystocia are almost twice as common as fetal forms. Jackson (1972) reported that 37% of dystocias were caused by uterine inertia, 13% by obstruction of the birth canal, and 9% by downward deviation of the uterine horns, whereas 14.5% were caused by

VetBooks.ir

breech presentation, 10% by simultaneous presentation, 3.5% by downward deviation of the head, and 4% by fetal oversize. The incidence of fetal dystocia increases when the litter is small, because the size of the individual fetus tends to be relatively large and is therefore more prone to causing obstruction. Irregularities of limb posture and even uncomplicated posterior presentation often cause dystocia when the litter is small, whereas had the litter been large and its individuals small, these irregularities would not have interfered with normal expulsion. Monstrosities are not uncommon: they are generally of the double type, but schistosomes, perosomus, and hydrocephalic specimens also occur. Together, bladder flexion and vaginal prolapse were reported to be the third most common cause of maternal dystocia in a study in Germany (Schulz & Bostedt 1995), whereas hypocalcaemia should also be considered as a cause of uterine inertia (Framstad et al. 1989).

Horse

There are relatively few studies that provide reliable information on the prevalence and causes of dystocia in the mare, although the prevalence is generally regarded as being low. For example, Vandeplassche (1993) quoted 4% for Thoroughbreds and trotters, 10% in Belgian draft horses (a figure which is relatively high due to fetal muscular hypertrophy), and 8% in Shetland ponies (because of their relatively large skull). Sabbagh et al. (2014) found that normal foalings occurred in 91% (Ardennais) to 95% (Breton and Comtois) of heavy horse foalings, with 1% to 2% of foalings requiring veterinary assistance. McCue and Ferris (2012) found that unassisted delivery occurred in 87% and dystocia in 10% of Thoroughbred and Quarter Horse foalings. Ginther and Williams (1996) reported that the prevalence of dystocia in Quarter Horses, Standardbreds, Thoroughbreds, and Miniature Horses was 16%, 10.5%, 8.9%, and 19%, respectively. Similarly, Rosales et al. (2017) found a prevalence of 8.4% in Thoroughbred foalings. The prevalence of dystocia is higher in primiparous than in pluriparous mares, although mares that are older at their first parturition tend to have a lower risk of dystocia than those which are younger (Sabbagh et al. 2014).

It is widely accepted that the majority of cases of equine dystocia are of fetal origin, with abnormalities of presentation, position, and posture typically outweighing fetomaternal disproportion. Thus, Ginther and Williams (1996) found that malposition of the body accounted for 23% and malposture of the extremities for 41% of equine dystocias. Frazer et al. (1997) similarly found that 87% of equine dystocias referred to a veterinary hospital were due to abnormalities of presentation, position, or posture. Curiously, however, in a recent survey of Thoroughbred foalings in New Zealand, only 28% of cases were due to malposture of head or forelimbs, whereas 44% were considered to be due to relative fetal oversize (Rosales et al. 2017). The latter figure is unusually high, with other surveys suggesting that fetal oversize is the cause of dystocia in only 0.8% (McCue & Ferris 2012), 2% (Frazer et al. 1997), 5% (Vandeplassche 1993, Byron et al. 2002), or 10% (Leidl et al. 1993) of cases.

The presentation of the fetus in normal and abnormal foalings is shown in Table 12.1, based upon the summarisation by Vandeplassche (1993) of 170,000 foalings. The fetus was in anterior presentation in 99% of normal births and in posterior presentation in most other normal births. However, posterior and transverse presentations were significantly overrepresented in cases of dystocia. Dorsosacral positions are more common than dorsoilial, but dorsopubic presentations are relatively uncommon. Transverse presentations are more commonly ventral than dorsal and more common in heavy horses than in light animals (Frazer et al. 1997: Table 12.2). Transverse presentation of the foal across the uterine body (either dorso-transverse or ventro-transverse) is well known; the transverse bicornual pregnancy, another form of transverse disposition in which the extremities of the fetus occupy the uterine horns, is notorious and peculiar to the equine species but, fortunately, very rare.

All forms of postural irregularity occur in the mare. The head and neck may be displaced laterally or downwards between the forelegs. Such displacements may be further complicated by rotation of the cervical joints. The limbs are frequently presented abnormally; one, several, or all of the joints of the limbs may be flexed, and the irregularities are classified according to their clinical significance as carpal flexion, shoulder flexion, hock flexion, and hip flexion. Such abnormalities of position and posture account for a large proportion of equine dystocias: Vandeplassche (1987) found that 58% of dystocias in which the fetus was in anterior

TABLE 12.1 Influence of fetal presentation on dystocia in 170,000 foalings in the mare

Presentation	Normal Foalings: n (%)	Dystocia Cases: n (%)
Anterior	168,130 (98.9%)	408 (68%)
Posterior	1,700 (1.0%)	95 (16%)
Transverse	170 (0.1%)	98 (16%)

	Dorsosacral	73 (68%)	Dorsosacral	11 (55%)	Ventral	12 (86%)
	Dorsoilial	21 (29%)	Dorsoilial	8 (40%)	Dorsal	2 (14%)
	Dorsopubic	13 (12%)	Dorsopubic	1 (5%)		

From Frazer et al. (1997)

VetBooks.ir

presentation were associated with flexion of the neck; McCue and Ferris (2012) found that one or both forelimbs were flexed in 30% of dystocias and that the neck was flexed (laterally or ventrally) in 4% of dystocias; Frazer et al. (1997) reported that 56% of malpostures were due to lateral or ventral flexion of the neck and that 51% had flexion of forelimb joints (noting that some fetuses had more than one abnormality, so the total is >100%); and Ginther and Williams (1996) recorded that forelimb flexion accounted for 67% of malpostures, retention of the head 8%, and abnormalities of both head and forelimb(s) a further 17% of dystocias. Dystocia in which the fetus is in posterior presentation are as likely to be in breech or bilateral hock flexion posture as they are to be in an extended posture. Unilateral forelimb flexions appear less common than bilateral flexions, whereas unilateral hindlimb flexions are uncommon.

Dystocia due to fetomaternal disproportion is much less common than in cattle and is not normally the consequence of fetal oversize due to prolonged gestation. More cases of fetomaternal disproportion are due to a relatively small pelvis than an 'oversized' fetus, especially in younger, primiparous mares. Prolonged gestation in the mare is characteristically due to either placental or uterine insufficiency, resulting in a dysmature, rather than an overgrown, fetus (Frazer, 2011).

Maternal dystocia is generally less common than fetal: Leidl et al. (1993) found that 17% of dystocias were due to uterine torsion, 4% were due to incomplete dilatation of the birth canal, and 3% to ventral deflection of the uterus (these figures compare with 61% due to faulty fetal disposition). Vandeplassche et al. (1972) stated that uterine torsion accounts for 5% to 10% of severe cases of maternal dystocia, a figure that corresponds well with the 3% of cases among referred dystocias reported by both Frazer et al. (1997) and Karadjole et al. (2008). Gross fetal monstrosities are rare, but occasional developmental anomalies that cause dystocia are wryneck (fixed lateral deviation), hydrocephalus, and malformation of the fetal limbs. Wryneck is likely to occur with transverse bicornual pregnancy. Uterine rupture was present in 8% of the cases reviewed by Karadjole et al. (2008).

Dogs and Cats

Bitch

The literature provides relatively scanty details concerning the prevalence or causes of dystocia in the bitch. There are many reasons for this difficulty, not least because of the tendency for breeders to intervene (in some cases prematurely and unnecessarily) and their propensity to attempt the treatment of all but the most severe cases themselves. Also, there are great variations between breeds in the risks for dystocia, so data for prevalence and causes will therefore be greatly influenced by the population of animals in the study. Overall prevalence of canine dystocia has been estimated at 5% of all births (Linde-Forsberg 2005) and 2% of births in bitches in Sweden that had animal insurance (Bergstrom et al. 2006).

In the survey of Darvelid and Linde-Forsberg (1994), maternal causes were responsible for 75% of cases of dystocia and fetal causes for the remaining 25% (Table 12.3). Uterine inertia was by far the most important cause, accounting for 72% of cases. The authors separated uterine inertia into 'primary complete' inertia, in which the bitch failed to expel any pups (49%), and 'primary partial' inertia (23%), in which the bitch delivered at least one pup and then stopped before whelping was complete. Thus 'primary partial' inertia probably equates to 'secondary uterine inertia' of classic obstetrical parlance. Of the 15% of cases of faulty disposition of the fetus, 5% were due to transverse presentation, 4% were breech presentations, and 1% had neck flexion. In a survey of the causes of dystocia in India (Shwetha et al. 2014), the relative proportion of cases due to maternal (61%) and fetal (39%) causes were relatively similar, but the relative contributions to the causes of fetal dystocia differed: 24% of cases were due to abnormalities of head posture and 7% to abnormalities of hindlimb posture. Fetomaternal disproportion accounted for 5% of cases. Munnich and Kuchenmeister (2009) found a similar ratio between fetal (22%) and maternal (38%) causes, but also noted that both fetal and maternal factors existed in 35% of cases. Interestingly, in the latter study, human interference with labour contributed to dystocia in 43% of cases, and 2.5% of cases were due to iatrogenic uterine spasm due to oxytocin 'abuse'. When the effect of human interference is taken into consideration, uterine 'inertia' was again the predominant cause. Fetomaternal disproportion occurs as a result of a narrow birth canal or when fetal oversize is present (usually as a consequence of low/singleton litter size).

TABLE 12.3 Causes of dystocia in 182 bitches

Cause	No. of Cases (%)
Maternal	
Primary complete uterine inertia	89 (49%)
Primary partial uterine inertia	42 (23%)
Other maternal causes	6 (3%)
Total	137 (75%)
Fetal	
Faulty disposition	28 (15%)
Fetomaternal disproportion	12 (7%)
Fetal monster	3 (2%)
Fetal death	2 (1%)
Total	45 (25%)

From Darvelid & Linde-Forsberg (1994)

The effect of breed upon canine dystocia has been reported in several studies. Thus, for example, the Dachshund and Scottish Terrier are particularly prone to primary uterine inertia. The Corgi shows extreme variation in the size of its puppies and, hence fetomaternal disproportion may occur. The severe congenital deformities of achondroplasia and brachycephalism, which are the characteristics of some breeds, adversely affect the birth process. Achondroplasia results in a reduction in the dimension from the sacrum to the pubic bone and thus reduces the size of the pelvic canal. Brachycephalic breeds, particularly the Pug, together with the Sealyham and Scottish Terrier, are prone to obstructive dystocia due to the fetuses having comparatively large heads and the dams having narrow pelves. More recently, the Boxer has been identified as having an unusually high level of dystocia: Linde-Forsberg and Persson (2007) reported that dystocia occurred in 28% of Boxer whelpings. Dystocia was due to uterine inertia in 60% of cases, fetal malpresentation in 26%, and fetomaternal disproportion in 3%.

Large fetuses, causing fetomaternal disproportion, are commonly encountered in bitches gravid with only one or two pups.

VetBooks.ir

A primigravid bitch of the small breeds often has trouble expelling her first pup but, provided timely assistance is forthcoming, she usually expels the remainder of her litter normally. If, however, assistance is delayed, the onset of secondary inertia may make the outcome serious. Munnich and Kuchenmeister (2009) reported an interesting interaction between breed size and litter size, such that miniature and small breeds showed a high incidence of dystocia, but there was also a significant difference between the risks of dystocia in miniature breeds with litters of one to three puppies versus large breeds with more than eight puppies.

Abnormalities of position are common in both anterior and posterior presentation. Failure of the fetus to rotate before presentation results in its engaging in the pelvic inlet in a ventral or lateral position, thereby causing dystocia. Traverse presentation is rare and, when it occurs, the bitch generally has a bicornual gestation with a single fetus: this presentation is generally accompanied by uterine inertia. Irregularities of limb posture are generally of little importance provided the puppy is of normal size. In fact, many puppies are born with their fore- or hindlimbs flexed. However, when the fetus is relatively large, these postural deviations may be the factor that causes dystocia. Not infrequently, a dam that attempts to expel a fetus with its forelimbs retained partially succeeds in that the head is born, but the thorax with the limbs becomes obstructed in the maternal pelvic inlet. Similarly, a fetus may have its hind parts born while its distended thorax is obstructing. Irregularities of head posture are common, and vertex presentation (in which the occiput is the part that first enters the pelvis) and lateral deviation of the head are frequently encountered. An interesting feature of the latter abnormality is that it often involves the last puppy to be born. Fetal hydrocephalus and anasarca occasionally occur, but other forms of monster are rare. Gross umbilical hernia (schistosomus) is seen in the achondroplastic canine types, as well as in kittens, but it is seldom a cause of dystocia.

Queen

Estimates of the prevalence of dystocia in the cat are largely based upon data from pedigree cats or breeding catteries; very much less information exists on the prevalence in nonpurebred domestic shorthaired cats than in the purebred and pedigree populations. Within these limitations the overall prevalence of dystocia in the cat has been estimated to be 6% (2928 litters from 735 queens: Gunn-Moore & Thrusfield 1995) or 7% (256 cat breeders: Holst & Frossling 2009) of births resulting in delivery by Caesarean surgery. Sparkes et al. (2006) reported that veterinary assistance had been sought in 15% of births (1056 litters), of which 8% also required Caesarean surgery. Holst et al. (2017) used insurance records of purebred cats to identify a prevalence of 67 cases of dystocia per 10,000 'cat years at risk' (CYAR). Of the cats identified with dystocia in that study, 56% underwent Caesarean surgery; there was a case fatality rate of 2%. The same study noted that the risk of dystocia in nonpurebred cats was only 22 cases per 10,000 CYAR, but this low prevalence was attributed to the fact that domestic cats are 'generally not used for intentional breeding, leading to a comparatively low population at risk' (p44).

Maternal causes of dystocia are more common than fetal causes. In the study of Ekstrand and Linde-Forsberg (1994), maternal causes, chiefly uterine inertia, accounted for 67% of dystocias (Table 12.4). Fetomaternal disproportion and faulty disposition were the most common fetal causes. Posterior presentation, which occurs in 40% of kitten births, does not cause dystocia per se, but breech presentation does (Ekstrand & Linde-Forsberg 1994).

TABLE 12.4 Causes of dystocia in queens

Cause	No. of Cases (%)
Maternal	
Uterine inertia	94 (61%)
Fetomaternal disproportion due to narrow birth canal	8 (5%)
Other maternal causes	2 (1%)
Subtotal	104 (67%)
Fetal	
Faulty disposition	24 (16%)
Fetal congenital defects	12 (8%)
Fetomaternal disproportion due to fetal oversize	3 (2%)
Fetal death	7 (5%)
Subtotal	46 (30%)
Other causes	5 (3%)
Total	155

From Ekstrand & Linde-Forsberg (1994)

Head flexion is the most common faulty disposition associated with anterior presentation.

Various studies have examined the effect of breed upon dystocia. Sparkes et al. (2006) found no effect of breed upon the risk of delivery by Caesarean surgery. Conversely, Ekstrand and Linde-Forsberg (1994) found that, in a large colony of cats of mixed breeding, the frequency was 0.4%, whereas in litters of Devon Rex it was 18.2%. Pedigree litters were at a significantly higher risk than cats of mixed breeding (the odds ratio being 22.6). In the purebred populations studied by Holst et al. (2017), British Shorthair and Oriental queens had a higher risk of dystocia than other breeds (Fig. 12.4). Gunn-Moore and Thrusfield (1995) identified that dolichocephalic and brachycephalic types have a significantly higher level of dystocia than mesocephalic types. This has been attributed to the large, wide, flat-faced head of the Persian kitten (Wilkinson 1984).

Aetiology

Fetomaternal Disproportion in Cattle

The causes of bovine dystocia have been widely explored in the literature (McDermott et al. 1992; Table 12.5). Calf birth weight (an 'intermediate' cause according to the schema of Mee (2008)) is the key fetal factor in determining the probability of dystocia, whereas the key maternal intermediate causes are parity and size. Importantly, these factors appear to pertain widely across many immediate causes of dystocia; thus although their contribution to fetomaternal disproportion may be readily apparent, they also are the most strongly associated intermediate causes of dystocia due to fetal maldisposition.

Fetomaternal disproportion occurs due to a mismatch between the birth weight and conformation of the calf and the size and conformation of the dam. Factors which determine calf birth weight

Simmental	729	8.8	6.2

From McDermott et al. (1992)

TABLE 12.6 Factors affecting the risk of dystocia in Holstein cattle

Factor	Effect Upon Odds Ratio for Dystocia
Season	15% higher in winter than summer
Calf sex	25% higher in males than females
Parity	4.7 times higher in first than later parities
Calf birth weight	13% increase per kg increase in birth weight
Dam's pelvic area	11% decrease per dm^2 increase in pelvic area

From Johanson & Berger (2003)

and conformation include the breed and conformation of the sire, gestation length, sex of the calf, and single *versus* multiple pregnancy. *In vitro* production of calf embryos can result in a 'large calf syndrome' in a proportion of such fetuses. The primary maternal factor that determines the risk of fetomaternal disproportion is the parity of the dam. This is further related to the age, weight, and skeletal maturity at first calving. Pelvic conformation, particularly narrowness of the pelvic inlet and the length of the sacrum, as well as the presence of intrapelvic fat, affect both primiparous and multiparous cows. Plane of nutrition affects both dam and calf through all of the aforegoing, as well as directly.

Many studies show an increase in the risk of dystocia as birth weight increases, although calf birth weight is itself determined by the sex of the calf, the breed of its sire, its gestation length, and environmental factors, such as season and year (Table 12.6). However, the relationship is not entirely straightforward, for the relationship between calf birth weight and difficult calving differs markedly between primiparous and multiparous animals (Fig. 12.5),

VetBooks.ir

From Berger et al. (1992)

such that the threshold at which the effect of increasing birth weight causes a significant increase in the risk of dystocia is much lower in primiparous than multiparous animals (Eriksson et al. 2004). The relationship is also compounded by the effect of litter size, such that, even though the birth weight of twins and triplets is lower than that of singletons, the strong relationship between multiple births and dystocia is such as to negate the effect of the lower birth weight of the multiple calves. To complicate the issue further, birth weight of calves born to primiparous animals increases as the weight of the heifer increases, but the incidence of dystocia decreases (Moran 1997), largely due to an improvement in the ratio between the dimensions of the dam and those of the calf (Johanson & Berger 2003; Tables 12.6 and 12.7).

Calf Birth Weight

Calf birth weight is the single most important fetal factor affecting the risk of dystocia in heifers (Meijering 1984, Morrison et al. 1985, Johnson et al. 1988), such that the larger the calf, the greater the chance of a difficult calving (Table 12.8). Linear estimates have shown that each kilogram increase of birth weight increases the rate of dystocia by 1.6% (Laster et al. 1973) to 13% (Johanson & Berger 2003). However, other studies have shown a nonlinear relationship between birth weight and dystocia, with the incidence of dystocia increasing significantly after the birth weight reached a certain threshold (Meijering 1984, Rice 1994). The threshold is determined chiefly by the parity and breed of the dam, as shown in the study of Eriksson et al. (2004) (see Fig. 12.5). Figures for the threshold therefore vary from study to study (which also varies with the definition of dystocia that was used in the study), so figures vary widely from approximately 30 to approximately 50 kg birth weight.

The relationship between birth weight and risk of dystocia is further complicated by the fact that the fetus does not grow homogenously but that the whole period of fetal development is characterised by sequences of positive and negative allometric growth of different parts of the fetal body. For example, the distal

Based on Joubert & Hammond (1958)

parts of the fetal limbs achieve peak growth rate earlier in gestation than do the proximal parts. Likewise, fetal muscle growth and intermuscular fat deposition is maximal in late gestation (Johnson 1974). Moreover, the growth of the fetus follows an exponential growth curve, with the greatest absolute increase in body weight occurring in the last trimester (although the highest relative growth occurs in the first trimester (Hickson et al. 2006)). Growth occurs by hyperplasia (mainly in early pregnancy) and hypertrophy (increasingly as pregnancy advances). Thus fetal growth can be retarded and, possibly, birth weight reduced by underfeeding of the dam in early gestation, but fetal growth rate is largely unaffected by the rate of maternal weight gain (Hickson et al. 2006).

Calf birth weight is, according to the schema of Mee (2008) an 'intermediate' cause of dystocia that itself depends on its own causal factors. Some of the 'ultimate' causes of birth weight are discussed here.

Breed of Sire. The effect of breed of sire upon the birth weight of the calf has long been recognised. Classic studies showed that the breed of both sire and dam contribute to the birth weight. Thus, when a Friesian bull is crossed with a Jersey cow, the birth weight approximates to the mean birth weight of the two breeds; but when a Jersey bull is crossed with a Friesian cow, the birth weight of the calf more closely approximates to that of the dam (Hilder & Fohrman 1949). Similar effects occur in the more extreme cross between the South Devon and Dexter breeds (Joubert & Hammond 1958: Table 12.9).

There have been many subsequent surveys that have shown similar results. In beef cows Laster et al. (1973) showed that Angus and Hereford cows bred by Simmental, South Devon, Charolais, and Limousin bulls experienced significantly more dystocia (32%, 32%, 31%, and 31%, respectively) than those bred by Hereford, Angus, or Jersey bulls (16%, 10%, and 6%, respectively). In 1986 Cundiff et al. showed similar breeds as being most commonly associated with high birth weight and hence dystocia. These data, along with the associated effects of sire breed upon gestation length are shown in Table 12.10. The strength of the relationship between birth weight and dystocia had, by that time, become so well established, that selection programmes were introduced into many beef breeds to try to reduce birth weight while not adversely affecting postnatal growth rate. The results of these programmes were illustrated by Ahlberg et al. (2016), who showed that the larger beef breeds (calves sired by Simmental, Charolais, Limousin, Maine-Anjou bulls) had fewer calving difficulties than would have been expected from the situation 30 years previously.

The effect of dairy sire upon the birth weight of dairy calves depends on the breed and parity of the dam, such that calves sired

Based on Cundiff et al. (1986)

by Jersey bulls have low birth weights and a low proportion of assisted calvings, which is remarkably unaffected by parity, whereas calves sired by Holstein bulls have higher birth weights and a much higher proportion of assisted calvings, especially in first parity dams (Table 12.11). This well-recognised phenomenon is widely exploited among dairy farmers when choosing a sire (i.e., Jersey) to use for breeding maiden heifers to minimise the risk of dystocia at their first calving. Interestingly, the results of similar reciprocal cross experiments between Holsteins and Brown Swiss or Norwegian Red have also shown that these other breeds, and their crosses with Holsteins, had lower dystocia and/or stillbirth rates than did purebred Holsteins (Heins et al. 2006, Mee et al. 2011, Yao et al. 2014).

Finally, the effect of beef breed sires upon birth weight and dystocia of calves born to dairy cows has been extensively studied in the UK dairy herd (McGuirk et al. 1998b; Table 12.12). Again, the large breeds (Charolais, Limousin, Blonde d'Aquitaine, Simmental and Piedmontese) are associated with higher levels of dystocia, particularly in heifers, than are the smaller Angus and Hereford. The Belgian Blue presents an interesting case, however. The 'double muscling' of Belgian Blue calves is commonly associated with dystocia, particularly in purebred animals (Fiems et al. 2001). Conversely, McGuirk et al. (1998a) found that the prevalence of dystocia in dairy heifers and cows bred to Belgian Blues was only 1.6% and 3.1%, respectively. A recent study in Poland (Przysucha et al. 2013) also found that the prevalence of assisted calvings (10.3%) and very difficult calvings (3.2%) of Belgian Blue–Holstein calves was no different to that of difficult calvings in purebred Holstein cows.

• **Fig. 12.6** Interaction between calf sex: male ●, female △, and parity on the odds of an assisted calving. (Based upon Mee et al. 2011.)

Sex of Calf. Many studies have shown, irrespective of breed, that birth weights of male calves are greater than female calves. The study of Johanson et al. (2011), which showed a mean birth weight of 38.6 (SD 5.3) kg for female calves versus a mean of 41.7 (SD 5.7) for males, would be typical of such studies. This increase in weight results in an increase in the risk of dystocia in male calves: Johanson and Berger (2003) estimated that the odd of a dystocia is 25% greater for a male than a female calf (Table 12.6). The relationship between calf sex, parity and dystocia is shown in Fig. 12.6.

Length of Gestation. Gestation length does vary between breeds and between individual sires (dams) within breed (see Table 12.10 for examples). It also varies with the sex of the calf, such that male calves usually have a few days longer gestation than do female calves. Gestation length affects the risk of both dystocia and perinatal mortality/stillbirth directly and through its effects upon calf birth weight, but the two are not synonymous. Examples of the relationship between gestation length and calving difficulty for Holstein–Friesian calves are shown in Table 12.13.

The heritability of gestation length is relatively high: h^2 for direct selection has been variously estimated at between 0.2 (Nogalski & Piwczyński 2012), 0.5 (Johanson et al. 2011), and 0.6 (Mujibi & Crews 2014), with the h^2 for maternal selection being roughly an order of magnitude lower. The genetic correlations between gestation length, risk of stillbirth, calving ease, and calf birth weight are consistently reported as being high (McClintock et al. 2005, Jeyaruban et al. 2016), providing opportunity for genetic selection to improve on calving difficulty/stillbirth rate. Genetic effects upon maternal and fetal components of dystocia are discussed later in the chapter.

Season and Climate. Although many studies have investigated the influence of season of year and climatic factors on birth weights and the incidence of dystocia, there is a lot of disparity between results. For example, in the temperate climate of the UK, McGuirk et al. (1999) showed (Fig. 12.7) that calf size and calf conformation declined in autumn and early winter and that there was a relationship between the average calving difficulty score and gestation length. Similarly, Colburn et al. (1997) found that the mean spring birth weights of calves born after a warmer-than-normal winter were 4.5 kg lower than those after a cold winter; the corresponding levels of calving difficulty were 35% and 58%, respectively. The

% unassisted calvings	48.3	79.9	82.7	82.8	86

Based on Sieber et al. (1989)

reduction in gestation length and increased calving difficulty were slightly out of phase with and preceded increase in calf size. In a more extreme winter climate Ugurlu et al. (2014) found that calf birth weight was lowest during the coldest part of the winter. In the semiarid climate of Sudan, Ali et al. (2015) showed that beef-breed calves that were born in the winter season had the highest birth weight, followed by those born in dry summers, whereas calves born in wet summers had the lowest birth weight. The findings of El-Nazeir et al. (2015) in Holstein crosses were not dissimilar, in that the birth weight of calves born in wet summers and the winter were higher than those born in dry summers. Mee (2008) summarised the potential mechanism for the effect of cooler weather upon birth weight as follows: 'cold weather … during the last trimester has been associated with increased dry matter intake, increased thyroid hormone concentration, increased blood and nutrient flow to the uterus and increased gestation length and reduced plasma oestradiol concentrations leading to increased birth weight and dystocia' (p97).

Effects of the Dam. Calf birth weight is affected by the age, parity, plane of nutrition, and body condition of the dam.

Birth weight of calves generally increased with both the age and the parity of the dam. Paradoxically, however, despite this increase in birth weight, the prevalence of dystocia decreases with both the age and the parity of the cow. Thus Sieber et al. (1989), from their study of Holsteins over an 18-year period (Table 12.14), showed that the body weight of the cows increased with parity, as did the birth weight of their calves, but the proportion of calvings that required assistance declined. Thus various authors have shown that heifers, which are older at their first calving, have a reduced risk of dystocia (Klassen et al. 1990, Berger et al. 1992, Hickson et al. 2009) than those which are younger, although it may be that as age increased beyond an optimal point the risk of dystocia increases. This, presumably, represents the interaction between the birth weight of the calf and the skeletal maturity of the dam.

The relationship between plane of nutrition of the dam and birth weight of the calf has also been of interest. Evidence from humans and laboratory animals suggests that permanent effects upon fetal (and, indeed, postnatal) growth rates can be induced by feed restriction in the first trimester of pregnancy. It has been postulated that it might be possible to exploit this phenomenon to reduce the birth weight of heifers' calves. However, neither Prior and Laster (1979) nor Hickson et al. (2009) were able to alter the birth weight of Angus calves by altering the plane of nutrition during the first trimester of pregnancy.

Effects of feeding later in pregnancy have also been extensively studied, but it is difficult to evaluate these results because much of it is contradictory (Meijering 1984, Hickson et al. 2006, and references therein). In summary, feed restriction of heifers in mid to late gestation commonly reduces calf birth weight, although without a consistent effect upon dystocia. This appears to be because feed restriction not only reduces the growth of the fetus, but also reduces the growth and skeletal maturity of the growing primiparous animals. Feed restriction of parous animals is much less consistent in its effect upon calf birth weight, with some studies showing a reduction in birth weight of calves born to feed-restricted dams and others showing no effect. The effect upon dystocia is either negligible or inconsistent. Heifers or older cows that are overfed during pregnancy can become obese; but although this seems to have no effect on birth weight (Arnett et al. 1971, Prior et al. 1979), calving performance and, consequently, stillbirth incidence may be affected negatively (Arnett et al. 1971, Lowman 1979) because of fat accumulation in the pelvic region (Grunert 1979, Lowman 1979).

The effects of the body condition score (BCS) of the dam on birth weight have been reviewed by Mee (2008) and Zaborski et al. (2009) (and see references therein). Mee noted that excess or inadequate BCS at calving in primiparous Holstein–Friesian cattle presents a significant risk factor for dystocia. He suggested an

VetBooks.ir

optimal BCS of 2.75 to 3.0 (0–5 scale) and attainment of 85% to 90% of mature bodyweight at first calving to minimise the risk of dystocia. Zaborski et al. (2009) also considered that BCS must be optimal to minimise the risk of dystocia and that both obese and thin cows have an increased risk of dystocia (and obese cows have a greater risk of metabolic disease in the peripartum period as well).

Taken together, it seems that attempting to manipulate calf birth weight by altering the plane of nutrition of the dam is a relatively unrewarding exercise. Excess feeding does not consistently increase calf birth weight, but can result in dystocia. Underfeeding may reduce calf birth weight in primiparous animals (although the effect is inconsistent in multiparous animals), but any benefit of reduced birth weight seems to be offset by deleterious effects upon the growth of the dam, resulting in an overall increase in the risk of dystocia.

Abnormal Offspring Syndrome (AOS). The use of *in vitro* matured (IVM), *in vitro* fertilised (IVF), and somatic cell nuclear transfer (SCNT)-derived embryos (see Chapter 44) has increased substantially in recent years, particularly in cattle, with great advances in this biotechnology. However, one of the disadvantages is that a proportion of the embryos derived from these methods have various developmental anomalies, collectively known as the 'abnormal offspring syndrome' (AOS) (Farin et al. 2006, 2015).

An increase in birth weight has been widely reported in calves derived from assisted reproductive technology (ART)-generated embryos. For example, Behboodi et al. (1995) reported 51 kg versus 36 kg, Kruip and den Daas (1997) a 4.5 kg higher birth weight, and van Wagtendonk-de Leeuw et al. (1998) a 10% increased birth weight. This increase in birth weight has been associated with a 2 to 3 day increase in gestation. The consequence is an increase in the dystocia rate and calf mortality rate; for example, Kruip and den Daas (1997) reported 25.2% dystocia and Behboodi et al. (1995) 62%, compared with 10% for artificial insemination (AI)-derived calves. The manifestation of AOS as increased fetal birth weight is, however, only one part of the syndrome: gestational failure in all stages of pregnancy and abortion; musculoskeletal deformities, disproportionate fetal growth; abnormal organ growth and physical/metabolic abnormalities that persist into postnatal life; abnormalities of placentation, including abnormal development of the allantois, placental vasculature, and, perhaps, hydrallantois – these are all part of the AOS. Current research into the mechanisms that result in this wide range of abnormalities has been reviewed by Farin et al. (2015).

Calf Conformation

The ability of a calf to be expelled unaided through the birth canal at parturition is dependent on its shape or conformation. This is seen in the most extreme situation of some fetal monsters (see Chapters 9, 14 and 15), such as fetal duplication, schistosomes, ascitic and anasarcous calves (in which the weight of the fetus is low but the conformation prevents normal expulsion), and in the condition of muscular hypertrophy (in which the muscle mass of the calf is increased disproportionately to its weight).

Muscular Hypertrophy ("Double Muscling"). Certain breeds of cattle, mainly beef, have a high frequency of muscular hypertrophy (double muscling). The condition is of genetic origin, resulting from mutations of the myostatin (Growth Differentiation Factor 8) gene (Grisolia et al. 2009). The highest frequency occurs in the Belgian Blue and Piedmontese breeds, but it also occurs in other breeds, including the Blonde d'Aquitaine and Charolais. Muscular hypertrophy is beneficial inasmuch as it results in a beef carcase that has a greater muscle content and, hence, meat of high lean content and high quality. However, the frequency of dystocia associated with double muscling is very high. Hanzen et al. (1994) and Fiems et al. (2001) both reported that 90% of pure breed Belgian Blues are delivered by Caesarean surgery, whereas Murray et al. (1999) reported a figure of 82% elective Caesarean surgeries in the UK. However, Arthur et al. (1989), who examined the effects of reciprocal crossbreeding of double muscled and normal sires and dams, found that the incidence of dystocia was highest when double muscled sires and dams were bred together, but that breeding a double muscled sire to a normal dam resulted in an incidence of dystocia that was not different from normal sire–dam breeding. This was interpreted in terms of the shape of the pelvis of the dam versus the muscular hypertrophy of the animal; thus the higher width of calves with hypertrophy causes dystocia when birth occurs through the more narrow pelvic opening of cows that themselves have muscular hypertrophy. These data are illustrated in Table 12.15. Zaborski et al. (2009) noted that, as muscular hypertrophy is caused by mutations of the myostatin gene, the genotyping and the appropriate mating management may reduce the dystocia rate.

TABLE 12.15 Reciprocal breeding between double muscled and normal cattle on the incidence of dystocia and perinatal mortality

Mating (Sire X Dam)	Calf Birth Weight (kg)	Difficult Calvings (%)	Perinatal Mortality (%)
DM x DM	31.9	26.7	13.4

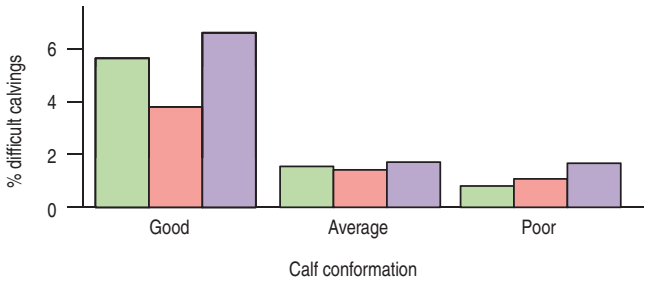
DM x N	34.7	9.5	6.6
N x DM	34.8	18.2	7

DM, Double muscled; *N*, normal.
Derived from Arthur et al. (1989)

Conformation of the Calf. Attempts have been made to assess the conformation of normal calves and to correlate this with ease of calving. Such methods have involved asking the farmer to assess the conformation of the calf as good, average, or poor, and then applying a numerical score from 1 to 3 to each subjective value (McGuirk et al. 1998a). Others have made a large number of fetal anatomical measurements, such as head circumference, foot circumference, width of shoulders, width of hips, depth of chest, body length, cannon bone length, and diameter (Nugent et al. 1991, Colburn et al. 1997). Using the simple approach, McGuirk et al. (1998a) found a statistically significant difference between calf conformation and incidence of difficult calvings and calf mortality (Fig. 12.8). In summary, well-muscled calves born from a beef sire and dairy cow or heifer resulted in more difficult calvings and increased calf mortality. Recently, in Australia and New Zealand there has been emphasis on advising farmers on conformation when they purchase new beef sires (Hickson et al. 2006). They are advised to avoid bulls that are wide at the point of the shoulder or have a wide space between the tops of the scapulae.

The results from more sophisticated measurements of fetal conformation have been contradictory. Neither Meijering (1984), Morrison et al. (1985), Sieber et al. (1989) nor Barrier et al. (2013) found any relationship between calf body measurements on ease of calving, except inasmuch as they affected birth weight, although Barrier et al. did find an association between calf conformation and

VetBooks.ir



• **Fig. 12.8** Relationship between the incidence of difficult calvings and calf conformation for calves sired by Limousin, Hereford, and Charolais bulls. (Redrawn from McGuirk et al. 1998b.)

stillbirth that was independent of effects upon dystocia. Nugent et al. (1991), who examined the relationship between calf shape and sire, expected progeny difference (EPD), or ease of calving, found that at constant birth weight, calves from higher birth weight EPD bulls tended to have larger head and cannon bone circumferences. However, at constant birth weight, body measurements were not associated with calving ease. In conclusion, they stated that calf shape seemed to add no information for the prediction of dystocia other than that provided by birth weight EPD.

Recent studies have, however, identified quantitative trait loci (QTL) that are variously correlated with the probability of dystocia, risk or stillbirth or fetal birth weight. Seidenspinner et al. (2011) associated pleomorphism of the placental growth factor gene with maternal calving ease and stillbirth rate, whilst Pausch et al. (2011) associated regions of Chromosomes 14 and 21 with paternal calving ease. Hoglund et al. (2012) identified a cluster of loci on Chromosome 18 (with other loci on Chromosomes 13, 9, 18, 3, and 1) that were associated with indices of paternal calving ease. Loci associated with adult stature and conformation have also been associated with calving ease: Saatchi et al. (2014) and Sahana et al. (2015) identified a cluster of genes on Chromosome 6 that are associated with maternal conformation, calf birth weight, and calving difficulty. More recently, Mao et al. (2016) have associated QTLs on Chromosome 18 with calving difficulty. Interestingly, these QTLs are also associated with maternal conformation, or are expressed in the placenta, or are involved in regulating the onset of labour, which, taken together, can be readily interpreted in terms of mechanisms that might affect aspects of birth weight and gestation length.

Thus the phenotypic relationship between dystocia, stillbirth, and measurable attributes of calf conformation remains difficult to quantify. Simple scores of 'difficult' conformation seem to be well associated with the likelihood and degree of dystocia, but attempts to characterise these malconformations in terms of the dimensions of specific body parts of the fetus have not yet succeeded. On the other hand, the relatively high heritability of dystocia traits and the recent identification of specific loci, and even genes, that are associated with fetal and maternal dystocia traits, seem to afford opportunity to better understand the aspects of calf conformation and birth weight that are critical to the risk of dystocia.

Maternal Factors

Parity. The effects of parity upon ease of calving have been reported in a great many studies; heifers generally have more assisted calvings and a greater degree of calving difficulty than parous cows. The degree of difficulty continues to decline as the parity of the animal increases, but the difference in the rate of dystocia between the first and second parity is usually much bigger than between second and subsequent parities (Zaborski et al. 2009). Parity is the most important maternal factor which affects ease of calving and, indeed, virtually every survey of the causes of dystocia highlights parity as a highly significant effect. In the present chapter, Tables 12.5, 12.6, 12.11, 12.12, and 12.14 and Figs 12.1 and 12.5 all show this effect. The disproportionately high rate of calving difficulty in Holstein heifers has also been noted.

TABLE 12.16 Relative risk of dystocia in Angus heifers at different ages

Age of Dam (months)	Sex of Calf	Calvings Assessed as: Needing Some Assistance (%)	Calvings Assessed as: Difficult (%)

	F	4.4	0.7

From Berger et al. (1992)

Pelvic Capacity of the Dam. The dam influences the incidence of fetomaternal disproportion primarily through her pelvic area. Pelvic area, in turn, is influenced by genetic effects, such as sire and inbreeding, and environmental effects, such as parity, weight at insemination, age, weight, and body condition at calving (Mee 2008). Primiparous animals have relatively smaller pelvic areas than parous animals because of their smaller stature and the relatively late maturation of the pelvis (Hiew & Constable 2015). Thus heifers that are smaller or younger at first parturition are at greater risk of fetomaternal disproportion than are those that are larger or older (Table 12.16). The risk of dystocia is also, therefore, related to the size and weight of the heifer at parturition (see Table 12.6), as well as the ratio between the birth weight of the calf and the size of the pelvis of the heifer (Table 12.17). Breed-related differences in the risk of dystocia can also be related to pelvic area, inasmuch as the ratio between pelvic area and heifer weight, and between pelvic area and calf birth weight, is significantly greater for Jersey heifers than it is for Holstein heifers (Nogalski & Mordas 2012).

Pelvic area can be estimated from internal measurements of pelvic height (perpendicular distance from the cranial end of the pubic symphysis to the ventral surface of the midsacrum) and pelvic width (largest distance between the shafts of the ilia) (Meijering 1984). From these measurements pelvic area can be calculated as the simple product of height × width, or by either treating it as an ellipse or by equations that regress actual area on these two measurable dimensions. Measurements are made transrectally using callipers (which can be difficult to obtain in some circumstances). For this reason the validity of the measurements and, hence, the whole concept has been criticised (Van Donkersgoed et al. 1990). Pelvic area can also be estimated by external measurements of the

pelvis, stature, and girth of the cow, with reasonable correlations between such measurements and pelvic area (Hiew & Constable 2015). The correlation between pelvic area and dystocia ranges from approximately 0.1 to 0.45 in beef heifers (Meijering 1984, Johnson et al. 1988), although others (King et al. 1993) have been unable to show any significant relationship. Consequently, despite the relationship between pelvic area and dystocia, the use of pelvic area as a predictor of dystocia in individual animals is of limited value (Van Donkersgoed et al. 1990). There appear to be many reasons for this. First, once a threshold pelvic area has been exceeded, further increases in pelvic area have a very limited effect upon the risk of dystocia (Mee 2008). Second, the correlation between pelvic area before parturition with that at parturition is low (Hiew & Constable 2015), particularly as the shape and area of the pelvis can change substantially during parturition; Meijering (1984) noted that increased mobility of the iliosacral joints and relaxation of the pelvic ligaments can increase pelvic height by up to 5% at the time of calving, with further increases occurring during abdominal straining.

Measurements of pelvic area have been used to cull very small yearlings as a means of reducing dystocia at first calving (Holm et al. 2014). If pelvic area measurements are made before service, animals with a small pelvic canal can be rejected for breeding or inseminated with semen from an easy-calving bull (low EBV for birth weight), whereas those with a larger pelvis can be bred to an average-calving bull. The heritability of pelvic area is relatively high, so it is potentially amenable to genetic selection. There has also been interest in the use of pelvimetry in bulls in an attempt to select sires that have a large pelvic area that might then be inherited by their female progeny. Results, however, have been equivocal (Crow & Indetie 1994, Kriese et al. 1994). However, Bennett and Gregory (2001) were of the view that direct selection for calving difficulty score or calf birth weight would be preferable because of their superiority in predicted genetic change.

Condition Score of the Dam. It is generally accepted that heifers or cows with a very high condition score are more likely to suffer from dystocia than those that are moderate to poor, the reason being that those in very good condition will have a substantial amount of retroperitoneal pelvic fat, which will reduce the overall size of the birth canal. Studies in both beef and dairy cattle have shown that body condition score over midranges has little influence on the dystocia rate. Thus, Spitzer et al. (1995) showed that the birth weight of calves born to beef heifers whose condition ranged from 4–6 (0 (emaciated) to 9 (obese) scale) were 28.9, 30.4 and 32.4 kg, respectively. Such birth weights are usually not associated with dystocia. Keady et al. (2001) likewise showed no effect of variation in midrange conditions scores of dairy cattle upon dystocia rate or calf birth weight.

Fetomaternal Disproportion in Sheep

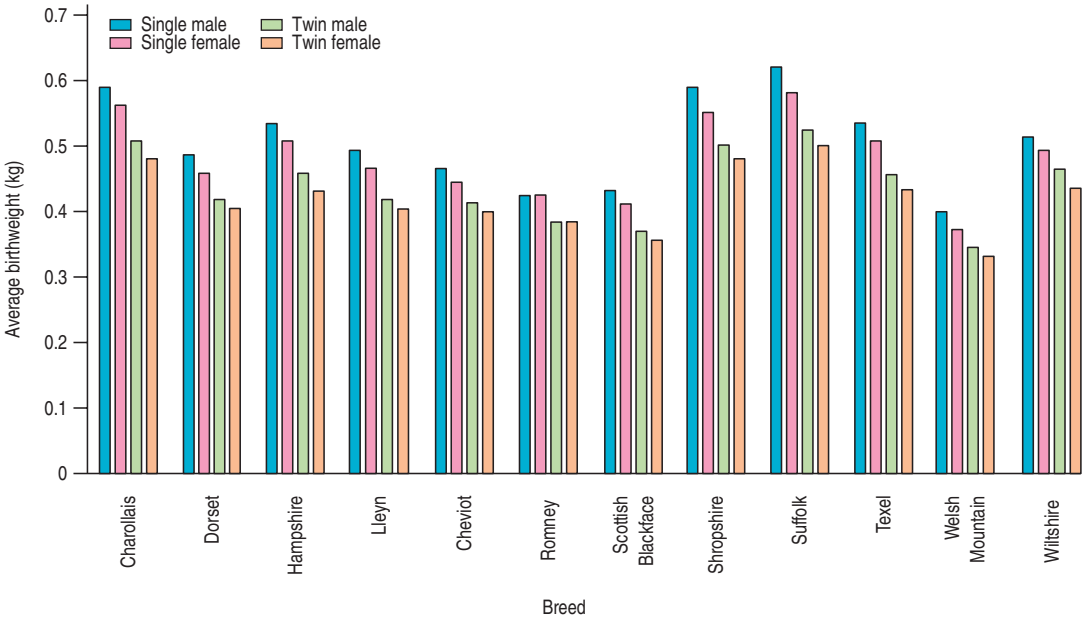
Fetomaternal disproportion in sheep occurs as a result of a large lamb or a small pelvis or, sometimes, the simultaneous occurrence of both.

Lamb Birth Weight

Lamb birth weight is determined by breed (see Gootwine (2005) for extensive data on different sheep breeds), number of lambs in the litter, season, and parity. As birth weight increases, so does the risk of dystocia, with the magnitude of the relationship being modified by breed (Fig. 12.9).

Examples of the variability between breeds are illustrated in Fig. 12.10. Many lambs are, however, crossbred rather than purebred, so the effects of crossbreeding upon lamb birth weight have been extensively studied. In the classic study of Hunter (1957), in which large (Border Leicester) and small (Welsh Mountain) breeds were crossed, the birth weight of Border Leicester lambs born to Welsh Mountain ewes was 1.1 kg less than that of Border Leicester lambs born to Border Leicester ewes; also, the birth weight of Welsh Mountain lambs born to Border Leicester ewes was 0.6 kg more than that of Welsh Mountain lambs born to Welsh Mountain ewes. Similar results were obtained in reciprocal embryo transfer experiments by Dickinson et al. (1962) (Welsh Mountain and Lincoln breeds) and Sharma et al. (2012) (Suffolk and Cheviot breeds), both of whom found that the size of the fetus was constrained by the maternal recipient breed. Thus the maternal influence can limit the size of a genetically larger lamb, as well as increase the size of a genetically smaller lamb. This relationship was quantified

VetBooks.ir



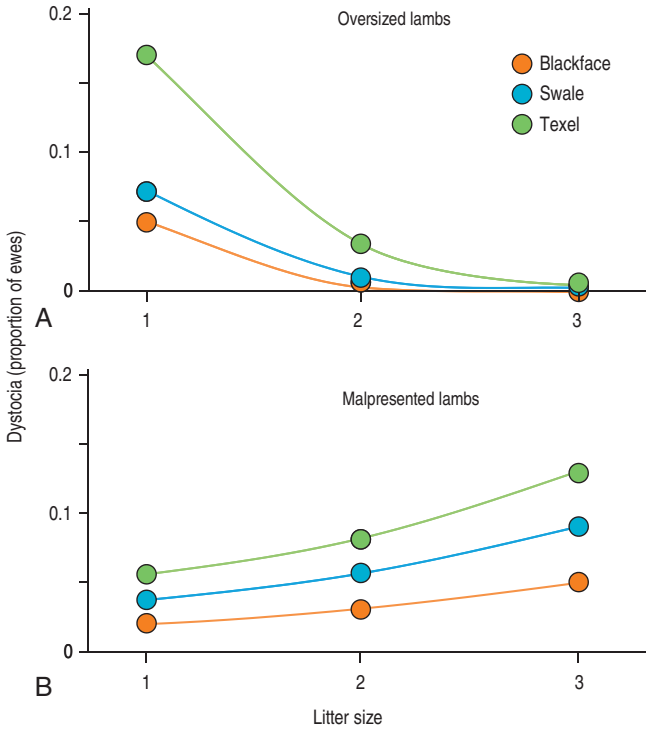
• **Fig. 12.10** Differences in average birth weight of lambs, according to sex, litter size, and breed. Single male ■, single female ■, twin male ■, twin female ■. (Modified from data obtained by Signet Breeding Services/AHDB Beef and Lamb and used with their permission.)

by Dickinson et al. (1962) as being related to the mature weight of the donor ($D^{0.83}$), the ratio of the weights of the donor and recipient ($(R/D)^{0.83}$), and the reciprocal of the litter size.

Litter size is closely related to birth weight, with single lambs being significantly heavier than multiples. Across a great many breeds, Gootwine (2005) showed that mean birth weights for single lambs was 4.6 ± 0.9 kg, twins 3.8 ± 0.8 kg, triplets 3.2 ± 0.8 kg, and quadruplets 2.9 ± 0.6 kg. Thus, as litter size increases, dystocia due to oversized lambs decreases (Speijers et al. 2010). Conversely, as litter size increases, the risk of dystocia due to malpresentation of the fetus increases (Fig. 12.11). Male lambs are consistently heavier than females. Smith (1977) noted that the mean weight of male lambs was 4.2 ± 0.3 kg versus 4.0 ± 0.3 kg for female lambs and that this difference was associated with 19% dystocias in male lamb births versus 14% in females.

Various selective breeding methods have been applied to try to reduce the effect of lamb birth weight upon dystocia. Heritability for lamb birth weight is moderate (h^2: 0.38) and is genetically correlated with lamb death risk traits (Everett-Hincks et al. 2014). Thus McSporran et al. (1977) were able to substantially reduce the prevalence of dystocia by breeding from ewes that had lambs of low birth weight and less difficulty at lambing. Unfortunately, there are unfavourable genetic correlations between birth weight and weaning weight and between the risk of dystocia and fleece weight (Brown et al. 2014), both of which could impede genetic selection for lower birth weight.

Because of the benefits upon both dystocia and lamb mortality of achieving lamb birth weights in the range of 4 to 6 kg, the effects of maternal nutrition upon lamb birth weight have been extensively studied. The consensus of these studies is that maternal nutrition has little effect. For example, in a meta-analysis of experiments with New Zealand Romney ewes, Schreurs et al. (2012) concluded that the influence of a ewe that is heavier at Days 0, 50, 100, or 150 of gestation on the birth weight of its lamb was very small. The effect is also more dependent on litter size than upon ewe weight. Likewise, there was neither an effect of dietary restriction during



• **Fig. 12.11** Relationship of dystocia caused by either (A) oversized lambs or (B) malpresented lambs with litter size for different sire breeds: Blackface ●, Swale ●, and Texel ●. (Redrawn from Speijers et al. 2010.)

mid- to late pregnancy (Kenyon et al. 2011) nor an effect of a high plane of nutrition (Corner-Thomas et al. 2015) upon lamb birth weight. It appears that the reason for the failure to find an effect of maternal nutrition is due to the ability of the placenta to compensate under such circumstances. Thus severe undernutrition during early and midgestation reduces the number of placentomes,

Suffolk	22.1	18.3	8.8	25.5	79.5

From Silva & Noakes (1984)

but they subsequently increase in size and alter their shape (Steyn et al. 2001). Therefore, if nutrient intake is increased in the last trimester, then the placenta is probably more efficient in nutrient transfer and the fetus grows more rapidly.

Parity affects lamb birth weight. Smith (1977) showed that birth weight increases from first (3.5 ± 0.1 kg) to second (4.1 ± 0.1 kg), to third (4.4 ± 0.1 kg) through to fourth (4.5 ± 0.1 kg) parity. Ewe lambs typically produce lighter lambs than do ewes. Corner et al. (2013) showed that birth weight of lambs from single-bearing ewe lambs were lighter (4.4 ± 0.1 kg) than those born of ewes (5.5 ± 0.1 kg).

Pelvic Capacity of the Dam

Assessments of the size of the maternal pelvis have been undertaken to determine the contribution of this factor to fetomaternal disproportion. Fogarty and Thompson (1974) showed that pelvic dimensions of Border Leicester and Dorset Horn ewes that lambed normally were larger than those which had dystocia. External pelvic dimensions were measured in a large number of different breeds, including several rare breeds which had not been subjected to selection pressures for growth traits and carcase quality (Silva & Noakes 1984). Table 12.18 shows the wide variation in pelvic size, with breeds such as the Soay, North Ronaldsay and Shetland having small pelvic dimensions, whereas the Scottish Blackface, Clun Forest, and Suffolk have larger pelvic dimensions. However, when the pelvic dimensions are compared with the body weights of the ewes for the different breeds, it is noticeable that the 'unimproved' breeds have relatively larger pelvic dimensions than the more selected breeds (Table 12.19). Because fetal weight is between 6% and 8% of maternal body weight, then the relatively smaller pelves of those breeds that have been subject to genetic selection to produce large lambs at birth are more likely to have dystocia than the rare breeds that have largely been left to the influences of natural selection.

Pelvic area of Romney ewes, as assessed by radiographic pelvimetry (McSporran & Wyburn 1970, McSporran & Fielden 1979), has been related to their risk of dystocia. Haughey and Grey (1982) and Cloete and Haughey (1990) confirmed that radiometry is a relatively accurate means of estimating the size of the pelvic inlet, whereas others (Bilbe et al. 2005) have used computerised tomography for the same purpose. Attempts to correlate external bodily measurements with internal pelvic dimensions have been shown not to be particularly useful.

TABLE 12.19 Ratio of pelvic dimensions: body weight of adult ewes of different breeds

Breed	Ratio of Medial Intertuber Ischial Dimension to Body Weight	Ratio of Sum of Pelvic Measurements to Body Weight
Unimproved Breeds		
Soay	1.0	1.0
North Ronaldsay	0.98	0.95
Shetland	0.72	0.72
Selected Breeds		
Scottish Blackface	0.53	0.48
Clun Forest X	0.55	0.51
Suffolk	0.43	0.43

From Silva & Noakes (1984)

Faulty Disposition of the Fetus

Presentation and Position

About 99% of foals and 95% of calves are delivered in anterior presentation. When sheep are pregnant with a single lamb, they show a similar percentage of anterior presentations to cattle, but with twins there is a considerable proportion of lambs born in posterior presentation. The polytocous sow, bitch and queen deliver 30% to 40% of fetuses in posterior presentation. In monotocous species posterior presentation is associated with an increase in the risk of dystocia. In the mare, although posterior presentation only accounts for 1% of births, it accounts for approximately 16% of hospital referrals for dystocia (Frazer 2011). In the cow dystocia occurs in approximately 50% of deliveries in uncomplicated (i.e., without hindlimb flexure) posterior presentation (Citek et al. 2011).

VetBooks.ir

In the ewe uncomplicated posterior presentation was responsible for dystocia in 10% of malpresented lambs, and breech presentation was responsible for dystocia in a further 12% (Dwyer & Bunger 2012). In polytocous species, uncomplicated posterior presentation has only a marginal effect upon birth difficulty, whereas flexion of the hindlimbs causes an increase in the risk of dystocia.

During pregnancy, the fetus assumes a disposition that occupies as little uterine space as possible. However, during parturition, it must assume a disposition that enables it to be expelled through the birth canal. These changes in disposition occur, according to species, before or at the time of labour. Faulty presentation appears to be a failure of the changes of disposition that occur during that time.

Horse. The equine fetus is freely movable in the uterus in the early stages of gestation and is equally likely to be in anterior or posterior presentation until the fifth month. Ginther (1998) described the selection of anterior presentation occurring after that time, due to closure of the uterine horns by the eighth month, thereby confining the fetus to the uterine body. Thus the probability of an anterior presentation increases after the fifth month, such that 98% of foals have adopted an anterior longitudinal presentation by 8½ months gestation (Vandeplassche 1957). Thereafter, the foal normally assumes a dorsopubic position, with the hindlimbs becoming encased in one uterine horn, so that the feet rest on the dorsal surface of the uterus, directed towards the cervix, often pushed into the rectogenital pouch. This 'entrapment' of the feet prevents the fetus from reverting to a posterior presentation (Ginther 1998). At this stage of gestation, the cranial part of the fetus can rotate between dorsoilial and dorsopubic positions (Frazer 2011). During parturition the head and forelimbs become extended, and the cranial portion of the fetus rotates into a dorsoilial position. This appears to be an active process on the part of the foal, possibly in response to increasing uterine tone: a fetus that is dead or nonviable is less likely to make this postural transition so is more likely to result in a dystocia due to malpresentation. Complete rotation of the foal into an extended, dorsosacral position is only completed during second stage labour. Posterior presentation predisposes the mare to dystocia because the rotation and extension of the fetal extremities is impeded; so posterior presentations are commonly in dorsoilial presentation, often with bilateral hip or hock flexion (Frazer 2011).

A small proportion (~0.1%) of foals becomes transverse presentations, in which the extremities of the fetus occupy the uterine horns, while the uterine body is largely empty. This presentation probably arises at about 70 days of gestation, when the uterus normally changes from a transverse to a longitudinal direction in front of the maternal pelvis as a result of the allantochorion passing from the pregnant horn into the uterine body. In the abnormal situation either the allantochorion does not intrude into the uterine body or the major, rather than the normally minor, branch of the allantochorion passes into the nonpregnant horn and is followed by the amnion, containing a fetal extremity. Normally, neither the amnion nor the fetus passes into the nonpregnant horn.

Cow. During the first 2 months of gestation, the calf has no definite polarity, and during the third month there are equal numbers of anterior and posterior presentations (Abusineina 1963). Throughout the fourth, fifth, and first half of the sixth months, the majority of fetuses were in posterior presentation, but during the sixth month the situation began to change so that, at the end of that month, anterior and posterior presentation frequencies were equal. By the middle of the seventh month, the majority of fetuses were in anterior presentation. Beyond the seventh month, posterior presentation was rare and transverse presentation exceedingly rare. However, posterior presentations are more common in bull than heifer calves, suggesting that the greater size of the male calf may interfere with the process of turning into anterior presentation (Holland et al. 1993). During the last week of gestation the fetus remains in a dorsopubic or left dorsolateral position (Dufty 1973), regardless of presentation, but as myometrial contractions start during first stage labour, the calf rotates into an anterior presentation, dorsosacral position, with the head and forelegs extended (Norman & Youngquist 2007). This period of rotation and extension is dependent on fetal movement in response to myometrial contraction: fetal activity is maximal about 3 days before parturition. This phase of activity has been referred to as the 'righting reflexes' (Fraser 1976a). Holland et al. (1993) noted that, if fetal muscles' competence of endurance was not adequate, the righting reflex would not occur and the resulting presentation would be ventral. The maintenance of myometrial activity is a prerequisite for these fetal movements. Jöchle et al. (1972) found that progesterone given to parturient cows caused a high incidence of postural dystocia, which could be due to maintaining the 'progesterone block' on the myometrium (see Chapter 6), thereby reducing the stimulation of the fetal calf to initiate its righting reflexes. It is also well recognised that there are increased frequencies of postural aberrations in premature births, in which uterine inertia is more prevalent, and with twins, in which there is not only an increased likelihood of uterine inertia, but also reduced space, thereby interfering with the ability of the limbs to extend.

The natural forces that bring about these changes in polarity are therefore reflex fetal movements that occur in response to: changes in the intrauterine pressure due to myometrial contractions; movements of adjacent abdominal viscera; or contraction of the abdominal musculature. The preponderance of posterior presentations in early gestation would be the expected result of suspending an inert body with the same centre of gravity as the fetal calf. With the development of the fetal nervous system, and a consequent appreciation of gravity, the fetal calf begins to execute righting reflexes that bring up the head from the dependent part of the uterus. Hence posterior presentation, rather than being regarded as an obstetrical accident, could be caused either by a subnormally developed fetus or by a uterus deficient in tone. In addition, the size of the fetus and uterine space influence the ease with which a fetus can change its polarity *in utero,* so there is a much higher percentage of posterior presentations in bovine twin births, with a higher than average percentage of posterior presentations occurring with excessively large fetuses.

Posture

Holland et al. (1993) noted that, in cattle, after the righting reflex (i.e., once the fetus has adopted an extended, dorsopubic position) a low level of fetal activity is required to maintain an adequate posture. If normal fetal muscular activity does not occur during this period, dystocia due to faulty posture can ensue. Thus Fraser (1976b) found that a reduction in fetal movements during the righting period was a primary cause of fetal malposture. Interestingly, during hypoxia, fetal movements are either markedly diminished or there are erratic limb and head movements (Dufty & Sloss 1977), which Holland et al. (1993) surmised could contribute to the development of abnormalities of posture.

Similar effects pertain to the sheep. Dwyer and Bunger (2012) concluded that malpresentation may occur if a large lamb is forced into an incorrect disposition during its passage through the birth canal or if the fetus is already incorrectly positioned at the onset

VetBooks.ir

of labour. Grommers et al. (1985) concluded that narrowness of the maternal pelvis was at least as important as fetal oversize to the pathogenesis of dystocia due to shoulder flexion. Lambs with one of both forelimbs retracted were significantly heavier than lambs in other presentations, whereas lambs in a breech or head back presentation were significantly lighter than lambs in other presentations.

Lateral deviation of the head is a postural abnormality that deserves special mention. It may be due to the same factors as those noted previously, but lack of uterine space may be more important, and it may arise during late gestation rather than during birth. A congenital deformity known as wryneck, in which the head and neck are fixed in flexion because of ankylosis of the cervical vertebrae, arises during the peculiar bicornual gestation of the mare (Vandeplassche 1987).

In polytocous species the relatively larger pelvis of the dam and smaller limbs of the fetus mean that the disposition of the fetal limbs is less important than in monotocous species. Thus many piglets, puppies, and kittens are delivered normally with their limbs in postures that would have caused dystocia in the foal and calf. However, if a female of a polytocous species is parturient with an abnormally low number of fetuses, there is likely to be some degree of fetomaternal disproportion and, in these circumstances, malposture of the limbs may cause dystocia. Moreover, the high proportion of flexion of the head/neck of malpresented puppies and kittens suggests that similar effects of hypoxia, fetal movement, and/or constraints of the maternal birth canal are likely to be contributors to the aetiology of such dystocias.

Maternal Dystocia

Dystocia due to maternal causes, including the aetiology of such dystocia, is discussed in Chapter 13.

Consequences of Dystocia

The consequences of dystocia are numerous, ranging from increased stillbirths and perinatal mortality to severe trauma to the offspring or its mother. Dystocia results in:

- Harm to the welfare of the dam,
- Harm to the welfare of the offspring,
- Increased risk of stillbirth or perinatal mortality of the offspring,
- Increased neonatal morbidity,
- Increased mortality rate of the dam,
- Reduced productivity of the dam,
- Reduced subsequent fertility and increased chance of sterility in the dam,
- Increased likelihood of puerperal disease in the dam, and
- Increased likelihood of subsequent culling of the dam.

Cattle

Stillbirth and perinatal mortality are major causes of economic loss in cattle, and both are highly related to dystocia. Thus Paterson et al. (1987) found that 46% of all preweaning deaths could be attributed to dystocia. Sloss and Dufty (1980) showed that about a third of the total of 17% of fetal and calf losses occur at the time of parturition and that most of these arise from calving difficulties. Calves born to cows that suffered from dystocia were five times more likely to die in the immediate perinatal period than those resulting from normal calvings (Azzam et al. 1993). Wittum et al. (1994) reported that 17.5% and 12.4% of calf mortality was associated with dystocia and stillbirth, respectively, and Johanson and Berger (2003) found that perinatal mortality of calves born after dystocia was 2.7 times that for calves born unassisted. Laster and Gregory (1973) found that calves born to dystocic calvings were four times as likely to die as those born from normal calvings. The severity of the dystocia affects the probability of a stillbirth. McGuirk et al. (2007) found that the calf mortality rate in dairy cows was 2.6% after normal calvings, which increased to 9% after slight dystocia, 54% after severe dystocia, and 27% after Caesarean surgery. Tenhagen et al. (2007) found higher rates of stillbirth after mild dystocia (live calves: 78% versus 98%) and severe dystocia (74% versus 92%) than in normal births. Waldner (2014), likewise, associated the risk of stillbirth with the severity of dystocia; in approximately 30,000 calvings in cow–calf herds, the odds ratio for stillbirth was 2.1 for an 'easy pull', 8.5 for a 'hard pull', 22.2 for manipulation, and 11.2 for Caesarean surgery, compared with unassisted calvings. Finally, Villettaz Robichaud et al. (2017) found that early assistance in cases of dystocia was associated with fewer calves being born dead than later assistance (odds ratio versus unassisted calvings: 1.5 and 10.3, respectively).

Culling rates are typically increased and milk yields decreased in cows that suffer dystocia. In a study in Bavaria, Sauerer et al. (1988) reported that the culling rate of cows that suffered from dystocia was increased by 18%, and the calving interval extended by 11–14 days. Milk yield was not affected unless the calf was stillborn, in which case the yields were reduced by 50 kg, 126 kg, and 148 kg for the first, second, and third lactations, respectively. In a large study of approximately 72,000 Holstein cows in the United States, Dematawewa and Berger (1997) showed that differences between cows that had a normal calving and those that had an extremely difficult calving for milk yield, fat yield, protein yield, number of days open, services/conception, and percentage cow deaths were 703.6 kg, 24.1 kg, 20.8 kg, 33 days, 0.2 services, and 4.1%, respectively (Table 12.20). McGuirk et al. (2007) estimated the likelihood of culling or retention in the (dairy) herd after dystocia, showing that cows that had severe dystocia were more likely to die, be culled, or have poor production than those

TABLE 12.20 Effect of dystocia on losses of 305-day milk, fat, and protein yields and on increases in days open, number of services, and cow deaths for cows in all lactations, relative to cows with dystocia score = 1

	Dystocia Score			
Trait	2	3	4	5
Milk (kg)	–74	–165	–193	–704
Fat (kg)	–2.5	–5.7	–6.2	–24.1
Protein (kg)	–2.2	–5.1	–5.7	–20.8
Days open	+7.4	+10.9	+16.5	+32.6
Services per conception	+0.06	+0.07	+0.10	+0.20
Cow death (%)	+0.24	+0.55	+1.48	+4.12

Dystocia scores: 1 = no problem; 2 = slight assistance; 3 = needed assistance; 4 = considerable force needed; and 5 = extreme difficulty
Based on Dematawewa & Berger (1997)

VetBooks.ir

TABLE 12.21 Percentage of cows experiencing various degrees of dystocia, and their fates

	Cows' Fate (%)			
Severity of Dystocia	Normal	Retained in Herd, but 'Poor'	Poor and Culled	Died
Normal	97.3	2.2	0.2	0.3
Slight	93.7	5.2	0.5	0.6
Severe	61.7	24.7	3.1	10.5
Caesarean surgery	80.0	13.3	6.7	0

Based on McGuirk et al. (2007)

that had normal calvings (Table 12.21). Similarly, Tenhagen et al. (2007) showed increases in culling rate, reductions in conception rate, and increased days from calving to conception according to the severity of dystocia.

Salman et al. (1991) identified dystocia as the disease with the largest veterinary treatment cost in the Colorado National Animal Health Monitoring System. Similarly, Miller and Dorn (1990) found that, in Ohio, 5% of the total cost of disease prevention and occurrence per cow per year was due to dystocia. Kossaibati and Esslemont (1995) estimated that, at that time in the UK, the direct and total costs were £141 and £310, respectively: figures that were influenced by the current commercial value of calves. Dematawewa and Berger (1997) estimated the costs due to dystocia to be $0.00, $50.45, $96.48, $159.82, and $397.61 for no assistance at calving, slight assistance, needed assistance, considerable force needed, and extreme difficulty, respectively. In a UK farm-based survey (1995–2002), involving approximately 10,000 noninduced calvings, the total costs of slight dystocia and severe dystocia were approximately £110 and £350 to £400, respectively (McGuirk et al. 2007). In that study, the major cost was associated with the increased labour required at delivery, the increase in the number of days open and the costs associated with cow and calf mortality, and cow culling.

Sheep

Losses due to dystocia in sheep are largely due to the increased incidence of perinatal lamb mortality. Hence most of the factors that affect the incidence of dystocia in sheep are also associated with the risk of perinatal lamb mortality (Welmer et al. 1983, Woolliams et al. 1983, Speijers et al. 2010). Because lamb vigour and suckling is also impaired in lambs that have been born as the result of an assisted lambing (Dywer & Bunger 2012), much perinatal lamb mortality that is ostensibly due to starvation or hypothermia may well have had an 'ultimate' cause of dystocia. Brown et al. (2014) also noted that most postmortem traits were highly correlated with lambing ease and, fascinatingly, that thoracic circumference of the lamb was related to the risk of death due to mismothering. Finally, Everett-Hincks et al. (2014) found that the direct genetic correlation between lamb birth weight and survival at 3 days postpartum was negative, such that the genetics responsible for heavier birth weight were correlated with lower survival rates, decreased viability at birth, and increased dystocia rates. The effects on fertility will be less apparent because in most production systems ewes have at least 6 months after they have lambed before they are served again. Severe trauma at parturition will result in lesions to the genital tract, which may cause subfertility or sterility. It is much more difficult to quantify other production losses, and evidence is equivocal whether severe dystocia affects postnatal growth rates. The compromises of ewe welfare that are due to dystocia are less equivocal. Scott (2005) noted that poor hygiene, mediocre husbandry, and the decision to slaughter dystocic ewes rather than seek veterinary attention for them result in significant risks to the welfare of ewes during the lambing period. He advocated the routine use of epidural analgesia during manipulative obstetrical procedures and the use of NSAIDs to provide postbirth pain relief. He also encouraged the provision of effective antibiotic treatment regimens for ewes requiring such treatment.

Pig

It is well recognised that in the sow most stillbirths occur intrapartum as a result of dystocia and the delayed expulsion of the litter. There are substantial data on stillbirth rates in sows. It is generally accepted that the rate should not exceed 7% of total piglets born, and if it exceeds 10%, then there is a need for an investigation (Carr 1998). Kirkden et al. (2013) summarised the relationship between stillbirth and dystocia by noting that stillbirth, low piglet viability in the immediate postnatal period, low vitality during the first few days of life, and postnatal mortality are all closely linked. They considered that perinatal asphyxia is the proximate cause in most cases of stillbirth, which also results in reduced viability and vitality, both of which increase the risk of postnatal mortality. Dystocia, in which human intervention is required, is associated with fetal asphyxia and, hence, is a risk factor for stillbirth (see Chapter 17).

Horse

Because of the relatively early separation of the placenta, foal survival is very short: thus if there is dystocia, there is a very high risk of stillbirth. In a survey involving 3527 cases of abortion, stillbirth and perinatal foal mortality in horses, 196 could be directly attributed to dystocia, and dystocia was probably also involved in a substantial number of the other causes of neonatal death. Birth-related trauma was present in 50% of dystocia cases. Dystocia was found to be responsible for 20% of foal mortality within 48 hours of birth (Haas et al. 1996). In a study of an equine referral hospital (Byron et al. 2002), involving 247 dystocias, 91% of the mares survived, but only 42% of the foals were born alive. Even fewer foals (29%) survived to time of discharge. The interval from hospital admission to delivery of the foal had no effect on foal survival rates. However, there was a significant effect on survival rate to discharge and the time interval from rupture of the allantochorion to delivery of the foal for the survivors and the nonsurvivors: 71.7 ± 34.3 and 85.3 ± 37.4 minutes, respectively (Byron et al. 2002). McCue and Ferris (2012) associated the risk of stillbirth or perinatal morbidity or mortality with the duration of second stage labour.

Mares that suffer from severe dystocia should not be served at the foal heat; if they are, pregnancy rates will be lower than normal for this stage and a small number will suffer from traumatic injuries, which may result in sterility.

Dog

Munnich and Kuchenmeister (2009) reported that dystocia was related to the risk of there being hypoxic and dead puppies within litters. They noted that the risk of hypoxic and/or stillborn puppies increased when there was fetal malpresentation, uterine inertia, or

VetBooks.ir

prolonged parturition. Prolonged labour was associated with an increase in stillbirths, particularly in the pups that were born later in the whelping process. Darvelid and Linde-Forsberg (1994) also noted that very small litter size was associated with uterine inertia, prolonged parturition, and an increase in the risk of dystocia or stillbirth.

Prevention

Fetomaternal Disproportion in Cattle

The following guidelines were proposed by Drew (1986–87) in relation to the breeding of Holstein–Friesian heifers in the UK for the prevention of fetomaternal disproportion.

Management at Service

- Ensure body weight at the time of service is more than 260 kg.
- Take care when selecting the service sire. Most dairy sires now have published estimated breeding values (EBVs) for traits such as gestation length and calving ease
  If breeding by artificial insemination bulls:
  - Select a well-proven bull of high genetic merit.
  - Select a bull that has been used successfully on heifers on several farms or, if this is not possible, one with a lower than average incidence of calving difficulties (low EBV for birth weight) and gestation length when used on cows.

  If breeding by natural service bulls:
  - Avoid bulls of large breeds.
  - Select a bull with a record of easy calvings or, if this is not possible, one that has a sire with a good record.

Management Before Calving

- Adjust feed levels to avoid calving in an overfat condition.
- Restrict energy intake in the last 3 weeks of pregnancy.
- Check iodine and selenium levels if calf mortality has been high in previous years.
- Ensure supplementary magnesium is provided during the transition period.
- Ensure that an adequate exercise area is available.
- Observe the heifers at least four or five times daily during the last 3 weeks of pregnancy, especially if short-gestation-length bulls are used.
- If possible, run a separate heifer group or run the heifers with dry cows. If fed with the milking cows, ensure concentrate feeding is restricted to the amount required to acquaint the heifer with her postcalving diet.

Management at Calving

- Calve grazed heifers in their field or paddock if possible. Housed heifers should calve in familiar surroundings. Avoid moving them to a calving box unless essential for adequate assistance.
- Ensure the field is well fenced to avoid the possibility of heifers rolling into positions in which it is difficult to assist.
- Observe hourly (approximately) when calving starts. Too frequent observations (more frequently than half-hourly) can delay calving.
- Be a good stockperson. Watch for signs of fear, abnormal pain, or distress and be ready to assist if these are noted or if calving is prolonged.
- Ensure that the stockpersons are trained to identify potential problems and know when to call professional help. If calving aids are used, instruction should be given as to the correct method of application.
- Call professional advice if an unusually high percentage of the first heifers to calve require assistance – there may be a herd problem, which will affect the whole group.

In the case of crossbreeding or purebreeding calves for beef production, the same principles apply. Thus:

- With well-grown heifers, when breeding purebred replacements, select sires on their ease-of-calving records (low EBVs for birth weight) and normal (i.e., not unduly long) gestation lengths for the particular breed.
- In crossbreeding for beef production from dairy herds, avoid sires of the larger breeds, such as Simmental and Charolais, for heifer inseminations; instead use a known 'easy calving' Angus or Hereford bull. For second and later parities choose a bull of a larger breed on his ease-of-calving record and gestation length.
- In beef production from beef breeds, for heifer pregnancies use either a sire of a smaller beef breed or a within-breed sire of good ease-of-calving record and gestation length. For later parities use a bull either of the same or larger breed, both based on their calving ease and gestation length.

When applying the previous principles in the production of offspring for beef, whether purebred or crossbred, it should be noted that the weight of the calf at birth, assuming equal gestation length, bears a direct relationship to its weaning weight and to its subsequent slaughter weight, on which the profitability of the enterprise largely depends. On the other hand, unduly large calves at birth predispose to calf deaths and to maternal morbidity, mortality, reduced milk yield, and infertility. Thus a breeder must consider how much increase in birth weight can be tolerated in return for increases in growth rate and weaning weight.

If dystocia due to fetomaternal disproportion is anticipated, gestation can be shortened by the premature induction of calving as described in Chapter 8.

Dystocia in Sheep

Meat and Livestock Australia (2016) recommendations for minimising the risk of dystocia are:

- **Genetics:** Use BVs for lambing ease and lamb birth weight can be used to assist in eliminating lamb birthing difficulties. When looking at BVs for birth weight, avoid both very low and very high birth weights.
- **Measure to manage:** Using tools, such as scanning all mated ewes to identify empties, single, and multiple carrying ewes, can be used to allocate feed most efficiently and help with monitoring lamb and ewe loss at weaning to identify losses. Overfeeding ewes bearing single lambs is associated with an increase in the risk of dystocia in such lambs.
- **Ewe condition:** Achieve a target condition score (CS) of 3 (1 (poorest) to 5 (fattest) scale) for ewes at the start of mating and maintain ewes at that condition score thereafter. If ewes reach a CS of 4, the risk of dystocia occurring increases significantly.
- **Keeping check:** Monitor ewes close to lambing so that timely and correct interventions can be made during birth.

Maternal Dystocia: Causes and Treatment

TIMOTHY J. PARKINSON, JOS J. VERMUNT AND DAVID E. NOAKES

Maternal dystocia includes defects of the birth canal and defects of the expulsive forces. The main maternal causes of dystocia are summarised in Fig. 11.1.

Defects of the Birth Canal

Pelvic Constriction

Developmental abnormalities of the pelvis are generally rare in animals. However, the pelvic inlet of the achondroplastic breeds of dog is flattened in the sacropubic dimension, and this, together with the large head of the fetus in brachycephalic breeds, is a common cause of dystocia. The role of inadequate pelvic size in the aetiology of dystocia due to fetomaternal disproportion is discussed in Chapter 13, and the management of such dystocias is discussed in Chapter 13.

Pelvic constriction after fractures, in which there has been poor alignment of the pelvic bones, can cause dystocia in any species. It is in those that are particularly prone to road traffic accidents, such as dogs and cats, that the frequency is highest. For this reason it is good preventive medical practice to ensure that any bitch or queen cat that has suffered from such an injury is radiographed before breeding, to ensure that the pelvic canal is capable of allowing a normal fetus to pass through at parturition without obstruction. In cattle, sacroiliac luxation can occur as a result of and as a cause of dystocia. It occurs during calving, probably as a result of marked relaxation of the pelvic ligaments and overexertion in rising after parturition. In severe cases the sacral area appears to be dropped, and both tuber coxae are very pronounced (Fig. 13.1). The reduction in crosssectional area of the pelvis will result in dystocia if the animal survives to a further calving.

Failure of Cervical Dilation

The cervix provides an important protective physical barrier for the uterus during pregnancy. Several days before and during the first stage of parturition, the cervix undergoes considerable changes in its structure so that it can dilate sufficiently to allow the passage of the fetus (see Chapter 6). Incomplete dilation occurs in cattle, goats, and sheep; in the latter species it is one of the more common causes of dystocia. The degree of incompleteness of cervical dilation varies from virtually complete closure to the situation in which there is just a small rim of cervical tissue present, which is sufficient to reduce the size of the birth canal and cause obstruction. The fact that it is a disorder of the ruminant cervix perhaps suggests a common aetiology because in all three common domestic species, the cervix is a tough fibrous structure with substantial amounts of collagen.

Cattle

In cattle incomplete dilation of the vulva or cervix may occur in both the heifer and the pluriparous cow. Mee (2008) noted that incomplete dilation of the vulva is more common in primiparous animals whereas incomplete dilation of the cervix is more common in pluriparous cows. There are a number of factors that contribute to the condition, of which failure of the hormonal mechanisms that cause the change in structure of cervical collagen during the early stages of labour is probably the most important (see Chapter 6). This, in turn, may be related to prepartum oestrogen concentrations and/or the effects of stress upon the birth process. Inadequate precalving oestrogen concentrations and a raised cortisol to progesterone ratio can result in impaired relaxation of the cervix and pelvic ligaments. These endocrine disturbances can, in turn, be the result of environmental factors, such as the continuous presence of an observer, confinement, or overcrowded calving accommodation. As a consequence, there is reduced uterine motility, cervical dilation, and abdominal contractions with resultant prolonged calving and dystocia (Mee 2008). Also, weak uterine contractions, which would be relatively ineffectual in causing dilation of the ripened cervix, are probably involved in the pathogenesis. In the pluriparous cow, hypocalcaemia (which may be subclinical) can impair uterine contractions and perhaps prevent cervical dilation. Likewise, failure of the fetus to engage in the cervix (such as can occur with a breech presentation or simultaneous presentation of twins) and uterine torsion can also be a cause of failure of cervical dilation. It is, however, important to recognise that premature intervention in a calving can lead to an incorrect presumption of failure of cervical dilation (i.e., if first stage labour is not fully completed at the time of intervention), which, in turn, can lead to iatrogenic damage to the cervix. Finally, it should be remembered that the period of time over which the cervix is dilated is relatively short. If the calf is not delivered during that time window, the cervix will start to close again, trapping the fetus within the uterus.

The characteristic signs of discomfort associated with the first stage of parturition are commonly only mild and transient, so that often it is difficult to ascertain accurately for how long labour has been in progress. On vaginal examination the degree of dilation

VetBooks.ir

• **Fig. 13.1** Sacroiliac luxation in a cow. The sacral areas appear to be dropped and the tuber coxae are excessively pronounced. (Courtesy Dr. Jakob Malmo.)

of the cervix varies from a lumen that is just a few centimetres in diameter through to a rim of cervical tissue about 5 cm broad separating the vagina from the uterus. In the latter case it is common for the amniotic sac to have passed through the cervix and be present at the vulva; it may also have ruptured with escape of amniotic fluid. Sometimes fetal limbs have passed into the cranial vagina. At this stage it is advisable to determine whether the cow is showing signs of hypocalcaemia and, if so, to correct the calcium deficiency, either by giving calcium orally or parenterally. Whether to wait for the cervix to dilate (i.e., assuming that the cow has not completed first stage labour), whether to attempt vaginal delivery, or whether to proceed to Caesarean surgery will depend on the extent to which there is failure of cervical dilation, the viability of the fetus, and an assessment of whether the cervix will complete dilation in response to gentle, sustained traction. Premature delivery by traction is likely to result in trauma to the cervix, reduced calf viability, and downer cows; however, waiting too long also results in impaired calf viability. It is probably sensible to leave the cow for a maximum of 2 hours and then, if there has been no progress in parturition, the alternative option should be followed (Mee 2004). In cases of abortion the cervix often fails to dilate properly and the fetus may be retained, subsequently to undergo putrefactive maceration in the uterus.

Sheep and Goats

Incomplete dilation of the cervix of the ewe and doe goat is descriptively named 'ringwomb'. It accounts for a substantial number of the ovine dystocia cases referred to veterinarians. It occurs most commonly in 3-year-old ewes and is commonly associated with prolonged gestation (Kerr & Dailey 1999). The aetiology of the condition appears to be multifactorial: Purohit (2006) identified hypocalcaemia, hypophosphataemia, trace element deficiencies, uterine inertia, and failure of the fetus to engage the cervix as predisposing causes, although Kerr and Dailey (1999) considered that none of these factors was directly causative. Many cases of ringwomb follow preparturient prolapse of the vagina (see Chapter 10), and both conditions occur in similar circumstances of breed and environment. The role of oestrogens in the condition is less clear than in the cow, as progesterone concentrations are relatively higher and oestrogen concentrations relatively lower in the ewe at parturition than in the cow (Klauke & Hoffmann 1992). Moreover, oestradiol does not cause dilation of the nonpregnant ovine cervix (Masoudi et al. 2014), although oestradiol in combination with high concentrations of oxytocin may do so (Masoudi et al. 2012). On the other hand, ringwomb has been induced experimentally by stilboestrol administration, so Hindson and Turner (1972) suggested that ringwomb might be caused by ingestion of oestrogenic substances by pregnant sheep. A mechanism that has been postulated to explain these effects is that alterations of the oestrogen to progesterone ratio affect intracervical synthesis of prostaglandins E and F and, because these regulate the collagen degradation and remodelling of the collagen matrix that occurs during first stage labour (Challis & Lye 1994), cause failure of cervical ripening. The continued ineffective uterine contractions may cause separation of the placenta from the cotyledons, which can result in death or loss of viability of the lamb (Kerr & Dailey 1999). As in the cow, dystocia can result in a previously dilated cervix closing again.

The condition is suspected when, after protracted restlessness, the ewe does not progress to the second stage of labour. Manual exploration of the birth canal reveals that the cervix is a tight, unyielding ring that will admit only one or two fingers. If it is possible to feel the intact allantochorion beyond the cervix, it is likely that the ewe has not yet completed first stage labour. If the membrane has ruptured and a portion of it has passed into the vagina, the condition is undoubtedly ringwomb (Winter & Hill 2003). If there is a fetid vaginal discharge and necrotic fetal membrane in the vagina, in the presence of a nondilated cervix, there is no doubt that the condition is abnormal and may be due to fetal retention after a failed abortion or dystocia due to some other reason in which the lamb(s) were not expelled after the cervix had dilated normally. When there is doubt over the diagnosis, the ewe should be left for 2 hours and then reexamined to ascertain if any further cervical dilation has occurred, as in normal first stage labour.

There are three main options for treating ringwomb: manual dilation, pharmacological dilation, or Caesarean surgery. Manual dilation is commonly the first recourse to manage cases of ringwomb. Winter and Hill (2003) describe the process of manual dilation, with the insertion of one or more well-lubricated fingers into the cervix and patiently massaging the cervix over 20 to 30 minutes until it relaxes. They emphasise the risks of causing trauma to the cervix by careless or overforceful attempts at manual dilation. Moreover, Caufield (1960) found that only about 20% of cases of cervical dilation failure recognised by him opened naturally and even these required some further assistance to lamb, whereas Menzies (2007) considered that cases of 'ringwomb' that respond to manual dilation are unlikely to represent a true failure of cervical softening.

Various spasmolytics and uterine muscle relaxants have been used in attempts to treat ringwomb. These have largely been unsuccessful, principally as none of these agents act upon the cervix itself. More success has been achieved by combinations of oestrogen, prostaglandin E, and oxytocin. Prostaglandin E can be used to dilate the ovine cervix for AI (Barbas et al. 2013), and there are some reports of its successful use in cases of ringwomb (Azawi et al. 2012, Menzies 2007). However, the method does not yet appear to be sufficiently successful to have become widely used.

Failure to adequately dilate the cervix by manual or pharmacological methods requires that the lambs are delivered surgically. The method of vaginal hysterotomy, whereby the cervix is retracted with vulsellum forceps and then incised by shallow cuts 'at the points of the compass' has been advocated in the past, but is now largely

VetBooks.ir

regarded as unacceptable on welfare grounds. Hence the preferred method for delivering ewes with ringwomb is Caesarean surgery.

Incomplete Relaxation of the Caudal Vagina and Vulva

This is a relatively common finding in dairy heifers. It seems to be associated with heifers that are in overfat body condition and in herds in which the animals have been moved just before calving, or in which the process of calving has been interrupted by too frequent observations or interventions (Mee 2008).

Treatment requires the patient application of slow and gentle traction. If excessive force is used because of impatience, then there will be perineal damage, which may be so severe that a third-degree perineal laceration will occur (see Chapter 20). If continuous progress is made, then delivery can be affected. Another approach is by inserting both well-lubricated arms (with hands clasped) into the vagina and progressively stretching the vulva and dorsal vagina 'at the 10 and 2 o'clock positions', using the bulk of the operator's biceps. This procedure should be carried out for 5 to 10 minutes. If the vulva will not dilate properly then an episiotomy should be carried out (see Chapter 14). If there is any doubt about the likelihood of success with continuing attempts at vaginal delivery, Caesarean surgery should be performed. There are occasions when large numbers of heifers in a group will be affected. The reason for this is not known; however, if a substantial number are affected, treatment with clenbuterol at the first signs of the onset of the first stage of parturition will delay calving and allow the heifer extra time for the vulva, vagina, and perineum to soften and relax, thus reducing the chances of dystocia.

Leidl et al. (1993) reported that 3% of the dystocias in mares referred to the obstetrics clinic of Munich Veterinary School were due to incomplete dilation of the birth canal; these were all associated with what was described as premature delivery (abortion).

Vaginal Cystocele

Vaginal cystocele is the name given to a condition occasionally encountered in the parturient mare and cow in which the urinary bladder lies in the vagina or vulva. It is of two types:

- Prolapse of the bladder through the urethra. This is more likely to occur in the mare due to the large diameter and distensible nature of the urethra, and the force of the straining efforts in this species. The everted organ will occupy the vulva and will be visible between the labia. The visible surface of the bladder is its mucosa, resulting in a red, 'velvety' appearance.
- Protrusion of the bladder through a rupture of the vaginal floor. When this occurs, the bladder will lie in the vagina or hang down from the vulva. A tear will be evident on palpation, and the outer surface of the misplaced bladder will be its serous coat (Fig. 13.2).

It is important to differentiate both of these types from protrusion of fetal membranes; this is particularly the case in the mare, in which the prolapsed and everted bladder and the velvety (villous) surface of the allantochorion are very similar ('red bag'). In both conditions, the first aim of treatment is to overcome straining; this is best achieved by the induction of epidural anaesthesia with or without sedation. This must be followed by retropulsion of those parts of the fetus that already occupy the vagina. In the case of the prolapsed/everted bladder, it is then necessary to invert the organ again by careful manipulation. When there is a protruded bladder, it must be replaced through the tear in the vaginal wall and the latter sutured. In the mare, if the tear is large, the procedure is best done under general anaesthesia. The fetus should then be delivered by traction after the correction of any faulty disposition.

• **Fig. 13.2** Prolapse of the bladder through a rupture in the floor of the vagina of a parturient cow. The presenting surface of the bladder is serosal, rather than the 'velvety' appearance when the organ is prolapsed/everted through the urethra. (Courtesy Dr. Jakob Malmo.)

Neoplasms

Neoplasms of the vulva and vagina may occur in all species and thus serve as potential causes of dystocia because of physical obstruction, although in fact they seldom do so. In the cow, papilloma, sarcoma, carcinoma (Fig. 13.3), and submucosal fibroma of the vagina and vulva occur, whereas in the bitch the vaginal submucous myxofibroma is common.

Neoplasms of the cervix are so rare in livestock as to be of no consequence in a consideration of the causes of dystocia.

Pelvic Obstruction by the Distended Urinary Bladder

Jackson (1973) described a type of porcine dystocia in which the birth canal was obstructed by the distended urinary bladder being forced back by straining in the form of a mound under the vaginal floor, where it acted like a ball-valve in the birth canal; it was associated with a very relaxed birth canal. Schulz and Bostedt (1995) reported bladder flexion and vaginal prolapse as the third most common cause of dystocia in sows in their survey in Germany. Bladder flexion, which is probably caused by straining, will cause kinking of the urethra, resulting in urinary obstruction and distention of the bladder. Careful catheterisation of the bladder relieves the condition, ensuring that the catheter is not forced through the urethral wall at the point where it is bent.

• **Fig. 13.4** Double external ostia of the cervix of a cow. There was a single internal os, with a bifurcation of the cervical canal at its midpoint.

Other Physical Abnormalities Causing Obstruction

Remnants of the paramesonephric ducts often persist in the cranial vagina of cattle. They generally have the form of one or more 'bands' passing from the roof to the floor just caudal to the cervix and are usually broken during parturition. Sometimes the fetus may pass to one side of them. Occasionally, however, a remnant is of such size and strength that it forms an effective barrier to the birth of the fetus. For example, the cervix may have a single internal os, but the canal then bifurcates, so that the cervix has two external ostia (Fig. 13.4). If both of the forelimbs pass on either side of it dystocia is unlikely to occur. It is important that the obstetrician recognises the abnormality that is present and does not confuse the condition with a partially dilated cervix. To examine the vagina satisfactorily, it is often an advantage to induce caudal epidural anaesthesia and repel the fetus into the uterus. Simple bands of tissue that cause the obstruction can be cut without risk, using a hook-knife or a guarded fetotomy knife of the Colin or Roberts type, but more substantial abnormalities may require Caesarean surgery.

Cases of bifid (septate) uterus and double cervix are occasionally seen on random postmortem examinations of bovine genitalia, and there is generally plentiful evidence that the animals involved have had one or more calves. The condition is surprisingly rarely associated with dystocia, although there are occasions in which both canals had dilated and one forelimb had passed into one canal and the head and the second forelimb had entered the other.

Torsion of the Uterus

Torsion of the uterus is a cause of dystocia in all domestic species. It is most common in buffaloes, relatively common in cattle, and relatively rare in other domestic animals. It is much less common in *Bos indicus* than in *Bos taurus* (Sloss & Dufty 1980). Differences in prevalence between species are considered to reflect differences in the mesenteric suspension and the musculature of the uterus. In the sow, bitch, and queen, torsion is usually of either a single uterine horn, or part of a horn, whereas in other species, the entire uterus rotates along its longitudinal axis.

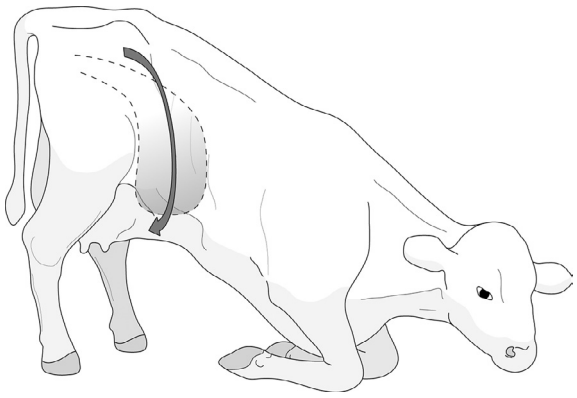
Cattle and Buffaloes

The prevalence of uterine torsion in cattle is around 0.25% of all births (Lyons et al. 2013), between 3% and 7% of cases of dystocia (Frazer et al. 1996) and between 15% and 25% of cases referred to a veterinary hospital (Pearson 1971). Torsion of the uterus is more common in buffaloes than cattle, with up to 80% of dystocia cases presented to veterinary hospitals being due to this particular cause. Purohit et al. (2011) consider uterine torsion to be the most common cause of dystocia in dairy buffaloes. The aetiology and management of torsion is similar for cattle and buffaloes and so will be considered together.

Aetiology

The aetiology of uterine torsion has been extensively reviewed by Ghuman (2010). Uterine torsion is a complication of late first stage or early second stage labour, although nearly all cases occur during first stage labour. Occurrences in midgestation, during second stage labour and the postpartum period have been described but are rare. There are a number of predisposing factors associated with the development of uterine torsion, but the main causal factors appear to be associated with the anatomy of the uterine attachments and the development of the uterus during late gestation. The bovine uterus is predisposed to torsion because of: (i) the attachment of the broad ligament along the lesser (ventral) curvature of the uterus, which thereby leaves the greater (dorsal) curvature free; (ii) the subilial attachment of the broad ligaments; and (iii) the relatively small increase in the length of the broad ligament of the pregnant horn in late gestation, compared with the massive increase of the pregnant horn beyond its area of attachment. As a consequence, (iv) the uterine horns are not fixed by the broad ligaments but are free within the abdominal cavity, and (v) the pregnant horn comes to lie between the rumen, intestines, and abdominal wall, where it is inherently unstable. Thus anything which causes the uterus to become more mobile is associated with increased risk of torsion (Frazer et al. 1996, Ghuman 2010). By this hypothesis the lower prevalence in *B. indicus* than *B. taurus* cattle can be

VetBooks.ir



• **Fig. 13.5** A cow in the process of transition between lying and standing. Note that she is resting on her knees (carpal joints) while the hind legs are fully extended, so that the longitudinal axis *(arrowed)* of the gravid uterus of the cow is almost vertical at this stage.

explained in terms of the attachment of broad ligaments on the dorsal side of the cranial portion of the uterus and the ventrolateral side of its caudal portion in *B. indicus,* thereby making it more stable than in *B. taurus.* The higher prevalence in buffaloes can be attributed to longer ligaments and a lack of muscular tone in the broad ligaments of buffaloes compared with cattle (Ghosh et al. 2013).

Predisposing factors are therefore those which cause increased mobility of the bovine uterus at the time when it is inherently unstable. These include, first, factors associated with increased abdominal capacity such as decreased rumen fill (particularly in concentrate-fed cattle; Frazer et al. 1996) and the depth of the abdominal cavity. Second, factors, such as hilly terrain, slipping, sudden movement of the dam, an unsteady walk, and repeated lying and rising, may also predispose to the condition (Ghosh et al. 2013). Third, movement of the uterus about its longitudinal axis may occur when the cow is attempting to rise to her feet from sternal recumbency, particularly when she is in a confined space. She first flexes her forelimbs, so that she bears most of her weight on both knees (carpal joints). This is followed by a forward lurching movement of the head, neck, and the rest of her body, so that both hind legs can be extended; she is now resting on her knees and hind feet. At this stage she may well rest temporarily before making the final effort to extend the flexed carpal joints and stand on all four feet. When the cow is bearing all of her weight on her knees and fully extended hindlimbs, the longitudinal axis of the uterus will be almost vertical, thus allowing it to rotate quite easily about this axis, especially when violent fetal movements occur at this stage (Fig. 13.5). Finally, the violent fetal movements that occur in response to the increasing frequency and amplitude of uterine contractions during the first stage of parturition, as the fetus assumes the normal disposition for normal birth (see Chapter 6), may be the final precipitating factor. Increased birth weight may increase the risk of fetal torsion, but torsion is not associated with fetomaternal disproportion (Aubry et al. 2008). A low ratio of fetal fluid to fetal size may also predispose to torsion (Schonfelder & Sobiraj 2005). Whether parity is associated with the prevalence of torsion is unclear; Ghosh et al. (2013) considered that pluriparous animals are at greater risk due to a decrease in uterine and mesometrial tone but others have not found any clear trend in the risk with age. In the series of cases reported by Frazer et al. (1996), the Brown Swiss breed was overrepresented, whereas the Hereford, Angus, and Jersey breeds were underrepresented compared with Holstein–Friesians. The presence of bicornual twins would appear to stabilise the parturient uterus, and this view is supported by the great rarity of uterine torsion in cases of twin pregnancy.

Clinical Features

Torsion in an anticlockwise direction (as viewed from behind the cow) is more common than in the clockwise direction, accounting for between 50% and 85% of cases (Manning et al. 1982, Frazer et al. 1996, Lyons et al. 2013). Although the uterus rotates about its longitudinal axis, the actual twist in the majority of cases involves the cranial part of the vagina; in the minority of cases in which the twist affects the caudal part of the uterus, there is minimal distortion of the vaginal walls. In the survey by Frazer et al. (1996) 34% of torsions were precervical and did not involve the vagina. In *B. indicus* more torsions are precervical than vaginal (Prabhakar et al. 1994). The most common degree of torsion is either between 90 degrees and 180 degrees (Wright 1958) or 180 degrees and 270 degrees (Pearson 1971, Frazer et al. 1996), perhaps reflecting the difference in severity of cases seen in the field versus those referred to veterinary hospitals. Williams (1943) noted that torsion of >45 degrees is sufficient to result in dystocia and considered that some dystocias attributed to abnormal fetal position (dorsoilial and dorsopubic) could actually be uterine torsions of low magnitude.

The most constant feature of uterine torsion is its association with parturition; Frazer et al. (1996) reported that 81% of their cases were at term. It is generally believed to occur during the first stage of labour because, immediately after it has been corrected, the cervix will be found to be dilated to a variable degree. However, if after correction the cervix is fully dilated or if before correction the membranes have ruptured and portions of them or the fetus are protruding through the cervix, the inference should be that the torsion occurred during early second stage labour. Roberts (1972) believed that torsions <180 degrees cause little interference with gestation and that such torsion, which often arises during advanced pregnancy and may persist for weeks or months, may resolve spontaneously or may be recognised when they cause dystocia at term. The severity of the torsion does not directly affect the survival of the fetus, fetal death being caused by loss of fetal fluids, separation of the placenta, and/or hypoxia due to construction of the uterine circulation.

Signs

Up to the onset of parturition the animal will have been normal, and when it enters the first stage of labour, the usual signs of restlessness due to subacute abdominal pain associated with myometrial contractions and cervical dilation are shown. By far the most common sign is a failure of normal progression of labour (Lyons & Gordon 2013), and the period of restlessness is either abnormally protracted or it wanes and does not progress into second stage labour. If the torsion does not occur until early second stage labour, then a short period of straining will have followed the restlessness but will have ceased abruptly. Beyond that the signs are rather vague; typically restlessness, straining, reduced feed intake, raised tail head, depression, and teeth grinding. Lyons and Gordon (2013) also noted displacement of the vulval commissure in some cases. In severe cases of torsion there may be increasing restlessness, but more probably all parturient behaviour will cease and, unless the animal has been closely observed, there may be no knowledge that parturition has begun. In the study by Frazer et al. (1996), there was pyrexia (23%),

VetBooks.ir

tachycardia (93%), tachypnoea (84%), straining (23%), anorexia (18%), and a vaginal discharge (13%).

If the condition is not corrected, the placenta will separate, and the fetus will die. Persistent low-grade abdominal pain, progressive anorexia, and constipation will develop. Eventually, the fetus will start to decompose and become emphysematous. Uterine tissues become compromised as a result of the hypoxia that results from compression of the uterine circulation: oedema accumulates in the wall of the uterus, after which degeneration of the myometrial fibres can occur. As a consequence, the uterus or vagina can rupture, major blood vessels of the uterus or broad ligament can rupture, adhesions to surrounding tissue, and/or necrosis of the cervix can occur.

It is also increasingly clear that there is a significant systemic reaction to uterine torsion. This can include loss of tissue fluid and electrolytes due to oedema and transudation and impairment of liver and renal function. Concentrations of haptoglobin, an acute phase protein, increase, which can be regarded as a good indicator of the degree of uterine tissue impairment (Schonfelder et al. 2007). Similarly, blood lactate concentrations may be an indicator of uterine tissue necrosis: Murakami et al. (2017) found that concentrations in cows with uterine necrosis (15 mmol/L) were much higher than in those without necrosis (3 mmol/L). Ghuman (2010) suggested that fluid therapy, plasma expanders (Dextran 40), and correction of acid/base imbalances materially improve the prognosis for cows with more serious/long-standing cases of uterine torsion. However, the use of plasma expanders is likely to be cost prohibitive in cattle practice.

Diagnosis

In cases involving the cranial vagina, diagnosis is readily made by vaginal examination of the cranial vagina, where spiral folds can be palpated. The direction of the spirals indicates the direction of the uterine rotation. The cervix may not be immediately palpable but, by carefully following the folds into the narrowing vagina, the fingers can usually be pressed forwards into the partially dilated cervix. Palpation of the cervix is difficult if the torsion is >180 degrees. When doubt exists about the diagnosis or when the site of the torsion is precervical, diagnosis is assisted by palpating the broad ligament *per rectum.* With the more usual anticlockwise presentation (viewed from behind), the broad ligament can be felt as a tight band running dorsally from the right side, ventrally to the left (Lyons & Gordon 2013). In torsions of less than 180 degrees, portions of the fetus may enter the vagina and the dystocia may be wrongly ascribed to faulty fetal position (lateral or ventral).

Treatment

Rotation of the fetus *per vaginam*. Many cases of uterine torsion can be corrected manually *per vaginam.* The aim of this method is to reach the fetus by insertion of the hand through the constriction of the cranial vagina and partially dilated cervix, and then to apply a rotational force to the uterus via the fetus. A prerequisite for attempting rotation *per vaginam* is that enough of the fetus can be felt to allow manipulation – ideally being able to palpate the head and neck. Success is also much more likely if the cow is standing. With a hand placed flat on the calf's neck, the calf is rocked back and forth while an assistant may apply external force to the abdomen to assist with the rocking of the calf. Once sufficient momentum has been achieved, strong force is applied to rotate the calf in a clockwise direction (in the case of the more common anticlockwise direction of torsion) (or vice versa for clockwise torsions). Once the calf starts to rotate, the operator's hand and arm are quickly turned around and the calf pushed up and over in the uterus in the direction opposite to that of the torsion, using the palm of the hand. Cases of <90 degrees of torsion are generally simple to resolve by vaginal rotation, and cases that are <180 degrees can usually be resolved. Torsions that are >180 degrees become progressively more difficult to resolve by vaginal rotation, as the degree of torsion increases. Long-standing torsions, in which adhesions have formed between the uterus and other abdominal viscera, are often resistant to resolution by vaginal rotation. Administration of clenbuterol before attempting manipulation appears to improve the probability of successful detorsion, although its efficacy is reduced in long-standing torsions or torsions of ≥360 degrees (Menard 1994). It appears to be helpful to have the rear of the cow higher than the front, and epidural anaesthesia may also help. If the calf is alive, the chances of successful detorsion are increased, as its spontaneous movements can aid correction.

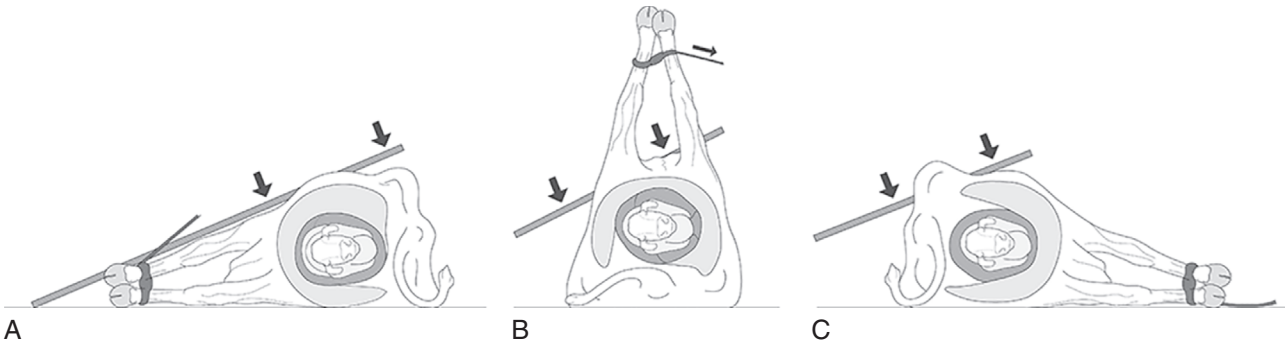
• **Fig. 13.6** Use of a detorsion rod to correct a uterine torsion in the cow. Each forelimb of the fetus is attached by snares above each of the fetlocks to the end of the rod. Rotational pressure applied through the handle successfully relieves many cases of uterine torsion. (Photograph courtesy Dr. Berthold Hesselink, Herberex, The Netherlands.)

Detorsion rods (Fig. 13.6) can be used as an alternative to manual rolling *per vaginam.* Snares are attached above each of the calf's fetlocks, then to the end of the rod. A broad handle allows a greater degree of rotational pressure to be applied to the calf than can be achieved by manual effort alone. The use of detorsion rods carries an increased risk of damage to either the uterus or the calf's limbs. Torsion of the uterus cranial to the cervix cannot be treated by vaginal manipulation nor can the rare cases of twists of 720 degrees or more.

Rotation of the Cow's Body: Correction by 'Rolling'. Rolling is indicated if the dam is recumbent, if the fetus is not approachable due to the severity of torsion, if the calf is obviously dead, if the torsion has occurred before the expected time of parturition, or if attempts at detorsion by vaginal manipulation have failed (Ghuman 2010). Rolling methods require an absolute minimum of two competent assistants, although three are preferable (Lyons & Gordon 2013).

The aim is to rotate the cow's body in the direction of the torsion while the uterus remains relatively steady. The cow is cast by Reuff's method on the side to which the torsion is directed. Thus for an anticlockwise torsion the cow is cast onto its left side, and for a clockwise torsion it is cast onto its right side. One assistant holds down the head while the hind and, preferably also the fore, feet are hobbled and attached to ropes. At a given signal

VetBooks.ir



• **Fig. 13.7** Schäfer's method for the correction of uterine torsion in the cow. The cow is cast into lateral recumbency and onto the same side as the direction of the torsion (right side for a clockwise torsion). (A) A plank, 3 to 4 m long and 20 to 30 cm wide, is placed on the flank over the abdomen. An assistant stands on the plank *(black arrows)*. (B) The cow is rolled over slowly to the right in the direction of the torsion. (C) Rolling is completed and the uterine torsion corrected. (Redrawn from Roberts and Hillman (1973).)

a sudden smart coordinated pull is made on the leg ropes so that the cow is rapidly turned over from one side to the other. A vaginal examination is then made to ascertain whether correction has occurred, in which case there is ready manual access to the cervix and probably to the fetus in the uterus, and there may be a flow of fetal fluids from the vagina. If no correction has occurred, the cow is slowly restored to her original position or the legs can be flexed under her body, and she can be turned 180 degrees over her legs on to the original side. The same procedure of rapid turning is then repeated.

Additionally, if the calf is accessible *per vaginam,* the veterinarian may try to better fix the position of the uterus by holding onto the calf while the cow is being rotated. However, Lyons and Gordon (2013) warn of the risk of injury to the veterinarian if this is attempted.

A modification of the foregoing traditional technique described by Schäfer (1946) entails the placing of a wide plank of wood or ladder, 3 to 4 m long and 20 to 30 cm wide, on the flank of the cow, such that one end extends over the paralumbar fossa and the other end rests on the ground. An assistant stands on the plank while the cow is slowly turned over by pulling on the leg ropes (Fig. 13.7). The advantages of this technique are that the plank fixes the uterus while the cow's body is turned and, because the cow is turned slowly, less assistance is required, and it is easier for the veterinarian to check the correct direction of the rolling by vaginal palpation. Moreover, the first rolling is usually successful. Nanda et al. (1991) suggested that, if the torsion is not resolved by three rolls, attempts to relieve it should be abandoned, and Caesarean surgery is indicated. Injury to the cow is more likely if more than three rolls are attempted, with buffalo cows being particularly susceptible.

Delivery After Detorsion. The majority of calves can be delivered *per vaginam* after detorsion of the uterus, either without further obstetrical assistance or after further manipulation and traction. However, the cervix is incompletely dilated in a significant proportion of cows after detorsion: 33% to 35% (Frazer et al. 1996, Aubry et al. 2008, Lyons et al. 2013) of cows that had had uterine torsion successfully corrected subsequently had incomplete cervical dilation. Some of these cows required delivery of the fetus by Caesarean surgery, but in some the cervix later dilated sufficiently to allow vaginal delivery. Lyons and Gordon (2013) noted that opinions differ on how long to leave the cow after correction before further intervention is required. If possible, the calf should be delivered immediately after correction, but when this is not possible, they recommended leaving the cow for up to 3 hours to allow second stage parturition to proceed. However, in cases in which the calf is dead, the cervix is unlikely to dilate further after the torsion has been corrected.

Surgical Correction. If the case cannot be corrected by either of the previous methods or if it is likely that the torsion has been present for longer than 72 hours, a laparotomy should be performed on the standing cow through the left or right flank and an attempt made to rotate the uterus by intraabdominal manipulation. Because a Caesarean hysterotomy may also be required before the torsion can be corrected – or after the torsion is corrected when the cervix will not dilate – a left flank approach is by far the most preferable (see Chapter 16). However, it should be remembered that in cases of uterine torsion there are often loops of small intestine displaced on the left side of the abdomen and that, owing to oedema of its walls, the uterus is unusually friable, and there will be copious amounts of peritoneal transudate in the abdominal cavity. Under paravertebral or field infiltration anaesthesia, a 15 to 20 cm incision is made in the left paralumbar fossa. A hand is inserted, the uterus located, and the direction of torsion confirmed. For an anticlockwise torsion, the hand is passed down between the uterus and the left flank, and a fetal handhold is sought; then an attempt is made to 'rock' the uterus and then rotate it by strongly lifting and pushing over to the right. For a clockwise twist, the hand is passed over and down between the uterus and the right flank and, as before, a swinging manoeuvre is followed by pulling upwards and over to the left. In cases in which it is impossible to rotate the uterus by abdominal manipulation, the fetus must be removed before the torsion can be corrected. The risk of opening the uterus before delivering the fetus is that, once it is removed, the position of the uterus may spontaneously correct itself, leaving the incision in the uterus inaccessible for closure. Otherwise, the uterus is closed, and the torsion resolved subsequently. In many cases, it is not possible to correct the torsion as described previously, as the twisted uterus will be grossly distended, with the uterine wall being oedematous and extremely friable. Attempting to obtain a fetal handhold carries the significant risk of uterine perforation. Therefore it may be best to carry out a laparotomy, using the lateral oblique approach, and subsequently rotate the uterus as is described in Chapter 16. This particular approach provides improved access to the gravid uterus compared with the commonly used left paralumbar fossa approach. It is further advised, once the torsion has been corrected, to allow some time to pass before incising the uterus and removing the calf, in the hope that some of the built-up oedema in the uterine

VetBooks.ir

wall will dissolve. Great care should be taken when suturing the friable uterine incision, making sure that a good seal is obtained.

Clenbuterol administration facilitates detorsion of the uterus and its exteriorisation for incision and closure (Vermunt 1987). Schonfelder and Hasenclever (2005) calculated the relative costs of euthanasia of cows with irreducible torsions versus the cost of Caesarean surgery and determined that it was far more cost effective to attempt Caesarean than to euthanise such cows.

Sequelae of Torsion. There are records of spontaneous recoveries, but it is generally believed that uncorrected uterine torsion will progress to fetal death, putrefaction, and fatal maternal toxaemia. Fetal maceration with maternal survival is possible. With the adoption of prompt treatment, the prognosis is favourable for mother and fetus, but delay leads to a progressive worsening of the prognosis for the dam (Prabhakar et al. 1994). Roberts (1972) recorded 4.3% maternal mortality. In Pearson's (1971) series of 168 more severe cases treated in a veterinary hospital, only 67 calves were born alive; however, it is certain that a better rate of survival is achieved in the less severe cases treated more promptly on farms. In the series by Frazer et al. (1996), cow survival was 78%, and calf survival was 24%.

Sheep and Goats

The frequency of uterine torsion in the ewe and doe goat is very low, as it does not appear to be a significant cause of dystocia in any of the published surveys. However, this may reflect the limited veterinary involvement with ovine dystocia rather than a true difference in prevalence (Scott 2011). A lower prevalence in the sheep and doe compared with the cow may be related to differences of the anatomy of the broad ligament, whose attachment is sublumbar in the ewe rather than subileal as in cattle; it is therefore postulated that the pregnant uterus of the ewe would be less unstable than that of the cow.

In its clinical signs the condition closely resembles uterine torsion in cattle but, because of the smaller size of sheep and goats, it is much more difficult to insert a hand into the constricted vagina. Mild torsions may be confused with incomplete cervical dilation (Scott 2011). Diagnosis can be aided by the use of transabdominal ultrasonography (Wehrend et al. 2002, Jung & Bostedt 2007). The probe should be placed immediately cranial to the pelvic brim, with the probe head directed vertically (Scott 2012). The oedema of the uterine wall results in gross thickening of its ultrasonographic appearance.

There are various ways of treating the condition. The ewe or doe can be given caudal epidural anaesthesia (and maybe also clenbuterol) and, with the hindlimbs held so that the animal is almost vertical, a relatively modest rotatory force on a fetal appendage or a rotatory movement of the dam's body is usually sufficient to correct the torsion. Rolling, with a modification of Schäfer's method for the smaller body mass of the ewe, has been described as a means of managing uterine torsion (Kumar et al. 2016, Teja et al. 2017, Velladurai et al. 2017). If these methods fail then Caesarean surgery must be undertaken. Long-standing torsions can become impossible to resolve without resorting to surgery because of the development of adhesions between the uterus and other abdominal viscera.

Horse

Torsion of the uterus is an uncommon, but serious, condition of the pregnant mare. The prevalence is difficult to estimate, as most series are published from referral clinics where only the more difficult cases are seen. Ginther and Williams (1996) saw no cases of torsion among the 11% of dystocias recorded in 517 spontaneous foalings, whereas Leidl et al. (1993), in a study from the Munich Veterinary School, found uterine torsion present in 17 out of 100 dystocia cases. Chaney et al. (2006) reported 86 cases of uterine torsion between 1985 and 2005 in four referral hospitals and Vandeplassche et al. (1972) reported on 42 cases.

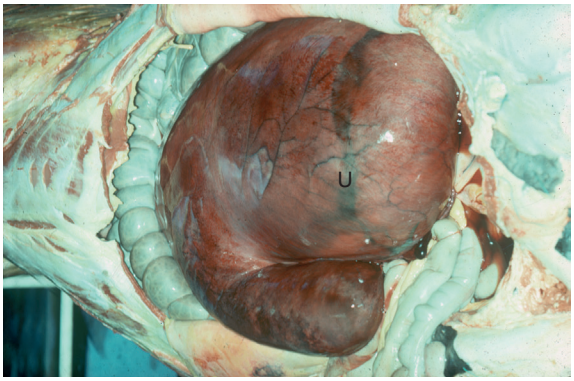
Uterine torsion is less common in the mare than the cow, perhaps due to the sublumbar attachment of the ovaries and dorsal attachment of the broad ligaments, which creates a more stable anatomical suspension of the equine reproductive tract than in the cow. The exact causes of uterine torsion are unknown, but suggested contributing factors include sudden falls or vigorous movement of a large fetus in a relatively small volume of fluid (Blanchard et al. 2010). Vandeplassche et al. (1972) found that twisting in an anticlockwise direction is the more common, and in the majority of cases, the extent of rotation was 360 degrees or more. However, of the cases reported by Riggs (2006), most were of 180 degrees.

Uterine torsion in the mare is much less strongly associated with parturition than it is in cattle: in the aforegoing surveys, more than half of the cases occurred before the end of gestation. Jung et al. (2007) reported uterine torsions that occurred between 5 months of gestation and term, whereas Pascoe et al. (1981) recorded the mean stage of gestation of mare with torsion as 9.6 months. Riggs (2006) considered that most cases occur in the last 60 days of gestation but before the onset of labour. The condition is therefore as much a differential diagnosis of colic as it is of dystocia: uterine torsions are commonly diagnosed as an acute event with the affected mare showing mild to moderate signs of colic (Riggs 2006). The possibility of uterine torsion should therefore always be considered in cases of colic during late pregnancy. Doyle et al. (2002) suggested that if any mare in late gestation shows signs of pyrexia, anaemia, tachycardia, and anorexia over a 2- to 4-week period, then chronic uterine torsion should be considered as one of the differential diagnoses. Diagnosis is readily established by rectal palpation of the crossed broad uterine ligaments, which also provides information on both the direction and degree of the torsion. The circulatory disturbance in the equine uterus is greater than with the same condition in cattle, with consequent risk to the survival of the fetus and the development of shock in the dam.

The main methods for correcting uterine torsion in the mare are: (i) vaginal correction in the standing mare; (ii) rolling the anaesthetised mare in lateral recumbency; (iii) flank laparotomy in the standing mare; and (iv) midline laparotomy in the anaesthetised mare.

If the mare is at full term and the cervix is sufficiently open to allow the fetus to be grasped, it may be possible to correct the torsion by rocking and applying rotational force to the fetus *per vaginam* (Riggs 2006). The ventrolateral aspect of the fetus is grasped, while the obstetrician's arm is resting on the dam's pelvic floor. The fetus is gently rocked until enough momentum is gathered to lift it up and over in the uterus in the direction opposite to that of the torsion. If successful, the fetus and uterus will rotate into the normal position and the mare will progress into second stage labour (Blanchard et al. 2010). Alternatively, the mare can be anaesthetised (e.g., xylazine/ketamine) and rolled in lateral recumbency by a method akin to Schäfer's method. The anaesthetised mare is placed into recumbency on the side of the torsion (right for clockwise, left for anticlockwise), a plank is placed over the dorsum of the abdomen to fix the calf, and the mare is then pulled over via dorsal recumbency onto her opposite side. This has proved to be a successful method of treatment: Wichtel et al. (1988) delivered six out of seven mares by this means, and

VetBooks.ir



• **Fig. 13.8** Uterine torsion in a mare, as exposed by midline laparotomy. Note the congested uterus *(u)*. Correction by rotating the uterus was impossible, and a dead foal was removed after hysterotomy; thereafter, correction of the torsion was possible.

Dabas et al. (2014) corrected torsion in two mares that were 9½ months pregnant by rolling. These mares went on to deliver live foals at term.

Surgical correction should be used if rolling has failed to resolve the torsion after a couple of attempts or if the condition is deemed unsuitable for nonsurgical management. Flank laparotomy was recommended by Vandeplassche et al. (1972) to allow rotation of the uterus by direct traction. The mare is placed in the stocks, under just enough sedation to ensure that she remains standing. After preparation of the paralumbar fossa, local anaesthetic is infused in a line just cranial to the incision site or in a grid pattern (Vasey & Russel 2011). A high flank incision is made on the side of the torsion (Jones 1976, Threlfall 2007). The uterine torsion is corrected by reaching under the uterus, grasping the legs of the foal and gently rocking the foal and uterus with a pull-and-lift motion until it is returned to a normal position (Blanchard et al. 2010). If there is sufficient space, one hand can be used to grasp a fetal limb through the underside of the uterus and pull towards the operator, while the other hand simultaneously pushes against the dorsal aspect of the uterus. Occasionally, access through incisions in both flanks is required (Vasey & Russel 2011).

Alternatively, the mare can be anaesthetised and a midline laparotomy performed. Pascoe et al. (1981) suggested that recumbent laparotomy should be used if the mare is intractable, the uterus is ruptured, there is an emphysematous fetus, or the uterus is likely to be devitalised. In uncomplicated cases detorsion can be achieved by grasping the limbs of the foal and rotating the uterus. In complicated cases, such as when adhesions have formed (Doyle et al. 2002), the uterus is very friable or has ruptured, or the fetus is dead, removal of the fetus from the uterus is indicated before detorsion can be achieved (Fig. 13.8). However, Jung et al. (2007) left the (live) fetus *in utero* if fetal reflexes were present and provided intensive treatment of the mare to maintain the pregnancy. Seventeen of 23 mares managed that way carried to full term (two aborted, and four either failed to survive surgery or were euthanised). Saini et al. (2013) removed the fetus from the uterus of all 12 full-term/late-gestation mares with torsions, resulting in survival of 9 of the 12 mares, but only one foal survived long term.

Chaney et al. (2006) reviewed the factors affecting mare and foal survival in 63 cases of uterine torsion. Overall mare survival was 84% but was higher (97%) if the torsion occurred at <10 months of gestation than if torsion occurred later (65%). Overall foal survival (54%) was also higher if torsion occurred at <10 months gestation (72%) than later (32%). Foal survival was highest when the torsion was corrected by standing flank surgery, although this was confounded with gestational age. More advanced gestations or those selected for correction by midline laparotomy were already compromised by fetal hypoxia and/or devitalisation of the uterus.

When dystocia is due to uterine torsion, an attempt should be made to pass a hand through the cervix and to rotate the uterus by manipulating the fetus. According to Vandeplassche (1980), this is facilitated by the use of caudal epidural anaesthesia and raising the hindquarters of the mare. In addition, because of its recorded value in correcting uterine torsion *per vaginam* in the cow, clenbuterol might be used. If these methods fail, Caesarean surgery must be performed.

Pig

Uterine torsion is very rare in sows (Jackson 1973). However, when it does occur, it can be difficult to diagnose, and frequently, this is only done at postmortem examination. Torsion can involve one entire horn or, more frequently, part of one horn, thereby trapping a fetus or fetuses proximal to the obstruction; in time, the uterine wall will rupture and the fetus or fetuses will become pseudoectopic. It is one of the differential diagnoses to consider if a sow has not completed farrowing and yet piglets can either be palpated or identified using transabdominal ultrasonography. The only method of treatment is correction after a laparotomy, or probably a hysterectomy.

Dog and Cat

Uterine torsion is uncommon in the bitch. In a series of 182 dystocias examined at a veterinary hospital in Stockholm over a 4.5-year period, two cases of uterine torsion (1.1%) were diagnosed (Walett-Darvelid & Linde-Forsberg 1994). One was in a 1-year-old Mastiff, which had two macerated fetuses in which the complex torsion involved both horns and cervix, and the other case was in a 4-year-old Giant Schnauzer with 13 pups in which there was 180 degrees torsion. Both cases were treated by Caesarean surgery. Umamageswari et al. (2014) reported a unilateral torsion in a parturient German Shepherd bitch: two dead fetuses were located cranial to the torsion, and the uterine horn was necrotic. Likewise, Eyarefe et al. (2012) found 270 degrees torsion of one uterine horn, with four dead fetuses distal to the torsion. Torsion and haemometra of a bitch that had occurred in midgestation (33 days) was reported by Otava (2011). Murugavel et al. (2013) found uterine torsion in a bitch that also had pyometra. Subsequent pregnancies after treatment of unilateral or partial uterine torsion by partial hysterectomy have also been reported (Kumru et al. 2011). The clinical signs may be of an obstructive dystocia when pups remain in the uterus; however, it is very difficult to determine the precise cause of the obstruction. However, the bitch may also present with vague signs of malaise or, alternatively, of an acute abdominal disorder. In pregnant bitches a few instances have been discovered on postmortem examinations when there were torsions of up to 180 degrees; the rare finding of encapsulated fetal bones in a bitch's abdomen may be a legacy of uterine torsion and rupture. If a uterine torsion is promptly diagnosed, management by Caesarean surgery should be successful. The use of oxytocin may cause uterine rupture.

In the cat, torsions of 90 degrees to 180 degrees, involving either one horn or the uterine body, have been described in near full-term pregnancies or parturient queens (Freeman 1988, Ridyard et al.

VetBooks.ir

• **Fig. 13.9** Ventral hernia in a ewe. (Courtesy Dr. Rob Lofstedt.)

2000, Dal-Bo et al. 2013), typically in association with sudden illness. Midgestation torsion was described by Thilagar et al. (2005) in a queen that exhibited a bloody vaginal discharge and signs of an acute abdominal disorder, whereas postpartum torsion in association with puerperal metritis was reported by Oliveira et al. (2016). As in the bitch, a precise diagnosis of uterine torsion as a cause of an obstructive dystocia is difficult, even with good quality imaging techniques. Often a diagnosis is made only at laparotomy, in which case a prompt hysterotomy or hysterectomy should be performed. Occasional instances of extrauterine abdominal fetuses have been recorded (Bark et al. 1980). These probably result from uterine rupture during pregnancy, possibly associated with uterine torsion, rather than from an ectopic pregnancy.

Displacement of the Pregnant Uterus

Ventral Hernia in the Mare, Cow, and Ewe

Occasionally in all three species, hernia of the pregnant uterus occurs through a rupture of the prepubic tendon and muscles of abdominal wall (Fig. 13.9). The accident is one of advanced pregnancy, occurring at the ninth month or later in the mare, from the seventh month onwards in the cow, and during the last month in the ewe; it usually occurs in older or aged animals. The aetiology is obscure: a traumatic origin has been postulated, but it may also be attributed to abnormalities of posture (Seyrek-Intas et al. 2011) or intrinsic weakness of the musculature. Regardless of the underlying cause, the abdominal musculature becomes in some way so weakened that it is unable to support the gravid uterus. The site of the original rupture is the ventral aspect of the abdomen, a little to one side of the midline (left in the case of the mare and right in the cow and ewe) behind the umbilicus. It generally commences as a local swelling about the size of a football, but rapidly enlarges until it forms an enormous ventral swelling extending from the pelvic brim to the xiphisternum. It is most prominent at the caudal end of the abdomen, where it may sink to the level of the hocks. By this time, practically the whole of the uterus and its contents have passed out of the abdomen to occupy a subcutaneous position. In cattle the bulk of the swelling is often situated between the hind legs, the udder being deflected to one side. Generally, the condition is complicated by gross oedema of the abdominal wall due to pressure on the ventrally situated veins; in fact, this oedema may be so great that it is impossible to palpate either the edges of the rupture or the fetus.

As a rule, gestation is uninterrupted. Pregnant mares can be managed by supporting the caudal abdomen, stall rest, and/or analgesia. Schutten (2016) and Moaddab and Siavosh (2017) both described mares that successfully carried pregnancies to term and delivered the fetuses at full term. In the mare, delivery of the foal by traction, despite the downward deviation of the uterus, is possible; however, cases can be visualised in which displacement of the uterus places the fetus beyond reach. In these it is advised that the mare is anaesthetised and placed in dorsal recumbency, and the hernia reduced by pressure. Attempts at delivery should be made with the animal in this position. In the ewe, surgical reduction of ventral hernias has been described, along with delivery of the lambs by Caesarean surgery (Dar et al. 2016), and a similar procedure has been reported in the cow (Choudhury et al. 2016). Cows and ewes may give birth spontaneously despite severe ventral hernia, although affected animals should be closely watched during labour in case assistance is needed. Nevertheless, it is important to consider whether it is in the interest of the dam's welfare that the pregnancy should continue, or whether it might be preferable for the animal to be euthanised.

Downward Deviation of the Porcine Uterus

Downward deviation of the uterus has been described by Jackson (1973) as the cause of 19 of 200 cases of porcine dystocia. Affected animals strained vigorously despite an empty vagina, and at a point about 15 to 22 cm in front of the pelvic brim the uterus deviated sharply in a downward and backward direction. It was very difficult to extract the obstructed piglets manually, and insertion of the arm up to the shoulder was necessary so that the obstetrician's elbow could be flexed within the sow's abdomen. Affected sows were deep-bodied and pregnant with large litters.

Retroflexion of the Mare's Uterus

Vandeplassche (1980) reported 18 cases of retroflexion of the mare's uterus occurring over 10 years at the Ghent Veterinary Clinic, in which there was severe colic in mares near term with the foal occupying the maternal pelvis. *Per rectum,* the foal could be pushed back into the abdomen. However, this manipulation provoked renewed colic, and the fetus soon regained its intrapelvic position. It was found that the muscle relaxant isoxsuprine lactate in doses of 200 mg and injected at regular intervals relieved the colic and allowed the foal to move forwards in front of the pelvis. Normal parturition followed in due course.

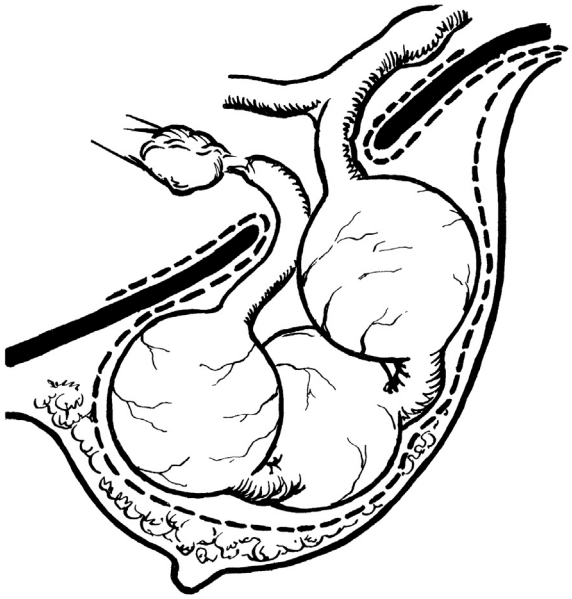
Inguinal Hernia in the Bitch

In the bitch, acquired inguinal hernia, through which the uterus may herniate, is relatively common. The incarcerated uterus then often becomes the focus of pregnancy. The condition can also occur in the cat but is rare in this species. The hernia is generally unilateral and may contain one or both uterine horns.

Often the history is that an inguinal swelling the size of a hen's egg has been recognised by the owner for months, but that during the last few weeks it has rapidly become larger. In other cases the recent development of a progressive swelling is the story. There may or may not be a history of recent oestrus and mating.

The lesion is obvious and, if a careful examination is carried out, it is unlikely that it will be confused with a mammary neoplasm or a local abscess. The condition is painless, and there is no systemic disturbance. Although it is tense and irreducible, there is little tendency for strangulation, provided the intestine is not involved. The latter complication is rare. In those cases in which pregnancy is advanced, it will probably be possible to detect fetuses on palpation, which can be confirmed by transabdominal ultrasonography.

VetBooks.ir



• **Fig. 13.10** Inguinal metrocele in a bitch gravid with three embryos of about 30 days.

The course of the condition depends primarily on the degree of tension in the hernial sac, and this will be influenced by its size and the number of fetuses involved. Sometimes, the fetuses will develop normally up to a certain point and then die, probably because of impaired blood supply to the herniated parts of the uterine horns, and then undergo resorption. The majority of cases will be presented when pregnancy has advanced about 30 days and each fetal unit is about the size of a golf ball, for by this time the size of the swelling is becoming alarming to the owner (Fig. 13.10). It is very unlikely, but not impossible, for such a pregnancy to go to term, with subsequent dystocia.

If an inguinal hernia is diagnosed in a pregnant bitch, these options should be considered:

- Reduce the hernia, obliterate the hernia sac, and allow pregnancy to take its normal course. In the vast majority of cases, it will not be possible to reduce the hernia by simple means.
- Enlarge the hernial ring by incision of the abdominal wall, obliterate the sac, suture the hernial ring closed, and allow the pregnancy to progress to term. This is the preferred method in terms of the outcomes of pregnancy and of the maintenance of the bitch's ability to breed. It presents, however, several technical difficulties. Precise incision of the abdominal wall forwards from the inguinal orifice is not easy owing to the presence of the large and tensely filled hernia sac. Moreover, effective closure of the neck of the sac may be difficult after incision of the parietal peritoneum.
- Dissect out the hernial sac, incise its apex, and expose the herniated uterus. Amputate the uterine horn involved. Obliterate the hernial sac. If it happens that the animal is also pregnant in an abdominally situated horn, this should be left intact. If, however, an abdominally situated horn is empty and it is desired that a hysterectomy be performed, it is relatively easy after locating the bifurcation to draw this horn into the hernia and remove it. As a rule, it is not possible to also draw the ovaries through the inguinal ring. This procedure is most often performed, as it presents no particular difficulties and cure of the hernia is certain.
- In those cases in which fetal development is at or approaching term, it may be decided to proceed as described previously but, instead of amputating the involved horn, perform a hysterotomy and extract the fetuses with their membranes.

Defects of Expulsive Forces

The expulsive force of labour is due to a combination of myometrial contractions and straining induced by the contraction of the abdominal muscles with a closed glottis. Because the abdominal muscles do not come into play until the myometrium has forced the fetus and fetal membranes into the pelvic canal and stimulated the pelvic sensory nerve receptors, it is logical to consider first the expulsive deficiencies that may arise in the myometrium. These may occur spontaneously or dependently and are called, respectively, primary and secondary uterine inertia.

Primary Uterine Inertia

The physiology of myometrial contractions during labour is described in Chapter 6. Primary uterine inertia implies an original deficiency in the contractile potential of the myometrium, thereby removing or reducing this component of the expulsive force and delaying or preventing the completion of the second stage of parturition. It is a common cause of dystocia in polytocous species, in which it has been shown to be responsible for 37% of dystocias in sows (Jackson 1973), 49% in bitches, and 37% in queen cats (Linde-Forsberg & Eneroth 1998). It also occurs relatively commonly in the cow, in which it is usually due to hypocalcaemia, as well as being a contributor to incomplete cervical dilation (see previous mention).

These factors may be involved in the cause of primary uterine inertia:

- The progesterone to oestrogen ratio is important as it influences uterine contractility in a number of ways (see also Chapter 6). Oestrogen increases: the synthesis of contractile protein; the number of agonist receptors for oxytocin and prostaglandins; the activity of myosin light-chain kinase (MLCK), which is involved in the phosphorylation of myosin and hence the biochemical changes involved in contraction; calmodulin synthesis, which increases MLCK activity; and the number of gap junctions. Progesterone has the opposite effects, thereby reducing myometrial contractility. In this context the findings of Bergström et al. (2010) are interesting, as they observed similar oestradiol concentrations in bitches with normal parturition and in those with uterine inertia, although the ratio of progesterone to prostaglandin $F_2\alpha$ (measured as PGFM) was higher in the animals with dystocia than in normal bitches. Such findings corroborate the notion of the dominant effect of progesterone in determining the onset and normality of labour. Others have suggested that partial failure of luteolysis may contribute to the development of uterine inertia in bitches.
- Oxytocin and prostaglandins are involved directly and indirectly in myometrial contractions. Any deficiencies in these hormones or their receptors, through which they exert their action, will prevent or reduce myometrial contractions.
- Calcium and related inorganic ions, such as magnesium, have a critical role in smooth muscle contractions. Any deficiency will impair these contractions, causing uterine inertia. This is a particular problem in dairy cows, particularly those at pasture because most cows experience a transient decline in food intake around the time of calving, which will result in reduced calcium intake. It is important to control feeding carefully during this

VetBooks.ir

transitional period because hypocalcaemia will cause uterine inertia, resulting in dystocia. Kraus and Schwab (1990) reported that bitches with primary inertia did not display calcium deficiency. However, Bergström et al. (2006) showed that, although low oxytocin concentrations were the direct cause of uterine inertia, the effects of low oxytocin were exacerbated by the presence of low concentrations of calcium. Discrepancies between results of the effects of calcium may reflect differences between total calcium and ionised calcium concentrations; Hollinshead et al. (2010) found that bitches, which were prone to uterine inertia, had higher concentrations of parathyroid hormone (PTH), lower concentrations of calcium, and higher blood pH than did normal bitches, suggesting that, by analogy with the similar situation in the cow, there may be merit in maintaining cationic/anionic balances in the diet of prepartum bitches.

- Overstretching of the myometrium, due to the presence of a large litter or excess fetal fluids (hydrallantois), or understretching, due to a small litter in polytocous species, can cause reduced uterine activity.
- There is anecdotal evidence that fatty infiltration between the layers of the myometrium can reduce its contractile efficiency.

The diagnosis of primary uterine inertia is made from the history and by an examination of the birth canal and presenting fetus. The dam is at or near term, as denoted by mammary changes and ligamentous relaxation in the pelvis (where this is normally apparent), although the psychological manifestations, coupled with restlessness due to abdominal discomfort, will have indicated that the first stage has passed. There may have been a few feeble abdominal contractions but no progress has been made or, in the polytocous species, after an adequate beginning of second stage labour all further activity has ceased. Linde-Forsberg and Eneroth (1998) refer to this as 'primary partial uterine inertia' to differentiate it from 'primary complete inertia' in which second stage fails to commence at all. It is difficult to distinguish this from secondary inertia, which is always a sequel to some other factor, such as an obstructive dystocia. Munnich and Kuchenmeister (2009) quantified this difference, finding 14% of dystocias were associated with a complete failure of myometrial contractions, compared with a total or 42% of dystocias in which 'inertia' of one form or another was diagnosed. Examination of the birth canal in the larger animals reveals a patent cervix, beyond which a fetus can normally be palpated, contained within its membranes. In the bitch and cat it is likely that no fetus or membranes will be felt.

It is essential that treatment should be attempted as soon as possible once other causes of dystocia have been ruled out as being responsible. In the large monotocous species, treatment is generally simple. By vaginal manipulation the membranes are ruptured and, if the fetus is in normal disposition, it should be delivered immediately by traction. In cows calcium borogluconate should be given even if there is no clinical evidence of hypocalcaemia.

In the sow there is evidence that hypocalcaemia is associated with some cases of uterine inertia (Framstad et al. 1989), but it is difficult to administer large volumes of calcium borogluconate as can be done in cattle. Treatment involves a combination of manual removal of any piglets that can be palpated in the vagina or uterus, together with the use of repeated doses of oxytocin. It is important to stress that oxytocin is a potent ecbolic, and doses of ≤10 IU i/m or ≤5 IU i/v should be used initially. Large doses tend to cause myometrial spasm rather than peristaltic contractions. In addition, the myometrium becomes refractory to repeated dosing, so it is important to provide an opportunity for an incremental dose regimen. The effect of different doses of oxytocin on the progress of parturition in sows has been described by Mota-Rojas et al. (2005, 2006) and Gonzalez-Lozano et al. (2009).

For the bitch and queen cat, in which primary uterine inertia is the main cause of dystocia, Linde-Forsberg and Eneroth (1998) suggested this treatment regimen:

- Vigorous exercise of the dam will sometimes stimulate uterine contractions.
- Digital stimulation of the vagina (feathering) will stimulate endogenous oxytocin release and may induce uterine contractions.
- Slowly inject 10% calcium borogluconate solution i/v (0.5–1.5 mL/kg body weight). This is in response to the notion that subclinical hypocalcaemia is a common cause of inertia.
- Leave the bitch for 30 minutes; if straining commences then repeat the calcium borogluconate treatment. If not, administer oxytocin at a dose rate of 0.5–5 IU i/v or 1 to 10 IU i/m in the bitch, depending on size, and 0.5 IU i/v or i/m in the queen.
- Perform a vaginal examination and remove any pups or kittens by gentle traction.
- Oxytocin treatment can be repeated, particularly if small numbers of the litter remain unborn.
- If calcium or oxytocin therapy is not successful or if the litter is very large or small (a single pup or kitten), then Caesarean surgery is indicated.

Nervous Voluntary Inhibition of Labour

In the series of canine dystocias reported by Freak (1962), in 17 of 272 cases, labour did not begin or, having begun, did not proceed. The factor common to all the affected bitches was the provision of a special parturition environment to which the bitch was unaccustomed. When the bitches were returned to their accustomed quarters, they proceeded to whelp. Birade et al. (2004), likewise, attributed uterine inertia to fear caused by firecrackers used in celebrations. Occasionally, bitches appear to be frightened by labour pains and voluntarily inhibit straining; tranquillising drugs are helpful in such cases.

Maternal excitement is a common condition of gilts, especially when they have been moved into a farrowing crate just before the onset of parturition. Gilts can become so excitable, aggressive, or disturbed that they appear unable to continue normal parturition. Sedation with azaperone (2 mg/kg i/m) leads to a resumption of normal farrowing. Oxytocin may also be given if there is any evidence of impaired uterine contractions. Azaperone is also used to manage maternal excitement that leads to litter savaging (Jackson & Cockcroft 2007).

Secondary Inertia

This is the inertia of exhaustion and is essentially a result, rather than a cause, of dystocia due to some other cause, usually of an obstructive nature. Nevertheless, in polytocous species, prolonged unsuccessful efforts to deliver one fetus may result in dystocia from inertia with regard to the remainder of the fetuses. Secondary inertia is frequently followed by retention of the fetal membranes and retarded involution of the uterus, factors that predispose to puerperal metritis.

Secondary inertia occurs in all species and, generally speaking, is a preventable condition. Its prevention depends on the early recognition that labour has ceased to be normal and the provision of appropriate assistance. Sometimes, in the bitch and queen

VetBooks.ir

cat, normal parturition will commence but, after expulsion of a few pups or kittens, it will then cease, even though there is no obstruction. Linde-Forsberg and Eneroth (1998) refer to this as 'primary partial inertia' and identify it as a major cause of dystocia, responsible for about 23% of the cases in both species in their study. It is very similar to the classical uterine inertia associated with large litters, making it difficult to distinguish between the two. If there has been an obstructive dystocia that has been corrected, and normal parturition has failed to resume, then this is clearly secondary uterine inertia.

In the monotocous species, correction of the cause of the dystocia that provoked the inertia is the essential feature of treatment. If this involves correction of faulty disposition, then the fetus should be removed immediately by traction. In the polytocous species, management of the case will depend on the duration of labour, the number of fetuses still unborn, and their condition. In an early case, delivery of the fetus causing the primary dystocia may be followed after a few hours by the return of uterine contractions, and parturition may proceed without further hindrance. Such is often the case in the sow and occasionally in the bitch and queen. When the case is of longer duration and there are still several young to be born, it is best to proceed with the delivery of the remainder. In the sow it is often possible to do this with the hand inserted into the uterus *per vaginam*. In the bitch it may be decided to attempt forceps delivery, but the protracted use of forceps when three or four fetuses remain unborn has very little to commend it. Calcium borogluconate and oxytocin therapy, as recommended for the treatment of primary uterine inertia, should also be tried. Because the fetuses will soon die, or may already be dead, an early decision on performing Caesarean surgery or hysterectomy is important.

Fetal Dystocia in Livestock: Delivery *per vaginam*

TIMOTHY J. PARKINSON, JOS J. VERMUNT AND DAVID E. NOAKES

Manipulative Delivery *per vaginam*

Principles

The aim of manipulative procedures in the monotocous species and ewes/does with multiple fetuses must always be to ensure that the fetus is in normal disposition before attempting delivery. In polytocous species it is possible for *per vaginam* delivery to occur with some slight postural abnormality. Correction of defects of presentation, position, and posture can be achieved only by intrauterine manipulation of the fetus. Retropulsion of the fetus into the uterus is essential for repositioning it.

After diagnosing the cause of dystocia and deciding on a plan of action, the obstetrician should consider whether the available facilities are appropriate, whether there is sufficient professional and other help available, and whether the equipment is adequate to carry out the treatment successfully. In severe forms of dystocia, more especially in mares, the veterinarian should always seek the assistance of a professional colleague and consider whether it might be appropriate to transport the animal to a place with hospital facilities, provided that the animal is in a fit state to travel.

In cases of prolonged dystocia, fetal fluids and the lubrication of the birth canal become lost. Retropulsion into the uterus is greatly facilitated by substituting the lost fluids, and delivery is greatly facilitated by lubrication of the birth canal. Sterile water is the best alternative for allantoic fluid, although nonsterile clean water is perfectly satisfactory. In the cow and mare, volumes of up to 15 litres, instilled into the uterus by gravity using a soft rubber or plastic tube (a stomach tube is satisfactory) and funnel, will greatly increase the mobility of the fetus in the uterus. For actual vaginal delivery a lubricant substitute for the amniotic fluid is required, and this may be in the form of a water-soluble, cellulose-based obstetrical lubricant. If not available, a substitute such as soap (particularly soap flakes) is well tried and effective. The value of fetal fluid supplements cannot be too strongly emphasised.

Prevention of straining by the administration of caudal epidural anaesthesia greatly facilitates retropulsion of the fetus. In some circumstances there may be benefit to produce relaxation of the uterine muscle through the administration of a tocolytic drug such as clenbuterol.

Obstetrical manipulation *per vaginam* should be performed as cleanly as possible. It is impossible to perform them aseptically because there will inevitably be some contamination. It is important to sterilise or disinfect instruments and equipment between animals to minimise the contamination of the uterus and to prevent spread of diseases between animals.

Gentleness is of prime importance, so as to reduce the amount of trauma to the dam's genital tract and also to the newborn. Recent study has also focused upon the adverse effects of dystocia upon neonates, especially as the consequence of uncontrolled traction. The prevention of pain and discomfort is likewise of great importance. Caudal epidural anaesthesia, sedation, or general anaesthesia should always be considered as a means of managing pain. Some form of post-delivery analgesia should be administered as a routine after treatment of dystocia.

After the successful delivery of the fetus or fetuses, the dam's genital tract should always be examined for the presence of others, noting that monotocous species can have twins and, rarely, more. The dam's genital tract should be examined for signs of injury and appropriate treatment administered (see Chapter 20).

The fetus(es) should also be examined to see if resuscitation is necessary, if there is evidence of respiratory acidosis, which should be treated, and if there are injuries. A list of equipment for resuscitation of foals is described in Chapter 6.

Obstetrical Manoeuvres

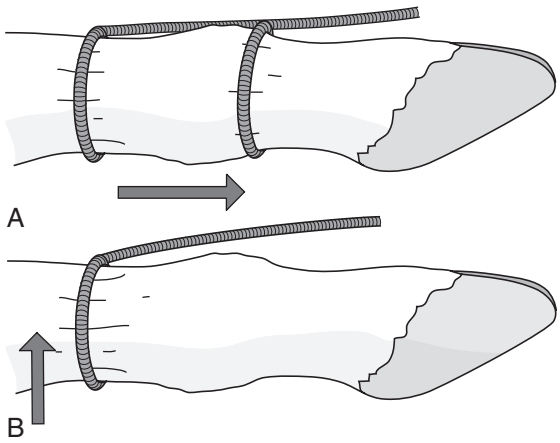
Retropulsion

Retropulsion means pushing the fetus in a cranial direction from the vagina (and the bony pelvic canal) back into the uterus. It is fundamental to all intrauterine measures that may be required to rectify defects of presentation, position, and posture because there will be inadequate space within the pelvis to perform even the simplest of manipulations. It is effected by pressure with the hand on the presenting bulk of the fetus; in some cases it is convenient for an assistant to repel the fetus as the obstetrician otherwise manipulates it, whereas in others, retropulsion can be applied by means of a crutch (see Fig. 11.6G). As far as possible, the repelling force should be exerted in the intervals between bouts of abdominal straining. Alternatively, caudal epidural anaesthesia may be induced to prevent the dam straining; however, it has no effect on myometrial contractions, which can be suppressed by the use of a tocolytic such as clenbuterol.

Extension

Extension refers to the extension of flexed joints when postural defects are present. It is carried out by applying a tangential force to the end of the displaced extremity so that it is brought through

VetBooks.ir



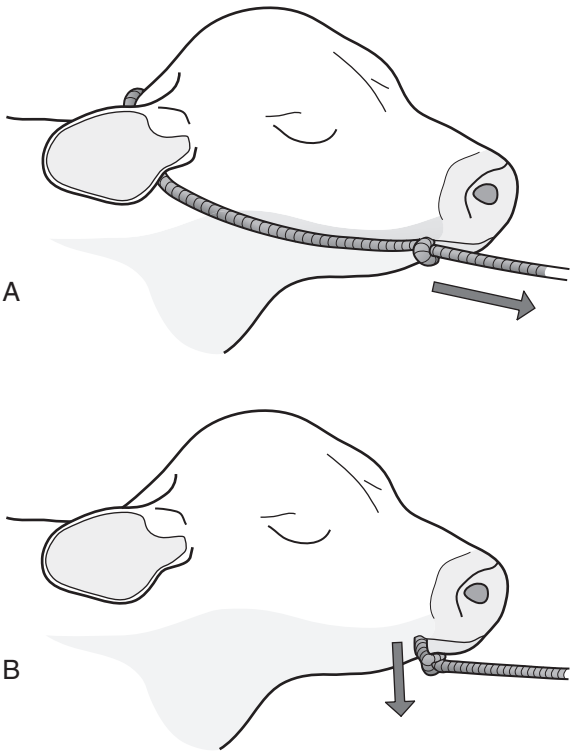
• **Fig. 14.1** (A) Correct placement of leg snares above and below the fetlock. (B) Incorrect placement only above the fetlock increases the risk of damage to that joint.

an arc of a circle to the entrance of the pelvis. The force should be applied preferably by hand or snares or, failing that, by hook(s).

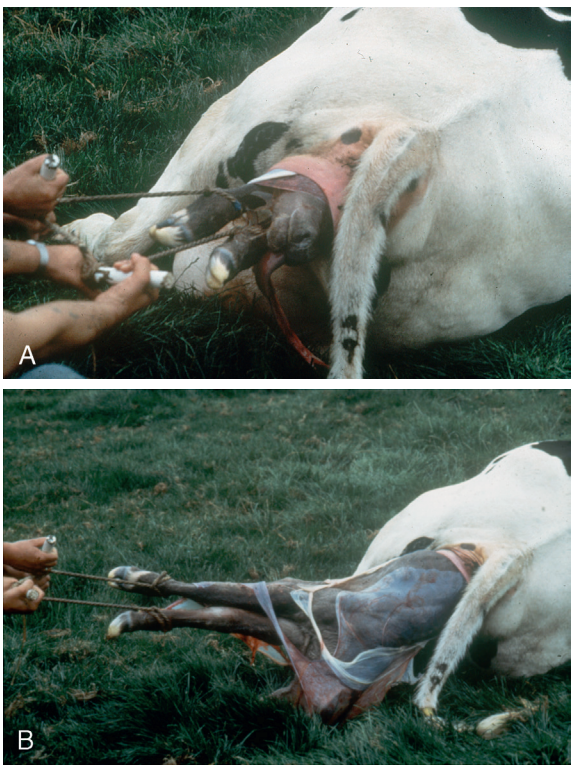
Traction

Traction means the application of force to the presenting parts of the fetus in order to supplement, or in some cases to replace, the maternal forces. Such force is applied by hand or through the medium of snares, hooks, or other mechanical traction devices. Limb snares should be double-hitched above and below the fetlocks (Fig. 14.1), and the head snare may be applied by the Benesch method, in which the loop is placed in the mouth and up over the poll and behind the ears (Fig. 14.2) or, alternatively, the centre of a single rope may be pushed up over the poll and behind both ears, leaving both ends of the rope protruding from the vagina. For replacement of a laterally deviated head, in which the operator's hand is insufficient, a thin rope snare applied to the mandible is valuable. However, this must only be used to correct the postural defect; traction, which might be used to effect delivery, must be applied by using a conventional Benesch head snare.

A very important consideration is the magnitude of the supplementary force that may be used because excessive force inappropriately applied can cause severe trauma to both dam and fetus. In the cow it is felt that the well-coordinated pull of four average persons should be the absolute limit. Fig. 14.3 shows traction being applied to a calf by two persons with rope snares; note the positioning of the loops of the snares proximal to the fetlock joint and the direction of the pull, which is along the normal path that the calf would take in a normal unassisted calving. Mechanical devices are now used extensively to apply traction; they must always be used carefully and sympathetically because they can cause severe trauma if used inappropriately. Table 14.1 gives some interesting data compiled by Hindson (1978), comparing the magnitude of the forces used to apply traction using a hydraulic drawbar dynamometer. This shows that calving jacks (or pullers) or pulley blocks generate over 5 or 6 times the force associated with a natural calving. However, for the stock person or veterinarian with little or no help, the pulley block and tackle or a calving aid, such as the HK calf puller or Vink calving jack (see Fig. 11.7), are invaluable. The most important aspect of applying effective traction is to coordinate the supplementary force with the straining effort of the



• **Fig. 14.2** (A) Correct placement of a head snare behind the ears and though the mouth (over the tongue). (B) Incorrect placement for applying traction. This position of a snare can, however, be useful for repositioning a laterally deviated head.



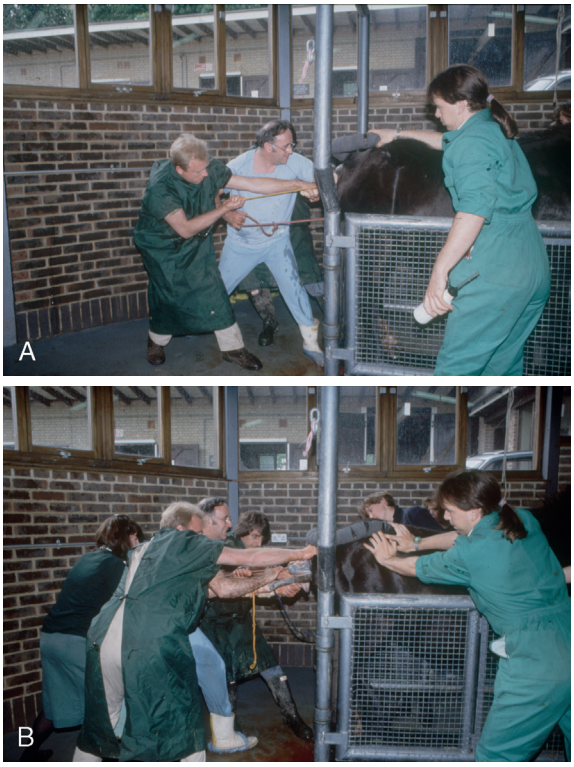
• **Fig. 14.3** (A and B) Traction by two persons, using rope snares to relieve dystocia in the cow.

VetBooks.ir

TABLE 14.1 Measurement of maximum tractive effort, as shown and recorded on a hydraulic drawbar dynamometer

Origin of Force	Tractive Effort (kg)
Cow at natural calving	70
Traction by one person	75
Traction by two persons	115
Traction by three persons	155
Calving jack	400
Pocket pulley blocks	445
Tractor	5000 +

Based on Hindson (1978).



• **Fig. 14.4** Traction by (A) two and (B) three persons to relieve dystocia in the mare.

dam. In the case of the cow, the slack in the calving snares should be 'taken up', as she strains, so preventing the calf from returning to its original site within the birth canal. Excessive traction is associated with fractured costochondral junctions of the ribs, tears of the diaphragm, and limb fractures in calves (Mee 1993) and foals (Schambourg et al. 2003).

In the mare the use of snares with two or three persons providing manual traction is usually sufficient (Fig. 14.4). In the ewe and doe goat, traction can be applied using simple fine cord snares or a fixed plastic head snare (see Fig. 11.9). In the sow, traction is nearly always applied using the hand, although fine cord snares and the plastic lambing snare can sometimes be very useful.

Rotation

Rotation entails alteration of the position of a fetus by moving it around its longitudinal axis, e.g., from a ventral to a dorsal position. It is more often required in horses than in cattle. To rotate the fetus, each forelimb should be secured with a snare and pulled into the birth canal. Apply copious lubrication. The most common method is to cross the limbs of the calf, one on top of the other, and try to rotate the calf. The head should be rotated at the same time. If a hand can be placed below the withers or below the shoulder joint of the fetus, so as to lift the chest upward and at the same time attempt to rotate the body, it may make rotation easier (Severidt et al. 2017). Mechanical force can be applied using of Cämmerer's torsion fork or Kühn's crutch. By repeating the process several times, it may be possible to rotate the fetus about 180 degrees.

Version

Version means the alteration of a transverse or vertical to a longitudinal presentation.

Sedation and Anaesthesia for Vaginal Delivery

Sedation, local analgesia, or general anaesthesia may be of benefit in managing obstetrical cases in terms of both ease of management of the case and the reduction of pain in the dam.

Sedation

Although most sedative drugs are not specifically licensed for use in pregnant mares, they can be particularly useful when dealing with a fractious animal. Although acepromazine has little or no effect on fetal cardiovascular function, it may not be very effective in sedating the mare. Detomidine and xylazine will effectively sedate the mare, but they affect fetal cardiovascular function and may reduce placental blood flow, with the obvious adverse consequences. If the fetus is already dead, xylazine may be the better of the two because it has a shorter duration of action (McGladdery 2001). Xylazine is the preferred sedative in cattle, either given by the IV route for a relatively short duration of action or by the IM route for a longer duration. However, the use of xylazine may cause contraction of the uterus, which may be unhelpful if further manipulations of the fetus are needed.

General Anaesthesia

General anaesthesia is better suited to the temperament of many mares than local analgesia, although in well-chosen cases epidural anaesthesia may be combined with sedation. When a complicated correction or fetotomy is required, it is best to use general anaesthesia, preferably in a veterinary hospital. Using hobbles and a hoist, it is relatively easy to place the mare in dorsal or lateral recumbency or to elevate her hindquarters. Such a change of position may greatly expedite obstetrical manoeuvres; in addition, elevation of the hindquarters will allow the foal to fall back into the uterus in the abdomen under the influence of gravity, thereby providing more space for any manipulative procedures. Because of pressure on the diaphragm, this technique may cause the anaesthetist some concern. Clarke et al. (2014) provide a thorough account of anaesthesia of obstetrical patients.

VetBooks.ir

Epidural Anaesthesia

Cattle

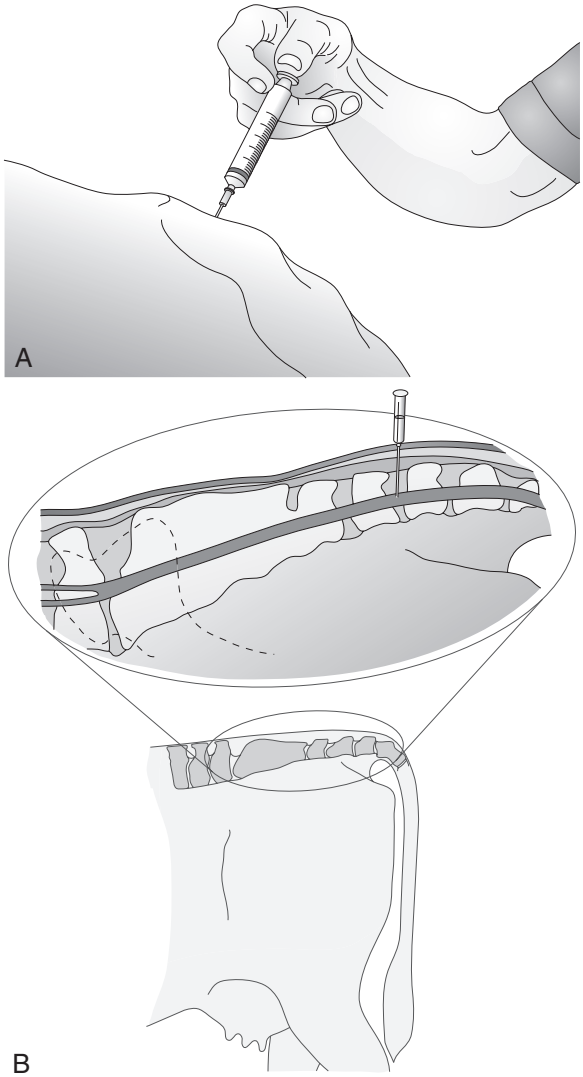
In cattle epidural anaesthesia is ideal for obstetrical purposes. It is a form of multiple spinal nerve block in which, by means of a single injection of local anaesthetic solution into the epidural space, the coccygeal and caudal sacral nerves are affected, thus producing anaesthesia of the anus, perineum, vulva, and vagina. The key advantage to the veterinarian is that, by abolishing pelvic sensation, reflex abdominal contraction (straining) is prevented. Thus intravaginal manipulations are facilitated, retropulsion is made easier, fetal fluid supplements are better retained, and faecal contamination of the perineum is reduced. Epidural anaesthesia also reduces pain in the dam, so the patient stands more quietly and will rise more quickly from recumbency once the delivery is completed. This form of anaesthesia is useful whenever straining is troublesome, as in prolapse of the uterus, vagina, rectum, or bladder. It is also indicated for episiotomy and for suturing lacerations of the vulva or perineum.

Provided that the epidural injection is made with due regard to asepsis and that an excessive volume of anaesthetic is not injected (thus causing the animal to become recumbent), the method is free from risk. It should be clearly understood that epidural anaesthesia does not inhibit myometrial contractions; it has no effect on the third stage of labour or uterine involution.

The preferred site of injection is the middle of the first intercoccygeal space (Fig. 14.5). This is located by raising and lowering ('pumping') the tail to identify the first obvious articulation behind the sacrum. The sacrococcygeal space can also be used; however, it is smaller than the first coccygeal space and in some older cows becomes ossified. The spinal cord and meninges are cranial to these points; the spinal canal contains only the coccygeal nerves, the thin phylum terminale, vasculature, epidural fat and connective tissue.

The area is clipped, thoroughly washed with an antiseptic solution or surgical scrub and dressed with surgical spirit. Some inject a small volume of local anaesthetic, using a fine needle, to desensitise the skin over the injection site; others do not. The epidural needle, which is 18 to 20 gauge and 2.5 to 5 cm long, is inserted into the middle of the space at right angles to the normal contour of the tailhead, exactly in the midline and directed downwards in the midsagittal plane. It is easier to ensure that this occurs by standing directly behind the cow. Some find it easier to direct the needle slightly cranially at an angle of about 10 degrees to 30 degrees from the vertical. The needle is passed downwards for a distance of 2 to 4 cm until it strikes the floor of the epidural space; it is then very slightly withdrawn. Confirmation that the needle is correctly placed is obtained by attaching to it the syringe and making a trial injection; if there is no resistance to injection, the needle point is in the epidural space. Alternatively, the hub of the epidural needle can be filled with anaesthetic solution. As the needle is advanced into the epidural space, the anaesthetic solution will be sucked in as a result of the slight negative pressure that exists there (the so-called 'hanging drop' technique). The tail becomes limp almost immediately, but it takes a slightly longer time interval (up to 10 min) before the perineum is desensitised and the straining reflex is completely abolished.

A dose rate of 1.0 mL/100 kg of 2% lignocaine hydrochloride injected at a rate of 1 mL per second will produce obstetrical anaesthesia lasting about 30 to 60 minutes; thus heifers and small cows require a volume of 5 mL and large cows 7 to 8 mL (Skarda 1996). Fat deposition in the epidural space of cows in high body condition reduces the effective volume of the space, so the amount of local anaesthetic should be reduced in such animals. Generally,



• **Fig. 14.5** Epidural anaesthesia in the cow. (A) Site of injection between vertebrae C1 and C2. (B) Longitudinal section through the caudal vertebrae of the cow, showing the relationship of the coccygeal vertebrae to the pelvis.

it is preferable to administer approximately 5 mL, then to 'top up' to effect. Giving too much local anaesthetic will, of course, affect the motor nerves of the lumbosacral plexus, resulting in long-term recumbency of the cow. The simultaneous injection of xylazine into the epidural space at a dose rate of 0.05 mg/kg diluted with 2% lignocaine to a volume of 5 mL can prolong the duration of anaesthesia for up to 3 hours (Grubb et al. 2002). Mild to moderate sedation typically also occurs as a result of epidural administration of xylazine, which can be controlled by the intravenous injection of tolazoline hydrochloride, an α_2-adrenoceptor antagonist, at a dose rate of 0.3 mg/kg (Skarda et al. 1990).

Sheep and Goat

Caudal epidural anaesthesia is a very useful, if somewhat underutilised, technique in ovine and caprine obstetrics because, although in both species there will be straining, the relative forces are much less than in the cow, and the ewe or doe can always be suspended by her hindlimbs. However, the uterus of both species appears to be more susceptible to rupture when manipulative procedures are performed. For this reason, and in the interests of welfare,

VetBooks.ir

anaesthesia should be used as a routine for all but the simplest of vaginal and uterine manipulations.

The injection can be made into either the sacrococcygeal or the first coccygeal interspace with a 20 gauge × 2.5 cm needle, using 2% lignocaine hydrochloride at a dose rate of 0.5 mg/kg (~2 mL for an 80 kg ewe) to provide caudal analgesia for up to 4 hours. The incorporation of 0.07 mg/kg xylazine (~0.25 mL of 2% xylaxine for an adult ewe) will prolong analgesia for up to 36 hours (Scott 1996). Ismail (2016) has recently reviewed other drugs that can be combined with various local anaesthetics to improve the quality or duration of analgesia.

Horse

The technique of epidural injection in the mare has been described by Robinson and Natalini (2002). The technique is similar to that in the cow, but, because the root of the tail is well covered by muscle and fat, the spines of all coccygeal vertebrae are more difficult to locate. The first coccygeal interspace is the preferred site. An imaginary line joining the two hip joints crosses the midline of the sacrococcygeal joint. The spinous process of the first coccygeal bone and, caudally, the first coccygeal interspace can be palpated in thinner horses. The first coccygeal interspace corresponds often with the first moveable joint in the tail and can be recognised when the tail is raised and lowered. It lies approximately 2.5 to 5 cm cranial to the origin of the tail hairs. It can also be recognised as being at the level of the caudal skin folds that are situated on each side of the tail (Robinson & Natalini 2002). It is important to ensure that the mare is adequately restrained. After the site has been clipped and thoroughly cleaned, a small bleb of local anaesthetic should be injected subcutaneously and into the surrounding tissue over the site. With the mare standing squarely and symmetrically, an 18 gauge × 4 to 8 cm needle (note that the needle needs to be longer than in the cow) should be inserted at about 10 degrees from the vertical and directed cranially until it strikes the floor of the spinal canal; it should then be withdrawn 0.5 cm before the injection is made (Fig. 14.6).

Traditionally, 2% lignocaine hydrochloride is effective, using a volume of 6 to 8 mL in a light hunter-type mare weighing 450 kg; proportionately larger or smaller volumes should be used in larger and smaller animals, respectively. It is important to err on the side of caution because too large a volume will cause ataxia, which is of much greater concern in horses than in cattle because of their different temperaments. An additional volume can be given if the needle is capped and left in place. It also takes longer for the anaesthesia to take effect in the horse than the cow. Other local anaesthetic agents can be used (in different volumes), as well as α_2–adrenoceptor agonists such as xylazine (0.17 mg/kg) and detomidine (60 µg/kg) in 10 mL 0.9% saline; the latter is used either alone or in combination with a local anaesthetic. A rapid-onset (5 minutes) and long-lasting (5 hours) caudal epidural anaesthesia was obtained, using a combination of 2% lignocaine hydrochloride (0.22 mg/kg) and 2% xylazine (0.17 mg/kg) (Skarda 1996).

Pig

Epidural anaesthesia is rarely used for obstetrical purposes in pigs other than for replacing prolapses of the vagina and uterus. The site of injection is the lumbosacral space, which can be located as follows: the wings of the ilia are joined by an imaginary transverse line; where this crosses the middorsal line, the needle is inserted perpendicularly and then directed forward at an angle of 20 degrees from the vertical until it strikes the floor of the vertebral canal. The needle is then withdrawn slightly and the injection made. The size of the needle varies depending on the size of the gilt or sow, but over 100 kg body weight, an 18 gauge 10 to 15 cm needle is satisfactory. The sow or gilt needs to be adequately restrained, preferably in a crate to prevent lateral movement (which can be the most difficult aspect of the technique and can make the difference between success and failure). For anaesthesia caudal to the umbilicus, a dose rate of 1.0 mL of 2% lignocaine hydrochloride per 4.5 kg body weight injected at 1.0 mL per 2 to 3 seconds should achieve anaesthesia by 10 minutes and last for about 120 minutes (Skarda 1996). It should be noted that injection at this site affects the nerves of the lumbosacral plexus and will cause posterior paralysis.

• **Fig. 14.6** Site of epidural anaesthesia in the mare.

Dystocia Due to Postural Defects: Anterior Presentation

Faulty disposition due to postural defects are a frequent cause of dystocia. Postural defects can usually be corrected by manipulation if they are treated early in second stage labour. However, in neglected cases associated with secondary uterine inertia, loss of fetal fluids, and a dead, emphysematous fetus that is tightly enclosed by the uterus, very serious dystocia may occur. Manipulative delivery for such cases is often not possible and can be difficult to resolve, even by fetotomy or Caesarean hysterotomy.

The mechanics of the correction of postural defects are simple in principle (although not always so simple in their application). Correction of all postural defects requires that the fetus is repelled into the uterus, as there is insufficient space within the pelvis/birth canal to reposition limbs. In turn, except for dystocias of short duration, retropulsion will require epidural anaesthesia, substitution

VetBooks.ir

of lost fetal fluids, and/or lubrication of the birth canal. If the uterus is tightly contracted over the fetus, administration of a tocolytic drug, such as clenbuterol, may also be indicated. After epidural anaesthesia and correction of the posture, the fetus must then be delivered by traction because the cow will not strain to aid expulsion. If it is possible to use both arms simultaneously inside the cow (i.e., one to push and the other to pull), it may be easier to correct a postural defect.

Postural Defects of Anterior Presentation in Cattle

Carpal Flexion Posture

One or both forelimbs may be affected. In the unilateral case the flexed carpus is engaged at the pelvic inlet; the other forefoot may be visible at the vulva. The simple recent case requires retropulsion at the fetal head or shoulder; the retained foot is then grasped (by cupping the digits in the hand) and, as the carpus is pushed/lifted upwards, the foot is carried outwards and finally brought forwards in an arc over the pelvic brim and extended alongside the other limb (Fig. 14.7A). More difficult cases require a snare attached to the retained fetlock to help extend the limb (see Fig. 14.7B). The fetal foot should always be carried over the pelvic brim in the cupped hand of the obstetrician (see Fig. 14.7C). More neglected cases may require substitution of fetal fluids and the use of lubricant to help mobilise the calf. Rarely, in very protracted dystocia or in cases of ankylosis, the limb cannot be extended in which case it must be cut through above the carpus by means of the wire saw fetotome (see Chapter 15).

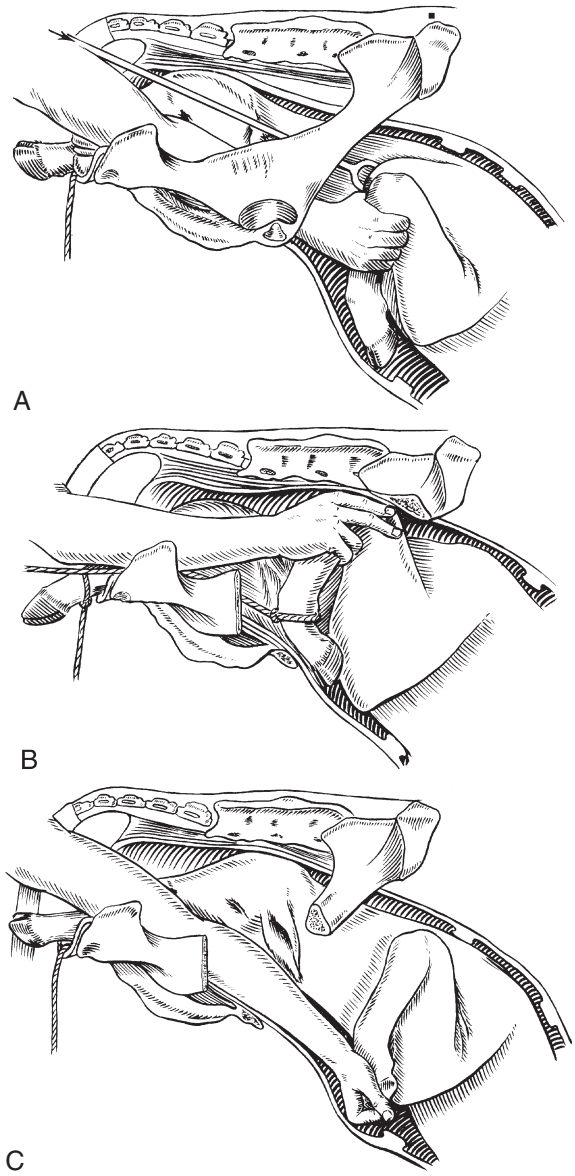
Incomplete Extension of the Elbow

This case is diagnosed on vaginal examination, with the digits emerging at the same level as the fetal muzzle instead of being well advanced beyond it (Fig. 14.8). Usually, the calf can be repelled by pushing on the head, after which each limb is pulled in turn in an obliquely upward direction, so as to lift the olecranon process over the maternal pelvic brim. Delivery is accomplished by traction on the head and both forelimbs.

Shoulder Flexion Posture: Complete Retention of the Forelimb(s)

This type of dystocia may be unilateral or bilateral. The diagnosis of bilateral retention is usually obvious by observing that the head partly or completely protrudes from the vulva, but in the absence of the forelimbs. In case of bilateral carpal flexion, the head cannot be advanced that far (Fig. 14.9A).

In a 'roomy' cow, with a small full-term or premature calf, the dystocia may be overcome by traction in the abnormal posture; in such cases, unless there has been much delay, correction of the abnormal posture is relatively easy. More usually, the malposture has to be corrected, which requires retropulsion of the fetus. It is, however, common for the protruded head to be very swollen and impossible to repel. When this occurs, there is little alternative but to amputate the head outside the vulva. To achieve this, eye hooks or the points of the Krey's hook are placed in the orbits (see Fig. 14.9B), and traction or downward pressure is applied to the head, so that the head can be forced completely beyond the vulva. It is then amputated either by disarticulation at the occipito-atlantal joint, using a sharp knife or scalpel, or by cutting through the neck (as close as possible to the calf's trunk), using a wire saw fetotome. As the fetus is then repelled, the retained forelimbs tend to come forwards; the calf's radius and ulna are then grasped and the defect is converted into carpal flexion posture and relieved accordingly (Fig. 14.10A and B).



• **Fig. 14.7** (A) Disposition of the calf: anterior presentation, dorsal position, unilateral carpal flexion posture. Correction using a hand and a crutch. (B) Correction using a hand and a digital snare. (C) Correction by hand alone. Note the method of grasping the foot.

In the more difficult case, the limb must be snared, at first proximally and then the noose passed down until it lies above the fetlock, the shank being placed from before backwards between the digits so as to flex the fetlock and pastern when traction is applied to it (Fig. 14.11). The digits are held in the cupped hand and the carpus is forced upwards while an assistant, pulling on the snare, helps the operator to bring the foot over the pelvic brim. In a delayed case, such a manoeuvre may be impossible and then removal of the limb is undertaken by percutaneous fetotomy (see Chapter 15).

Lateral Deviation of the Head

Lateral deviation of the head is a very common form of ruminant dystocia. The head may be displaced to either side. The presentation

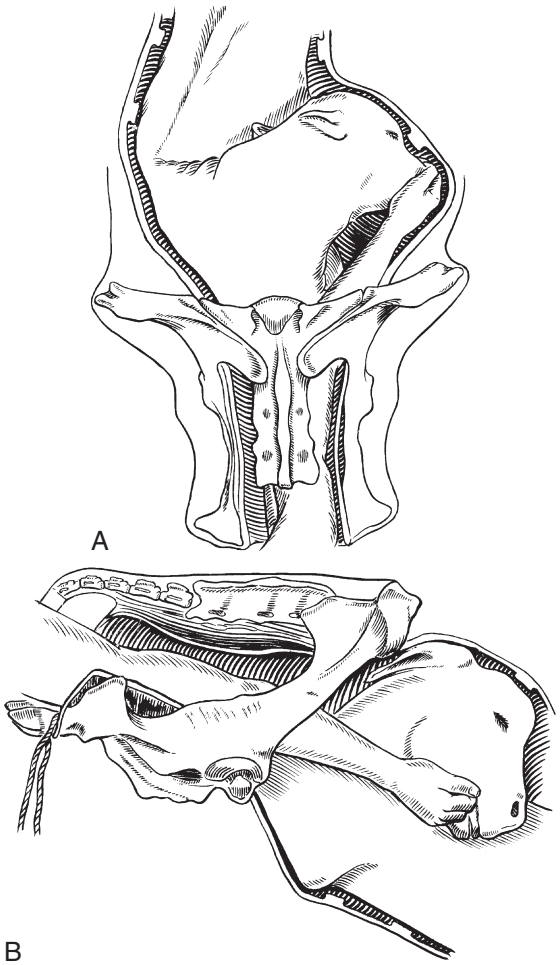
is typically of both forelimbs presented at the vulva, but, on vaginal examination, the head is not present in the birth canal. Of course, one should ensure that the calf is not misdiagnosed as being in posterior presentation. When presented in early second stage labour, this malposture can often be corrected by hand. The lubricated hand is introduced and the fetus is repelled by pushing forwards at the base of its neck. The hand is then quickly transferred to the muzzle of the calf, which is firmly grasped and brought round through an arc until the nose is in line with the birth canal (Fig. 14.12A). During this action it is important that the muzzle is fully cupped in the hand to protect the uterine wall from the sharp incisor teeth of the fetus. In a more inaccessible case, the muzzle may be reached after preliminary traction on the commissure of the mouth (see Fig. 14.12B) or on the mandible. It is important to place a head snare as well as forelimb snares before the fetus is delivered by traction.

In more protracted cases of dystocia due to head displacement, with greater loss of fetal fluid and with the uterus contracted on the calf, it is more difficult to rectify the posture. Replacement of fetal fluids, lubrication, and epidural anaesthesia are all required. A special head cord of smaller calibre than those used on the limbs is carried in as a running noose and slipped over the mandible of the calf, where it is tightened, and the shank of the snare is handed to an assistant (Fig. 14.13A). The operator reintroduces a hand, grasps the calf's muzzle, and, as it is manipulated to extend the neck, the assistant is directed to apply gentle traction. It is obviously important that this head snare should be passed around the greater curvature of the neck to the mandible. Should the snare inadvertently be passed across the concavity of the neck curvature to the mandible, pulling on it will accentuate, rather than relieve, the displacement (see Fig. 14.13B and C). Whichever method is used to correct this malposture, it is important to protect the tubular genital tract as the neck is extended from the possibility of cuts by the sharp lower incisor teeth of the calf; this is best done by cupping the hand over the calf's mouth. The correction of this postural defect can also be facilitated by casting the cow in lateral recumbency on the side opposite to the direction of the neck flexion; this allows the gravid uterus to sink slightly to one side, thereby providing more space to correct the deviation.

Ventral Deviation of the Head

This is an uncommon type of dystocia in cattle. It usually takes the form of 'vertex posture' in which the calf's nose abuts on the pubic brim and the brow is directed into the pelvis (Fig. 14.14A). The more severe varieties of downward deviation of the head, namely 'nape presentation' and 'breast–head' posture (in which the head is flexed vertically between the forelimbs (see Fig. 14.14B)) are rare



• **Fig. 14.12** Disposition of calf: anterior presentation, dorsal position, lateral deviation of the head. (A) Correction by hand. (B) Preliminary 'hooking' of the commissure of the mouth before grasping the muzzle of the calf.

in cattle; when present, they have usually been caused by traction on the limbs before the head was fully extended.

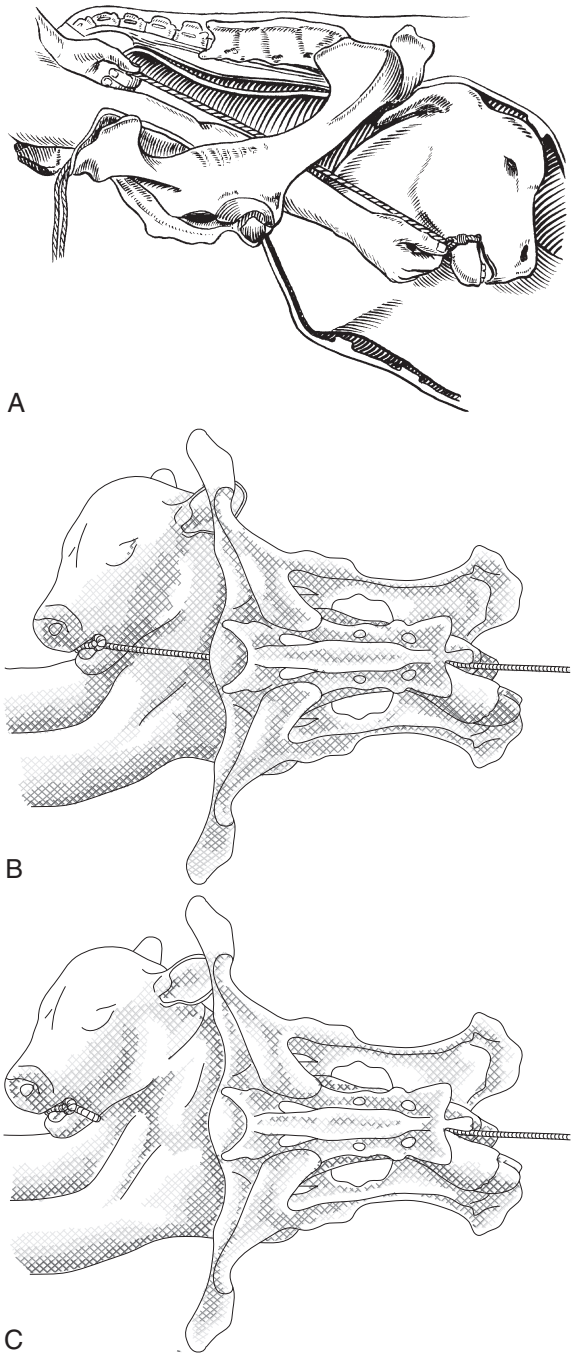
Provided sufficient retropulsion can be achieved, vertex posture is easily overcome. Neglected cases are likely to require caudal epidural anaesthesia and fetal fluid replacement. The calf is repelled by applying pressure to the forehead with one hand (or the thumb) while lifting the mandible over the pelvic brim with the other hand (or the fingers of the same hand).

More severe degrees of downward displacement of the head are treated in a similar way, but, if difficulty is experienced, returning one or both of the forelimbs back into the uterus may provide enough room to rotate the head. In difficult cases of downward deviation in which the calf is still alive, Caesarean hysterotomy should be considered. If the calf is dead, then the head and neck should be removed by means of percutaneous fetotomy.

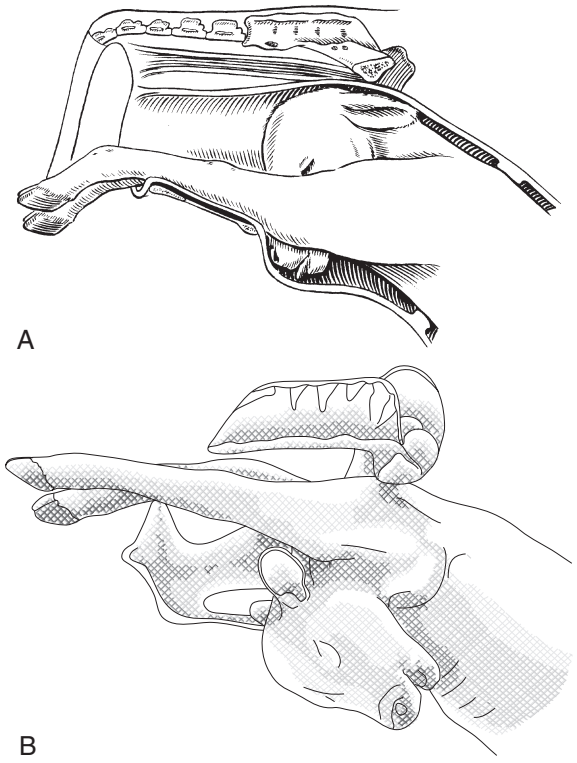
Postural Defects of Anterior Presentation in Horses

Although showing a lower incidence in horses than in cattle, defects of limb posture cause more serious dystocia in mares than in cows. This is due to the severe pelvic impaction that is consequent upon the mare's very strong expulsive efforts and to the longer limbs of

VetBooks.ir



• **Fig. 14.13** Disposition of calf: anterior presentation, dorsal position, lateral deviation of the head. (A) Application of the mandibular snare. (B) Incorrect direction of traction, which will exacerbate rather than relieve the dystocia. (C) Correct direction of traction, with the snare passed around the greater curvature of the neck.



• **Fig. 14.14** (A) Disposition of the calf: anterior presentation, dorsal posture, downward displacement of the head ('vertex posture'). (B) The 'breast head' posture.

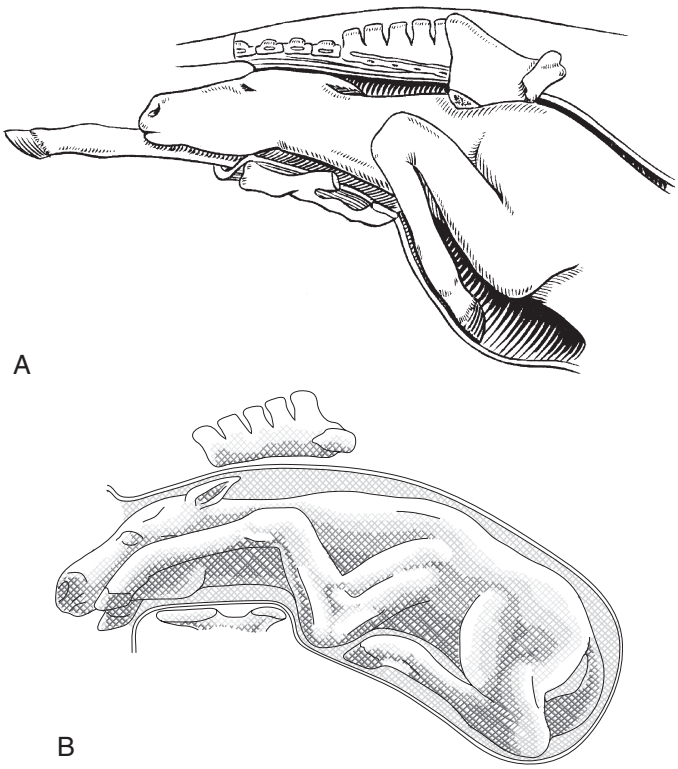
the foal. The principles of correction are the same as for the cow, but adequate retropulsion of the fetus is essential in order to create sufficient room for extending the longer limbs of the foal. Foot snares are great aids to manual extension of the limb. In order to prevent rupture of the uterus or vagina, correction of posture must be done with the utmost care. Although the obstetrician is ever mindful of the urgency of equine dystocia, if an impacted fetus is found to be already dead, the advantage of anaesthetising the mare and placing her in lateral or dorsal recumbency should be considered.

Carpal Flexion Posture

If only one limb is affected, the fetal nose and one forelimb are present at the vulva, but the mare makes no progress with delivery despite straining. The retained limb may be present at the pelvic inlet, or the flexed carpus may be pushed up into the vagina so that it comes almost up to the level of the vulva.

The principles of correction are the same as for the cow: the fetus is repelled as far as possible, and the carpus is pushed upwards and forwards to bring the foot within reach. The carpus is rotated dorsolaterally, and the flexed fetlock is brought medially and caudally into the birth canal (Frazer 2011). During the final extension of the limb the birth canal is protected from injury by holding the fetal foot in the cupped hand. There is a tendency for a foal in carpal flexion posture to become impacted in the maternal pelvis (Fig. 14.15A); the procedure required will depend on the degree of impaction, on the relative size of both the fetus and the birth canal, and on the duration of second stage labour. For irreducible carpal flexion in a dead foal fetotomy is undertaken by means of the wire saw fetotome, the section being made through the carpal joint (see Chapter 15). A snare is then placed above the carpus and the fetus is delivered by pulling on this as well as on the other limb and head. Bilateral carpal flexion can be managed by unflexing each limb in turn. However in the case of an irreducible bilateral carpal flexion affecting a normally developed full-term foal, it is unlikely that the foal will still be alive so that fetotomy is indicated, one or both carpal joints being sectioned as required. Pathological contracture of the tendons can also hinder unflexing of the carpus: one or both joints may be affected (Vandeplassche 1987). Some

VetBooks.ir



• **Fig. 14.15** (A) Disposition of the foal: anterior presentation, dorsal position, unilateral carpal flexion posture. Note the tendency to impaction in this malposture. (B) Disposition of the foal: anterior presentation, dorsal position, incomplete extension of elbow posture. Note the impaction of the elbows below the pubis.

of these cases may be resolved by repositioning, but more severe cases will require removal of the flexed limb by fetotomy.

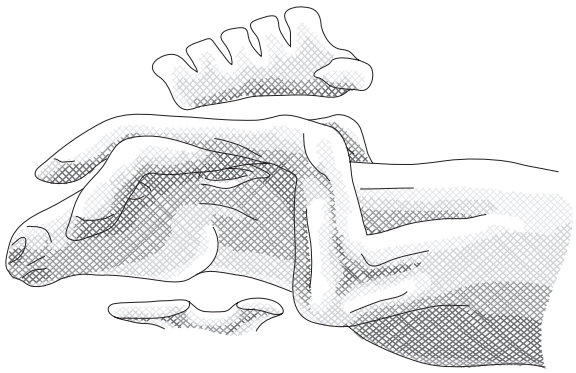
Incomplete Extension of the Elbow

This condition is uncommon. As in the cow, the fetal nose and tips of the feet are presented together at the vulva such that the feet are not extended beyond the nose as would be the case in a normal delivery (Figure 14.15B). The condition is relatively easy to correct, by repelling the fetus and pulling each limb in turn into a fully extended position.

Shoulder Flexion Posture

It is much more common for one than both shoulders to be flexed. When one forelimb is retained, the head and one forelimb are presented at the vulva. The second forelimb is absent, but the shoulder joint and proximal parts of the limb can be palpated on that side. When both shoulders are flexed, only the head is presented at the vulva. The more slender head and longer neck of the foal allows for more room in the maternal pelvis for the hand and arm of the obstetrician than is available in the same type of bovine dystocia, but the great length of the forelimbs makes manual repositioning of the foreleg difficult. Copious amounts of fetal fluid supplement should be infused and the fetus repelled. The limb is grasped around the humerus, and the hand, or a snare, is advanced to the radius. Extension of the shoulder is difficult (Steiner et al. 2008), requiring that it is moved medially and caudally and then elevated in order to achieve a carpal flexion posture. If a snare can be placed around the radius, one hand can be used to apply traction to the distal limb while the other repels the fetus (Frazer 2011). Once converted into a carpal flexion, it can be corrected into normal posture. Anaesthesia of the mare and elevation of her hindquarters may aid in correcting the malposture.

The difficulty of correcting shoulder flexion means that, when both legs are involved and the fetus is alive, Caesarean hysterotomy is indicated. Likewise, for many cases of unilateral flexion, Caesarean hysterotomy may be preferable to lengthy manipulation. In some mares with a large pelvis and which are carrying a relatively small foal, it may be possible to extract the fetus with one shoulder flexed. However, this method poses significant risk of trauma to the birth canal of the mare and of rib fractures in the foal. If the fetus is dead and it is impossible to retrieve the retained foreleg, it can be removed by fetotomy. The fetotomy wire is passed between the upper forelimb of the foal and its thoracic wall after which the muscular attachments are severed (Jackson 2004).



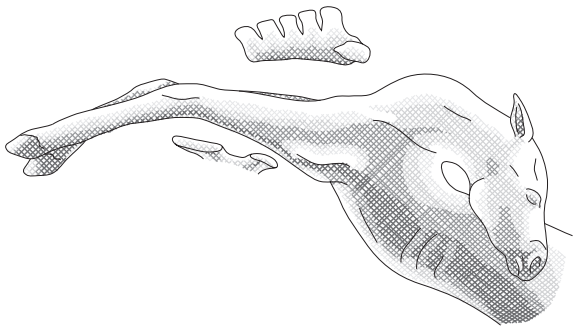
• **Fig. 14.16** Bilateral foot–nape posture of the foal. The special danger of this malposture is that the digits press against the vaginal roof during straining, with the risk of its rupture and penetration.

Foot–Nape Posture

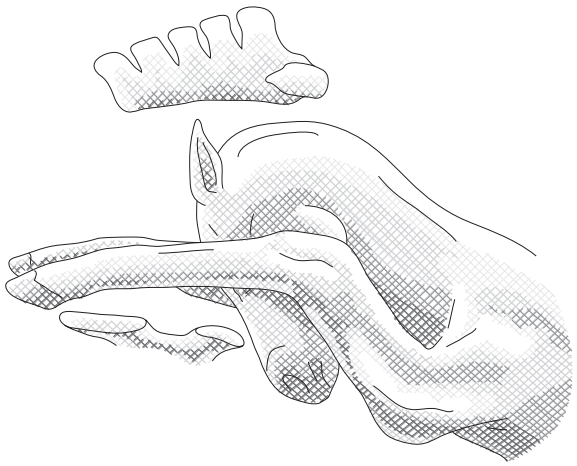
In the mare the foot–nape posture is usually bilateral (unlike the cow, in which the anatomy of the forelimbs means that it is more likely to be unilateral). Bilateral foot–nape posture is therefore a condition that is peculiar to the horse, which is made possible by the slender head and long limbs of the foal. Mares present with severe, nonproductive straining. Vaginal examination reveals the fetal head in a normal extended position in the vagina, but the forefeet are found resting on the nape of the neck or on the fetal head. The forelegs may be crossed on the nape of the neck (Fig. 14.16). There is a significant risk of the feet becoming impacted in the dorsum of the vagina, possibly rupturing it and even penetrating the rectum (Benesch & Wright 1951, Jackson 2004). The upper forelimb is identified; then, as the head is repelled and raised, the foot is lifted from its position across the fetal neck and pulled to the appropriate side. The other foot is similarly manipulated and, finally, the head is again raised and each foreleg placed underneath it. Traction is then applied to the head and both forelimbs.

Penetration of the vaginal wall is a common consequence of this malposture. Sometimes the foot penetrates both the vagina and rectum, resulting in a rectovaginal fistula, and, if straining continues when the foot is in the rectum, the entire rectovaginal shelf and anal sphincter can be torn, resulting in a third degree perineal laceration. When one foot is already protruding from the ruptured perineum or rectum, it is preferable to incise the perineum (rather than subjecting it to uncontrolled tearing), deliver the fetus, and then repair both the lacerated and the incised tissue. If repositioning is unsuccessful and the fetus is dead, amputation

VetBooks.ir



• **Fig. 14.17** Disposition of the foal: anterior presentation, dorsal position, lateral deviation of the head. The fetal nose lies well towards the foal's stifle.



• **Fig. 14.18** Disposition of the foal: anterior presentation, dorsal position, ventral deviation of the head.

of the fetal head or the upper limb – whichever is easier – could be considered. The upper limb is sectioned through the radius by means of the wire saw, and it should then be possible to replace the other limb under the head; the stump of the radius must be carefully controlled during the final delivery. Removal of the entire limb by percutaneous fetotomy of the shoulder may be an alternative.

Lateral Deviation of the Head

This is a serious malposture that is very difficult to correct by vaginal manipulation. Because of the long neck of the foal, the head is out of reach, with its muzzle situated close to the foal's stifle. The long head and muzzle add to the difficulty of correcting such malpostures (Fig. 14.17), and immediate recourse to Caesarean hysterotomy is often the best option for management. Retention of the head is the most common reason for referral of equine dystocia cases to a veterinary hospital.

The fetal forelegs are in the vagina or protrude through the vulval lips, but the head is not presented. Maternal straining may be intense. Vaginal examination confirms the absence of the fetal head in the pelvis, but the base of the neck is palpable and deviates sharply to the right or left (Jackson 2004). Frazer (2011) also noted that deviation of the head can sometimes occur as a secondary consequence of the foal retracting its head during vaginal manipulation. The expulsive forces of the mare can then push the head ventrally or laterally, resulting in this particular malposture. Other cases of lateral deviation of the neck are due to 'wryneck', in which there is a congenital curvature of the cervical vertebrae that cannot be corrected by manipulation (Vandeplassche 1987).

The deviated head is generally beyond the reach of the obstetrician. If the muzzle can be reached, traction can be applied, either by hand or by means of a rope snare. When a snare is used, the internal hand repels the rest of the head and neck. Alternatively, a rope or snare can be placed around the neck to draw the head within reach. Other methods of delivery require the use of special instruments to try to retrieve the head: Kühn's crutch, Blanchard's long flexible hook, and the Krey–Schottler double hook. Their use requires considerable skill and caution (Frazer 2011), and with the availability of safer general anaesthetic methods, they are rarely used these days.

In cases of 'wryneck', when it is quite impossible to extend the neck, the head and neck must be amputated by means of the wire saw fetotome (see Chapter 15), or a Caesarean hysterotomy must be performed (see Chapter 16).

Ventral Deviation of the Head

Downward deviation of the head is less rare in horses than in cattle; nape posture is the most likely to be encountered. The position of the head varies from just being tucked between the forelimbs through to the mandible resting on the sternum (Fig. 14.18). Extension of the head in a mild case can be achieved by repelling the fetus and lifting the muzzle (Jackson 2004). More severe cases can be managed by the application of a mandibular snare: with firm pressure placed upon the fetal brow with one hand, the snare is gently pulled upwards and backwards. The most severe ventral deviations may require the fetus to be deeply repelled and one or more forelimbs to be placed into carpal flexion. Frazer (2011) noted that ventral deviation of the head and bilateral carpal flexion occurs when the fetus has died at the time of first stage labour. If this occurs, the head should be extended before the carpal flexions are corrected. If manipulation does not resolve the dystocia in a reasonable period of time, Caesarean hysterotomy is indicated.

In view of the fact that spontaneous delivery of a foal in nape posture has been observed, it has been suggested that, when the head has projected so far into the vagina that the ears are visible at the vulva, successful delivery by traction without repositioning has occurred; however, this approach is not advisable.

In obstinate cases of nape posture with impaction of a dead fetus at the pelvic brim, fetotomy may be considered. However, the introduction and correct placing of the wire between the markedly flexed head and the neck appears to be very difficult.

Postural Defects of Anterior Presentation in Sheep and Goats

Postural defects are common causes of dystocia in ewes and goat does. The methods of correction are virtually identical in the two species, except that goats tend to resent physical restraint more. When affected sheep and goats are promptly presented, correction is relatively simple and in many cases is successfully carried out by the shepherd or herdsperson. In the following description of the procedures, when reference is made to sheep or ewe, readers can assume that it is the same for does unless otherwise stated. Manipulation is more difficult in the case of large singletons, but delay in providing obstetrical aid is the most frequent cause of difficulty. Repeated ineffectual maternal expulsive efforts cause expulsion of

VetBooks.ir

the fetal fluids, impaction of the fetus, and close envelopment of the fetus by the uterus. Secondary uterine inertia supervenes and, in protracted cases, the lamb dies and undergoes emphysematous decomposition. Thus even a simple postural defect in such a situation may be very difficult to correct. The veterinarian is likely to see the more serious cases of postural abnormality in which there has been considerable delay and in which unskillful attempts at correction may have caused damage to the ewe's birth canal.

Gentleness of manipulation within the ovine genital tract is most essential; otherwise, serious contusion or laceration of the vagina, cervix, and uterus may result, which is especially liable to be followed by fatal shock or infection. The wool should be clipped from around the perineum and tail base, and this area should be thoroughly washed. Except for the simplest of manipulative procedures, caudal epidural anaesthesia should always be used. The ewe should then be placed in lateral or dorsal recumbency on a hay or straw bale or, if possible, on a table, with the hindquarters overhanging one end. Alternatively, the ewe may be gently restrained when standing or held by an assistant, so that its head and neck rest on the floor, as the hindquarters are raised by grasping the hindlegs above the hocks. The assistant straddles the ewe and maintains the animal in the supine position with her hindquarters at a convenient height for the operator. Fetal fluid supplements, particularly cellulose-based obstetrical lubricants as substitutes for amniotic fluid, should be infused into the uterus. With the advantages provided by raising the ewe's hindquarters and instilling fluid, the majority of postural defects will be readily overcome. The principles of repositioning adopted for the various postural aberrations are the same as those used for the cow. Many cases can be rectified by the hand alone, but snares (including the simple head snare shown in Figure 11.9) may sometimes be useful.

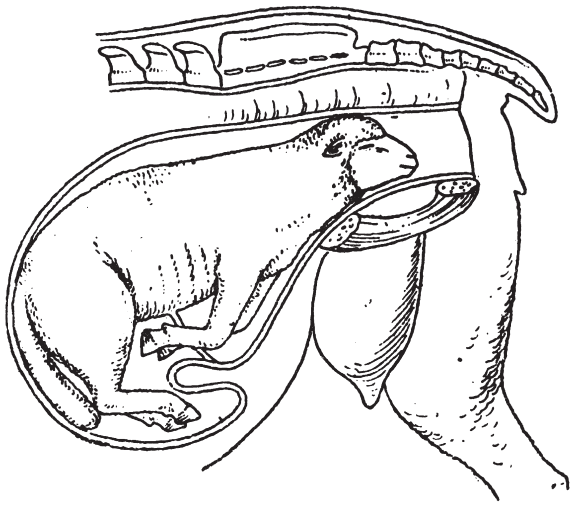
Carpal Flexion Posture

With the ewe held as previously described and with the instillation of fluid in delayed cases, retropulsion is easily achieved. A finger is crooked around the carpus to straighten the leg and the hand cups the foot to protect the uterus. The leg is then grasped by the fetlock to pull the limb clear of the vulva. The ewe is then lowered on to her side and gentle traction is applied each time she strains (Winter & Hill 2003). After delivery of the fetus, the uterus is inspected for the presence of another lamb. Owing to uterine inertia, a second (or third) lamb may fail to be advanced to the pelvic brim. The obstetrician should therefore bring the fore or hind extremity into the pelvis; expulsive efforts of the ewe should then recommence and gentle traction is applied to help delivery.

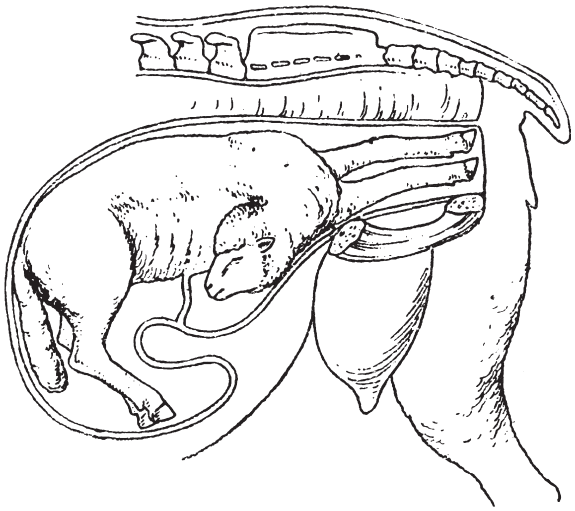
When there has been gross delay and it is found to be impossible to extend the leg of an emphysematous fetus, the carpal joint should be sawn through with fetotomy wire. Copious lubrication is indicated and further fetotomy may be required as described for fetomaternal disproportion. As an alternative, unrelieved carpal flexion may be dealt with by Caesarean hysterotomy (see Chapters 15 and 16).

Shoulder Flexion Posture

Cases of unilateral shoulder flexion that are seen early and in which there is still adequate natural lubrication can be delivered without correction, provided there is no fetomaternal disproportion as well. Winter and Hill (2003) recommend that the ewe is placed in lateral recumbency with the retained limb uppermost, as the limb is more likely to become jammed against the pelvis if it is on the underside. When this is not possible or when both forelimbs are flexed (Fig. 14.19), the ewe's hindquarters should be raised, the fetus repelled, and replacement of fetal fluid provided as necessary. It is then usually possible to reach the lamb's radius/ulna (forearm) and to convert the defect to carpal flexion posture and then to proceed as previously described. It may be necessary to repel the visible leg in order to reach the retained one. In the case of a grossly oversized fetus, when it is found to be impossible to advance the leg, Caesarean hysterotomy may be necessary. When the fetus is emphysematous, the retained limb may be amputated using a wire saw fetotome. After the removal of one limb it is usually possible to deliver the fetus.



• **Fig. 14.19** Disposition of the lamb: anterior presentation, dorsal position, bilateral shoulder flexion posture.



• **Fig. 14.20** Disposition of the lamb: anterior presentation, dorsal position, lateral deviation of the head.

Deviation of the Head

Lateral deviation of the head (Fig. 14.20) is a very common cause of ovine dystocia. As in the cow, it presents with both forelimbs in the vulva, but the head is not in the birth canal. It is important before starting to correct the malposture to ensure that the limbs

VetBooks.ir

are indeed forelimbs and that they both belong to the same fetus. The head can be deviated laterally (which is the more common postural defect) or ventrally. The methods used for correcting such deviations are similar to those described for cattle. Fresh cases can be managed by repelling the fetus and simple manual repositioning of the head. Longer standing cases or those that cannot be managed by simple manipulation can be managed by elevating the hindquarters of the ewe, together with caudal epidural anaesthesia and the instillation of lubricant as required. Winter and Hill (2003) suggested that the hindquarters should be only partially raised, so that the lamb's head does not fall too far back into the abdomen. The forelimbs can then be repelled and flexed to create space for repositioning the head. A snare may help to straighten the head, or the mandible can be cupped in the hand. Once the head has been corrected, it is advisable to attach a head snare before delivering the lamb by traction. When there is insufficient room to correct the deviation, the displaced head of an emphysematous lamb may be amputated with a wire saw fetotome, but a Caesarean hysterotomy may be preferred.

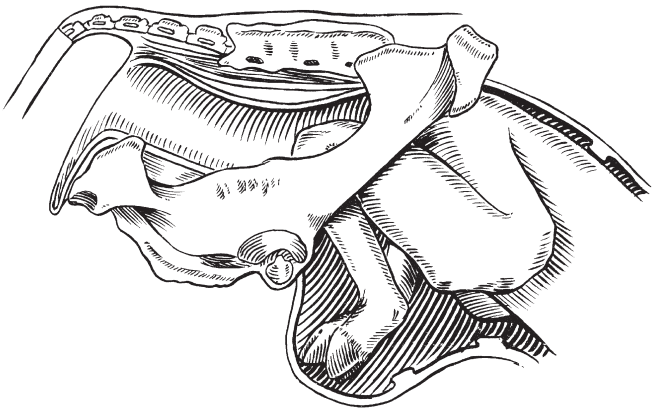
Dystocia Due to Postural Defects: Posterior Presentation

Faulty posture of the hindlimbs is more difficult to correct than abnormalities of the forelimbs, particularly in horses. The defects now to be considered concern the lack of extension of the hock and hip joints, which may affect one or both limbs. In calves it is occasionally found that the umbilical cord runs between the hindlimbs and over the posterior aspect of one or other. In this case it is necessary to create a hock flexion in order to replace the cord in its correct position. Failure to do this may result in its occlusion, causing death of the calf. Owing to the difficulty of extending the retained limbs, due to lack of space in front of the pelvis, there are three essential requirements in attempting to correct this cause of the dystocia: epidural anaesthesia, fetal fluid supplementation, and retropulsion. All manipulations should be conducted very carefully and gently because the danger of accidental perforation of the uterus is a real one. The variable factor exerting the greatest influence on the relative difficulty of the corrective procedure – as well as on the outcome of the operation – is the duration of dystocia before treatment. Cases attended in early second stage labour may be delivered quite easily, but when there has been considerable delay, with consequent loss of fetal fluid, uterine contraction, and death of the fetus, a most difficult and protracted fetotomy or Caesarean hysterotomy may be necessary. A large proportion of stillbirths are associated with fetuses in posterior presentation.

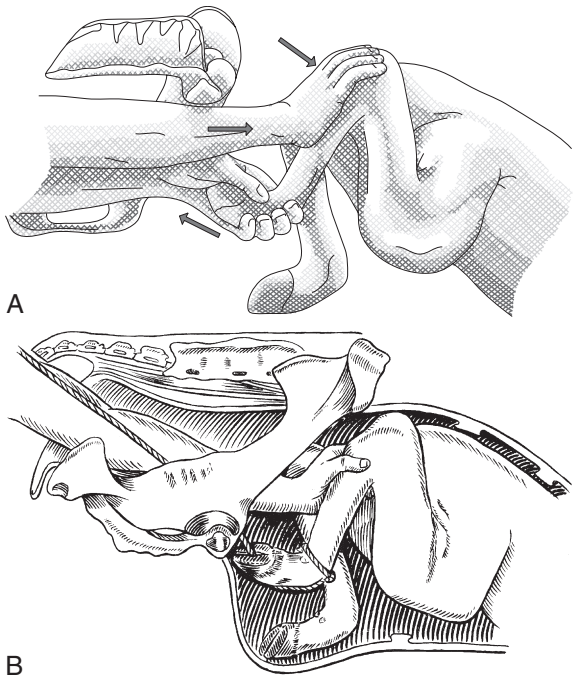
Postural Defects of Posterior Presentation in Cattle

Hock Flexion Posture

The condition is commonly bilateral (Fig. 14.21). The points of the hock may be felt in front of the pelvic brim or may be firmly engaged in the maternal birth canal. An estimate needs to be made of the likely degree of difficulty in correction, and a decision made on whether epidural anaesthesia and/or fetal fluid replacements will be needed. The aim of the manipulative procedure is to extend the hock joint(s), for which enough space must be created. In early cases, with or without epidural anaesthesia, the posture may be corrected by hand. The fetus is first repelled by pressing forward



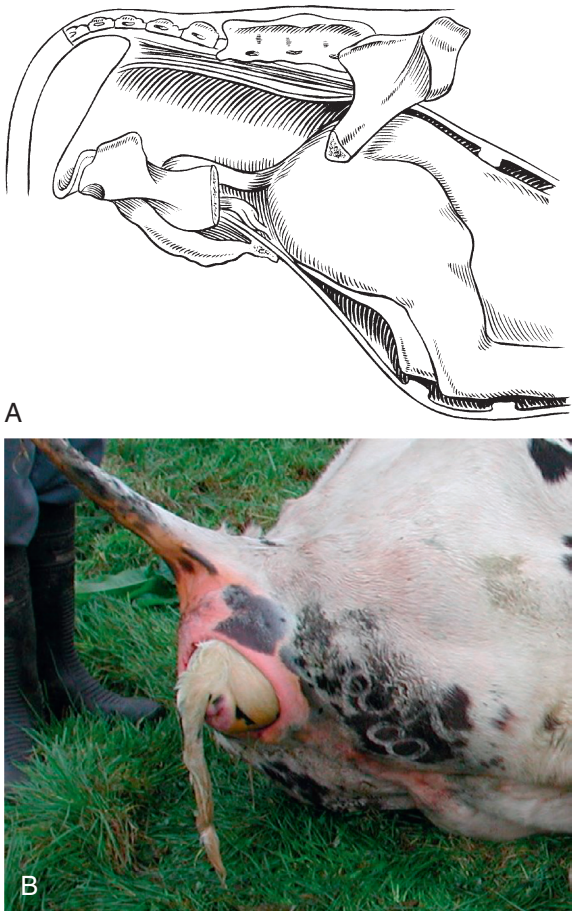
• **Fig. 14.21** Disposition of the calf: posterior presentation, dorsal position, bilateral hock flexion posture.



• **Fig. 14.22** Correction of hock flexion in the calf. (A) Manual correction by medial and posterior movement of the foot with one hand and lateral, forward, upward repulsion of the hock with the other hand. (B) Correction of hock flexion using the hand and a digital snare.

on its perineum. The foot is flexed in a cupped hand and drawn backwards and medially as, with the other hand, the point of the hock is grasped and pushed upwards, forwards and laterally (Fig. 14.22A). The foot is eventually lifted over the pelvic brim, and the limb is extended in the vagina. In cases in which it is found to be impossible to extend the hock owing to the lack of space, an assistant is directed to pass in an arm and to press forwards and upwards on the point of the hock as the operator again tries, as before, to bring the foot into the pelvic canal. An alternative method is to supplement manual extension by traction on a snare fixed to the retained foot in this way: One end of an obstetrical snare – to which may be attached Schriever's introducer – is passed into the birth canal, around the hock flexure, brought out, and passed through the loop at the other end; the running noose thus formed is applied to the metatarsus. The noose is then manipulated

VetBooks.ir



• **Fig. 14.23** (A) Disposition of the calf: posterior presentation, dorsal position, bilateral hip flexion posture ('breech presentation'). (B) Clinical appearance of breech presentation, with the tail protruding from the vulva. (B: Courtesy Dr. Jakob Malmo.)

down the limb until it lies in the pastern, the shank of the noose being placed between the digits, so that when traction is applied to it the fetlock and pastern, joints are flexed (see Fig. 14.22B). After again repelling the fetus the obstetrician grasps the foot and, as the assistant pulls on the snare, the extremity is lifted over the pelvic brim.

In the occasional case in which it is impossible to extend the hock and the calf is dead, simple fetotomy may be performed (see Chapter 15). If the calf is alive, then a Caesarean hysterotomy will be necessary.

Hip Flexion Posture and Breech Presentation

Bilateral hip flexion is more common in cattle than unilateral flexion. When both hips are flexed, the condition is described as a 'breech presentation' (Fig. 14.23A). The calf's tail is presented, either through the vulva (see Fig. 14.23B) or palpated on vaginal examination. The difficulty of the dystocia depends on how long standing it is: fresh cases are relatively easy to manage, but neglected cases that are heavily impacted in the pelvis or in which a hand cannot be passed to the hocks of the calf can be very difficult to manage. Many cases of breech presentation occur in twin calvings, with the benefit that the calf may be smaller than if it were a singleton. However, the co-twin is often also in posterior presentation.

The aim of the treatment is to convert the breech presentation into a bilateral hock flexion and then proceed accordingly. Most cases of breech presentation will require epidural anaesthesia unless the calf is very small. Some will also require fetal fluid replacement. The manipulative procedure is to repel the calf's perineum forwards and upwards with the aim of bringing the retained limbs within reach, so that the leg may be grasped as near to the hock as possible. Traction on the limb converts the posture into hock flexion, from which point the hock is extended as described previously. If it is impossible to bring the hock within reach, a fetotomy should be performed if the calf is dead, or Caesarean hysterotomy if it is alive.

In cases of a small fetus, delivery may be attempted with the fetus still in the breech presentation. Snares are introduced between the upper limbs and the pelvis of the fetus and then picked up from below. Using a Schriever's introducer will make this procedure a lot easier. Subsequently, the fetus can be delivered by traction on both snares.

Postural Defects of Posterior Presentation in Horses

Uncomplicated Posterior Presentation

Posterior presentation in the mare carries with it an increased risk of fetal hypoxia, due to compression of the umbilical cord in the birth canal, premature rupture of the umbilical cord, or rupture of the cord while the head of the foal is still in the uterus. Uncomplicated posterior presentation can be managed by gentle traction. However, a high proportion of foals in posterior presentation also have abnormalities of posture or position, probably due to compromise of the normal process of rotation and extension of the extremities (Jeffcott & Rosdale 1979). Hence foals in posterior presentation appear to be predisposed to being in a dorsoilial position (Frazer et al. 1997) or to have bilateral malpostures of the hindlimbs (Frazer 2011).

Hock Flexion Posture

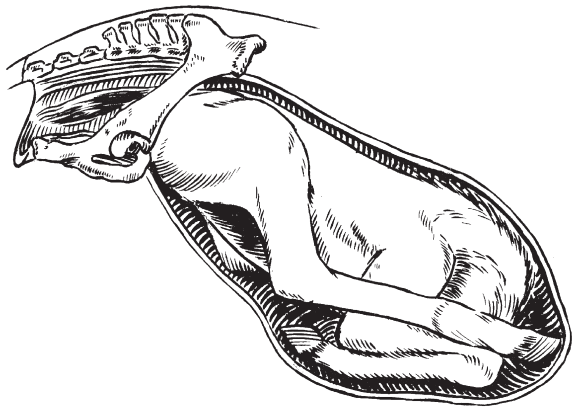
Hock flexion is much more difficult to manage in the mare than in the cow, owing to the very long limbs of the foal. Hence many cases have to be managed by Caesarean hysterotomy or fetotomy rather than vaginal manipulation. Bilateral hock flexion may present with the tail present at the vulva and the flexed hocks at the pelvic inlet. Unilateral flexion will present with a single hindlimb protruding through the vulva (Jackson 2004).

In principle, the methods used for correcting hock flexion are like those described for cattle, but, owing to the longer limbs of the foal, the procedure is much more difficult. For manipulation, the fetus has to be repelled well forwards, a process that is likely to require fetal fluid substitution and/or the administration of a tocolytic drug. An assistant may help to repel the fetus, although there are risks to the safety of personnel when two people are working closely behind the mare. Even so, repelling the fetus may only be possible in the anaesthetised mare with her hindquarters elevated. Straightening the hock is more risky than in the cow, as the hock will be forced against the dorsal wall of the uterus, and there is further risk to the floor of the uterus from the foal's hoof as it is difficult to reach the foot to cup it in the hand (Frazer 2011). Use of a crutch to repel/elevate the hock and of a snare to provide traction on the distal limb has been described. If the foal is alive, it may be preferable for an early recourse to a Caesarean hysterotomy; if it is dead, fetotomy may be the best means of resolving the malposture (Embertson 1992, 1999, Frazer et al. 1997).

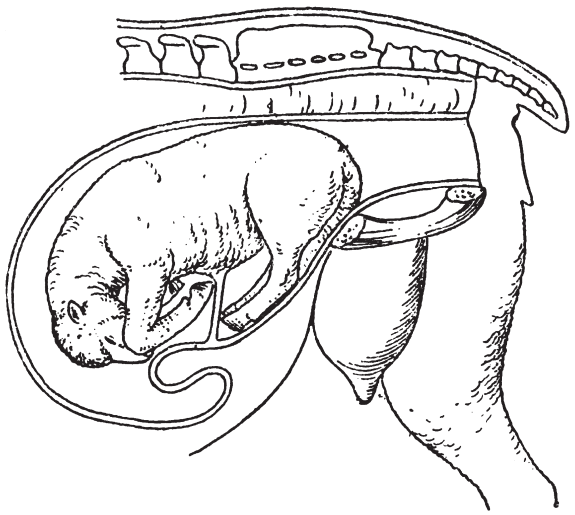
Hip Flexion Posture and Breech Presentation

Correction of hip flexion posture, especially breech presentation (Fig. 14.24), is difficult. In addition to the difficulties of managing

VetBooks.ir



• **Fig. 14.24** Disposition of the foal: bilateral hip flexion posture ('breech presentation').



• **Fig. 14.25** Disposition of the lamb: posterior presentation, dorsal position, bilateral hip flexion posture ('breech presentation').

hock flexion (see previous mention), each limb has first to be converted from hip flexion to hock flexion. As in cow, hip flexion is converted into hock flexion by repelling the fetus, grasping the hock, and drawing it backwards towards the pelvic inlet. Also, as in the cow, a bilateral hip flexion should be converted into a bilateral hock flexion before attempting to extend either hock. There is a very real danger of trauma to the uterus and birth canal during these procedures. There may be benefit in anaesthetising the mare and placing her with the hindquarters elevated. However, if after a proper effort, attempts to extend the hindlimbs are unsuccessful and the foal is still alive, no time should be lost before resorting to Caesarean hysterotomy. If, as is more likely, the foal is dead, then under general anaesthesia and after amputation of one or both hindlimbs by means of the wire saw fetotome, it should be possible to deliver the foal by traction. Frazer (2011) recommended converting a breech presentation into a bilateral hock posture before cutting both limbs through the distal tarsal bones.

Postural Defects of Posterior Presentation in Ewes and Does

A considerable proportion of twin lambs and kids are in posterior presentation, and because of the lack of uterine space, especially when both lambs occupy one uterine horn, one or both hindlegs may fail to extend into the vagina (Fig. 14.25). Thus, in flocks with a high proportion of twins, hock flexion and hip flexion postures will be common causes of dystocia.

These malpostures may be corrected in the manner described for cattle but, because twin lambs are smaller than singles and because it is a simple matter to raise the ewe's hindquarters, the requisite manoeuvres are much more easily performed than in cattle. In all delayed cases, fetal fluid substitution is indicated. The manipulation of the fetus, including its retropulsion, should be carried out in a very gentle manner. In cases of irreducible malposture in dead lambs, appropriate fetotomy or Caesarean hysterotomy can be performed.

Dystocia Due to Faulty Position

Faulty position of the fetus is encountered more frequently in horses than in ruminants. This is considered to be due to the fact that, in late gestation or first stage labour in horses (but not in cattle), a physiological rotation of the fetus from the ventral to the dorsal position occurs; however, occasionally this turning fails. In this case the fetus is in an anterior presentation (occasionally posterior) but with its vertebral column applied to either one side of the uterus (right or left lateral position × 2 dorsoilial position) or facing the floor of the birth canal (ventral position × 2 dorsopubic position). The process whereby the ruminant fetus sometimes comes to lie in ventral position is not understood. It is unlikely to be a gestational position; more probably it arises during the first stage of labour, when the uterine peristaltic force generates a vigorous reflex response in the fetus that causes it to rotate about its longitudinal axis.

In order to make birth possible, fetuses in lateral or ventral position must be rotated into the normal upright (dorsosacral) position. This can be achieved by first repelling the fetus and then rotating it by appropriate force applied to the presenting extremity. Such rotation is easier to perform with the patient standing. Epidural anaesthesia is useful for this manoeuvre.

Anterior Presentation/Lateral Position in the Cow and Horse

These abnormalities of position are best managed in the standing position. If there is a concurrent malposture, it is generally best to correct this first, before correcting the malposition.

In the case of a live calf or foal, it may be possible to correct a lateral position by means of evoking a convulsive reflex by the fetus with pressure from the thumb and middle finger on the fetal eyeballs (the latter being protected by the eyelids). By applying a rotational force in the appropriate direction, the fetus can be turned into the dorsal position. The fetal nose and forelimbs are then advanced into the maternal pelvis, and the maternal expulsive efforts are assisted by grasping both forelimbs and gently pulling on them and, at the same time, applying a rotational force.

Alternatively, snares can be applied to the head and both forelimbs. One hand is advanced under the thorax on the side of the ventrally placed limb, grasps the shoulder joint, and moves it upwards and in a medial direction. Simultaneously, traction is placed on the upper limb in the opposite directions (e.g., downwards and left for a right lateral position). Another approach is that rotation is performed by repelling the fetus as far cranially as possible, crossing the snares in the appropriate direction, and

VetBooks.ir

then applying traction. Such a force tends to result in the snares becoming more or less parallel, which can only occur if the fetus rotates about its longitudinal axis. It is important to ensure that the snares are crossed in the right direction so that rotation of the fetus is not increased. The use of detorsion rods for correction of abnormalities of position has also been described. For all of the methods described to be effective, epidural anaesthesia and fetal fluid substitution are likely to be necessary.

Anterior Presentation/Ventral Position in the Horse and Cow

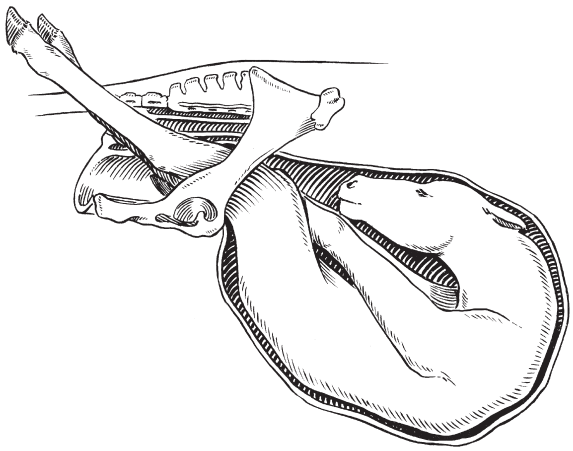
The same methods as described previously for the correction of a lateral position defect can be used, although the procedures will usually need to be repeated several times. Placing the dam with the hindquarters raised will facilitate the procedure. If the calf or foal should rest on its back with the head and limbs flexed on to its neck and thorax, the fetus must first be repelled so that the head and forelimbs can be extended. Rotation is then carried out.

Posterior Presentation/Lateral or Ventral Position in the Horse and Cow

Lateral presentation can be managed by the veterinarian introducing a hand and grasping the stifle region of the upper limb. Simultaneous retropulsion and downward pressure are applied to rotate the fetus through 90 degrees.

Ventral position can be managed by the veterinarian introducing a hand between the fetal hindlimbs and up to the inguinal region, where one of the thighs is grasped; then, pushing forwards, the operator rotates the fetus through a half circle. Failing this, traction on crossed limb snares should be used. If the hindlimbs are protruding far enough from the vulva, an alternative procedure is to place a traction bar (a length of broom handle will suffice if a specific instrument is unavailable) between the projecting hindlimbs and to secure it to them by means of a snare; rotational force is then applied to the traction bar.

There is a grave risk that the hind feet of a foal in posterior presentation/ventral position will penetrate the vagina and rectum (Fig. 14.26). In such a case a Caesarean hysterotomy should be performed and the rectovaginal fistula repaired later.



• **Fig. 14.26** Disposition of the foal: posterior presentation, ventral position, extended posture; penetration of the dorsal wall of the vagina and dorsal wall of the rectum, resulting in a rectovaginal rupture.

Dystocia Due to Defects of Position in Sheep and Goats

The methods of treatment are those described for the horse and cattle. By raising the ewe into the inclined supine position and infusing fetal fluid substitute, rotation is much easier in this species; instruments are seldom required.

Dystocia Due to Faults of Presentation

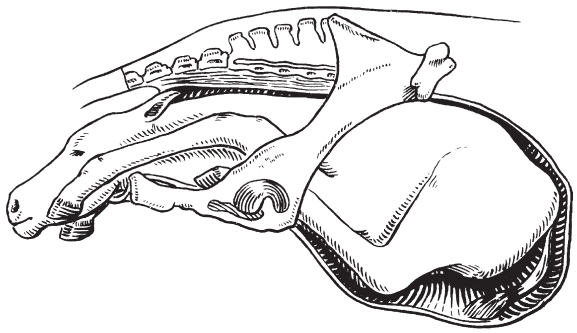
Instead of the long axis of the fetus being in line with the birth canal, it may be disposed vertically or transversely to the pelvic inlet. Owing to limitation of space in the sagittal plane, absolute vertical presentation is not possible, but oblique vertical presentations do occur - rarely, and then more often in mares than cows. Vertical presentations are described according to whether the fetal vertebral column or abdomen is presented at the pelvic inlet, i.e., dorsovertical or ventrovertical presentations. Transverse presentations are even more uncommon and are almost exclusively encountered in the mare; they may be ventrotransverse or dorsotransverse. Finally, there is the bicornual transverse presentation of the mare, in which the limbs of the fetus are positioned in the uterine horns rather than in the uterine body. All of these faults of presentation are difficult to manage, the bicornual presentation especially so. When correction of the malpresentation is possible by vaginal manipulation, it is achieved by version of the fetus into a longitudinal presentation. In principle the nearer extremity is moved towards the pelvic inlet, although it is simpler to convert to a posterior than an anterior presentation (i.e., two appendages being manipulated rather than three). Many cases cannot be delivered by manipulation, so resort often needs to be made to fetotomy, hysterotomy, or manipulation via a laparotomy. Transversely presented foals are often larger than normal, as the placenta fully occupies both uterine horns, which adversely affects the prospects for vaginal delivery. Likewise, dystocia due to transverse presentation may be associated with weak signs of labour: because the fetus does not engage into the pelvis, abdominal straining may be minimal. Hence, the signs of labour may not be recognised.

Oblique Dorsovertical Presentation in the Horse

This is the rarest of the malpresentations, with occurrence largely restricted to the mare. In the dorsovertical presentation, the fetus lies with its back or withers directed towards the pelvic inlet whereas the body of the fetus is 'lying' in the uterine body. Benesch and Wright (1951) were of the opinion that this presentation occurs when premature rupture of the fetal membranes occurs before fetal extension and rotation has occurred. The presentation is extremely difficult to resolve because no fetal limbs are accessible.

Vaginal delivery has been described, but would be very difficult indeed to carry out successfully. The process is that, according to whether the head or breech is nearer the pelvic inlet, conversion into anterior or posterior longitudinal presentation may be attempted. An attempt is made to bring the fetal extremity (head and/or limbs) to the pelvic inlet and first to convert the defect into a ventral longitudinal presentation. The fetus can then be rotated to the dorsal position as described earlier. Retropulsion and the presence of copious fluid (natural or artificial) in the uterus are both essential. A grip is taken on the fetus by means of Krey's hook as near as possible to the more proximal fetal extremity. Then, as retropulsion is applied, the hook is pulled on with a view to bringing the fore or hind end of the fetus to the pelvic

VetBooks.ir



• **Fig. 14.27** Disposition of the foal: oblique ventrovertical presentation ('dog-sitting position'). Note the presence of the hind feet in the pelvic canal.

inlet. After adjustments of position and posture, the fetus is then delivered by traction.

In principle, if manipulation is not possible, it should be possible to resolve the case by fetotomy or Caesarean hysterotomy but reports of such management are exceedingly rare. Benesch and Wright (1951) suggested that fetotomy should be undertaken as though the case were a dorsotransverse presentation.

Oblique Ventrovertical Presentation in the Horse and Cow ('Dog Sitting' Position)

This presentation is less rare than the dorsovertical position, but is still very uncommon. Its occurrence is largely restricted to the mare, although occasional cases occur in ruminants. In the 'dog sitting position' the fetal head, neck, and forelimbs are presented in the vagina, but, as one or (usually) both hips are flexed, the distal parts of the hindlimbs are also in the birth canal or pelvic inlet (Fig. 14.27). Sometimes, only one hindlimb is flexed (which has been called a 'hurdling' position). Frazer et al. (1997) considered that the unilateral posture is more common in mares than the bilateral.

The initial stages of birth appear normal, with the head and forelimbs presented at the vulva. Thereafter, despite further straining by the dam or traction by assistants, no further progress is made. Close examination shows that the forelimbs are less far advanced than normal (which also occurs in cases of elbow flexion). Insertion of a hand into the vagina reveals the presence of the hind feet resting on the pelvic floor. Sometimes the hind feet can even be present in the vagina. Because of the co-presentation of the hind feet into the pelvis, further traction on the fetus will cause its greater impaction into the pelvis, as well as increasing the risk of damage to the cervix.

Correction of this malposition is difficult. It may be possible to correct cases that have not become impacted by cupping the feet and pushing them off the pelvic brim as far forward into the uterus as possible. However, the obstetrician's arm is often not long enough to do so, especially in the mare, and there is a significant risk of damage to the uterine floor. Once the hind feet have been repelled, the fetus is delivered by traction.

When the fetus is impacted, which is usually the case, other methods are needed. After epidural anaesthesia and substitution of fetal fluids, Roberts (1986) suggested placing a Kühn's crutch around the pastern joints of the hindlimbs as a means of repelling them into the abdomen. An alternative method has been described, by which the fetus is converted into a posterior presentation/ventral position, then turned into the dorsal position. Benesch and Wright (1951) described placing snares on the hind pasterns and a crutch near the elbows of the forelimbs. The forelimbs are then repelled and the hindlimbs are drawn forwards, after which the hindlimb snares are used to rotate the fetus into the dorsal position. Baldwin et al. (1991) rightly suggested that, if the fetus is dead, repelling the fetus should not be attempted in the standing mare, as the repelled limb is likely to remain flexed, posing a high level of risk of rupture of the uterine wall. In such circumstances, the mare should be anaesthetised and positioned with the hindquarters elevated, before attempting manipulation.

Resolution of this malposition by Caesarean hysterotomy or fetotomy is equally not straightforward. Caesarean hysterotomy will be difficult unless the fetus can be repelled into the uterus; Jackson (2004) suggested that laparotomy and hysterotomy may be a preferable alternative approach. A relatively small incision is made in the uterus, through which the malpositioned limbs are detached from the pelvis and extended back into the uterus. The fetus is thereafter delivered *per vaginam* by traction, and the uterine incision closed.

Fetotomy is complicated and beyond the capabilities of all but the most experienced practitioners. A transverse cut is made through the trunk, the fetus eviscerated, and the lumbar vertebrae removed close to the pelvis. After applying snares to the hindlimbs, the fetus is repelled into posterior presentation and delivered by traction. Alternatively, one forelimb can be removed, costochondral junctions cut, and the fetus eviscerated. The pelvis is then split to remove one hindlimb and the tail, and the segments of the fetus delivered (Baldwin et al. 1991). If the fetus has been drawn so far into the birth canal that the head and shoulders are through the pelvis, fetotomy is the only recourse for delivery.

Dorsotransverse Presentation in the Horse and Cow

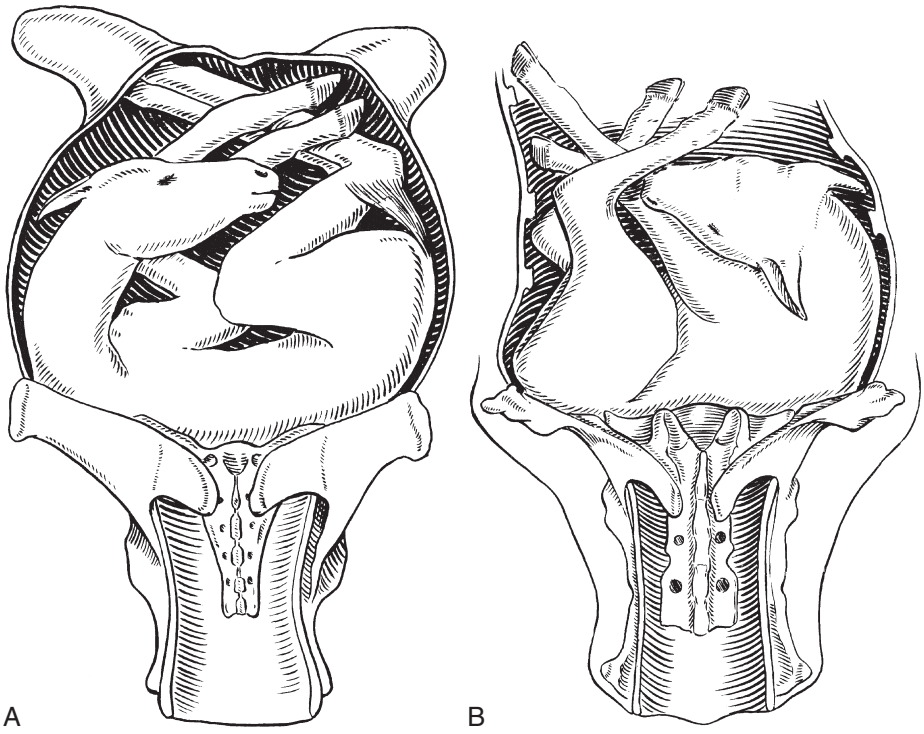
This is an extremely rare cause of dystocia (Fig. 14.28A and B), in which the spine of the fetus is presented towards the birth canal. Oblique variants of it also occur in both the mare and cow. Delivery by manipulation is difficult or, in many cases, impossible. Hence, the preferred method of delivery is by Caesarean hysterotomy, regardless of whether the foal is alive or dead (Vandeplassche 1987).

If manipulation is attempted, replacement fetal fluids should be instilled and the mare should be anaesthetised and placed on her back; a cow should be given epidural anaesthesia. The obstetrician should ascertain whether one extremity is nearer the pelvic inlet. The technique of correction required involves repulsion of the fetus and the advancement of its nearer extremity to the birth canal; so, unless one extremity is within easy reach, uterine version is likely to be extremely difficult or impossible. An attempt is made by manipulation of the proximal fetal extremity to turn the fetus into ventral position, anterior or posterior presentation. The next step is to rotate the fetus into dorsal position. Finally, it is delivered by traction. If after a short, determined effort, it is obvious that version cannot be achieved, Caesarean hysterotomy should be performed immediately. Fetotomy is very difficult to carry out in this type of dystocia and, consequently, is not recommended (Vandeplassche 1987).

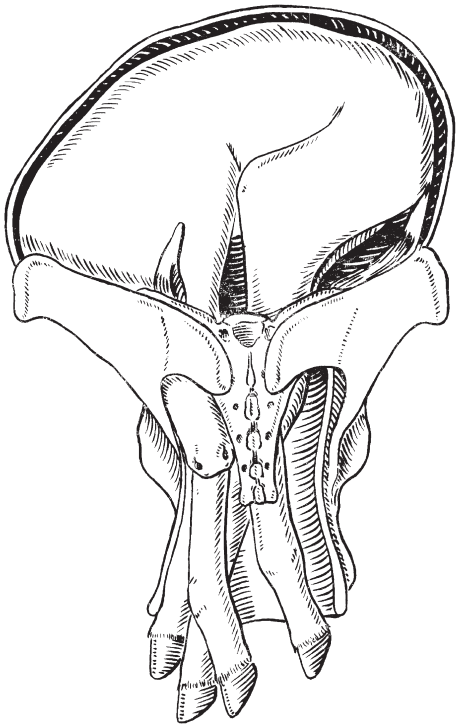
Ventrotransverse Presentation in the Horse and Cow

This presentation, in which the abdomen and limbs of the fetus are presented towards the birth canal (Fig. 14.29), is more likely to be seen in the mare than the cow, and oblique variants of it are

VetBooks.ir



• **Fig. 14.28** (A) Disposition of the foal: dorsotransverse presentation; uterine body gestation. (B) Disposition of the calf: dorsotransverse presentation.



• **Fig. 14.29** Disposition of the foal: ventrotransverse presentation; uterine body gestation.

more usual. A variable number of fetal appendages may enter the maternal pelvis. It is possible that the head as well as the forelimbs are in the vagina, but it is usual for two or more legs only to be presented. The condition must be distinguished from twins and double monsters and from schistosoma reflexus (see Chapter 9).

Fetal abnormalities, such as limb deformities, angulation and/or ankylosis, and vertebral deformities, such as 'wryneck', occur in a significant proportion of such cases. Roberts (1986) believed that this is due to restriction of fetal movement *in utero*.

The method of choice for delivery of a fetus in this position is Caesarean hysterotomy because delivery by vaginal manipulation will be time-consuming and require much experience (Frazer 2011). If attempted, the aim of vaginal interference is first to convert the abnormality into longitudinal – usually posterior – presentation, ventral position; this means that the hindlimbs are extended into the pelvis, as the head and forelimbs are repelled into the abdomen. General anaesthesia and elevation of the hindquarters are helpful in the mare. Unless progress with version is soon apparent, Caesarean hysterotomy is recommended for both mare and cow.

Bicornual Transverse Presentation in the Mare

In the bicornual type of transverse presentation peculiar to mares, the fetal extremities are disposed in the two horns, and its trunk lies across the cranial portion of the uterine body (Fig. 14.30). Ventral displacement of the uterus may have occurred, and if so, it may be impossible to palpate the fetus. As soon as the presentation is recognised, a Caesarean hysterotomy should be performed.

Dystocia Due to Defects of Presentation in Sheep and Goats

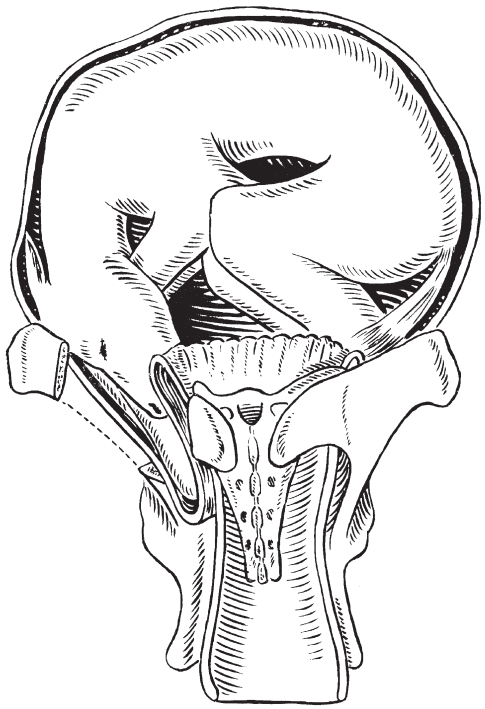
The methods of treatment are similar to those described for the mare and cow. By raising the ewe into the inclined, supine position and by infusing fetal fluid substitute, version is much easier in this species, but in protracted dystocia Caesarean hysterotomy may provide an easier solution.

VetBooks.ir

Dystocia Due to Twins

Twin gestation in cattle often culminates in dystocia. Mee et al. (2011) and Olson et al. (2009) respectively determined that the risk of dystocia in dairy cows carrying twins as 2.4 times or 3.7 times that of cows carrying singletons (see also Table 14.2). Twin foaling in mares is uncommon because abortion is a more probable outcome. However, equine twins that survive to term may well cause dystocia: Leidl et al. (1993) reported 4% of referred cases of equine dystocia were due to twins. In sheep and goats the prevalence of maldisposition of fetuses increases with litter size, although the birth weight of the fetuses is reduced. Thus the effect of twins versus singletons is generally that the prevalence of dystocia is reduced, but in litters of three or more lambs, it is increased (Dwyer & Bunger 2012) (see also Chapter 12). In general, the smaller size of twin fetuses facilitates manipulative correction and delivery; for the same reason, natural or obstetrical delivery may be possible despite maldisposition of a fetus.

The relative importance of unilateral or bilateral twin pregnancies to the development of dystocia was studied by Echternkamp et al. (2007) in calves born to cows selected for twin ovulations.



• **Fig. 14.30** Disposition of the foal: ventrotransverse presentation with ventral displacement of the uterus in the mare; bicornual gestation.

They found that the survival at birth of twin calves derived from unilateral pregnancies was lower and the risk of dystocia higher than in calves derived from bilateral pregnancies (Table 14.2). These differences may perhaps be attributed to a greater risk of simultaneous presentation when a twin from each horn approaches the pelvic inlet, but a greater risk of malposture and/or inertia when both fetuses occupied the same horn. Overall, therefore, the risk of stillbirth in twin-born calves is significantly greater than that of singletons: Olson et al. (2009) calculated the odds ratio for stillbirth of twins as 7.8 times that of singletons. It has been suggested that the second-born twin is more likely to survive than the first-born.

Twin dystocia is of three types:

- Both fetuses present simultaneously and become impacted in the maternal pelvis (Fig. 14.31A and B). Fetuses may be both in the same presentation, or one may be anterior and the other posterior.
- One fetus only is presented but cannot be born because of faulty disposition, usually due to failure of normal extension of limbs or head because of insufficient uterine space.
- Uterine inertia due to either overstretching of the uterus by the excessive fetal load or premature birth. When inertia is present, birth of the first or second fetus does not proceed even when the presentation is normal.

In the treatment of twin dystocia, the first essential is to determine which fetal appendage(s) is (are) presented and its (their) relationship to each of the fetuses. Each appendage must be traced back to the trunk to which it attaches before any further action is undertaken. If this is made a rule, the obstetrician will not blunder into applying traction simultaneously to two fetuses. Nor should twins be mistaken for a schistosome, double monster, or ventrotransverse presentation of a single fetus.

When a twin is presented with an abnormality of posture, it is managed as though it were a single fetus; in such cases the presence of twins may not be known – but may be suspected on account of small fetal size and the history of the dam – until the uterus is searched after delivery and another fetus found. Again, the association of uterine inertia with twins may be known only after delivery of the first fetus. Breech presentations are common in ruminant twins, and the second fetus is often also in posterior presentation.

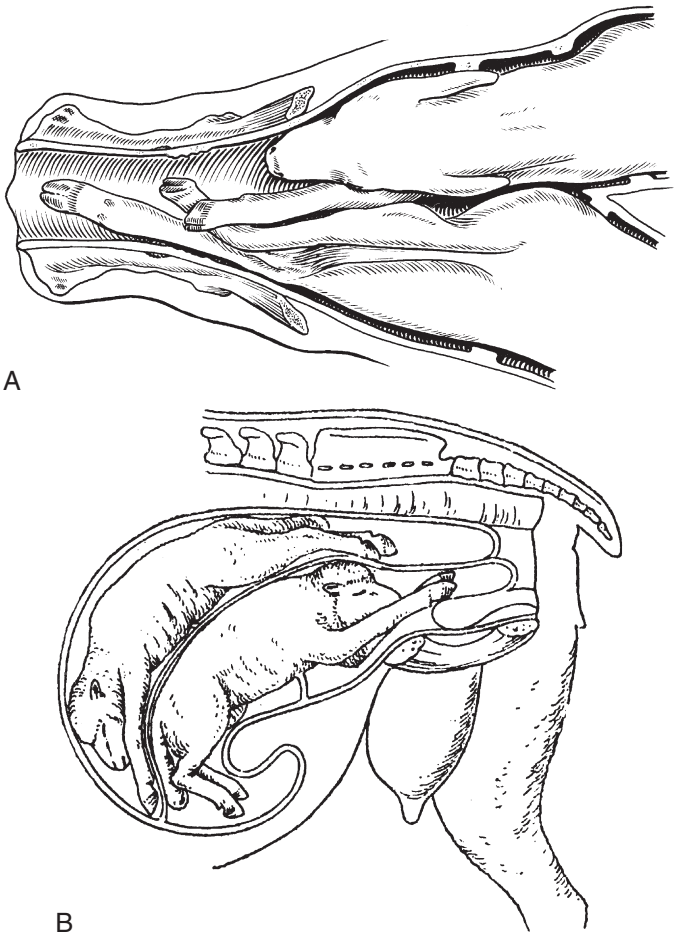
When twins are known to be present and retropulsion is required to allow one fetus an unimpeded assisted exit or to provide space in order to correct a simple malposture, it should be performed very carefully. In cattle, and especially in sheep and goats, there is a much greater likelihood of causing uterine rupture when twins are present. Spontaneous rupture has been observed when both fetuses were in the same horn.

TABLE 14.2 Effect of fetal number and location *in utero* on calf survival at birth, calving assistance and fetal malpresentation

Number and Disposition of Pregnancies	n	Calf Survival at Birth (%)	Calving Assistance (Total) (%)	Malpresentations (%)
Single	1587	97.2	22.5	5.5
Twin, unilateral pregnancy	1284	83.0	57.8	47.4
Twin, bilateral pregnancy	1158	94.0	49.8	33.6

Derived from Echternkamp et al. (2007).

VetBooks.ir



• **Fig. 14.31** Simultaneous engagement of (A) bovine and (B) ovine twins. In each figure, one twin is in anterior presentation, dorsal position, shoulder flexion posture; the other is in posterior presentation, dorsal position, extended posture.

Simultaneous presentation of twins (see Fig. 14.31A and B) is treated in logical sequence. The polarity of the fetuses is determined, the more advanced fetus recognised, and its presenting extremity appropriately snared. Any defect of presentation, position, or posture must be diagnosed and treated; correction may be facilitated by epidural anaesthesia. Then, with continuing retropulsion on the less advanced fetus, the nearer one is brought into the pelvis and delivered by simple traction. The other fetus, which may be presented in the opposite direction, is then appropriately manipulated. If one fetus is in posterior presentation, there may be benefits in delivering it first, as there are only two appendages to manage. The delivery of ovine twins is more easily achieved if an assistant holds the ewe by its hindlegs in an inclined, supine position. When the ewe is delivered of twins, the uterus should always be examined for another fetus(es).

In occasional cases of prolonged delay, corrective manipulation is impossible, and fetotomy of the presenting fetus may be required. Severe pelvic impaction of dead fetuses may be more readily relieved by Caesarean hysterotomy.

Retention of the fetal membranes is more common in cows with twin births than singleton births (Bell & Roberts 2007). In sheep the risk of retained fetal membranes is only increased if there is also dystocia.

Most cases of equine twin conception are followed by early death of one or both of the conceptuses (see Chapter 31). About 2% of equine gestations start as normal twins, but mummification or abortion frequently occurs, so that less than 1% reach term. Vandeplassche et al. (1970) reported data from 44 cases of equine twin gestation. All pairs were of dizygotic origin (i.e., nonidentical). In 33 of 34 twin pregnancies, it was found that one fetus occupied each horn; in the remaining cases the twins were in the same horn. Of 44 live foals born, 37 were reared. The study showed that there was a much smaller likelihood of viable twin foals being born to thoroughbred mares than to Belgian draught mares, and this difference might be related to a better uterine capacity in the draught mare (Vandeplassche et al. 1970). Retention of fetal membranes is likely to occur after twin foal births (Threlfall 2011), although possibly only if there has also been concurrent dystocia (Provencher et al. 1988).

Dystocia Due to Fetomaternal Disproportion

Fetomaternal Disproportion in Cattle

Fetomaternal disproportion is the most common cause of dystocia in cattle, particularly in primiparous animals. Its aetiology and prevalence are discussed in Chapter 12. Although the precise aetiology may be of an oversized calf or an undersized dam, the clinical signs and management are essentially identical. The clinical signs are of a cow that is unable to complete second stage labour, despite straining unproductively for a time in excess of the normal duration of second stage labour (i.e., about 2 hours for a multiparous cow). The fetus is in a normal disposition and the allantochorion ('water bag') has ruptured. If in anterior presentation, the two forefeet are visible at the vulva, often accompanied by the fetal nose. Many cases of fetomaternal disproportion do not receive timely veterinary intervention; often, when the veterinarian arrives, the animal has been in second stage labour for several hours, and there is a certain degree of secondary uterine inertia present.

The first main point of difficulty is associated with the birth of the fetal head. In heifers this can be due to a failure of the posterior vagina and vulva to adequately dilate. The next point of difficulty is associated with the entrance of the fetal chest and shoulders into the birth canal. The shoulders are normally the greatest presenting diameter of the fetus, so the greatest effort is typically expended in delivering this part of the fetus.The hips are the final main point of difficulty. If the gestation was prolonged, the relatively high growth rate of the fetal pelvis can result in the hips becoming 'locked' within the maternal pelvis.

Some cases of apparent fetomaternal disproportion occur when the fetus has died (usually during a neglected labour), and it has become decomposed and emphysematous. The presence of fetal emphysema results in a fetus whose diameter is too great to pass through the birth canal.

Fetomaternal disproportion can be managed in one of four main ways:

- The normal expulsive forces may be supplemented by external traction on the fetus. This method is frequently employed successfully by stock managers.
- The diameter of the vulval opening may be increased by episiotomy.
- The fetus may be removed by Caesarean hysterotomy.
- The overall size of the fetus may be reduced by fetotomy. The use of fetotomy is generally restricted to when the fetus is already dead.

Assessment of which of these methods to use will be guided by the degree of disproportion, the duration of the dystocia, whether or

VetBooks.ir

not the calf is alive, and the value of the calf. Welfare and survival of dam and fetus and preserving the dam's subsequent fertility are also important considerations.

In the case of a group of animals in which dystocia is being caused by fetomaternal disproportion, consideration should be given to inducing early parturition in the remainder of the group.

Assessment of Disproportion

Assessment of the degree of disproportion is made by observation of the presenting parts and palpation of the fetus within the vagina. No single method provides unequivocal evidence of the degree of disproportion, but, taken together, identification is generally reliable.

Size of the Fetal Limbs. The diameter of the fetlocks are generally a good guide to the size of the calf (Hindson 1978, Ko & Ruble 1990), although there are discrepancies, as in the case of the Belgian Blue calf whose shoulders are much wider than the lower limbs would suggest and in the emphysematous calf whose trunk is massively disproportional to the size of its feet. Hiew et al. (2016) explored the relationship between front foot circumference and various parameters of calving difficulty in Holstein cattle, finding that there was a significant linear relationship between body weight and foot circumference but not between calving difficulty score and foot circumference.

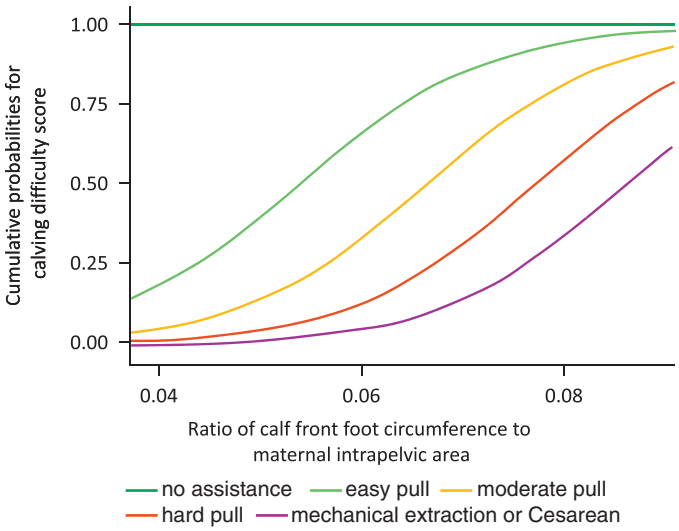
Size of the Head. Palpation of the fetal head (width of poll or muzzle) also gives an indication of the body size of the calf. Colburn et al. (1997) could not find a direct relationship between head circumference of calves and calving difficulty score, although the circumference of calves born to bulls with a low EPD (expected progeny difference) for birth weight was smaller than of those born to bulls with a high EPD. Nugent et al. (1991) likewise found that calves sired by bulls with a high EPD for birth weight had smaller canon bones and a lower head circumference than did those sired by low EPD bulls. In neglected cases of fetomaternal disproportion, the head can become swollen and oedematous, giving a false impression of its size.

Pelvic Area: Ratio of Pelvic Area to Calf Size. The relationship between pelvic area and the risk of fetomaternal disproportion are discussed in Chapter 12. Basic assessment of the relative size of the fetus and the dam's pelvis is made by passing a lubricated hand around the fetus within the pelvis to estimate the amount of space between the fetus and pelvis. If the head is tightly wedged inside the pelvis or if the shoulders appear to be impacted in the pelvic inlet, it is likely that there is a significant degree of disproportion. If the calf is in posterior position, a hand can be used to explore the amount of space between the calf and the dam's pelvis. If the thighs and hips have entered the pelvis, it is likely that the calf can be delivered. If, however, the thighs are not in the pelvis and appear to be wedged at the pelvic inlet, delivery of the calf is less likely.

Hindson (1978) found a significant correlation between the external distance between the medial interischial tuberosities and both the vertical and horizontal pelvic diameters. From this, he devised a formula to obtain a figure for the traction ratio (TR). It is as follows:

$$\text{TR} = \frac{\text{Interischial distance}}{\text{Calf's digital diameter}} \times \frac{P_1}{P_2} \times \frac{1}{\text{E}}$$

where P_1 = the party factor of 0.95 for heifers; P_2 = a correction factor of 1.05 for posterior presentation; E = a factor for breeds with muscular hypertrophy. Traction ratios greater than 2.5 are unlikely to have dystocia due to fetomaternal disproportion; between 2.3 and 2.5, traction is likely to be successful; between 2.1 and 2.3, substantial traction may be required which may not be successful; 2.1 or less, the method of treatment should be by Caesarean hysterotomy. However, a number various of the predictive equations of calf birth weight that were developed for estimation of the weight of beef calves, based upon the size of fetal extremities (Thomas 1996, Tozer et al. 2002) underestimated fetal weight of modern Holstein cows (Hiew et al. 2016). Nonetheless, the ratio between digit circumference and maternal intrapelvic area is predictive of calving difficulty (Hiew et al. 2016). The relationship is not simple, however, and is best understood in terms of the probability of a difficult calving for any fetal foot to maternal pelvis ratio (Fig. 14.32).



• **Fig. 14.32** Ordered logistic regression of the ratio of calf front foot circumference to maternal intrapelvic area as a predicted cumulative probability for the calving difficulty score. Calving difficulty score was categorised on a five point scale: 1, no assistance; 2, easy pull; 3, moderate pull; 4, hard pull; 5, mechanical extraction or Caesarean. (From Hiew et al., 2016.)

Position of the Legs. If the forelimbs are crossed over within the birth canal, it usually indicates that the elbows are being forced medially by the pressure of the pelvic wall. Likewise, if the forefeet are rotated so that the soles of the feet tend to face each other, this also indicates excessive width of the shoulder. Neither of these signs gives an absolute indication of disproportion, as they can occur with normal-sized calves.

Advancement of the Calf. Moderate traction is applied to the calf to determine whether this will advance it through the pelvis. As a rule, if no progress has been made within 10 minutes of traction, it is unlikely that the fetus can be delivered by that means. NADIS (2017) define progress in a calf in anterior presentation as follows: "reasonable traction should deliver the calf when two people pulling can extend both front legs such that the fetlock joints protrude one hand's breadth beyond the vulva within 10 minutes' traction. Such movement of the calf's forelegs represents extension of both elbow joints into the cow's pelvis". A calving jack or calf puller can substitute for the two people (see Fig. 11.7). Likewise, if it is possible to bring the head and the elbows of the two forelimbs caudal to the brim of the pelvis, it is likely that traction will be successful. Similarly, if the calf is in posterior presentation, reasonable progress is indicated by progress of the hocks beyond the vulva (Mortimer 2017). Unsuccessful traction should be abandoned after 10 minutes, as the prognosis for both

(B) If one shoulder is not advanced, the diameter of the trunk can be sufficient to prevent delivery of the fetus.

cow and calf after subsequent Caesarean hysterotomy worsens with the duration of traction.

Delivery by Traction

Anterior Presentation

The vast majority of cases of mild to moderate fetomaternal disproportion are successfully treated by the application of manual traction to the presenting feet, in many cases by farm staff. Delivery of more severe cases is expedited by first applying a head snare (see Fig. 14.2) so that an axial pull may be put on the fetus.

The animal is suitably restrained. A loop is made in the head snare, and this is carried into the vulva where part of the loop is placed in the calf's mouth and the remainder pushed up over the forehead and behind the ears. A simpler alternative, which is easier to apply and less stressful to the calf, is to push the centre point of a rope snare over the forehead and behind the ears, leaving both ends of the snare outside the vulva. A good axial pull, which also tends to depress the calf's poll ventrally, can be achieved by simultaneous traction on both ends of the snare. Each of the other snares is placed above and below the fore fetlock of the calf (see Fig. 14.1). As the head rope is held taught, traction is applied to one foot snare, with a view to advancing one shoulder through the pelvic entrance. Then the other leg is advanced in the same manner. Traction upon the head should not be excessive. In this way, one shoulder is kept in front of the other, resulting in a reduction of fetal diameter (Fig. 14.33A and B). At all times, traction should be synchronous with the expulsive efforts of the cow and, as far as practicable, the initial pulling should be upwards; once the head engages the vulva, however, the direction of traction should be obliquely downward. Birth of the head is facilitated and rupture of the perineum is less likely to occur if, as downward traction is maintained on the head snare, the obstetrician inserts both hands, 'cups' them over the occiput, and presses vigorously downwards. When the fetal head is born, all three ropes may be pulled on as the cow strains and the direction of traction should progressively approach to the near vertical. After each bout of straining and with each small advance of the fetus, the veterinarian should ascertain by further examination that delivery is proceeding satisfactorily. Once the calf's head, neck, and shoulders are delivered, the obstetrician should rotate the calf (see Figure 14.36B) at the time that further traction is applied. The aim of this is to line up the calf's hips, being the biggest diameter of its hindquarters, with the biggest diameter of the dam's pelvis, thus lowering the risk of the calf becoming 'hip-locked'. At all stages of traction it is important that the veterinarian should determine that the disposition of the calf continues to remain normal, as well as its progress through the birth canal by vaginal examination. Frequent applications of lubricant to the vagina and to the fetal occiput are indicated, and the veterinarian should be satisfied with gradual progress.

Posterior Presentation

The capacity of the fetus to survive obstructive dystocia is reduced if it is in posterior presentation; such cases therefore require prompt action. The principles of delivering a fetus in posterior presentation are similar to those of a fetus in anterior presentation: the obstetrician should first attempt to assess the degree of disparity between the fetus and the dam's birth canal. Delivery by traction should first be tried, unless there is gross disparity. Delivery of a fetus in posterior presentation can be more difficult than one in anterior presentation because of the abruptly presenting buttocks and contrary direction of the fetal hair. The tail can become reflected in a cranial direction over the calf's back, which will not only impede delivery but can also cause significant trauma to the dorsum of the cow's vagina. It should therefore be ensured that the tail is between the calf's buttocks before applying traction.

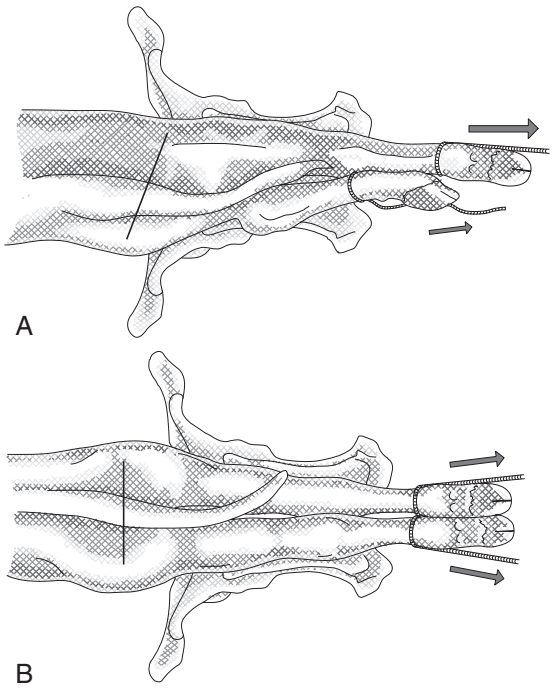
The hind feet are usually visible at the vulva. Snares are applied above and below the fetlocks, and the position of the fetal tail is checked. In delayed cases, fetal fluids should be supplemented, and copious lubrication applied to the vagina and vulva. One hindlimb is advanced in front of the other to minimise the presenting diameter of the fetal pelvis into the birth canal (Fig. 14.34A and B). Thus with one leg repelled as far as possible, the other is pulled on so as to bring its stifle over the pelvic brim. The repelled limb is then similarly managed. A simple way of assessing the likely success of traction can usually be predicted if both stifle joints can be brought into the pelvis after a moderate amount of traction.

There is a misunderstanding, particularly among some stockpersons, that calves in posterior presentation need to be pulled out very rapidly, otherwise they will die. One must remember that the calf's life will not be compromised until its umbilical cord becomes trapped against the maternal pelvis. In practical terms therefore, traction should be controlled until such time as the calf's tail-head and anus begin to emerge from the cow's vulva. Once this point is reached, delay should be avoided. If the hindquarters can be delivered, the forequarters usually follow. In cases of posterior presentation in which traction has not succeeded, the fetus must be removed by Caesarean hysterotomy or fetotomy.

Management of Delivery by Traction

As far as possible, traction should coincide with the abdominal contractions of the cow. It is not unusual for a cow to go down when heavy traction is applied; however, this is not necessarily

VetBooks.ir



• **Fig. 14.34** Disposition of the calf: posterior presentation, dorsal position, extended posture; fetomaternal disproportion. Delivery by traction. (A) Traction is applied to alternate hind limbs to advance one hip in front of the other to reduce the diameter of the calf's pelvis. (B) If one hip is not advanced, the diameter of the pelvis can be sufficient to prevent delivery of the fetus.

• **Fig. 14.35** Fracture of the distal metacarpal epiphysis from excessive force exerted through a wrongly applied limb snare. (Courtesy Dr. Jakob Malmo.)

a disadvantage, provided that she does not fall awkwardly and injure herself. In fact, with the patient in left lateral recumbency (i.e., rumen down), traction may be applied to better advantage, particularly if manual or by means of a pulley block. However, in the case of some calving jacks, recumbency can be an inconvenience. The tractive forces exerted by calving aids and pulley blocks are much greater than those associated with natural calving or the use of manual traction by people. Despite the obvious advantages of mechanical aids to traction, there are some important disadvantages:

- The amount of excessive force that can be applied in unskilled hands;
- The fact that the pull is continuous and unrelenting, which may lead to damage of maternal soft tissues – in natural birth the calf would be advanced some way with each contraction and then go back a little before the next contraction pushes it even further; and
- The fact that the direction of pull has to be at least slightly down towards the udder. If it is horizontal or away from the udder, then the rump bar merely slips down the perineum away from the vulva when traction is applied. This means it is very difficult to apply force in the same direction as the expulsion forces of the cow. In case of anterior presentation, force should ideally be applied in a slightly upward direction until the calf's head is within the pelvis, then in a horizontal direction until the calf's head and chest have been delivered, and, finally, in a progressively more downward direction until the calf's hips have been born.

If no progress has been made after 10 minutes of judicious traction, the dystocia must be managed either through Caesarean hysterotomy or fetotomy. Fetotomy should be reserved for cases in which the calf is dead. Some oversized fetuses can be delivered by a small number of cuts (e.g., the removal of a forelimb or a forelimb together with the head and neck), but some will require delivery by means of a full fetotomy, involving five or six cuts. Note that full fetotomy is the method of choice for a calf that is emphysematous and decomposing.

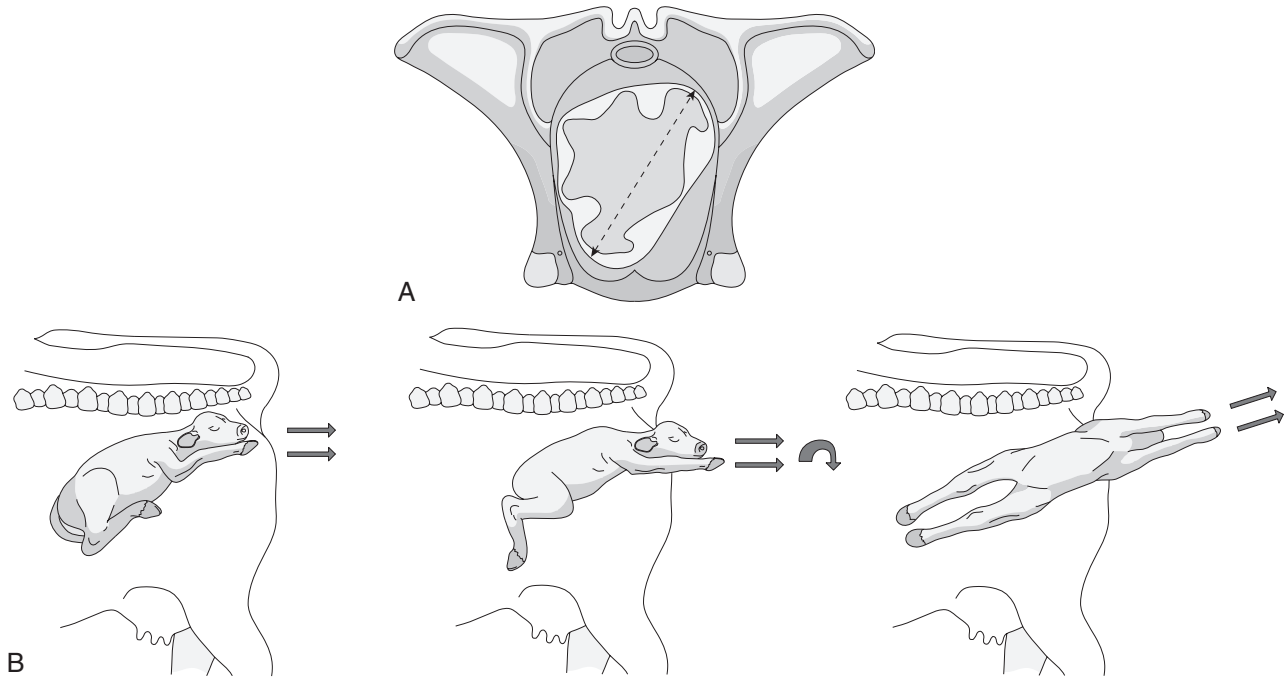
Assessment of the likely success of traction to relieve dystocia due to fetomaternal disproportion is very much based on the veterinarian's experience. Although it is probably reasonable to attempt vaginal delivery in the vast majority of cases, knowing when to refrain from such an attempt or when to cease with traction and move to an alternative method of delivery is a key decision in achieving a successful outcome. Sadly, however, it is very common for the calf to have died before veterinary assistance is requested, with the result that usually it is only the cow that can be saved.

Excessive traction can cause trauma to the cow, including damage to the birth canal, tearing of the perineum (see later in this chapter), haemorrhage from uterine blood vessels, and damage to the lumbosacral plexus. Schuijt (1990) also showed that excessive force is the most important cause of vertebral and rib fractures in calves, many occurrences of which are mistaken for fetal asphyxia. Hiplock is a particular risk for fetal trauma, and underestimation of the size of the fetus carries a particular risk for vertebral fractures. Wrongly placed foot snares can result in significant damage to the legs: epiphyses can be damaged or limbs even fractured (Fig. 14.35).

Episiotomy

If the vulva is relatively small for the size of calf that is to be delivered (as is commonly the case in Holstein–Friesian heifers) and that, despite giving the vulva time to relax and stretch, it is clear that further traction on the calf risks tearing of the vulva and perineum, episiotomy should be performed. If the vulva is stretched to the point of tearing, the dorsal commissure will rip uncontrollably, usually directly towards the anus and rectum – potentially

VetBooks.ir



• **Fig. 14.36 (A)** Aligning the maximum diameter of the fetal hips with the maximum diameter of the maternal pelvis, to prevent the development of 'hip-lock'. (B) Rotation of the calf as a routine component of the management of fetomaternal disproportion.

resulting in a third degree perineal laceration (see Chapter 20). The risk of uncontrolled tearing can be managed by performing an episiotomy, i.e., an incision on one or both sides of the vulva (Freiermuth 1948). The upper third of the vulvar labium is incised at the junction between the mucosa and skin in the shape of a slight arc in a dorsolateral direction. Cutting directly upwards into the perineal raphe is contraindicated, as this does not reduce the risk of uncontrolled tearing through the perineum and formation of a third degree perineal laceration. The requisite depth of the vulvar incisions can be decided only by trial and error, on the basis of the minimum amount to allow delivery. By gentle traction on the fetal head so as to cause firm engagement of the occiput in the vulvar orifice, it is easy to ascertain the necessary depth of the incision. Local infiltration, rather than epidural anaesthesia, should be used so as not to interfere with the maternal expulsive efforts. However, some obstetricians believe there is little, if any, need for local anaesthesia because the vulvar lips will be quite numb at the time of maximal stretching. The episiotomy wound should be repaired by suturing immediately after delivery to re-establish normal morphology of the vulva. A deep incision may require separate repair of the skin and subcutaneous tissues, but not the mucosa layer. In most cases, however, placing deep sutures through the skin and subcutis is all that is required for repair.

Delivery of the Fetal Pelvis

Obstruction sometimes occurs as the fetal pelvis engages the dam's pelvic inlet, in either anterior or posterior presentations. This problem is variously ascribed to the greater trochanters of the femurs and the overlying muscle of the calf impinging on the shafts of the ilia of the dam ('hip-lock') or to the stifles of the calf impacting the brim of the maternal pelvis ('stifle-lock'). The umbilical cord is compressed, and the calf may try to start breathing, albeit not totally efficiently, due to compression of its abdomen in the birth canal. So long as the calf is breathing adequately, rapid extraction of the fetus is not necessary. The fetus must be disengaged from the maternal pelvis by retropulsion and rotated through an angle of 45 degrees or even 90 degrees to better align the greatest diameter of the maternal pelvis with the width of the greater trochanters (Fig. 14.36A and B). The direction of traction should now be vertically downwards until birth is completed. The nostrils of the calf are freed from amnion or mucus, and resuscitation is initiated. The genital tract of the cow or heifer is explored: first in order to ascertain that another calf is not present and second to make sure that it has not sustained significant injury.

In the case of impacted 'hip-lock' by a dead fetus when it is impossible to repel and rotate the calf to a sufficient degree to allow its delivery, the dystocia has to be managed by fetotomy. The calf is pulled as far out of the vulva as possible, its trunk is transected as close to the fetal pelvis as possible, after which the fetal hindquarters are cut in half (see Chapter 15). When this has been completed, each part of the hindquarters can then be delivered one after the other.

Similarly, in a posterior presentation, if the fetal pelvis becomes impacted in the birth canal, the calf should be repelled a little, rotated through 45 degrees, and traction again applied. This latter manipulation, which brings the greater diameter of the fetus into the largest pelvic dimension, is often successful; it may be accomplished by simply bending the protruding metatarsi and using them as levers in a rotary manner.

Fetomaternal Disproportion in the Horse

Disproportion as a cause of dystocia is uncommon in horses. Apart from being more urgent, the occasional case of relative oversize is treated along similar lines to the bovine case, with the exception that, because of the late osseous union of the fetal skull, traction should not be applied to the foal's head except to maintain its alignment with the birth canal.

VetBooks.ir

Although the length of gestation is very variable in the mare, in some cases exceeding 365 days (Rosales et al. (2017) reported an interquartile range of 343 to 355 days and a maximum of 429 days), excessively large fetuses are rare in horses. Unlike the situation in cattle, in which prolonged gestation is normally associated with fetal oversize, prolonged gestation in the mare is more usually associated with placental insufficiency and the birth of an undersized fetus. Owners can become anxious about the viability or risk of oversize of the fetus when gestation is prolonged, but neither is likely to be an issue in overdue mares (Frazer 2011). Fetomaternal disproportion, when it does occur, is usually seen in primiparous mares; such mares may need assistance in the form of traction. If it is confirmed by trial traction that the fetus is unlikely to be delivered by traction *per vaginam* then a Caesarean hysterotomy is the preferred option for management.

Fetomaternal Disproportion in the Sheep and Goat

Oversize is a common cause of dystocia in ewes carrying single lambs. Ewes of the smaller breeds are often mated to larger rams, and, although the fetal size is controlled to a large extent by the dam, bulky body features derived from the ram, such as a large head and coarseness of shoulders and buttocks, often cause difficulties. Most cases are successfully overcome by farm staff applying traction to the forelegs. More severe cases may be presented for veterinary assistance, in which they may be treated as described for the cow. When traction – using fine snares, copious lubricants, and a high standard of cleanliness – does not succeed, Caesarean hysterotomy or fetotomy may be employed. Where the fetus is dead, fetotomy is indicated. In these species the subcutaneous methods of limb removal are relatively easily carried out. Although quite practicable, the percutaneous technique, using the wire saw protected by Glattli spiral tubes, is rarely used these days.

Fetomaternal Disproportion in the Pig

Dystocia due to fetomaternal disproportion may occur in immature primigravid gilts, especially when pregnant with a small litter. In such cases it can be treated by traction using a hand, snare, or forceps. If this fails, then Caesarean hysterotomy is indicated; fetotomy is not an option.

Dystocia Due to Fetal Monsters

Monstrosities most often cause dystocia in dairy cattle, the most common example being schistosoma reflexus; next in order of frequency are: ankylosed calves, including perosomus elumbis; double monsters; dropsical fetuses, including anasarcous and hydrocephalic calves; and achondroplastic monsters (see Chapter 9). The same varieties occur, but to a lesser extent, in sheep and goats. With the notable exception of 'wryneck', monstrosities are uncommon in mares. Instances of hydrocephalus, double monsters, and perosomus elumbis occur occasionally in pigs.

Silva Filho et al. (2015: Brazil) gave an interesting account of the relative frequencies of bovine fetal monsters. They found that fetal monsters accounted for 7% of dystocias, and, of these, 35% were schistosomes and 25% were duplicate forms. Sarkar et al. (2014: India) found a slightly higher proportion (11%) of fetal monsters in cattle referred for dystocia. They reported a similar proportion of duplicate abnormalities, but only 8% schistosomes. The most common abnormality in that series was arthrogryposis (27%). However, schistosomes are not common in the overall population of cows; Knight (1996) found only 1.3% of cases of bovine dystocia were due to this cause.

With the exception of anasarcous fetuses, gross malformation is often associated with ankylosis of joints and muscular atrophy; consequently, many monsters weigh less than normal calves. This lower weight, coupled with the fact that they are sometimes associated with abortion or premature birth, means that a monster may be sufficiently small to be passed spontaneously. However, a grossly irregular development, including bending or twisting of the vertebral column and ankylosis or duplication of limbs, means that a wider than normal fetal diameter presents at the pelvic inlet, usually causing severe dystocia.

Principles of the Delivery of Monstrosities

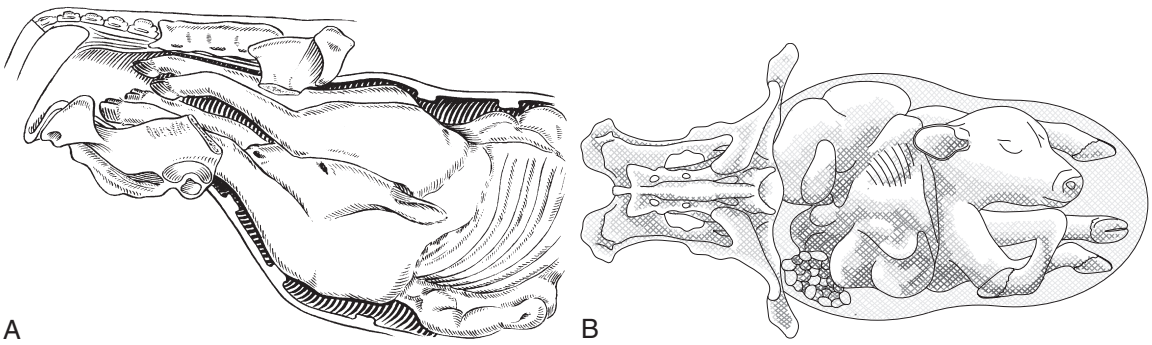
Recognition of the exact disposition of the fetal extremities and an estimate of fetal size may be very difficult. The obstetrician must then consider whether careful traction – with due regard to lubrication and protection of the birth canal from irregularly disposed appendages – is likely to succeed. Before an attempt at vaginal delivery, the diameter of anasarcous, ascitic, and hydrocephalic fetuses may be reduced by appropriate multiple or single fetotomy incisions. If fetotomy or moderate traction does not soon succeed, a Caesarean hysterotomy must be employed. Occasionally, monstrosities present baffling problems to the obstetrician. This happens when the presenting part of the fetus is normal but the distal extremity is grossly malformed; birth proceeds normally until the malformed portion engages the pelvic inlet. The cause is not apparent and may be impossible to ascertain. Examples are provided by: perosomus elumbis in which the front half of the calf negotiates the birth canal but the ankylosed and distorted hindlimbs become impacted; a hydrocephalic fetus in posterior presentation; and cases of anterior duplication in posterior presentation. In these instances, forceful but unsuccessful traction has usually been applied before the arrival of the veterinarian. This history, together with the normal appearance of the presenting portion, should make one suspicious that an abnormality is present in the distal portion. Caesarean hysterotomy often provides the easiest solution but not necessarily the most appropriate. In many cases, a partial fetotomy, involving a few strategically carried out cuts, may resolve the dystocia.

Obstetrical Management of Schistosoma Reflexus

This most familiar bovine monstrosity requires special consideration. The features of the malformation were described in Chapter 9. Schistosoma reflexus may also occur in other ruminants, as well as in pigs, and may present viscerally or by its extremities. Some fetuses in visceral presentation are born without assistance.

With this type of dystocia, fetal viscera may be seen protruding from the vulva (Fig. 14.37A and B); if not, they are soon located within the birth canal by vaginal exploration. The fetal viscera may be mistaken for those of the mother, in which case uterine rupture may be suspected. However, it should not be difficult by careful examination to dispose of this suspicion, with the absence of a uterine tear and the continuity of the viscera with the fetus being soon established. Most schistosomes will need to be delivered by fetotomy, if in visceral presentation, or by Caesarean hysterotomy if the extremities are presented. Sometimes, however, vaginal delivery

VetBooks.ir



• **Fig. 14.37** Schistosoma reflexus. (A) Presented by its extremities. (B) Presented by its viscera. Fetuses presented by the viscera can often be delivered *per vaginam,* but those presented by their extremities are best delivered by Caesarean hysterotomy.

• **Fig. 14.38** (A) Friesian cow with a schistosoma reflexus calf in visceral presentation resulting in the appearance of fetal viscera at the vulva. (B) Schistosome delivered from the cow shown in (A). (Courtesy Dr. Jakob Malmo.)

without fetotomy may be possible if the fetus is small. If this is to be attempted, a Krey hook should be fastened to the presenting fetus and reasonable traction, with adequate lubrication, applied. At the same time, the veterinarian should pay particular regard to the possibility of damage by bony fetal prominences to the birth canal. In this way the expulsive efforts of the cow are gently aided, and smooth delivery may be achieved. Fig. 14.38B shows a schistosome delivered by manipulation and traction from the cow shown in Fig. 14.38A. When a schistosome presents by its extremities, the excessive fetal diameter, together with the ankylosis of joints, is likely to prevent natural or manipulative delivery *per vaginam,* and, unless the fetus is very small in relation to the maternal pelvis (as might occur in a schistosome twin to a normal calf), time should not be wasted on an attempt at vaginal delivery. Caesarean hysterotomy will be required because fetotomy is difficult in this type of presentation.

Defects of Presentation, Position and Posture in Livestock: Delivery by Fetotomy

JOS J. VERMUNT AND TIMOTHY J. PARKINSON

By definition, fetotomy (originally referred to as embryotomy) is dissection of a fetus into two or more parts within the uterus and/or vagina. Its purpose is to reduce the size of the fetus such that delivery through the birth canal becomes possible. It is in the cow that the procedure is most frequently used, mainly because of the size of the uterus and the possibility to introduce instruments to the full extent of the fetus *in utero.* Nowadays, fetotomy is mostly carried out when the fetus is dead; however, exceptions may be when the value of the cow and her rebreeding ability and/or milk production are greater than the value of the calf. In this case the fetus should be killed first by grasping its umbilical cord, which can be reached in most cases, and severing it with a sudden pull; death follows quickly due to exsanguination. Although the fetotomy procedure can be effective in relieving dystocia in the mare, hind, ewe and doe goat, there are problems and thus limitations. For example, in the mare the vaginal wall often becomes oedematous after minimal obstetrical manipulations, resulting in a severe reduction in the lumen of the birth canal. Thus those manipulations required to perform fetotomy are likely to induce these changes quickly, making it very difficult because of reduced space. In addition, the mare is much less stoical than the cow, possibly requiring sedation or general anaesthesia. If dystocia can be relieved by one simple procedure then it may be worth considering (the techniques used are generally the same as those described later in this chapter for the cow); if not, then Caesarean hysterotomy should be considered as the method of choice. In ewes and doe goats the main difficulty with performing fetotomy is the small size of the dam. However, limited fetotomy can be done quite successfully to relieve dystocia; some shepherds are very skilled at performing a subcutaneous fetotomy (see later in this chapter) when the fetus is emphysematous and undergoing extensive putrefaction. Dystocia in hinds is frequently due to postural defects, and partial fetotomy can be carried out quite effectively in this animal species. Fetotomy is not applicable as a method of correcting dystocia in animal species that give birth to several offspring at a time. The various techniques described later in this chapter relate to the cow.

Fetotomy should not be considered as an alternative for Caesarean hysterotomy but is indicated in certain cases of dystocia. The decision guidelines based on 'diagnostic traction' (for anterior presentation, whether the fetlocks can be delivered a hands-breadth outside the vulva, or the hocks to the level of the vulva in case of posterior presentation) are a useful aid to decide whether or not fetotomy is indicated. If delivery of a dead fetus by traction is not possible without danger to the cow, the veterinarian must consider the option of Caesarean hysterotomy or a fetotomy. If the dead fetus can be delivered by the employment of limited fetotomy, such as the removal of a forelimb or a forelimb together with the head and neck, then this will certainly be the method of choice; unfortunately, having embarked on a fetotomy the obstetrician frequently finds that total dismemberment will be necessary. Because of the difficulty in assessing the extent of fetotomy required, and the knowledge that total fetotomy is a tedious and arduous task, there is an increasing tendency for veterinarians to resort to Caesarean hysterotomy in cases in which the fetus cannot be delivered by reasonable traction (see Chapter 14). The decision-making process of whether to do a Caesarean hysterotomy or a fetotomy to resolve a dystocia depends to a large extent on whether the veterinarian possesses the skill and working knowledge to perform and complete the chosen procedure equally well. It is unfortunate that, with the greater ease and increased success rates of Caesarean hysterotomy, veterinarians in many parts of the world have lost the skills required to perform fetotomy successfully.

Both Caesarean hysterotomy and fetotomy procedure have a place in veterinary practice and both should be used when appropriate. If an assisted vaginal delivery is not possible, Caesarean surgery is the method of choice if the fetus is alive and viable. Fetotomy must be given first consideration if the fetus is dead, especially when it is emphysematous and the cow is toxic. It is important for the veterinarian to be decisive, so that neither Caesarean hysterotomy nor fetotomy is used as a last resort when the cow and operator are likely to be exhausted and the birth canal traumatised. The decision of what procedure to use should be made promptly after it becomes clear that delivery by traction is not justified. A common mistake is the use of too great and too prolonged traction in the case of fetomaternal disproportion before the decision to perform either procedure is reached; about 5 minutes without any obvious progress is a reasonable period of time. In the case of faulty disposition the same considerations apply if after 15 minutes no progress has been made.

VetBooks.ir

Two basic types of fetotomy have been described in the veterinary literature, i.e., subcutaneous fetotomy and percutaneous fetotomy (Norman & Youngquist 2012). Subcutaneous fetotomy was developed in the late 18th century and is carried out with the use of knives, chisels, and hooks. Fetal parts are systematically removed while leaving the skin attached to the remainder of the fetus, which is still inside the uterus. At least one distal part of a limb is left attached to the skin, thus providing a point for attaching a calving rope or chain, and enabling traction to be applied to the rest of the fetus. In addition, the retained fetal skin perfectly protects the dam's birth canal and uterus from being damaged (Paiba 1995). Nowadays, subcutaneous fetotomy is rarely taught as a practical procedure at veterinary schools around the world; nevertheless, the procedure will be briefly outlined later in this chapter for completeness.

Since the early 20th century, percutaneous fetotomy has become the method most commonly employed, and this procedure will be described later in this chapter in detail. The technique involves the dismemberment or dissection of a fetus by cutting through skin, muscles, ligaments, and bone using braided wire (Mortimer & Toombes 1993, Frazer 1998). It is faster than subcutaneous fetotomy, but damage to the uterine wall and birth canal during cutting and manipulation of the fetus is a potential risk in all cases of percutaneous fetotomy.

In comparing the facility with which a calf may be removed by subcutaneous or percutaneous fetotomy, it must be clearly appreciated that the most troublesome part of the percutaneous method is the correct placing and retention of the wire. Given strong multifilament wire, the actual sawing process should present no difficulty. Occasionally, the two methods may be combined, e.g., the subcutaneous procedure for the forelimb(s) and percutaneous fetotomy for the head, trunk, and hindlimbs. No matter what method is used, in order to successfully perform a fetotomy, it is essential that the veterinarian has the technical knowledge and experience and uses the proper equipment plus copious amounts of obstetrical lubricant. The procedure should always be carried out under caudal epidural anaesthesia in all ruminant species (see Chapter 14) and in the mare under sedation or general anaesthesia.

Indications

In order to save the life of the cow, a fetotomy is commonly carried out under the following circumstances (Norman & Youngquist 2012, Jimenez et al. 2015):

- To correct dystocia due to fetomaternal disproportion – an oversized fetus in a normal cow or a normal size fetus in an undersized (usually juvenile) cow;
- To correct maldispositions (presentation, position, posture) of the fetus that cannot be corrected or in which correction would be an unacceptable risk to the cow;
- To correct dystocia due to the fetus and dam being in a 'hip-lock' that cannot be corrected by fetal rotation;
- To relieve dystocia caused by incomplete cervical dilatation; and
- To deliver a pathologically enlarged fetus (e.g., fetal gigantism, emphysematous calf, fetal dropsy, or anasarca) or fetal monster (e.g., schistosoma reflexus, perosomus elumbus).

Fetotomy must not be used when the birth canal is obstructed or reduced in size, as in the case of uterine torsion.

Experienced veterinarians generally agree that a combination of forced traction and fetotomy increases the risks to the cow and prolongs the calving procedure rather than shortening it. Either a partial (limited) or complete (total) fetotomy may be required to resolve dystocia. A partial fetotomy will normally suffice when dealing with a maldisposition. Usually, the offending appendage(s) can be quickly amputated, after which the fetus is delivered by traction. One should be aware that in protracted cases the uterus may be tightly contracted around the fetus and the repelling necessary to allow mutation may result in uterine rupture. Partial fetotomy is also useful in cases of a dead calf in 'hip-lock' or an abnormal fetus. If all relevant parts of the fetus are too large in relation to the cow's pelvis (oversized fetus), then a complete fetotomy will be required, usually involving four to six cuts. The size of each amputated piece should be small enough to be delivered with a minimum of traction by the obstetrician. A total fetotomy may be a difficult and physically very demanding procedure when there is extreme fetal oversize, an emphysematous calf, and the fetus is in ventral position. Furthermore, incomplete dilatation of the birth canal, a contracted uterus, or a restless cow, as well as a faulty cut, all can significantly prolong a fetotomy. However, a well-trained and experienced obstetrician should recognise a hopeless case; once a fetotomy is started, it should be completed. The whole procedure, when performed by an experienced operator, should, as a rule, take no longer than 1 to 1.5 hours. A prolonged fetotomy will only result in increased trauma to the cow's uterus and birth canal, as well as exhaustion of both the cow and operator.

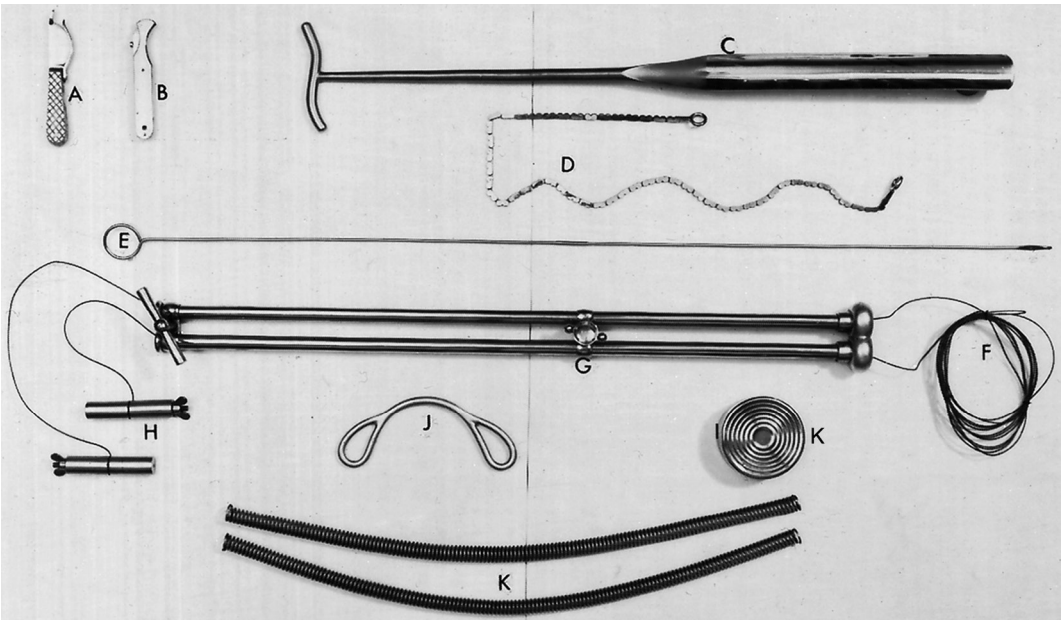
Fetotomy offers a good alternative to Caesarean hysterotomy if there is enough room in the pelvic canal to accommodate and correctly place the instruments. Using the correct technique and approach, recovery time and the amount of aftercare are generally less than is needed after Caesarean hysterotomy. As mentioned before, particularly with maldispositions, it is often possible to deliver the fetus without having to do a complete fetotomy. However, most experienced obstetricians will also admit that deviation from the 'recommended approach' often results in more cuts (and consequently more time) being required to complete the procedure. Also, an incorrectly placed cut can expose sharp bone fragments that may readily lacerate the reproductive tract.

Instrumentation

A set of high-quality, correctly designed instruments (Fig. 15.1; see also Fig. 11.6) is essential to perform a percutaneous fetotomy, and these should include the following:

- Fetotome (either the Utrecht model, which essentially is a two-barrelled flat tube, or the double-tubed Swedish modification of the original Thygesen's fetotome (see Fig. 15.1)). The head of the instrument is the part that will be positioned inside the cow's uterus or vagina and in constant contact with the obstetrical wire. It should be smooth, rounded, and made of very durable tempered steel and hardened chrome to minimise problems with wire handling and cutting. Cheaper versions often develop deep grooves on the head due to the cutting action of the obstetrical wire. These grooves cause the wire to break, leading to enormous frustration on the part of the obstetrician. The Utrecht model has a handle near its butt end, enabling the instrument to be firmly gripped, and a notched plate immediately behind the handle that permits anchoring of a calving chain under tension, which greatly facilitates maintaining the correct position of the instrument. The use of a fetotome protects the cow from wire injuries and allows for cuts to be made in different planes, i.e., towards and away from the operator, as well as at right angles to the longitudinal axis of the instrument.

VetBooks.ir



• **Fig. 15.1** Instruments for fetotomy: (A) Robert's guarded knife. (B) Unsworth's guarded knife. (C) Spatula for use in subcutaneous fetotomy. (D) Persson's chain saw, now superseded by multifilament, braided obstetrical wire. (E). Wire threader for use with (G). (F) Multifilament obstetrical wire. (G) Fetotome (Swedish modification of Thygesen's model). (H) Wire hand grips. (J) Shriever's wire introducer. (K) Gättli's spiral tubes, used to protect the genital tract from the cutting wire.

Because of the relatively large size of the modern dairy cow, it is important to use a fetotome of adequate length.

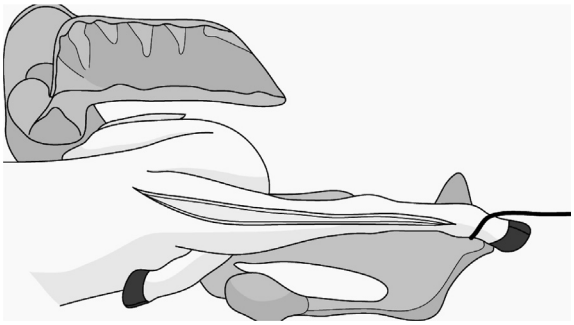
- Wire threader (see Fig. 15.1): a flexible shaft with an eye on one end for threading approximately 4 to 5 m (or four to five times the length of the fetotome) of obstetrical wire through the tube(s) of the fetotome. The Utrecht fetotome is about one meter long and may serve as a good guide for drawing out the correct length of wire. Some wire threaders have a small brush attached at the opposite end, which is very useful for clearing the barrels of lubricant, hair, and debris between cuts, and when cleaning up afterwards.
- Hand grips or wire handles – these should permit quick and secure attaching and fastening of the wire, and have a strong and comfortable grip. For ease of working, the 'split-bar'–type hand grips with a wing-shaped fastening nut are preferred.
- Krey–Schottler hook (see Fig. 11.6) – this double-jointed hook is an essential piece of equipment. When attached to a calving rope or chain, it is used to grasp onto severed portions of the fetus, particularly the vertebral column, and to apply traction to the fetus. A properly designed Krey hook should have a 'stop'; the latter is a safety feature that prevents exposure of the sharp points when the hook is closed. If this 'stop' is missing or worn, there is a real risk of a laceration occurring if the hook accidentally slips off a fetal part during traction.
- Wire introducer or guide (see Fig. 15.1) – also an essential piece of equipment. A curved introducer facilitates passage of the wire around or over a fetal part, typically the neck, a limb, or the severed hind parts. Alternatively, the wire can be attached to a calving chain or handle to assist in passing the wire around fetal parts.
- Curved finger knife (e.g., Unsworth's guarded knife) – this is only required for certain cuts. For example, it may be used to cut a 'notch' for the wire when removing a retained forelimb or hindlimb.
- Calving chains plus handles (see Fig. 11.6) – at least one chain and handle are required. The chain is used to 'anchor' the fetotome to a limb of the fetus and the handle to facilitate removal of parts of the fetus that have been cut off.
- Obstetrical or fetotomy wire – the quality varies between brands, but it is essential to select a good grade of wire. It is important that fetotomy wire is stored in a dry place (i.e., not in the obstetrics kit); it will corrode very quickly when damp or wet, causing it to become weakened. Poorly manufactured or improperly maintained (corroded) wire breaks easily.
- A pair of sharp, side-cutting pliers – these are essential for clean-cutting the obstetrical wire.
- Hand pump plus plastic tubing – this is for infusing lubricant into the uterus and around the fetus.
- Spatulas or chisels, hooks, and guarded knives, such as Robert's knife, are required for performing subcutaneous fetotomy.

Subcutaneous Fetotomy

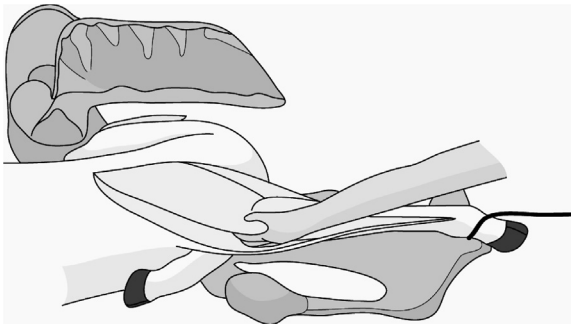
Subcutaneous Fetotomy: Removal of a Forelimb (Anterior Longitudinal Presentation)

A foreleg may be removed by subcutaneous or percutaneous fetotomy. The simpler method, which will now be described, is subcutaneous removal, for which the essential instrument is a guarded fetotomy knife. When both forelegs are equally accessible, it is immaterial which one is removed, but the right-handed operator will find it easier to carry out fetotomy on the left forelimb of the fetus. This leg is chained – around the pastern rather than above the fetlock – and sustained traction is applied to it by an assistant. The obstetrician makes a small incision with a scalpel

VetBooks.ir



• **Fig. 15.2** Subcutaneous fetotomy, used to amputate the extended forelimb. Stage 1: the skin has been incised from the fetlock up to the scapular cartilage using a Robert's fetotomy knife.



• **Fig. 15.3** Subcutaneous fetotomy, used to amputate the extended forelimb. Stage 2: the skin surrounding the limb is dissected from the underlying tissues using fingers and hand and extending as high as possible over the scapula.

into the skin in front of the fetlock joint. Into this 'nick' the beak of a Robert's fetotomy knife is inserted, and a longitudinal incision is made up the front of the limb from the fetlock to the scapular cartilage (Fig. 15.2).

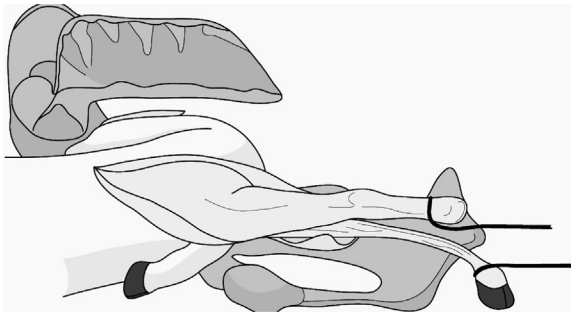
The knife is now laid aside, and the second step in the procedure is literally the 'skinning' of the limb *in situ* (Fig. 15.3). This requires strong fingers, but with application, it may be completed in about 10 minutes. (The separation of the skin from the muscles lying over the scapula completes this second step.)

The third step involves the division of the adductor muscles between the scapula and rib cage. This is achieved by reintroducing the Robert's knife, and by vigorous probing with the beak of the knife, the muscle mass is divided into several 'strings'; then each of these in turn is engaged and severed with the knife.

The fourth step (Fig. 15.4) is to disarticulate the fetlock joint so that the digits are left connected to the detached skin of the metacarpus. A chain is then attached to the metacarpus. In order to get a more secure hold, an additional half hitch may be applied above the first loop.

The chain, with a traction bar or handle attached, is then handed to an assistant. The final step in the procedure consists in avulsion of the skinned forelimb by forceful traction while the operator applies counterforce to the anterior aspect of the fetus. In this way, the remaining muscle attachments to the top of the scapula are severed and the limb comes away.

In many cases, the removal of the one forelimb gives a sufficient reduction in fetal diameter, when there is fetomaternal disproportion, to allow delivery. The principles of traction previously described are applied and, in this case the distal part and skin of the amputated limb provide a safe traction point for a chain. Should delivery not



• **Fig. 15.4** Subcutaneous fetotomy used to amputate the extended forelimb. Stage 3: after the attachments of the pectoral muscles in the axilla have been severed and the fetlock joint disarticulated, traction is applied to the 'skinned' limb. Note that the digits are still attached to the skin.

be possible after this procedure, the other foreleg must be removed in the same way, after which moderate traction is usually successful. Occasionally, after removal of one or both forelimbs – and despite partial rotation of the fetus – the hindquarters become locked at the pelvic inlet (so called 'hip-lock'; see Chapter 14). Now, the calf should be delivered as far as possible, and the protruding part of the trunk completely severed. The fetal abdomen is eviscerated, after which one of the hindlegs must be removed. There are two ways of doing this, and the one chosen will depend largely on the mobility of the retained extremity. If it is possible, the posterior part of the calf should be repelled and one of the hindlimbs brought forward with the aid of a chain; the limb is then removed by subcutaneous fetotomy (to be described later in this chapter). If it is not possible to grasp the limb and bring it forward, it must be amputated in this way: Using a direct-cutting fetotomy knife, such as Unsworth's, an incision is made over the hip joint of the leg to be removed. The muscle mass lateral to the femoral head is severed, and the upper extremity of the femur is isolated. Around this a chain is passed and the teres ligament can be ruptured by vigorous abrupt traction, and the articular head freed from the acetabulum. The chain loop is then made secure below the greater trochanter, and sustained traction is applied. This causes the leg to be drawn out from its skin; difficulty occurs over the calcaneus, but a few strokes with the fetotomy knife will free this part as well. The hind digits should be left attached to the skin and the leg disarticulated at the fetlock joint. After one of the hindlimbs is removed, the remainder of the posterior part of the fetus can be withdrawn by traction, using the Krey hook, which should be attached to the lumbar vertebral stump and the skin of the severed trunk, together with the skin and digits of the amputated limb. Amputation of both hindlimbs is rarely needed.

In cases in which 'hip-lock' occurs after partial fetotomy of the front extremity, Graham's (1979) method of causing fetal pelvic collapse could be considered as an alternative to further dismemberment of the fetus. In this method, fracture and collapse of the fetal pelvis is caused by introducing a long-handled hook through an incision in the fetal perineum. The 75 cm blunt hook engages the pelvic brim, and the fetal pelvis is fractured by abrupt backward traction. The procedure is repeated once or twice so as to ensure sufficient pelvic collapse. Traction on the unextended, lubricated breech, with the aid of Krey hooks, may then succeed.

Complete fetotomy, as described previously, is tiring and time-consuming and requires substantial skill, as well as the appropriate equipment. If the fetus is emphysematous and undergoing putrefaction the tissues may break down more readily, even with modest force, thus making the task much easier.

VetBooks.ir

Subcutaneous Fetotomy: Removal of the Hindlimb (Posterior Longitudinal Presentation)

A 'nick' is made in the skin just above the fetlock on the posterior aspect of the extended fetal leg. Into this is placed the 'beak' of a Robert's fetotomy knife, and with it, an incision is made from the fetlock up the back of the limb to the anterior gluteal region. The skin is separated from the leg, and the muscles above the hip joint, as well as the adductor muscles, are severed. The femoral head is detached from the acetabulum by introducing a traction bar underneath the Achilles tendon and forcibly rotating the limb laterally (anticlockwise in case of the left hindleg). The skin is then cut sufficiently around the fetlock joint to give scope for disarticulation, and a chain is placed over the freed end of the metatarsus. Sustained traction on the chain by one or two assistants, together with counterforce applied to the posterior aspect of the calf by the obstetrician, usually causes avulsion of the skinned limb.

After removal of the skinned leg, traction on its foot – still connected to the trunk by the skin of the leg – and on the other limb often results in delivery of the calf. If not, then the other hindlimb must be removed in a similar fashion. This will allow either complete extraction or delivery of the posterior half of the calf.

Should the forequarters become obstructed at the pelvic inlet, then further fetotomy is required as follows. As much of the calf as possible is withdrawn from the vulva and amputated. Evisceration is now carried out. The remainder is repelled and then, with an Unsworth's knife, an incision is made in the skin over the scapular cartilage, and the muscles that connect the scapula to the spine are severed. By blunt dissection the upper end of the shoulder blade is isolated, to which a Krey hook should be attached and traction applied. In this way the limb is drawn out of its skin as far as the fetlock joint, at which point it is disarticulated and removed. The digits, with skin attached, together with the Krey hook gripping the thoracic vertebral column, serve as traction points for extraction of the remainder of the calf. In rare cases the other forelimb needs to be removed before the anterior half of the fetus can be delivered.

Percutaneous Fetotomy

Some General Rules

A fetotomy, partial or complete, can be performed on both the standing or recumbent cow. Both positions have advantages and disadvantages, and sometimes there is no choice due to available, or lack thereof, facilities or the condition of the cow. From the obstetrician's point of view the standing position is far more convenient but is less safe for the cow. If the cow is sitting in sternal recumbency and unable to rise, elevation of the hindquarters will be helpful initially. As the procedure progresses, access to the fetus becomes easier with the cow in complete lateral recumbency. Alternatively, she can be placed in left lateral recumbency right from the start, with the first part of the fetus to be amputated situated uppermost. In this position the rumen will not be pushing the uterus down. In order to amputate the other extremity, the cow should be rolled over on to her right side so that part of the fetus is now uppermost. This manoeuvre may need to be repeated if a total fetotomy is to be performed.

One of the major problems during a fetotomy arises from breaking of the wire. When threading the wire, it must be handled very carefully, especially avoiding it from getting kinked. Such kinks produce weak spots at which the wire may break when sawing. Fetotomy wire, which is multifilament in design, tends to curl very easily, even after one or two cuts. Therefore it is important to examine the wire after each cut and, if necessary, to replace it if it is kinked or frayed. To lessen the chance of breaking the wire when sawing, it is advised to rotate the wire through the fetotome as each cut is made. A new length of wire should be used for each fetotomy procedure.

The procedure should be carried out as near aseptically as feasible. Several buckets of clean, warm water and disinfectant should be available: one to thoroughly clean the tail, vulva, and perineal area of the cow before starting the fetotomy; another for the instruments used during the procedure; and. finally. one or two for cleaning up afterwards.

Before Getting Started

If there are suspicions of low-grade hypocalcaemia being present, particularly in case of third parity or older cows, calcium borogluconate should be administered intravenously before starting the fetotomy procedure to reduce the chances of the cow becoming recumbent. The cow should be restrained in a calving box, head bail, or crush, ensuring that there is adequate room behind the animal, enough for manipulation of the fetotome and wire, and two to three people.

Medication

Epidural anaesthesia should be used routinely to relieve pain as well as straining (Chapter 14). In some cases, though, it may only partially stop abdominal straining. However, it does reduce the sensitivity of the birth canal and hence the pelvic reflex that will be elicited by vaginal manipulations. Tranquilisation may be indicated in case of a fractious animal, but general anaesthesia is rarely required. Administration of broad spectrum antibiotics before starting the fetotomy procedure should be given due consideration.

The use of tocolytic drugs, such as clenbuterol and isoxsuprine, is controversial. The myometrium is not responsive to these agents to any great degree if the fetus has been dead for some time – even less so when it is emphysematous. In case the uterus does respond, the chances of a fold of the relaxed uterine wall becoming trapped in the wire loop are greatly increased. If this goes unnoticed, the result could be catastrophic for the cow.

Lubrication

Lubrication is one of the main keys to success. Petroleum-based lubricants (e.g., Vaseline) are preferred to water-based products because of their tendency to stick to tissues and resist dilution by fetal fluids. However, they are more difficult to remove from arms and hands afterwards. A good alternative is a polyethylene polymer product, which should be mixed with water. However, water-based lubricants can be utilised satisfactorily, provided large volumes are frequently used. Initially, 5 to 10 litres of thick obstetrical lubricant should be infused into the uterus as deeply as possible. A wide-bore stomach tube and pump greatly facilitates the application. Ideally, the lubricant should be slightly warmed as this may improve the degree of uterine relaxation that is achieved. Regular reapplication of lubricant is required to ensure a relatively nontraumatic delivery. Insufficient use of lubricant can be, and often is, the cause of failure. Apart from facilitating the removal of the fetal segments, it also protects the delicate tissues of the cow's reproductive tract, as well as the hands and arms of the obstetrician. Skin infections on the arms of the obstetrician, usually caused by *Listeria* spp. or *Salmonella* spp., are not uncommon, especially after fetotomy of a dead fetus. Hence it is commonly advised to wear disposable

VetBooks.ir

plastic sleeves. However, these puncture or rip quite easily and also may become caught up in the wire, making the procedure much more difficult; so, many obstetricians dispense with them.

Assistance

Before starting a fetotomy, the total plan for the procedure should be properly thought through with regards to the particular case on hand. The obstetrician's task is to carefully guide the threaded fetotome through the dorsal half of the vagina and into the uterus, always making sure that the wire has not twisted or is crossed over itself. It is crucial that the wire does not come in contact with maternal tissue during the sawing process. The head of the fetotome should reach the point for final sectioning before the wire is guided forward to reach its correct position. The operator must ensure that the head of the instrument remains positioned at the intended site, at the same time paying attention to the relative position of the uterine (intercornual) septum. If one assistant is available, the obstetrician covers the head of the fetotome with one hand and maintains the position of the fetotome with the other hand. Some veterinarians like another assistant to hold the external part of the fetotome (i.e., to maintain the position of the instrument), whereas others prefer to be in complete control of the instrument themselves. With either approach, at least one assistant is required to control wire tension during its placement and to do the actual sawing. During the sawing, the operator's hand should always remain in full contact with the fetus. Sawing should not be started before a final check on the position of the fetotome has been made. Once the obstetrician has confirmed that the wire is snugly positioned around the fetus and the head of the fetotome is protected by the veterinarian's hand, sawing can begin.

The correctness, especially of the first cut, is of paramount importance. Initially, there should be slow, short and continuous sawing strokes, using moderate force. After the wire becomes firmly embedded in the tissues beneath the fetal skin, strokes of the wire can be lengthened with more pressure applied. Finally, long, continuous strokes should be made, using strong pressure. Long strokes use the maximum length of available wire, which spreads the wear and also reduces the amount of heat produced and the likelihood that the wire will break. Tension on the wire must not be relaxed during the cutting procedure nor must the sawing be stopped until it is complete. Doing so results in the wire getting trapped and damaged, causing it to break. When correctly done, the cutting action is fast, with the sectioning completed in a relatively short period of time.

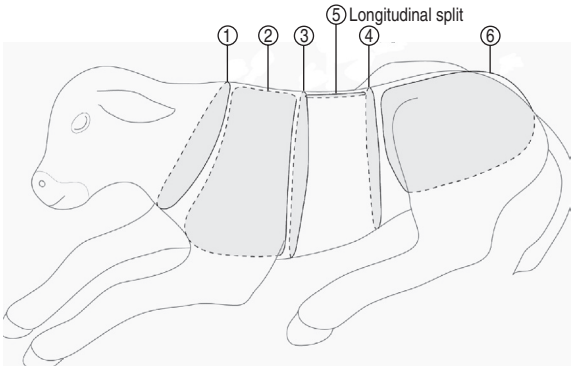
Total Fetotomy

Although the successive cuts of a total fetotomy may vary somewhat according to the individual case and the personal preference of the obstetrician, the following approach for dealing with a fetus in anterior or posterior presentation is recommended.

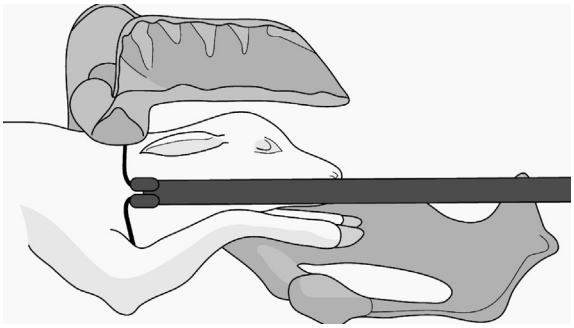
Fetus in Anterior Longitudinal Presentation (Fig. 15.5)

Cut 1: Amputation of the Head

Sometimes the fetal head needs to be removed to allow access to the forelimbs, especially if they are flexed. Both tubes of the fetotome are threaded, and the wire loop is passed over the fetal head so that it is situated behind the ears. If there is adequate room, the head of the fetotome is introduced alongside the head and positioned between the mandibles, caudal to their posterior borders. When space is limited, the instrument should be positioned on the lateral surface of the fetal head, with the head of the



• **Fig. 15.5** Drawing of a calf in anterior longitudinal presentation showing the successive cuts required for a total percutaneous fetotomy. Cut 5 is required only if the amputated thoracic/lumbar ring is too big to be extracted.



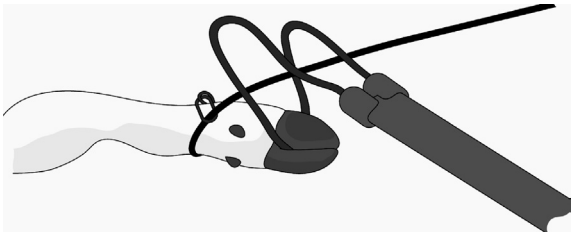
• **Fig. 15.6** Percutaneous fetotomy: positioning of the fetotome for amputating the head.

fetotome situated at or just beyond the caudal aspect of the ramus of the mandible (Fig. 15.6). If there is sufficient room, most of the fetal neck may be removed simultaneously. For this, the wire loop should be guided forwards along the neck as far as possible, and the head of the fetotome should now be placed alongside the neck, close to the scapula. After the head (with or without the neck) has been amputated, it can be extracted using a Krey hook secured into the calf's eye sockets.

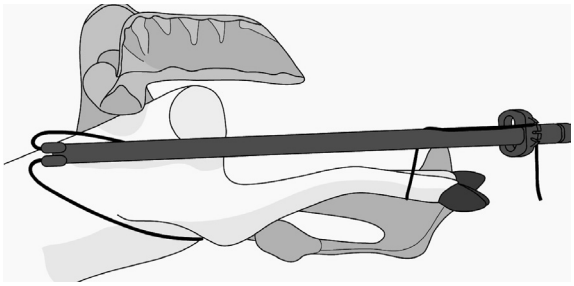
Cut 2: First Forelimb

In some cases the removal of one entire forelimb (including the shoulder joint and scapula) may reduce the diameter sufficiently to permit extraction of the remainder of the fetus. A calving chain is placed around the pastern, and the leg is pulled into extension, ensuring that the distal portion of the limb protrudes from the vulva. Both tubes of the fetotome are threaded and the free end of the chain is passed through the wire loop from above. The wire loop should then be placed between the claws to briefly anchor it (Fig. 15.7). The fetotome is then advanced along the lateral aspect of the forelimb and shoulder until the head is situated above and slightly behind the dorsal aspect of the scapula. The calving chain is then anchored into the notched plate of the fetotome handle, which keeps the forelimb extended. The wire loop is removed from between the claws and guided up the medial aspect of the limb as the assistant applies slight tension on the wire handles. The wire should become seated in the axilla, and it is important to check that the wire is also situated medial to the elbow. Traction is applied to the limb once more so that, when the chain is anchored back into the notched plate, the forelimb is held in full

VetBooks.ir



• **Fig. 15.7** Percutaneous fetotomy: temporary positioning of the fetotomy wire between the claws of a forelimb.

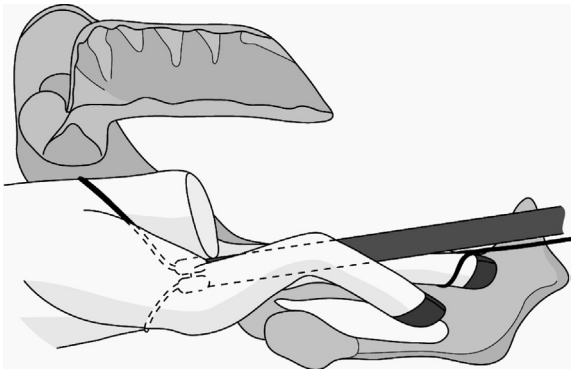


• **Fig. 15.8** Percutaneous fetotomy: amputation of a forelimb, showing the positioning of the fetotome and wire to ensure complete amputation of the extended limb.

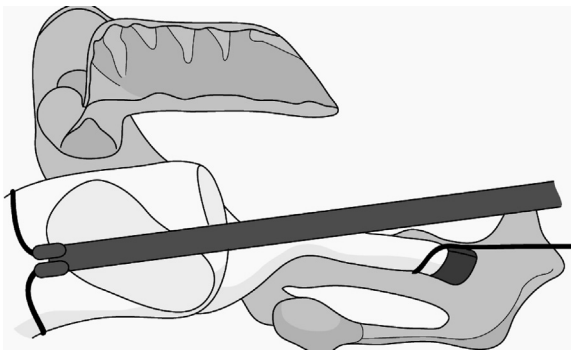
extension (Fig. 15.8). During the sawing process the obstetrician should cover the head of the fetotome with one hand. The head of the fetotome must remain dorsocaudal to the scapula for an acute-angled cut; this will ensure that the wire cuts through the muscle attachments so that the entire scapula will be removed. If the fetotome is allowed to move backwards by the assistant's sawing action, the cut is likely to be made through the distal scapula or, even worse, the shoulder joint or proximal humerus. In the latter case the diameter of the fetus is not reduced to any extent (because the shoulder joint is not removed), and there is a very sharp piece of bone left, still firmly attached to the remainder of the fetus. Furthermore, a suitable traction point (for anchoring a calving chain) no longer exists on that side. If the cut has been made through the scapula, the retained piece of bone must be detached manually by severing the muscle attachments one by one, which can be quite difficult, especially in the case of a fresh fetus.

An alternative technique is to loop the wire around the neck stump and forelimb and to push it backward along the outside of the elbow and scapula so it will lie behind the caudal angle of the scapula, where a deep incision has been made with a finger knife to accommodate the wire. The head of the fetotome is brought up to the base of the neck on the side opposite to the foreleg being removed (Fig. 15.9). With the wire loop correctly placed, the cut is easily completed. After this cut, an attempt may be made to deliver the remainder of the calf by traction. A chain is placed on the attached limb, and with the aid of the Krey hook, another point of traction is available on the neck stump (i.e., the exposed lower cervical vertebral column). If an oversized fetus still cannot be delivered after the first two cuts (i.e., head/neck and one complete forelimb) have been made, another three to five cuts may be necessary to completely dismember the remainder of the fetus.

Sometimes, it is possible to remove the head, neck, and one forelimb all in one piece. To do this, the fetotome is introduced and positioned as described previously for the forelimb, but the wire loop is now guided along the opposite side of the head and neck until it is seated near the thoracic inlet. If done correctly, this



• **Fig. 15.9** Percutaneous fetotomy: an alternative approach to amputate the left forelimb and neck after amputation of the head.



• **Fig. 15.10** Percutaneous fetotomy: transverse division through the trunk after amputation of the head/neck and right forelimb.

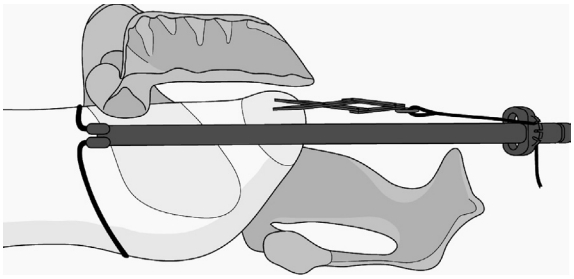
cut then runs obliquely across the fetal neck and thorax, creating an opening in the thorax through which complete evisceration of both thoracic and abdominal contents is carried out. Now, the fetus may be partially or completely extracted, depending on its size, by using the remaining forelimb and the vertebral stump as traction point.

Cut 3: Second Forelimb

This may be removed in a similar manner to that described previously for the first forelimb. Often, it is possible to have the wire loop situated on the opposite side of the neck stump or thoracic inlet. For this cut in particular, it is important that the fetotome remains in direct contact with the skin of the fetus and is not mistakenly advanced into the nonpregnant horn before the sawing process is started. If this happens, part of the uterine septum will be amputated, with catastrophic results for the cow.

If there is adequate room, all or at least a large part of the thorax may be incorporated in this cut. The wire loop is guided around the thorax and positioned as far back as possible (Fig. 15.10). It is important that the sawing is continued until all ribs and vertebral column are completely severed. If the sawing action is interrupted, there is a high probability of the wire getting stuck in bone tissue. Trying to free the wire will usually cause it to break. Once this transverse cut has been completed, the detached segment of fetus is carefully withdrawn from the birth canal, using the Krey hook attached to the vertebral stump as a second traction point. If carried out correctly, the thorax will now be cut to such a degree that all thoracic and abdominal organs can be removed by hand; the evisceration will substantially reduce the overall size of the remainder of the calf.

VetBooks.ir



• **Fig. 15.11** Percutaneous fetotomy: division of the thorax with a single cut showing the position of the obstetrical wire behind the sternum.

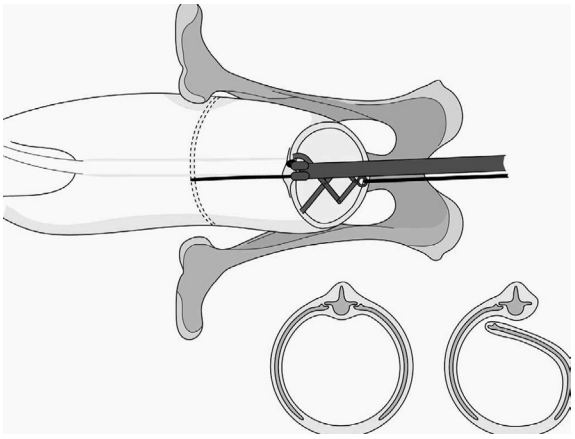
Cut 4: Thorax

The Krey hook is attached to the severed vertebral column, and the chain is passed through the wire loop of the prethreaded fetotome from above. The wire loop should be held just outside the vulva, as the fetotome is advanced over, or along, the dorsal aspect of the fetus to just behind the last ribs (if possible). The Krey hook is pulled tight, and the chain is anchored into the notch plate. The wire loop is then guided around the thorax, using a 'sweeping' motion, to end up just behind the sternum (Fig. 15.11). Before sawing, the operator should check the position of the wire to ensure that the fetotome was not rotated when being positioned and that the wire did not become twisted (best done by running the fingertips along the head of the fetotome and checking the wire inlets). During the sawing procedure the obstetrician should hold both the Krey hook and the shaft of the fetotome with one hand, while holding the handle of the fetotome with the other. Some sideways movement of the head of the fetotome should be anticipated during the sawing process, but this may be minimised by also grasping some fetal skin with the hand that holds the Krey hook and the fetotome inside the cow. Initially, short sawing strokes should be used until the wire becomes properly embedded. Extraction of the amputated chest (or part thereof) is generally fairly easily accomplished by controlled traction on the Krey hook.

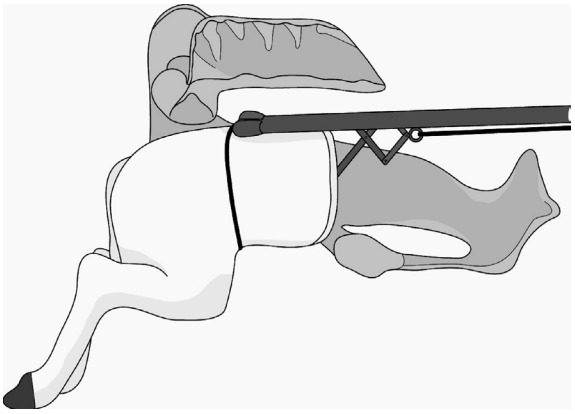
If it turns out that this portion of the thorax is still too big to extract safely, then another longitudinal cut is required to reduce its diameter by severing the ribs. The wire is removed from one of the fetotome tubes and attached to an introducer. When attaching the wire, it is important to leave a relatively long tail on the loose end of the knot to prevent it from acting as a cutting device. With the fetotome held outside the cow, the introducer is advanced over the dorsal aspect of the thorax and pushed down over the edge of the amputation site. A hand is inserted into the thoracic cavity and pushed through the diaphragm to retrieve the introducer with the wire attached. The wire is then looped back through the thorax and the fetotome rethreaded. The head of the fetotome is positioned adjacent to the Krey hook, which is anchored to the vertebral stump. It is important that the cut is made through the ribs near their vertebral attachments (Fig. 15.12). Now, this part of the thorax can be collapsed (more or less folded into a compact mass) for easy delivery.

Cut 5: Lumbar Area

If the fetus is very big, it may be physically impossible to guide the wire around the remainder of the fetus; thus it will be necessary to amputate the lumbar area first (Fig. 15.13), before bisecting the hindquarters. The approach is the same as described for the thorax section.



• **Fig. 15.12** Percutaneous fetotomy: longitudinal cut required to reduce the diameter of the thorax.



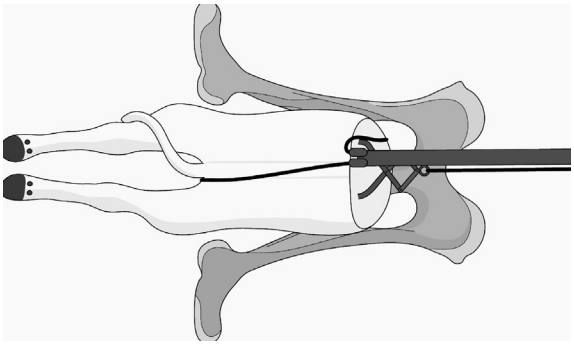
• **Fig. 15.13** Percutaneous fetotomy: positioning of the fetotome and wire to amputate the lumbar area.

Cut 6: Hindquarters

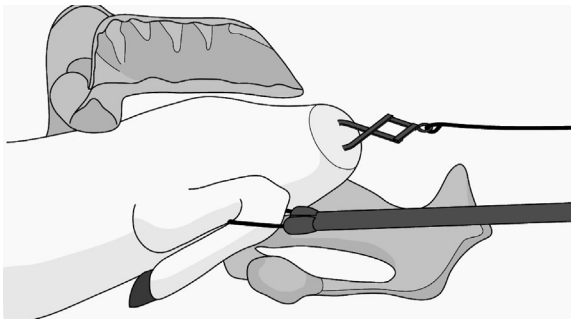
The final cut involves a longitudinal division of the hindquarters. Only one tube of the fetotome is threaded. The Krey hook should be attached to the vertebral stump and the hindquarters pulled towards the cow's pelvic inlet. The wire introducer, with the wire attached, is advanced over the dorsal aspect of the sacrum and the tailhead and pushed down behind the perineum. It is retrieved from below by passing a hand underneath the calf and between the hindlimbs. It is important to confirm that the wire is indeed retrieved from between the hindlimbs (there should be a stifle joint on either side of the retrieving hand). The wire is then pulled out and the fetotome rethreaded. Ideally, the hindquarters should be divided into equal (more or less) parts. For this, the wire should be situated on one side of the tail while the head of the fetotome is placed against the opposite side of the vertebral column, adjacent to the Krey hook (Fig. 15.14). This ensures that the cut through the fetal pelvis is made in only a slightly diagonal manner. Now, each half can be withdrawn in turn, using the Krey hook.

In some cases of dystocia, either due to fetomaternal disproportion or as a result of inadequate rotation of the calf during delivery by traction, the forequarters of a fetus in anterior presentation are delivered and then the situation of a 'hip-lock' develops (see Chapter 14). A partial fetotomy can be used to quickly relieve the dystocia. The forepart of the calf is amputated by a transverse cut through the lumbar area. The fetus is eviscerated, after which the introducer, with the wire attached, is passed over the dorsal aspect

VetBooks.ir



• **Fig. 15.14** Percutaneous fetotomy: positioning of the fetotome and wire to bisect the hindquarters.



• **Fig. 15.15** Percutaneous fetotomy: carpal flexion with the fetotomy cut made through the distal part of the carpal joint.

of the hindquarters and retrieved ventrally. The cut is completed and the divided hindquarters delivered as described previously.

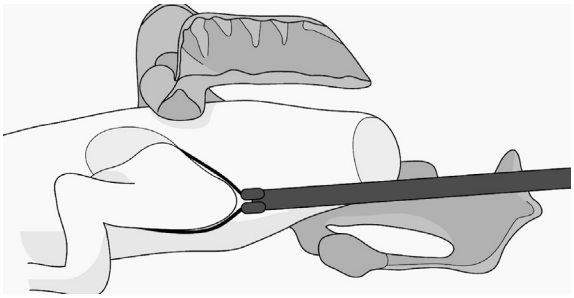
Correction of Fetal Malpostures

Carpal Flexion

Dystocia due to uni- or bilateral carpal flexion can be difficult to correct manually, especially if the dystocia has been prolonged and the uterus is contracted. It may not be possible or safe to repel the fetus and correct the faulty disposition without the risk of rupturing the uterus. In these cases the dystocia can be relieved by partial fetotomy. The head and neck should be amputated first, followed by a fetotomy cut that should be made through the distal part of the carpal joint. One tube of the fetotome is threaded, and the introducer, with the wire attached, is passed around the flexed carpal joint. After rethreading the fetotome, the head of the instrument should be positioned against the distal row of carpal bones (Fig. 15.15). Now, the distal forelimb is amputated and removed. If done correctly, there will be no sharp bone fragments, and a calving chain can be anchored against the tuberosities of the distal radius, providing an excellent traction point for delivery of the remainder of the fetus by traction. If the cut is made too high, i.e., through the distal radius, a sharp piece of bone will be the result, and there will be no traction point for the chain. The obstetrician will also need to deal with a sharp piece of bone if the cut is made too low, i.e., below the joint.

Unilateral or Bilateral Shoulder Flexion: Percutaneous Removal of a Retained Forelimb(s)

In many cases, extravulval decapitation needs to be performed first, to provide more space for subsequent procedures. A disadvantage is that this removes a point of attachment for a calving



• **Fig. 15.16** Percutaneous fetotomy: position of the fetotome and wire for amputation of the forelimb in case of shoulder flexion.

chain to apply traction; therefore a Krey hook will be required as a substitute. A finger knife is used to make an incision through the skin just medial to the dorsal aspect of the scapula and then down into the connective tissue between the scapula and thorax. In the first instance, only one tube of the fetotome is threaded, and the wire is attached to the introducer, which is then passed over the scapula and down between the thorax and the reflected forelimb. The wire is retrieved from below, and the fetotome is rethreaded. The instrument is advanced along the neck until it becomes positioned at the medial aspect of the shoulder and then held in that position. The free hand pushes the wire loop into the previously made incision (Fig. 15.16). Tension is applied to the wire to ensure that the loop is situated medial to the body of the scapula. During the sawing process the head of the fetotome must be maintained medial to the shoulder joint. Alternatively, the head of the fetotome can be positioned dorsal to the posterior angle of the scapula. However, considerable force is now required to maintain the instrument in this position when the muscles, which attach the limb to the trunk and the skin at the base of the neck, are cut. The amputated forelimb is withdrawn, using the Krey hook.

In case of bilateral shoulder flexion, an attempt should again be made to extend the other retained forelimb. If this is possible, traction on both the limb and the neck, using the Krey hook on the latter, should result in delivery. Alternatively, the fetus may be withdrawn without extending the other foreleg. If both these attempts fail, then the other, now mutated forelimb must also be removed. The subsequent procedure is the same as that described previously for fetomaternal disproportion of the second forelimb.

Lateral Deviation (Flexion) of the Head

In very obstinate neglected cases of dystocia due to lateral deviation of the head with the fetus being dead and in the occasional congenital rigid curvature of the neck called 'wryneck', correction is impossible and decapitation is required. 'Wryneck' is a relatively common disorder of the fetal foal, and this is a useful method of correcting this type of dystocia in the mare.

One tube of the fetotome is threaded, and the end of the wire, attached to the introducer, is passed in, over, and around the fetal neck. It is best achieved by first pushing the introducer over the neck, then between the neck and thorax, before retrieving it from beneath the neck. Once the fetotome has been rethreaded, it is advanced until the head of the fetotome is positioned adjacent to the thoracic inlet (Fig. 15.17). Tension should now be applied to the wire so the operator can check that the wire loop is seated as close to the thorax as possible. Once the cut is made, the severed neck can be grasped, either by hand or with the use of the Krey hook, and the neck plus attached head can be removed. Alternatively, the detached head and neck can be repelled into the uterus to be

VetBooks.ir

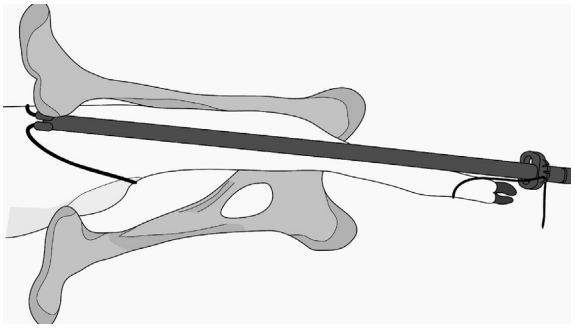
• **Fig. 15.19** Percutaneous fetotomy: amputation of a hindlimb, showing the positioning of the fetotome and wire to ensure complete amputation of the extended limb.



• **Fig. 15.20** Percutaneous fetotomy: position of the fetotome to amputate the second hindlimb.

retrieved later, when the fetotomy is completed or the remainder of the fetus is delivered. In some cases of lateral deviation of the head, access to the flexed neck can be facilitated by first amputating the forelimb on the side opposite that to which the head is displaced (as described previously for fetomaternal disproportion of the first forelimb).

Downward Displacement of the Head (Ventral Flexion of the Neck)

Downward deviation of the head is rare in cattle; still, this postural defect can prove very difficult to correct by means of manipulation, and amputation of the head is indicated in obstinate cases. In this situation the introduction and correct placing of the wire between the markedly flexed neck and chest can be difficult to achieve. With the help of the introducer, the wire should be passed underneath the flexed neck. The head of the rethreaded fetotome is positioned on top of the neck between the shoulder blades. When the cut has been made, the fetus should be repelled into the uterus before the amputated head and neck can be retrieved and removed.

Fetus in Posterior Longitudinal Presentation (Fig. 15.18)

Cut 1: First Hindlimb

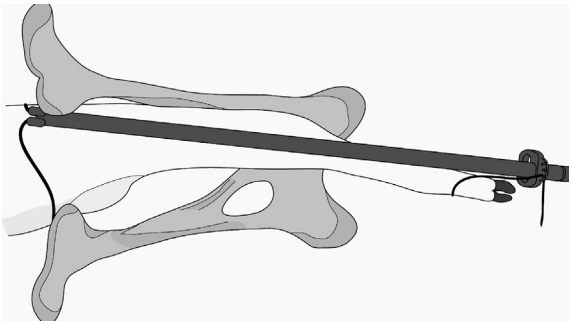
If the hindlimbs are extended, a similar procedure to that described for the extended forelimb can be used. Both tubes of the fetotome should be threaded. A calving chain is attached to the pastern of the hindlimb to be amputated and passed from above through the wire loop, which is then temporarily placed between the claws. Now, the fetotome is advanced along the lateral aspect of the hindlimb until the head of the instrument is situated near the greater trochanter of the femur. After the chain is anchored into the notch plate of the fetotome, the wire loop is removed from the interdigital space and guided up the medial aspect of the limb. The wire should be positioned between the tail and the ischiatic tuberosity opposite to the leg to be amputated. It is important to check that the wire is also situated medial to the stifle joint. Traction should then be placed on the chain to fully extend the entire leg. The fetotome is advanced further until the head is positioned just beyond the greater trochanter near the lumbar vertebrae (Fig. 15.19). The chain is anchored back into the notch plate and the limb amputated. If properly carried out, this cut will be diagonal across the pelvis, removing the entire hindlimb, including the hip joint. Now, the width of the fetus is reduced such that it may be possible to extract the remainder of the calf. A chain is placed on the attached limb and, with the aid of the Krey hook, another point of traction is available on the perineal area of the severed pelvis. If the fetotome inadvertently moves backwards during the sawing process, the cut will be made through the proximal femur; as a consequence the width of the fetal hindquarters is not reduced, and there is also a sharp piece of bone to deal with.

An alternative approach is to place the wire loop over one foot and pass it up the limb laterally, so that it lies anterior to the tuber coxa in which a deep cut in the skin and underlying tissues, previously made with a finger knife, helps to retain it. The head of the fetotome is positioned next to the anus, on the opposite side of the leg to be amputated. It is important to make sure that the tail and tailhead of the calf are included in the wire loop. If not, the wire may slip down the limb during the sawing process and the cut will be made through the distal third of the femur.

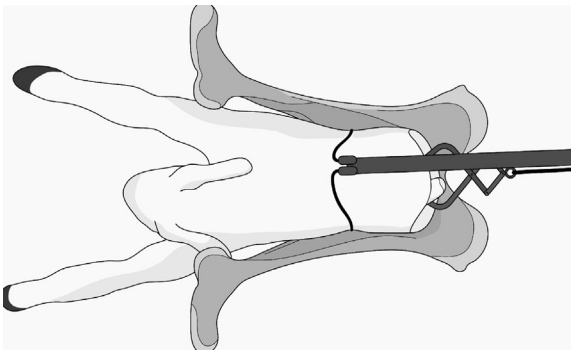
Cut 2: Second Hindlimb

If delivery is not possible after removing one hindlimb, the second limb can be removed in a similar manner (Fig. 15.20). It is often possible to pass the wire loop past the fetal pelvis so it is situated in the lumbar area, just caudal to the last rib (Fig. 15.21). In this situation the fetotome should be positioned further forward on the fetus. This cut allows delivery of the remaining hindlimb along with the entire fetal pelvis. Alternatively, the prethreaded fetotome can be advanced over the dorsal aspect of the pelvis and lumbar spine, and the wire loop guided up ventrally. Now, the resulting transverse cut allows extraction of the hindlimb and the remainder

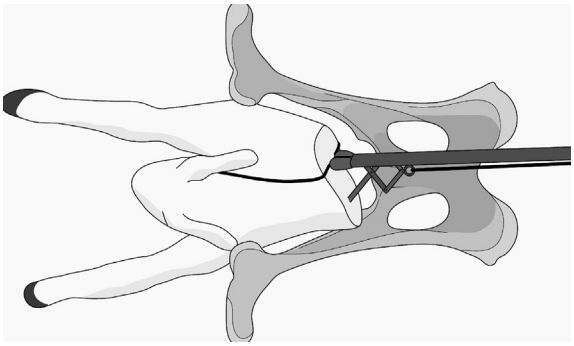
VetBooks.ir



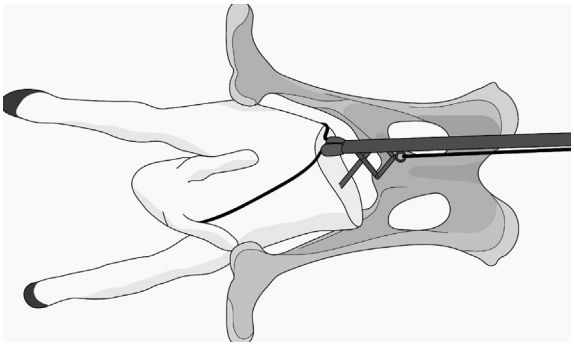
• **Fig. 15.21** Percutaneous fetotomy: position of the fetotome and wire to amputate the calf's pelvis and second hindlimb.



• **Fig. 15.22** Percutaneous fetotomy: position of the fetotome and wire to bisect the thorax.



• **Fig. 15.23** Percutaneous fetotomy: position of the fetotome and wire to amputate one complete forelimb.



• **Fig. 15.24** Percutaneous fetotomy: position of the fetotome and wire to diagonally divide the forequarters.

of the pelvis. If both hindlimbs have been removed, the Krey hook should be attached to the fetal pelvis and the wire loop positioned transversely around the lumbar area of the fetus. Once the pelvis has been removed, the remainder of the fetus is drawn towards the cow's pelvic inlet and eviscerated before the next cut is made.

Cut 3: Thorax

If the remainder of the calf cannot be extracted, then its trunk must be bisected, the transverse division being made as far forward as possible. Both tubes of the fetotome are threaded, and the fetus is pulled towards the cow's pelvic inlet, using the Krey hook which is attached to the vertebral stump. The chain is passed from above through the wire loop, which is held outside the cow's vulva. Now, the fetotome is advanced over the dorsolateral aspect of the thorax, so that the head of the instrument becomes situated just caudal to, or between, the calf's scapulae (Fig. 15.22). The wire loop is then guided around the thorax (using a 'sweeping' motion), ensuring that, ventrally, it becomes positioned just cranial to the sternum. The fetotome is held in position by the same hand that holds the Krey hook. When the diameter of this section of the fetus is still too large to allow delivery, then the rib cage should be cut longitudinally and collapsed, as described for fetotomy with the fetus in anterior longitudinal presentation.

Cut 4: The Forequarters

If it is still not possible to extract the anterior portion of the fetus, using the Krey hook attached to the severed vertebral stump, then one or if necessary both forelimbs need to be amputated. Only one tube of the fetotome is threaded, and the wire, with the aid of the introducer, is passed forwards between the neck and the limb, where it is retrieved by reaching underneath the calf. The wire, positioned between the elbow joint and the chest, is withdrawn and the fetotome rethreaded. The head of the instrument should be positioned against the severed end of the vertebral column, next to the Krey hook (Fig. 15.23). The severed limb(s) and the remainder of the fetus may be brought out one by one, using the Krey hook.

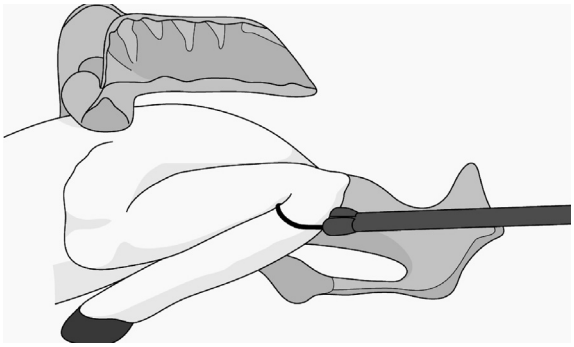
An alternative method is to diagonally divide the forequarters, in which case usually only one cut is required. Again, only one tube of the fetotome is threaded and the Krey hook attached to the vertebral stump. The wire loop is completed as described previously, but now the head of the fetotome is either placed on the opposite side of the Krey hook or against the lateral aspect of the opposite thoracic wall (Fig. 15.24). In the latter case some blunt dissection is required (i.e., creating a little pouch) before the head of the fetotome can be positioned firmly between the scapula and the thorax. When starting the cut, short strokes with the wire should be made. Once the wire has become fully embedded, the head of the fetotome is moved to the lateral surface of the scapula and the cut continued using long strokes. If this oblique cut is carried out correctly, the larger portion will be one forelimb and the main part of the thorax, whereas the other portion comprises the head and neck, the other forelimb, and the remainder of the thorax. These portions can now be withdrawn one by one, paying attention to any sharp bone fragments.

Correction of Fetal Malpostures

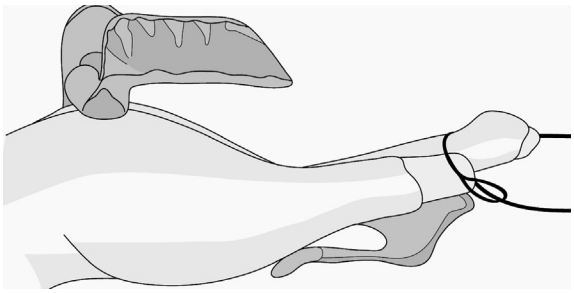
Hock Flexion

In cases of uni- or bilateral hock flexion, amputation of the limb(s) virtually eliminates the risk of uterine rupture that may accompany attempts to repel the fetus and correct the malposture, especially

VetBooks.ir



• **Fig. 15.25** Percutaneous fetotomy: hock flexion with the fetotomy cut made through the distal part of the tarsal joint.



• **Fig. 15.26** Percutaneous fetotomy: showing how amputation at the level of the hock should be done to ensure that there is a still a traction point left (right- vs left hindlimb), but without the presence of sharp bone fragments.

in protracted dystocia cases. A similar approach to that described for carpal flexion should be used (Fig. 15.25). The main aim is to retain a point of traction for the calving chain and not to have sharp bone fragments (Fig. 15.26).

Hip Flexion

One tube of the fetotome is threaded and the free end of the wire, attached to an introducer, is passed over the dorsal aspect of the fetus and directed down between the body wall and the stifle of the most accessible retained hindlimb. Now a hand is passed in underneath the calf and the introducer retrieved ventrally, thus completing the loop. After rethreading the fetotome, the instrument is passed along the vagina, and the head of the fetotome is placed against the perineum of the calf. At this stage a crucial step in the procedure is to include both the fetal tail and tailhead in the loop of the wire and, when sawing takes place, hold the head of the fetotome firmly against the ischiatic tuberosity opposite to the leg being amputated (Fig. 15.27). In this way the femur will be sectioned through its articular head. After removal of the severed limb, the hip flexion of the other retained hindlimb can often be corrected because more room has now been created for mutation. If this hip flexion cannot be resolved safely, the retained hindlimb should be similarly amputated.

In cases in which the calf's posterior end is jammed tight into the cow's pelvis, it may be difficult, if not impossible, to repel the calf, and an alternative approach may be chosen if the calf is relatively small. The prethreaded fetotome is advanced along the dorsal aspect of the calf until the head of the instrument is situated above the last ribs, and the wire loop is placed around the back of the calf, approximately 2 to 3 cm below the calf's ischiatic tuberosities (Fig. 15.28). The resulting cut severs both hindlimbs

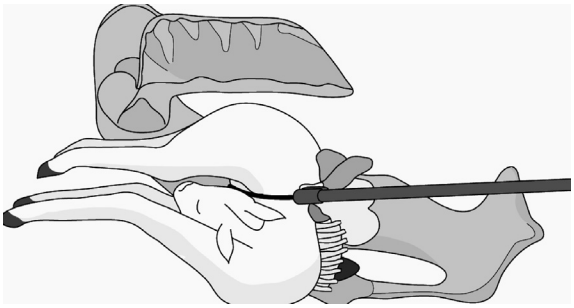
through the proximal femur and continues through the abdomen, finishing at the thoracolumbar region. The amputated hindlimbs are removed one by one, followed by the pelvis, the abdominal viscera, and finally the anterior part of the fetus, using the Krey hook.

Fetal Monsters

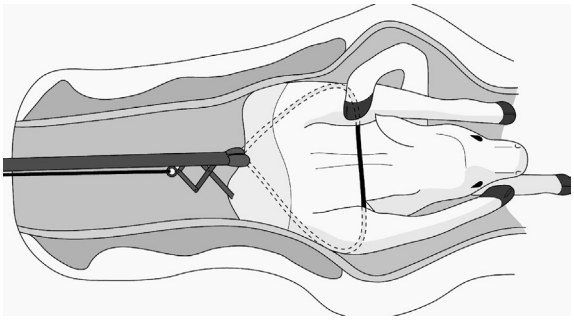
General Principles

Fetal monsters are occasionally encountered as causes of dystocia in cattle. The diversity of abnormal conformations may test the resourcefulness of many obstetricians. Because of the worthless nature of fetal monsters, fetotomy, whether partial or complete, to achieve vaginal delivery should be given primary consideration. When the fetus is alive, it must be killed first by manually severing the umbilicus. If it is possible to reduce the fetal diameter, by making a small number of simple cuts to enable a vaginal delivery, then percutaneous fetotomy should be attempted. Thus for ankylosed fetuses, including 'wryneck' and perosomus elumbus, for cases of anterior duplication, and for schistosomes presented viscerally, fetotomy is indicated. The hydrocephalic fetus, whose cranial bones are too hard to be reduced by puncture, must have its head's dome sawn off using obstetrical wire. If the entire head is amputated, then the difficulty of withdrawing the grossly enlarged head still remains. In cases of fetal ascites ('water belly'), typically only the anterior half (head, neck, and forelimbs) of the fetus can be delivered, with the grossly distended abdomen preventing further extraction (see Chapter 9). Now, a finger knife is used to incise the fetal abdomen at several sites, enlarging the incisions

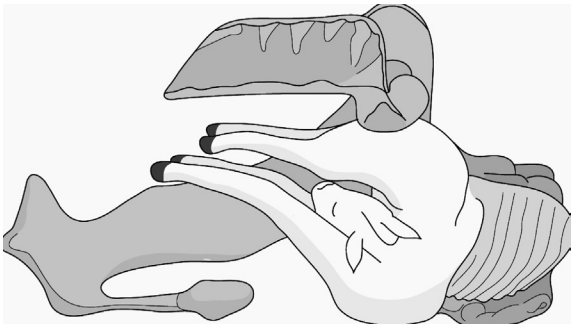
VetBooks.ir



• **Fig. 15.29** Percutaneous fetotomy: position of the fetotome and wire to bisect the fetal trunk of a viscerally presented schistosoma reflexus calf after removal of the viscera.



• **Fig. 15.30** Percutaneous fetotomy: alternative approach for bisecting a viscerally presented schistosoma reflexus calf.



• **Fig. 15.31** A schistosoma reflexus calf presenting by its extremities.

by hand. During controlled extraction of the fetus, the excess abdominal fluid will escape into the uterus. Alternatively, a partial fetotomy, similar to that described for 'hip-lock', can be carried out. However, if the abdominal cavity is not opened first, it may be very difficult, if not impossible, to retrieve the introducer from underneath the hugely distended abdomen. Perforation of the diaphragm will release most of the abdominal fluid, and it may now be possible to pass the wire around the hindquarters. Cases of fetal anasarca (see Chapter 9) cause dystocia because of the large increase in fetal volume associated with the accumulation of excess fluid in subcutaneous tissues, particularly of the head and hindlimbs. Delivery of severely affected fetuses usually requires partial fetotomy or multiple incisions of the subcutaneous tissues.

When it is obvious that several fetotomy sections will be required because of excessive fetal size (as in anasarca and extensive duplication) or a very irregular presentation, the obstetrician should resort to a Caesarean hysterotomy. This will be less demanding for the operator and, in general, better for the immediate health and future breeding potential of the cow.

The same principles and considerations apply to dealing with monstrosities in sheep, goats, and deer.

Percutaneous Fetotomy in the Obstetrical Management of Schistosoma Reflexus

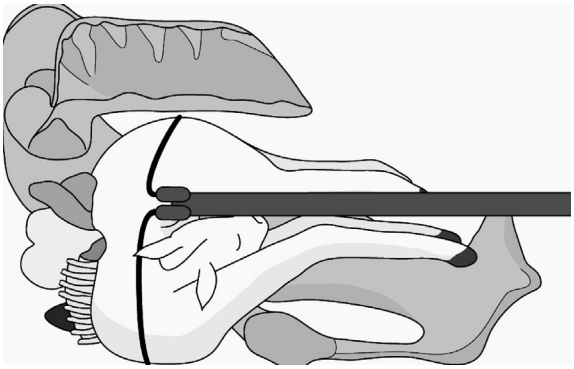
The more common presentation is for the fetus to be presented with its viscera exposed. First, a thorough examination should be carried out to ensure that rupture of the uterus has not resulted in prolapse of maternal organs. After killing and eviscerating the calf, usually only one to three cuts will be required on these relatively small fetuses. Before embarking on the fetotomy procedure itself, it is wise spending some time making oneself familiar with the presented case, as correct placement of the wire is the most difficult part of the entire procedure. The rigidity of the curved spine and ankylosed limbs prevents repelling of any fetal part, and inappropriate cuts will leave many sharp bone fragments that can easily traumatise the birth canal. The vertebral angulation should be clearly identified, as this is the site of the first fetotomy cut in order to bisect the fetal trunk (Fig. 15.29). One tube of the fetotome should be threaded and the wire, attached to an introducer, and carried inside in a similar manner to that described for amputating a flexed carpus or tarsus. If necessary, a finger knife can be used to make incisions in the large skin folds, thus facilitating the ventral retrieval of the introducer. The Krey hook should be attached to the point of spinal angulation and the head of the fetotome positioned next to it. During the sawing process the obstetrician should hold both the Krey hook and the fetotome with one hand and the handle of the instrument outside the cow with the other.

Once the cut is completed, the fetal 'halves' are carefully extracted, using the Krey hook. Sometimes, extra cuts may be needed to further reduce these fetal parts, as sharp bone fragments frequently result. To allow atraumatic delivery, the cow's birth canal should be protected when the fetal segments are delivered.

Alternatively, the wire may be passed around the spinal flexure of the fetus (Fig. 15.30). Passing the curved introducer around the rigid fetus may be a tedious task; using a smaller tool such as a wire handle may make this procedure easier. When accomplished, the fetotome is rethreaded, and the instrument passed into the vagina until its head abuts on the fetus. The fetal vertebral column is then cut through, and the smaller fetal segment is removed. Should difficulty arise over withdrawal of the remaining portion, it too may need to be divided perpendicularly to the first section, again using obstetrical wire.

When a schistosome presents by its extremities (i.e., three or four legs, with or without the head), the disproportionate diameter of the fetus, complicated by ankylosed joints, is likely to prevent natural or manipulative vaginal delivery (Fig. 15.31). Unless the fetus is very small in relation to the maternal pelvis – as might occur in case of a schistosome twin to a normal calf – time should not be wasted on an attempt at delivery by means of vaginal extraction. A Caesarean hysterotomy or fetotomy will be required instead. It is often possible and easier to deal with such a presentation by the latter method. A Caesarean hysterotomy will require a very large uterine incision and carries the risk of uterine rupture during extraction of the fetal monster, unless a fetotomy is carried out from the laparotomy site (Bezek & Frazer 1994) (see Chapter 16). If possible, the prethreaded fetotome is introduced, and the wire loop guided up and around all four limbs. When placed correctly, the wire will also encompass the head and parts of the thorax and pelvis (Fig. 15.32). A calving chain attached to one or two limbs can be used to anchor the fetus to the instrument. If the cut is successful, the head, neck, forelimbs, and part of the pelvis with

VetBooks.ir



• **Fig. 15.32** Percutaneous fetotomy: position of the fetotome and wire to bisect a schistosoma reflexus calf presenting by its extremities.

hindlimbs attached can be withdrawn. Sometimes, the head and one or two limbs need to be removed separately to make birth possible. Another cut through the point of spinal angulation may be necessary to divide the remaining fetal trunk, so these parts can then be extracted safely without causing trauma.

After successful delivery of a schistosome, the uterus should always be examined closely for any injury and to ensure the absence of a second fetus.

Percutaneous Fetotomy in the Obstetrical Management of Perosomus Elumbus

This type of fetal monster is usually not very large and the forepart of the fetus is typically born without any assistance. Difficulty will be encountered when the obstetrician tries to complete the delivery because the hindlimbs are commonly ankylosed and twisted. Attempts to withdraw the fetus by traction may result in perforation of the uterus. Delivery can be accomplished by means of a partial fetotomy similar to that described previously for managing cases of 'hip-lock'.

Postoperative Management and Care

In many cases the dam requires less care after a fetotomy than after a Caesarean hysterotomy. Upon completion of a fetotomy, the fetal membranes should be removed only if they are detached. This is followed by a thorough lavage of the uterus with large volumes of warm water or a 'saline solution' (9 g of common salt/litre of water) at body temperature, using a wide-bore stomach tube. The fluids may be fortified with a povidone-iodine solution (<1 mL/litre of fluid) or other mild disinfectant. The warm saline solution is believed to have both a soothing and a stimulating effect on the uterus, and this, together with the excavation of uterine fluid, lubricant, and debris, may promote involution. Although some obstetricians advocate using cold water in order to stimulate uterine contractions, there is no evidence that this is of any real benefit. Fluids should be infused incrementally (4–5 litres at the time) and then siphoned out until the efflux is clear. Normally, 20 to 30 litres of water are needed, and it is important that approximately the same volume of fluid is siphoned out from the uterus as has initially been infused. Oxytocin (20–40 IU) and a nonsteroidal antiinflammatory agent are mandatory; these medications should be administered for 2 days. If there is evidence of shock, fluid therapy is also indicated – hypertonic saline solution (4–5 mL/kg) given intravenously followed by 20 to 25 litres of water orally. Intrauterine antibiotics are of limited value at this stage, but systemic broad spectrum antibiotics should be administered for at least 4 to 5 days, particularly in protracted cases. In addition, the administration of calcium borogluconate to facilitate uterine involution should be given due consideration. There is some anecdotal evidence suggesting that the uterus will contract and involute quicker if the cow is allowed exercise rather than being confined to a stall (Norman & Youngquist 2012). A transrectal examination of the entire genital tract should be carried out 2 to 3 weeks later, at which stage any adhesions can be easily identified. This is also the correct time to administer intrauterine antibiotics to treat chronic endometritis.

Defects of Presentation, Position and Posture in Livestock: Delivery by Caesarean Hysterotomy

JOS J. VERMUNT, TIMOTHY J. PARKINSON AND DAVID E. NOAKES

Cattle

The Caesarean hysterotomy is one of the most common surgical procedures performed by veterinarians in cattle practice and is considered as a routine obstetrical technique. It has good maternal and fetal survival rates and is often less exhausting, faster, and safer than fetotomy (Parkinson 1974, Cattel & Dobson 1990). There are three main goals for doing Caesarean hysterotomy: (1) survival of the cow; (2) survival of the calf; and (3) maintenance of fertility. A prompt decision to perform Caesarean hysterotomy is important for optimum success (Dawson & Murray 1992). Ideally, it should be carried out when a live calf cannot be delivered after 15 to 20 minutes of manipulation. The cow is a good surgical risk, provided that the environment is suitable for aseptic abdominal surgery. Urgent intervention is indicated if there is evidence of fetal hypoxia, as shown by markedly increased movements of the fetus and expulsion of meconium, identifiable in the amniotic fluid. A successful outcome depends on several factors:

- Skill and speed of the surgeon
- Duration of dystocia
- Physical condition of the dam
- Availability of skilled assistance
- Surgical environment
- Concurrent disease
- Presence of a live calf

Indications

The reasons for surgery include most causes of dystocia, but analysis of published data shows that these six main indications account cumulatively for 90% of all Caesarean operations:

1. Fetomaternal disproportion (relative and absolute fetal oversize)
2. Incomplete dilation or induration of the cervix
3. Irreducible uterine torsion
4. Fetal monsters
5. Faulty fetal disposition (presentation, position, or posture) that is not correctable by vaginal manipulation
6. Fetal emphysema

In individual published series, their relative frequency of these indications varies considerably depending primarily on the breed of cattle predominantly at risk and, to a lesser extent, on whether fetotomy is routinely practiced. If the birth canal is fully dilated, fetal causes of dystocia may be amenable to relief by fetotomy, but failure of cervical dilation and irreducible uterine torsion are absolute indications for surgery. Nonsurgical delivery may seem advisable if the fetus is grossly infected, but laparohysterotomy is often obligatory in such cases because of premature uterine involution, emphysema of the fetus, or constriction of the birth canal. In many cases of dystocia, fetotomy may be the preferred option. However, the most important factor in choosing between Caesarean hysterotomy and fetotomy is likely to be the veterinarian's preference and relative experience with either technique (Schultz et al. 2008).

The indications for Caesarean hysterotomy and the reasoning behind an appropriate decision have been extensively discussed (Cox 1987, Pearson 1996, Green et al. 1999). In all cases the prognosis and cost should be discussed with the owner before surgery and, when necessary, written, informed consent should be obtained.

Fetomaternal Disproportion

Fetomaternal disproportion is consistently the most frequent overall indication for Caesarean hysterotomy in cattle. Four particular forms may be encountered.

Physical Immaturity of the Dam

In herds in which bull and heifer calves are kept together or in which a bull runs with suckling cows, calves may conceive at a surprisingly early age. It is not uncommon for heifers to be parturient at term when only 14 months old and, in exceptional cases, at only 1 year of age. Even at 18 months of age, the maternal pelvis is still immature and usually too small for normal vaginal delivery. This form of fetomaternal disproportion is also known as 'relative fetal oversize' (see Chapters 12 and 14).

Fetal Oversize

The majority of cases of disproportion are animals that are mature and at normal term. In this situation of 'absolute fetal oversize',

VetBooks.ir

the maternal pelvis is of normal size but the fetus is abnormally large, although normally developed in all other aspects. Among dairy breeds the Holstein–Friesian is more susceptible to this form of dystocia during the first pregnancy than the Ayrshire or Jersey. Certain beef breeds are also frequently affected with fetomaternal disproportion and not only during the first pregnancy. Double muscling or generalized muscular hyperplasia is well recognized in certain breeds such as the Belgian Blue.

The management of dystocia caused by fetomaternal disproportion depends largely on experienced clinical assessment of how much traction can safely be exerted without risk of serious birth canal trauma or, worse still, impaction of the fetus after only partial delivery. This is the most worrying of all obstetrical problems to be encountered in cattle practice, with ample scope for errors of judgment, which may often lead to death of the fetus and sometimes the dam. In many cases of fetal oversize, the fetal head cannot be drawn into the maternal pelvic cavity and the decision to perform a Caesarean hysterotomy is obvious. In others, traction is more effective and the decision is less clear. The difficulty lies in knowing when to stop traction in preference of surgery. Excessive force in such animals may merely exacerbate the degree of dystocia and compromise the success of a subsequent Caesarean operation. One practical guideline is that Caesarean hysterotomy is indicated if the head and both elbows in anterior presentation or both stifles in posterior presentation cannot be pulled into the pelvic canal using moderate manual traction by one person. As a rule of thumb, the elbows are introduced into the pelvic cavity if the fetlock joints extend for at least one hand width beyond the cow's vulva. Similarly, the stifles are introduced if the hock joints extend for at least one hand width beyond the cow's vulva. However, even then, if the calf has a large chest or pelvis, subsequent difficulty can still be encountered. The frequent finding in hospital referrals of fractured limb bones in oversized calves suggests either an unreasonable degree of traction or traction in a wrong direction. In heifers in particular, hurried traction early in second stage labour should be avoided unless there is obvious dystocia because the vestibule and vulva have not relaxed sufficiently and perineal damage is more likely to occur (see Chapter 14). If in doubt about the decision, it is probably better for the welfare of the cow and calf to perform Caesarean hysterotomy (Green et al. 1999). From an ethical point of view, the deliberate adoption of breeding policies that require delivery by means of Caesarean hysterotomy cannot be justified.

It is not uncommon for several heifers in a group to require more than normal assistance or delivery by Caesarean hysterotomy. If the time interval permits, the premature induction of parturition in the later calving animals within 10 days of the anticipated term may be of considerable benefit in such a situation (see Chapters 6 and 8). When elective surgery is required, it should ideally be performed during the first stage of labour.

Fetal Monsters and Infection

The most extreme form of disproportion is when there is pathological fetal oversize such as fetal anasarca and achondroplasia, which greatly increases the crossoperational diameter of the fetus. Conjoined twins are usually also too large for vaginal delivery. More common than all of these, however, is emphysema due to secondary putrefaction, which frequently develops in protracted cases of dystocia.

Postmaturity

A moderate prolongation of pregnancy up to 290 days or thereabouts is a normal feature of certain breeds, but in occasional animals of any breed, gestation may last for considerably longer, even beyond 400 days. There is continued fetal growth *in utero* with postmaturity, particularly of the skeleton. In such cases, dystocia at term is due not simply to fetal oversize but also to inadequate relaxation of the birth canal. There is also the problem of 'giant' calves associated with *in vitro* maturation/fertilization (Chapters 9 and 12).

Incomplete Cervical Dilation

Incomplete dilation of the cervix (see Chapter 13) is a common cause of dystocia in cattle; however, it should be diagnosed only after careful assessment of the findings on vaginal exploration. Cervical dilation during the first stage of labour is a gradual process and the presence of a cervical rim is not in itself an indication of dystocia, provided that the fetal membranes are still intact. Care should be taken in such cases not to perforate the membranes unless the cervix remains incompletely dilated 2 hours or so later. Slow or arrested dilation in multiparous cows may be associated with uterine inertia associated with parturient hypocalcaemia; in these animals, the response to calcium therapy is usually rapid. If, on initial or subsequent examination, the cervix is incompletely dilated and the membranes have already ruptured, with a fetal extremity presented against or through the cervix, or if the fetus is already dead, then further cervical dilation is unlikely to happen. If the cervical rim is shallow and membranous or if it stretches sufficiently for the head to be drawn into the vagina, then normal safe delivery may be possible. In the other cases, irrespective of the degree of dilation, the cervix is usually too thickened and indurated for a vaginal delivery to be safely attempted, and further delay will only result in fetal death and a greater risk of intrauterine infection. The presence of an incompletely dilated cervix after the birth of one twin, with the other fetus still *in utero* and often in a breech presentation, clearly indicates that the cervix starts to close again soon after becoming fully dilated. The frequent finding of faulty fetal disposition in cases of apparent failure to dilate may indicate that, in these cases at least, the cervix is in fact constricting and the cause of dystocia is fetal rather than maternal. Failure of the cervix to dilate or remain dilated is not uncommon in cases of premature calving and can result in the fetal head becoming trapped in the anterior vagina. Incomplete dilation of the cervix is an important complication of uterine torsion. After successful manipulative correction of the torsion, the cervix is often only partially dilated and seldom dilates further (Pearson 1971). In such cases the cervical rim may be substantial; however, it is usually thin and will stretch in response to traction on the fetus. Incising the cervical rim in the midline dorsally during traction may allow safe vaginal delivery. However, it should be remembered that the fetus (in cases of uterine torsion) may be larger than normal and that the cervical incision may tear, causing severe haemorrhage or uterine rupture.

Irreducible Uterine Torsion

Torsion of the uterus in cattle (Chapter 13) constitutes a major indication for Caesarean hysterotomy, either because the torsion is irreducible or because the cervix fails to dilate after vaginal correction. In most cases of postcervical torsion, the degree of cervical dilation and vaginal twisting permits the introduction of a hand into the uterus for manipulation of the fetus. However, if the torsion affects the cervical canal proper or uterine body (i.e., precervical torsion), the fetus is totally inaccessible, and such torsions are an absolute indication for Caesarean hysterotomy. In cattle, uterine torsion differs from all other causes of dystocia in that one or both of the fetal membranes usually remain intact even if the placenta

VetBooks.ir

• **Fig. 16.1** Schistosoma reflexus which presented viscerally. A skin pouch envelops the trunk, head, and limbs. (Courtesy Dr. Jakob Malmo.)

separates, unless they are deliberately perforated. The presence of fetal fluids thus protects the fetus and the uterus from infection; in this respect the condition carries a favourable prognosis. Torsion, however, may still have serious detrimental effects on the uterus. Rotation through 360 degrees is common, and even two or three complete revolutions of the uterus sometimes occur. The greater the degree of uterine rotation, the greater is the interference with the venous circulation within the uterus and its mesometrial and mesovarian attachments. The combination of uterine displacement and oedematous swelling of its wall may well result in perforation of the uterine body, especially by the fetal head. In extremely protracted cases a fetal extremity may impinge, through a uterine tear, on the urethra or segments of large intestine and, consequently, cause rupture of the urinary bladder or gut, respectively.

In most cases of uterine torsion, the prognosis is excellent, although paradoxically the surgery may be technically difficult, first because small intestine is usually displaced and impedes access to the uterus and second because the presence of fetal fluids may make the uterus difficult to handle and impossible to exteriorize for suturing. Perforation of the oedematous uterine wall can easily occur during the intraabdominal manipulation of the grossly distended uterus.

Fetal Monsters

Schistosoma reflexus is by far the most common gross structural defect in cattle. Occasional cases are born spontaneously without assistance, whereas others may be extracted with moderate and controlled traction. Most affected fetuses, however, cause dystocia because the characteristic angulation of the spinal column greatly increases the crossoperational diameter, although the body weight is usually less than normal for the breed. The fetus is presented in one of two ways: its exposed viscera may protrude from the vulva or three or all four limbs and head may lie in the vagina and can be felt to be attached to the misshapen trunk. The latter presentation may cause confusion, particularly in cases in which the appendages are enclosed in an inverted pouch of the skin, which is all that can be palpated (Fig. 16.1).

Schistosome cases occur sporadically in several breeds, sometimes as a twin to a normal fetus (Fig. 16.2), and may still be alive at delivery. It should be noted that they are seldom associated with protracted parturition, presumably because they cause obvious manifestations of dystocia. The dystocia is best relieved by fetotomy (see Chapter 15), although some veterinarians prefer to do a Caesarean hysterotomy. It must be realized, however, that longer than normal abdominal and uterine incisions are usually necessary

• **Fig. 16.2** Schistosoma reflexus twinned to a normal calf.

when a hysterotomy is carried out. Furthermore, extreme care is needed in manipulating the fetus from the uterus in order to avoid serious uterine tearing, which easily follows excessive traction. This manoeuvre may be facilitated by the lubricating effect of residual amniotic fluid. The prognosis after Caesarean hysterotomy is usually good; however, the cow should not be rebred to the same sire.

Cases of achondroplasia or bulldog calf deformity and anasarca or fetal dropsy cause dystocia due to widespread subcutaneous accumulation of tissue fluids, which greatly increases the crossoperational diameter of the fetus. This causes gross disproportion, irrespective of the body weight of the fetus; however, the body weight may also be considerably increased (see Chapter 9). Both congenital defects may also be associated with severe fetal ascites, placental oedema, and hydrallantois.

Lesions of the fetal central nervous system may cause muscle contraction of the limbs, which prevents normal extension in preparation for birth. Arthrogryposis, sometimes associated with torticollis and kyphosis (Fig. 16.3A and B), has been shown to result from viral infection (e.g., Akabane virus, bluetongue virus, Schmallenberg virus) of the dam during pregnancy and is also recognized as a genetic abnormality in the Charolais breed (see Fig. 16.3C). Because the muscle contraction fixes limb joints in either flexion or extension, depending on the joint, the condition is sometimes called ankylosis. However, the bones are not fused. Spina bifida is less common in cattle but causes similar contractions, usually of the hindlimbs only because the lesion is located in the thoracolumbar region. Fetal anencephaly and the deformity described as perosomus elumbus may also cause limb abnormalities. In most cases of muscle contraction, the musculature of affected limbs is palpably underdeveloped. The degree of contraction is often too severe for a successful attempted delivery. However, if the forelimbs in an anterior presentation can be brought into the vagina, traction may cause the flexed hindlegs to perforate the uterus below the pelvic brim. Conjoined fetuses occur occasionally with varying degrees of fusion. These monsters generally require delivery by Caesarean hysterotomy unless only the head is duplicated, in which case a simple or partial fetotomy will readily relieve the dystocia.

VetBooks.ir

• **Fig. 16.3** (A and B) Fetuses with varying severity of torticollis and muscle contracture of the limbs. (C) Congenital arthrogryposis of a Charolais calf.

Faulty Fetal Disposition

Provided that the cervix is fully dilated and remains so, most early cases of faulty fetal disposition can be corrected manually or relieved by relatively simple fetotomy. However, the loss of fetal fluids followed by uterine contraction often makes such manipulations difficult and time-consuming and more likely to result in rupture of the uterus. In protracted cases, constriction of the cervix may then cause the fetus to start to decompose and become emphysematous.

Fetal Emphysema

In cattle fetal emphysema is a frequent complication of protracted parturition and, irrespective of the primary cause of dystocia, is often the immediate indication for Caesarean hysterotomy. However, such cases should be assessed carefully and realistically before the surgery is undertaken because fetal putrefaction can seriously influence maternal survival afterwards. Hence fetotomy may be an alternative and frequently better option (see Chapter 15). Bacterial culture of such fetuses usually yields a heavy growth of coliforms or coliforms and clostridial organisms. The latter infection is associated with a high maternal mortality rate in the immediate postoperative period, possibly because of endotoxaemic shock. On cursory examination the clinical status of these cows may seem reasonable despite gross uterine distension; the pulse rate, however, is usually significantly raised and the animal noticeably quiet on handling. Such premonitory signs are likely to be followed, as soon as the uterus is incised, by the onset of rapidly deteriorating shock, which is sometimes fatal within 12 to 24 hours despite intensive supportive therapy. Experience suggests that coliform infection alone is less serious than clostridial putrefaction; however, preoperative differentiation is not possible. Despite the significant mortality rate in this group of cases, surgery may nevertheless be worthwhile if either fetotomy or slaughter is not an alternative option.

Miscellaneous Indications

Occasionally, animals are encountered with full cervical dilation and a normal-sized fetus in which the caudal part of the birth canal is too constricted for delivery, even after episiotomy (see Chapter 14). The condition is particularly associated with Friesian heifers. The natural termination of a pathologically prolonged pregnancy (postmaturity) may also be associated with absence of normal parturient changes in the vagina and vulva and thus a need for Caesarean hysterotomy.

Abortion in late pregnancy sometimes requires treatment by Caesarean hysterotomy for several contributory reasons such as incomplete birth canal dilation, cervical constriction, fetal deformity, and faulty fetal disposition. Such cases are uncommon, but nevertheless important, because they may be associated with specific zoonotic infections such as leptospirosis, salmonellosis, and possibly listeriosis.

Fetal mummification and hydrops uteri may now be treated initially by inducing parturition using prostaglandins, but a Caesarean hysterotomy may still be necessary if induction fails or the birth canal is insufficiently dilated for vaginal delivery. Neal (1956) described two-stage Caesarean hysterotomy for cases of hydrallantois. A left flank incision is made as for a normal Caesarean. Once the uterus has been identified, large-bore sterile tubing is used to drain the allantoic fluid through a stab incision in the uterine wall, with the tube being retained by a purse-string suture. The allantoic fluid is drained slowly as the heart rate of the animal is continuously monitored; if the rate increases, drainage is suspended for 10 to 15 minutes. When as much fluid as possible has been drained from the uterus, the tube is withdrawn and the purse-string suture closed. Alternatively, a rumen trocar plus cannula can be used, which is inserted through the skin and muscle layers of the right lower flank and then directly into the grossly distended uterus. Once the trocar is removed, allantoic fluid will flow from the cannula. Now, Caesarean hysterotomy can be carried out straight away rather than waiting 24 hours as originally described by Cox (1987).

Laparotomy is essential in cases of uterine rupture. If this disorder occurs as a preparturient complication, the fetus usually lies completely free within the abdominal cavity and, if the cord is not twisted, may survive until the placenta separates at term (a pseudoectopic pregnancy). More frequently, however, uterine rupture occurs as a complication of dystocia, particularly uterine torsion, or as a result of manipulation of a fetus that is oversized or has

VetBooks.ir

faulty disposition. Rupture of the uterus during parturition may result in considerable uterine haemorrhage and hypovolaemic shock.

Repeated dislocation of the sacrococcygeal articulation during assisted delivery in successive parturitions or a healed fracture of the maternal pelvis can result in deformation or a significant bony obstruction at the site, creating an uncommon indication for surgery.

Restraint, Preparation for Surgery, and Anaesthesia

One of the paramount goals of a Caesarean hysterotomy should be to limit the contamination of the peritoneal cavity with uterine contents. Peritoneal cavity contamination, particularly in cattle with dead, emphysematous fetuses, greatly increases the risk of peritonitis, limits the cow's chances of survival, and limits the surviving cow's productivity. Several different surgical approaches have been described for the Caesarean operation in both standing and recumbent cattle, with each approach having its own advantages and disadvantages (Schultz et al. 2008). These comprise the left paralumbar fossa celiotomy (standing or recumbent), right paralumbar fossa celiotomy (standing or recumbent), ventral midline celiotomy (recumbent), ventral paramedian celiotomy (recumbent), ventrolateral celiotomy (recumbent), and lateral oblique celiotomy (standing or recumbent). A low-flank celiotomy has been developed as an alternative approach for the delivery of an emphysematous fetus in the recumbent animal. Considerations crucial to the choice of approach include the following:

- The type of dystocia
- The surgeon's experience and confidence
- The nature of the environment (e.g., whether or not there is a crush or head bail for standing restraint)
- The availability of assistance
- The temperament of the animal
- The demeanour and physical condition of the cow (e.g., whether it can stand for the entire procedure, whether the rumen is distended, or whether there is evidence of calving paralysis due to prolonged dystocia)

The options of patient positioning for Caesarean hysterotomy are the following:

- Standing (suitable for left or right paralumbar fossa approach and lateral oblique approach)
- Dorsal recumbency (suitable for ventral midline and ventral paramedian approach)
- Sternal recumbency (suitable for left or right paralumbar fossa approach)
- Lateral recumbency (suitable for ventrolateral and low-flank approach)

The choice of positioning largely depends on the surgeon's preference and the demeanour of the animal, as well as available facilities. In a cow capable of tolerating surgery when standing, the left paralumbar fossa or flank approach is the standard technique for a viable or recently dead, uncontaminated fetus. Other indications for this approach include cows with a large udder, extensive oedema of the udder and ventral abdomen, or prolific ventral abdominal vascularity close to the milk vein such as occurs in mature dairy cows. One advantage of the left flank incision is that the rumen's anatomical position prevents exposure of the intestines. However, in individual cases, a large rumen, particularly if the animal is straining, may interfere with surgical access to the abdomen. Another advantage of the flank approach in the standing animal is easier correction of a uterine torsion. Finally, wound dehiscence is more manageable in the flank compared with lower abdominal incisions.

The standing left paralumbar fossa approach is the most commonly used approach for an uncomplicated Caesarean hysterotomy. In general, paralumbar fossa approaches are often preferred by large animal veterinarians because most of them are familiar with these. They are sufficiently similar to that used for rumenotomy and for either the right or left approaches for correcting abomasal displacement, so that most practitioners have a great degree of comfort with them. The standing left paralumbar fossa approach is described in detail later in this chapter.

Restraint, Facilities, Sedation, Assistance

For standing left paralumbar fossa surgery, the animal should be restrained in a calving pen using a halter tied in such a manner that the animal's right flank is against a wall and the head in the corner in order to limit movement during surgery. Alternatively, the cow can be restrained in a crush or head bail, which must provide good access to the left side of the animal. If needed, the animal can also be positioned against the exit gate of the left bail area in the milking parlour. A strategically fastened side rope should prevent the animal from turning around. The halter should be tied with a quick release knot in case the cow suddenly becomes recumbent. Nose grips may be required for additional restraint. A rope can be attached to the right hindleg above the fetlock and laid underneath the animal's body so that, if the cow becomes recumbent during surgery, the rope can be pulled to enable the animal to lie in right lateral recumbency. The tail should be tied out of reach of the surgery site, usually to the halter along the right side of the animal or to the animal's right hock.

Usually, the surgeon has little choice when selecting the environment for Caesarean hysterotomy. Many successful surgeries have been performed under less than ideal circumstances in pastures, barns, sheds, and milking parlours. If a hospital facility is not available, consideration must be given to choosing the cleanest possible surroundings, as the operating environment has been shown to be a significant source of organisms that may contaminate the wound. Also, the location for surgery should be selected carefully with the objectives of ensuring good lighting, facilities for restraint, and a suitable floor surface. Avoid doing surgery in buildings occupied by large numbers of other cattle. Ideally, use a clean calving pen or other unoccupied building. Clean bedding should be provided, although vigorous shaking of straw will cause unwanted clouds of dust. Adequate lighting should be available to illuminate the intended surgical site. The surgeon should ensure that the light is not situated such that the surgical site is in the shadow cast by the surgeon; equally, the light must not shine in the eyes and distract the surgeon. Many veterinarians carry a portable halogen lamp and stand for use on the farm; alternatively, the surgeon may choose to wear a head torch.

Facilities for restraint should be appropriate for the size of the animal and designed to avoid injury to animals or humans. A ring fixed in the wall of a calving box and offset 50 cm from the corner is ideal; if the animal goes down the offset ring encourages the animal to lie on her right side. The floor surface should provide adequate friction for animal and surgeon. Slippery concrete floors can lead to accidental falls during surgery. A 20 to 30 cm thick base of sand with clean straw on top provides an ideal surface. Facilities for the calf should also be prepared at this stage; a warm, straw pen complete with resuscitation equipment would be ideal.

Sedation should be avoided if possible because it can cause recumbency during surgery and may be detrimental to fetal survival. If sedation is deemed necessary, xylazine is commonly used (0.05–0.1 mg/kg i/m or half this dose rate i/v; however, the latter

VetBooks.ir

may not be a licensed route of administration in some countries). Unfortunately, xylazine has also a myotonic effect, causing uterine contractions, which make the uterus friable (Hoeben et al. 1997). Such contractions may make exteriorization of the uterus rather difficult and suture placement more problematic, increasing the likelihood of uterine tears during closure. Furthermore, xylazine can cause ruminal tympany, thus obstructing the surgical wound. If sedation is indicated, such as when cows struggle or remain fractious, it is advised to administer xylazine after the uterine closure is completed. Acetylpromazine maleate (0.05–0.1 mg/kg i/m or i/v) can also be used as a sedative, and it does not induce uterine contractions. However, it will take quite some time for this drug to take effect and the degree of sedation is relatively minor.

Alternatively, surgery may be performed on the recumbent animal; this is particularly indicated in case of fractious animals. If the cow is not already recumbent, a sedative can be administered (xylazine 0.2 mg/kg i/m, or 0.1 mg/kg i/v) or the animal may be cast using a rope. She should be placed in right lateral or semisternal recumbency with the body slightly tilted to the right. Bales of straw may be used to prop the cow in a stable position for surgery. In addition, the legs may be hobbled, although some surgeons prefer the left hindleg to be extended caudally and fixed by a rope.

Two or more assistants are usually required for successful surgery: as a minimum, one to restrain the cow and one to deliver the calf and provide appropriate care after the procedure. Communication with the assistants by the surgeon is important. Briefly describe how the surgery will be performed and outline the role of each assistant and how to proceed in the case of a crisis such as the cow becoming recumbent during surgery.

Anaesthesia

Regional anaesthesia may be accomplished by a variety of methods. The choice of anaesthetic method differs between surgeons and the selected surgical site. For flank incisions, paravertebral anaesthesia of the nerves associated with the transverse processes of T13, L1, L2, and sometimes L3 is commonly recommended. Each site is infused using 20 to 30 mL of a 2% lignocaine solution: around 15 to 20 mL to block the ventral nerve branches and 5 to 10 mL for the dorsal branches (Cox 1987). Signs of successful anaesthesia are a warm, hyperaemic and flaccid flank with no response to pain when tested with a hypodermic needle. The advantage of paravertebral anaesthesia is that the whole flank musculature is desensitized and flaccid, which facilitates exploration of the abdomen during surgery as well as closure of the wound. Also, the flank incision can be readily extended if necessary. One particular disadvantage is that the technique is more difficult to carry out than other methods, especially in fat or heavily muscled animals, in which case the landmarks are difficult to identify (Edmondson 2008). In addition, the cow may be unsteady after surgery because of loss of lumbar muscle tone and paresis of the ipsilateral hindlimb. Special care must be taken not to inject an excessive dose of anaesthetic solution around L3, as this spinal nerve contributes branches to the femoral and obturator nerves. Finally, the effect of vasodilation in the muscle layers causes a greater degree of haemorrhage that may require haemostasis.

A local anaesthetic line block and inverted–L block of the flank are excellent alternatives to paravertebral anaesthesia. An 18–gauge × 1.5–inch needle is used to administer 2% lignocaine hydrochloride at several sites, the number of sites being dependent on the length of the proposed incision. At each point, 5 mL of local anaesthetic is injected subcutaneously in each direction of the incision line and a further 10 mL into the musculature. Normally, only a total of 80 to 100 mL of lignocaine is required; larger volumes of local anaesthetic solution infiltrated into the incision area may have an adverse effect on wound healing. The technique is quick and reliable and requires minimal training. However, the parietal peritoneum may not be effectively anaesthetized, causing a reaction by the patient when it is incised. Sloss and Dufty (1977) reported particular problems of inadequate analgesia with an inverted L-block in fat animals. A similar reaction will occur if the incision has to be extended during surgery in order to extract the calf. Furthermore, because the flank is not flaccid, apposition and suturing of the muscle layers can be difficult.

High epidural anaesthesia or lumbosacral epidural block (anterior block), also using 2% lignocaine, can provide excellent anaesthesia of the flank, although such anaesthesia usually causes recumbency, which may be prolonged in cattle. Caulkett et al. (1993) reported that epidural anaesthesia using 0.07 mg/kg xylazine produced good analgesia for Caesarean hysterotomy in 45% of cases without causing severe ataxia. However, there was a prolonged time to the onset of anaesthesia, and it was not effective in 17% of cases.

Preoperative Preparation

Preoperative administration of antibiotics is strongly recommended (Cox 1987). Commonly, a broad spectrum antibiotic will be chosen, with ceftiofur sodium at 1 mL per 50 kg live weight being a good choice, as this antibiotic has no required milk withholding time. In beef cattle, long-acting tetracyclines could be administered. Tocolytic agents, such as isoxsuprine lactate (220–250 mg; when xylazine sedation is used, it is recommended to increase the dose by 100%) and the β_2–adrenoceptor stimulant clenbuterol hydrochloride (0.3 mg) administered by intramuscular or slow intravenous injection, are widely used and can facilitate the manipulation and exteriorization of the uterus during surgery. Furthermore, these tocolytic drugs counter the myotonic effect of xylazine on the uterus. A low or caudal epidural injection (posterior block), using 1 mL/100 kg live weight of 2% lignocaine, is essential to alleviate abdominal straining (see Chapter 14). Unfortunately, severe tenesmus occasionally fails to be prevented by epidural anaesthesia. It should also be noted that too high a dose of local anaesthetic solution may result in ataxia and/or recumbency. In case of anterior presentation (with the head of the fetus entered into the pelvis), it is important to repel the calf back into the relaxed uterus after the epidural and tocolytic drugs have taken effect. This will reduce the chances of continuous straining and of the cow becoming recumbent during surgery. (Note: tocolytic drugs may have milk and/or meat withholding times which also apply to the calf when delivered.) Cows that are markedly dehydrated may need to be given fluid therapy before surgery, such as hypertonic saline solution (4–5 mL/kg) given intravenously, followed by 20 to 25 litres of water orally.

A wide surgical field should be prepared. Initially, dirt and dust should be brushed from the flank and back of the animal before the operative field is clipped or shaved. In case of a flank incision the entire flank should be clipped from below the transverse processes dorsally to just above the milk vein ventrally, and from the last rib to the hindleg, level with the tuber coxae. The skin should be prepared using a surgical scrub (7.5% povidone-iodine or 4% chlorhexidine gluconate solution), followed by surgical spirit. Sterile drapes should be applied; in the standing animal a large, moisture-resistant drape with a suitable window can be placed over the back of the cow and down the flank. A useful alternative in the field is to use a wide roll of plastic film wrapped around the cow's body leaving only the surgical site exposed.

VetBooks.ir

Surgeons and assistants should ideally wear protective surgical scrub suits, even in the field situation. Alternatively, a clean and disinfected apron can be used. Many practicing veterinarians prefer not to wear gowns and gloves, in which case the surgeon's arms (all the way up, including the armpits and shoulders) should be bare, washed, and scrubbed thoroughly. At all times, however, emphasis should be placed on thoroughly clean surgery. Due consideration should be given to wearing long-sleeved plastic gloves (rectal examination sleeves with the finger tips cut off, and the gloves held in place with elastic bands) and surgical gloves, particularly by those veterinarians who do not wear protective gloves for claw trimming and other work in cattle practice that causes gross contamination of the hands.

Operative Technique (Described for a Right-Handed Person)

The adequacy of anaesthesia should be carefully tested before surgery because muscles and peritoneum may remain sensitive despite skin desensitization.

In all situations it is important to exteriorize the uterus. This helps to limit the contamination of the abdominal cavity, thus aiding in the prevention of peritonitis. The choice of surgical procedure has a direct bearing on whether the practitioner is able to exteriorize the uterus. Large fetuses, large cows, and small stature all limit the ability of the obstetrician to exteriorize the uterus.

Standing Left Paralumbar Fossa Approach

The left flank incision is the most common technique and most appropriate for the standing animal. The rumen helps to retain the abdominal viscera within the abdominal cavity. Absolute requirements for this approach include an appropriate restraint facility and a cow capable of standing through the entire procedure. The surgeon has to judge whether the animal will remain standing during the procedure; if not, recumbency should be induced before surgery.

A clear contraindication for this approach is a large fetus that will prevent exteriorization of the uterus. In such cases, lifting the uterus plus calf towards the paralumbar incision will be difficult and sometimes impossible for some veterinarians.

After preparation of the flank and appropriate anaesthesia for the incision site (Fig. 16.4), a vertical skin incision is made in the middle of the left flank starting 10 cm ventral to the transverse processes and extending approximately 30 to 40 cm long (Fig. 16.5). If the breed of dam or other indication for surgery suggests that a future elective Caesarean hysterotomy(s) may be necessary, the incision should be made at close to cranial border of the flank just behind the last rib, thus allowing for subsequent incisions more caudally.

With the left flank approach these muscle layers are incised: cutaneous, external abdominal oblique, internal abdominal oblique, and the transverse abdominal muscle. The external and internal abdominal oblique muscles are sharply incised in the same direction using a scalpel. Haemorrhage from these muscle layers is usually minimal; however, when large vessels are involved, haemostats should be applied and the vessel ligated if necessary. The aponeurotic transverse abdominal muscle is split vertically by blunt dissection. The peritoneum is tented and incised at the dorsal aspect of the incision using a scalpel, taking care not to puncture the rumen, which lies immediately beneath the peritoneum. At this stage, entry into the abdominal cavity is obtained, which is usually signalled by the sound of air rushing into the potential space. The incision is then extended vertically with blunt-tipped scissors rather than a scalpel, so as to reduce the risk of cutting abdominal organs. Often, a variable amount of peritoneal fluid, sometimes blood tinged, is immediately apparent in the abdominal cavity. Greater volumes are present in cases of prolonged dystocia, uterine infection, torsion, or rupture. Additionally, in case of uterine torsion or uterine infection, there may be large fibrin clots present in the abdomen. In case of uterine torsion the small intestines may also be displaced to a position immediately caudal to the rumen to such an extent that loops may spill through the abdominal incision. The surgeon should explore the abdomen to identify the uterus, and the uterine tone and disposition of the calf should be noted. Frequently, the tip of the pregnant horn is

• **Fig. 16.8** During delivery of the calf's hips, the body is rotated and traction is directed caudally and laterally, at the same time rotating the calf in a manner similar to a vaginal delivery of a calf in posterior longitudinal presentation. (Courtesy Dr. Jakob Malmo.)

located in the left lower quadrant of the abdomen, close to the flank incision.

Calf in Anterior Presentation

The hindlimbs of the calf are situated in the tip of the pregnant uterine horn. With the calf in anterior presentation, it is ideal to anchor one or both hindlimbs in the incision, which holds the uterine horn outside the abdomen. Rather than attempting to lift the entire uterus, a common method to exteriorize the gravid uterus is for the left hand to first locate the calf's digits, then follow the metatarsus down to finally cup one or both hocks. Then the right hand grasps the digits in the tip of the horn from behind. The limb is now rocked towards the incision, and the tip of the horn is lifted through the incision. The hock is then elevated, so levering the lower limb up through the incision. Often, it is then possible to wedge the hock into the ventral aspect of the incision, while the digits are retained by the flank above the dorsal aspect of the incision (Fig. 16.6), thereby relieving the tension on the surgeon's arms. (Note: The tip of the uterine horn should not be grasped without including one of the calf's limbs. Attempts to manipulate or grasp the uterus, rather than the calf, will often cause uterine tears and abdominal contamination.)

Exteriorization of the uterus before making the incision is a critical step in the subsequent success of the surgery. However, traction on the uterus may require considerable strength and tenacity on the part of the surgeon. Manipulation of the uterus also stretches the mesometrium and can cause pain, which is manifested by the cow displaying signs of discomfort. Furthermore, once the uterus is being handled the myometrium often starts to contract, making exteriorization more difficult unless a tocolytic agent has been administered before surgery.

The uterine wall is incised over the calf's leg using a scalpel or scissors. The incision needs to be made large enough to allow removal of the calf without further tearing of the uterus or the need to extend the uterine incision. As a general rule, an incision from the tip of the digits to either the metacarpus or metatarsus is sufficiently long to permit extraction of the calf without causing uterine tears. If the incision in the uterus is made too short, the uterus may tear uncontrollably during extraction of the calf. The incision should be made over the greater curvature of the uterus, parallel to the longitudinal muscle layers of the myometrium, and distant from both the cervix and very apex of the pregnant horn. This area has the fewest large blood vessels. The greater curvature runs between and parallel to rows of cotyledons, which are both visible and palpable through the uterine wall. If these are incised inadvertently, they must be ligated to avoid substantial blood loss. If the uterine incision extends too close to the cervix, its suture repair will be very difficult. Also, care should be taken to avoid incising the calf, particularly if fetal fluids are sparse.

The membranes (allantochorion and amnion) are ruptured manually, and the calf's fetlocks are grasped by the surgeon, exteriorized, and passed to an assistant. Alternatively, sterile calving chains can be placed around the calf's hindlimbs and handed over to an assistant, who initially pulls the calf up in a dorsolateral direction until the calf's pelvis emerges from the flank incision (Fig. 16.7). Then lateral traction is applied such that the calf is rotated and removed in a manner similar to a vaginal delivery of a calf in posterior longitudinal presentation (Fig. 16.8). At the same time, the surgeon attempts to retain the uterus outside the abdomen in order to curtail contamination.

Exteriorization of the pregnant horn can be difficult and is not always possible, for example when the uterus is firmly contracted (even when tocolytic drugs have been administered). A large fetus and lack of physical strength may also make exteriorization more difficult. In these cases, incising the uterus has to be done within

VetBooks.ir

the abdominal cavity because the uterus has become friable or is liable to damage by further manipulation. However, such an incision may lead to gross contamination of the abdominal cavity with fetal fluids, which are unlikely to be sterile, particularly if dystocia was the indication for surgery. Furthermore, incision within the abdomen is often made more difficult by bouts of straining by the dam. This 'blind' incision should be made on the cranial aspect of the greater curvature of the pregnant horn by using a Robert's fetotomy knife (see Fig. 15.1) or a scalpel blade, in which case the surgeon's fingers should shield its cutting edge. Often, it is impossible to make a long enough incision, and it is safer to first make a small incision, then grasp one or both limbs of the calf through the incision and pull these into the flank incision. While an assistant applies gentle traction to the calf, the uterine incision can be carefully extended further.

A live calf should be attended to by an assistant while the surgeon examines the uterus, initially for the presence of a second fetus. In addition, any lacerations of the uterine wall should be noticed and repaired. Fetal membranes should only be removed at the time of surgery if they are lying free within the uterus or can be easily detached, which is uncommon. Otherwise, they are returned to the uterine lumen. Any protruding tags are trimmed so as not to incorporate these in the suture line of the uterine incision. This approach is justified on two grounds. First, it should be assumed that, if fetal membranes can be physically separated, they will be expelled naturally and more completely by uterine contractions. Second, if deliberate detachment of fetal membranes is attempted before they would normally separate and be expelled, then there may be haemorrhage or incomplete removal, either of microvilli or of larger masses of placental tissue. It is common practice to place antimicrobial pessaries in the uterine lumen before final closure of the hysterotomy wound, but the value of this is questionable. If fetal membranes are subsequently expelled naturally, so are the pessaries. If they are retained, then the antimicrobials will have no more than a minimal local effect in the lumen and are probably ineffective in controlling deep infection.

Calf in Posterior Presentation

Adequate rotation of the uterus (if required) is a prerequisite for success (see later in this chapter, under 'Rotation of the Calf'). Delivery of the calf through the abdominal incision is similar to that for a normal anterior longitudinal presentation. In case of posterior presentation the head and forelimbs of the calf are situated in the uterine horn. Often these structures together are so bulky that it is difficult, if not impossible, to get sufficient grip to elevate the pregnant horn and bring it into or near the incision. This technique is therefore recommended: With the left hand, the digits of the calf's underlying (most ventral) forelimb are grasped from above, and traction is applied so the tip of the uterine horn may be elevated high enough to bring the greater curvature into sight. An incision of about 15 cm can now be safely made with the right hand. The next step is for the left hand to grasp the metacarpus through the incision. Because this grip is firmer, the tip of the uterine horn can be elevated enough to allow the incision in the greater curvature to be extended, making sure to avoid cotyledons. The membranes are ruptured and chains applied to the forelimbs, which are handed over to an assistant who initially pulls the calf upwards. At the same time, the surgeon manipulates the head through the uterine incision. A finger and thumb grip in the orbits is often helpful in manoeuvring the head through both the uterine and abdominal incisions. Once the head and shoulders are outside the flank incision, the calf is slowly extracted by lateral traction. Often, there is a small amount of inconsequential uterine fluid spillage into the abdomen.

Occasionally, the hindquarters of the calf may still be wedged within the vagina such that vaginal repelling by an assistant is required. If so, the part of the calf protruding from the vulva (i.e., most of the hindlimbs) should be properly cleaned and lubricated before delivering the calf through the flank incision. The fact that many cows urinate immediately after removal of such a presented fetus suggests that urine has been retained because of compression on the animal's urethra.

Rotation of the Uterus

If the tip of the pregnant horn (left or right) is located in the right lower quadrant of the abdomen, it will be necessary for the surgeon to rotate the uterus along its longitudinal axis (clockwise) in order to bring the calf's limbs towards the flank wound (Schuijt & Van der Weijden 2000). This may be quite difficult to achieve in case of a big fetus or a surgeon of small stature. However, it is essential that the uterus is rotated because it allows the pregnant horn to be exteriorized. The uterus should be incised as close to the tip of the horn as possible, not over the upper part of a fetal limb situated in the body of the uterus. Incisions made in or near the body of the uterus usually can only be sutured within the abdominal cavity, which is extremely difficult.

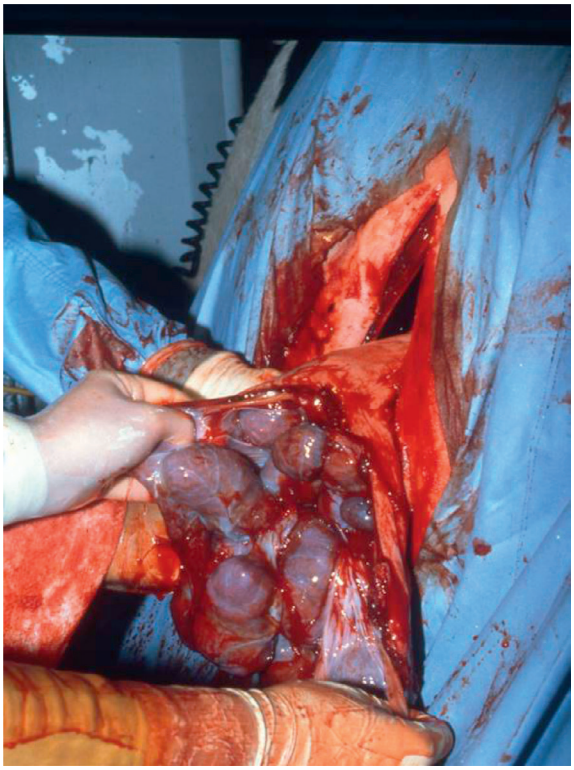
There are two techniques for rotating the uterus such that the tip of the pregnant horn will come within reach and can be exteriorized as described previously:

1. Traction should be applied on a leg with the left hand while pushing the dorsal aspect of the uterus away from the surgeon with the palm of the right hand. Alternatively, both hands should be put against and under the back of the calf (which is situated in the body of the uterus, against the greater curvature, and facing towards the surgeon). The uterus is then elevated and pushed/rolled over to the other side of the abdomen. The same technique can be attempted if the indication for Caesarean hysterotomy is irreducible uterine torsion. The uterine incision can then be made after the torsion has been corrected. However, in cases of irreducible uterine torsion, the uterine wall is often oedematous and friable; thus extreme care must be taken not to perforate the uterus with the fingers.
2. The surgeon's right hand and forearm are brought beneath the body of the uterus such that the hand can be placed on the dorsomedial (upper) aspect of the tip of the pregnant horn. With the hand so positioned, the uterus is rotated about 90 degrees by pushing and pulling the tip of the horn underneath the uterus while lifting and thrusting the body of the uterus towards the opposite side of the abdomen using the surgeon's forearm and elbow.

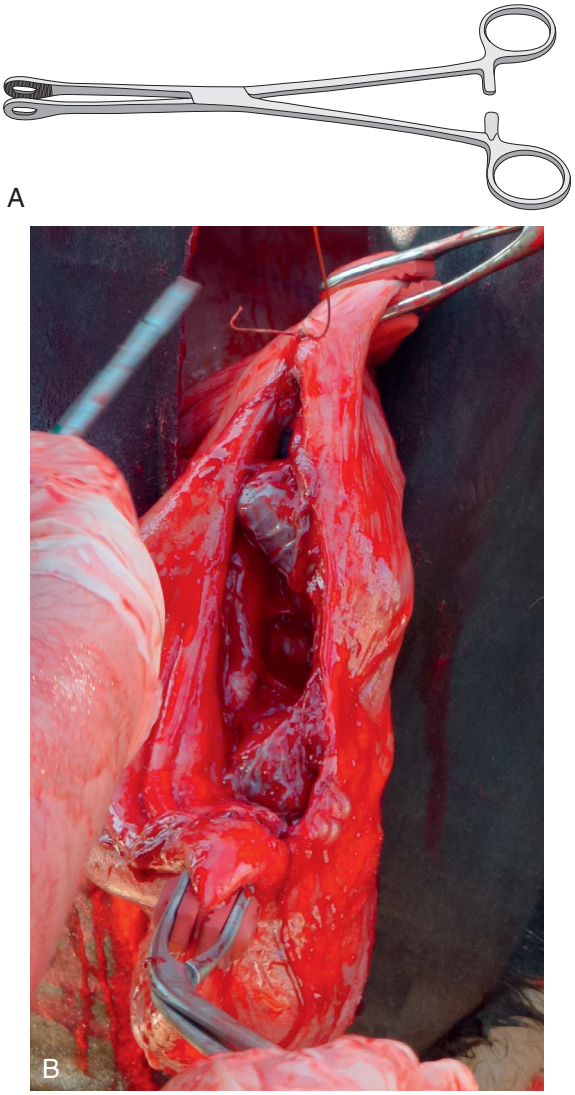
Closing the Uterine Incision

Before closing the uterine incision, the uterus should always be checked for the presence of a second calf. The edges of the uterine incision are inspected for haemorrhage, particularly from cotyledonary vessels (Fig. 16.9). It is advisable to exteriorize both uterine horns before the genital tract begins to involute, as this will facilitate inspection and repair of the incision. Large vessels that are bleeding should be ligated. The uterus is supported by an assistant or held using uterine forceps (Fig. 16.10A and B) such that the entire uterine incision is kept outside the flank incision. The uterus is closed with absorbable monofilament suture material, such as chromic or plain catgut (6 USP or 10 metric), polyglycolic acid, and polyglactin 910. Studies have investigated

VetBooks.ir



• **Fig. 16.9** Closing the uterine incision. The edges of the uterine incision are inspected for haemorrhage, particularly from cotyledonary vessels.



• **Fig. 16.10** (A) Uterine forceps for an assistant to hold the uterus (B) when the Caesarean incision is sutured by the surgeon.

uterine healing when a number of different suture materials were used. Surprisingly, large sized plain catgut is probably the suture material of choice. Synthetic absorbable sutures persist longer in tissues and have been associated with more dramatic scarring of the uterus (Newman & Anderson 2005). Additionally, catgut has advantages over the synthetic suture materials, particularly when the uterus is friable, because the latter may have a 'cheese wire' effect, making them more prone to cause uterine tears when tension is placed on the suture line. Braided suture materials seem particularly prone to cause tearing of the uterus as they are tightened. On the other hand, catgut causes greater tissue reaction and therefore is more likely to produce adhesions. The suture material and a large round-bodied (tapered) needle should be prepared for use before starting the surgery.

Suturing should start at the cervical end of the uterine incision, because this part of the uterus will retract into the abdominal cavity once the uterus starts to involute. A variety of suture patterns have been employed; all are continuous inverting patterns with the objective of creating a watertight seal by apposing the serosal surfaces while causing a minimum of subsequent adhesions and uterine scarring. The Utrecht method (Fig. 16.11), which is a modified Cushing pattern turned to a 30 to 45 degree angle away from the incision, is routinely used these days. The suture should start approximately 2 cm above the upper end of the incision, using oblique bites, so the knot will be buried within a fold of the inverting tissue. Similarly, the continuous interlocking, inverting pattern is inserted using oblique bites. These should begin about 2 to 3 cm from the incision edge but are inserted some distance back from the emerging previous bite (Fig. 16.12A). Each bite should exit the uterine tissue near the edge of the incision and then be pulled tightly. It is important not to perforate the uterine wall; sutures should be placed only partial thickness, incorporating the serosa and muscular layer of the uterus. Great care should be taken to avoid fetal membrane tags becoming incorporated in the suture line. The above mentioned suture pattern approximates the serosal surfaces, with the wound edges not inverted too much (uterine healing occurs across the wound edges rather than on the apposed serosal surfaces). The final knot is buried in the same manner as the knot at the beginning of the suture line. If done correctly, there will be no leakage of uterine fluid and little, if any, exposed suture material. Exposed suture material forms a nidus for adhesions to develop after intraabdominal surgery. If there is any leakage, the incision line should be oversewn with a second layer.

The advantage of this suture pattern is minimal adhesion formation after surgery. A single layer is usually sufficient, and this pattern is particularly efficient if the uterine wall is flaccid during repair of the incision. Alternatively, a Lembert suture pattern can be used with the needle passing at right angles to the incision, or a Cushing pattern, in which the needle passes parallel to the incision. Regardless of the suture pattern used, a rapidly involuting

• **Fig. 16.11** Utrecht uterine suture technique. (A) The initial knot is buried in a fold of uterine wall. (B) The round-bodied needle is directed at an angle oblique to the incision. (C) This suture pattern produces a continuous interlocking, inverting, watertight repair. (Adapted with permission from Turner AS, McIlwraith CW. *Techniques in Large Animal Surgery,* 2nd ed. Philadelphia: Lea & Febiger; 1989.)

uterus means there will be less tissue in each bite of suture material than at the time of suturing, which potentially may loosen the suture line. Many surgeons oversew the first suture line with a second continuous pattern, particularly if the uterus is friable and where the suture material has the tendency to tear through the tissues.

Once the uterine incision has been closed and the uterus checked for any tears, the surface is rinsed with sterile fluids (e.g., Hartman's solution) to remove any blood clots and other debris. The uterus is then returned to its normal position within the abdomen, ensuring that there is no twisting of the genital tract (see Fig. 16.12B). At this point, oxytocin (20–40 IU) may be administered intramuscularly to hasten uterine involution. However, uterine contractions induced by oxytocin may incite abdominal straining, which will make suturing of the flank incision more difficult. Often, it is better to wait until the surgery is completed. The abdominal cavity is inspected for large blood and fibrin clots; if present, these should be carefully scooped out by hand. The administration of a water-soluble antibiotic, such as crystalline penicillin, within the abdominal cavity is recommended by some surgeons, but not others (Cox 1987). Metronidazole should not be administered because its use is prohibited in food-producing animals in Europe and many other countries, despite having been recommended by some surgeons (Dawson & Murray 1992).

The intraabdominal use of carboxymethyl cellulose (CMC) has been studied in sheep and recommended for prophylaxis against postoperative uterine adhesions (Moll et al. 1992). Nowadays, CMC is widely used in abdominal surgery in large animals, particularly horses, to prevent the formation of bowel adhesions. However, its effectiveness as an adhesion prevention compound after Caesarean hysterotomy in cattle has yet to be proven.

Closing the Flank Incision

The peritoneal cavity should be closed as quickly as possible to reduce the chance of bacterial contamination. The abdominal flank incision is repaired in two layers: peritoneum and transverse abdominal muscle in the first layer, and internal and external abdominal oblique muscles in the second. A simple continuous suture pattern is used, starting at the ventral commissure of the incision. Care is taken to fully appose the peritoneum and transverse abdominal muscle to avoid leakage of air from the abdominal cavity into the muscle layers after surgery (Sloss & Dufty 1977). Air leakage is not as likely after surgery on a recumbent animal because less air has been sucked into the abdominal cavity during surgery. The amount of air present within the abdomen can be reduced by an assistant compressing the opposite ventral abdomen and flank immediately before closing the upper aspect of the peritoneal incision. Sutures should be placed approximately 1 cm apart, using absorbable monofilament suture material (e.g., chromic catgut, 3 USP or 7 metric). When suturing the muscle layers, more tissue of the internal abdominal oblique muscle should be incorporated in each bite, i.e., the needle should enter the external abdominal oblique muscle closer to the edge of the incision than is the case for the internal abdominal oblique muscle. This technique will ensure good apposition of the two muscle layers (Fig. 16.13). To reduce dead space between the suture lines, deeper bites with the suture can be made periodically into the deeper suture line (that of the peritoneum and transverse abdominal muscle), thus intermittently anchoring the suture into the underlying tissue. Infusing tissue friendly antibiotics between the suture layers may be considered. Before closing the skin, it is advised to place several simple interrupted tension sutures wide and deep through the full thickness of the abdominal muscle layers.

• **Fig. 16.12** (A) Placing the Utrecht pattern of sutures. The continuous, interlocking, inverting pattern is inserted using oblique bites that begin about 2 to 3 cm from the incision edge and that are inserted some distance back from the emerging previous bite. (From Kersjes et al. (1985) with permission.) (B) The repaired hysterotomy incision. (Courtesy Dr. Jakob Malmo.)

• **Fig. 16.13** Closure of the abdominal wall. (Courtesy Dr. Jakob Malmo.)

The skin incision is closed in a standard fashion, such as a simple interrupted horizontal mattress or cruciate pattern (Fig. 16.14), using a cutting needle and nonabsorbable suture material such as sheathed monofilament nylon (3 USP or 6 metric). Moderate tension should be applied to the sutures to bring the wound edges into complete apposition. This will ensure a good seal and promote first intention healing. In case of infection occurring the most ventral suture can then be removed to allow drainage and/or flushing of the wound. Although often described, the use of a continuous suture pattern, such as the Ford interlocking pattern (Fig. 16.15), is not recommended by the authors because of its associated risk of the suture line coming undone. Nowadays, this risk is markedly increased because the majority of cows are kept in loose housing systems or not housed at all.

Standing Lateral Oblique Approach

An alternative to the left paralumbar fossa approach in the standing cow is the left or lateral oblique approach, involving a slightly oblique incision from caudodorsal to cranioventral, about 45 degrees from vertical. The incision is started about 10 cm cranial and 10 cm ventral to the tuber coxae, extending cranioventrally to end about 3 cm caudal to the last rib (Fig. 16.16). The advantages of an oblique incision are that the internal abdominal oblique and transversus abdominis muscles can be split in the direction of their respective fibres and there is improved access to the genital tract (Cox 1987). Potential disadvantages are incision of the circumflex iliac artery if the incision is extended too far caudodorsally and lack of anaesthesia if too far cranioventrally when using paravertebral anaesthesia.

The abdominal wall incision should be closed in three layers, each of them in a simple continuous pattern. The peritoneum and

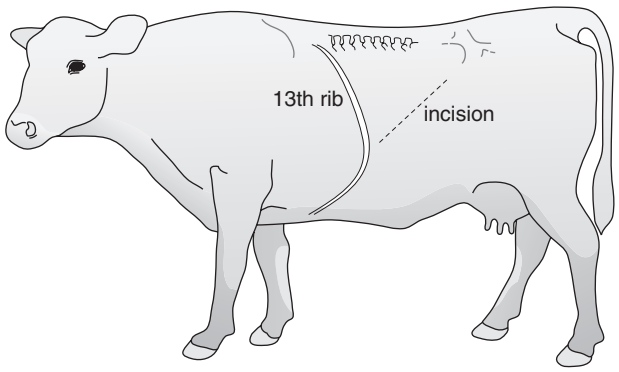
transversus abdominis muscle are incorporated in the first layer, whereas the internal and external abdominal oblique muscles are sutured separately. Herniation is less problematic with this approach than with the ventral approaches (Schultz et al. 2008).

The lateral oblique approach allows better manipulation and far easier exteriorization of the apex of the gravid uterus than the standard flank or paralumbar fossa approach. It has been suggested that this approach is preferable for Caesarean hysterotomy in the standing animal with a dead fetus (Parish et al. 1995). It also has clear advantages for surgeons with either smaller stature or less physical strength.



• **Fig. 16.16** Incision site for Caesarean hysterotomy: left flank – lateral oblique approach, used in the standing or recumbent animal.

Standing Right Paralumbar Approach

The right flank incision is uncommon; however, it is indicated if the left flank approach is obstructed by adhesions as a result of previous surgery. Although access to the uterus is good, the small intestine is difficult to retain within the abdominal cavity and interferes with the surgery. Most veterinarians purposefully avoid this approach; however, some surgeons believe that right horn pregnancies are more manageable using the right paralumbar approach. This approach may be helpful when a large calf can be palpated in the right horn with its limbs directed towards the right side of the animal and in cows with a life-threatening hydrops condition of the uterus (Schultz et al. 2008).

Recumbent Left Paralumbar Approach

This approach varies little from the standing left paralumbar approach. However, additional assistance will be required to cast the cow, if not recumbent already, and to position the animal in right lateral recumbency. The incision is made somewhat more ventral than in the standing left paralumbar approach. Exteriorization of the pregnant uterine horn is often quite demanding because the gravid uterus tends to fall away from the incision. Closing the flank incision is also more difficult, due to increased tension on the muscle layers.

Recumbent Right Paralumbar Approach

This approach is rarely used, as it is very similar to that of the recumbent left paralumbar approach. It has the additional complication of not having the rumen present to retain the abdominal viscera within the peritoneal cavity (Campbell & Fubini 1990).

The various ventral approaches are discussed later in this chapter under the heading of 'The Emphysematous Fetus'.

Postoperative Care

Calf

The calf should be dried and the navel dressed with an antiseptic immediately after delivery. Once surgery is completed, 2 to 3 litres of the dam's colostrum should be administered to the calf using an oesophageal feeding tube if necessary. The dam should

VetBooks.ir

be introduced to the calf promptly, particularly in the case of a suckler cow and calf, to form a maternal bond.

Dam

The wound should be cleaned after surgery; how ever, no wound powder, spray, or antiseptics are applied to normal skin incisions. The teats and udder are examined, and oxytocin (20–40 IU) is administered intramuscularly to stimulate further uterine involution. In addition, calcium borogluconate should be administered intravenously to mature dairy cows to prevent hypocalcaemia and further promote uterine involution. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) should be considered, at least in animals that have had severe dystocia, uterine torsion, or uterine infection before surgery. If there is evidence of surgical shock, the administration of intravenous fluids is indicated; 2 to 3 litres of hypertonic (7.2%) sodium chloride (4–5 mL/kg live weight) will be particularly effective. This should be followed by 20 to 25 litres of water given orally if the cow does not drink voluntarily. Systemic antimicrobial therapy should be directed towards the most common bacteria present in the postpartum uterus (i.e., *Trueperella pyogenes, Escherichia coli, Fusobacterium* spp. and *Prevotella* spp.) and should be administered for an appropriate period of time, usually 3 to 5 days or until the fetal membranes are expelled. Appropriate choices are procaine penicillin, ceftiofur, amoxicillin, ampicillin, and oxytetracycline. Many cows exhibit significant signs of pain after surgery (Kolkman et al. 2010) such that Barrier et al. (2014) recommended the routine use of meloxicam after surgery to promote a more rapid return of normal moving and lying behaviour patterns.

The dam is often reexamined 24 to 48 hours after surgery, at which time particular attention should be given to the animal's rectal temperature, demeanour, appetite, and faecal consistency. After surgery the faeces are often dry, and the cow may be mildly constipated. Pyrexia, depression, inappetence, and diarrhoea may indicate the onset of peritonitis. Normally, the faetal membranes are expelled 4 to 6 hours after delivery. However, appropriate treatment should be instituted if they are retained. Skin sutures should be removed no sooner than 3 weeks after surgery. In addition, a postnatal examination of the genital tract can be performed at the same time because endometritis is more common after Caesarean hysterotomy. Insemination should be delayed until more than 60 days after surgery.

The Emphysematous Fetus

Although fetotomy is generally the preferred procedure to achieve delivery of an emphysematous calf, a Caesarean hysterotomy is indicated when obstetrical manipulations or fetotomy is not possible. This may be because the uterus is contracted around the swollen calf, there is little or no uterine fluid present, the cervix is incompletely dilated or is constricting again, or the uterus is friable and therefore easily damaged. The veterinarian may also be inexperienced in carrying out a fetotomy.

In case of an emphysematous fetus, the main aim of Caesarean hysterotomy is survival of the dam; maintenance of fertility is of relatively little concern because of the life-threatening nature of the condition. Because it is often a salvage procedure, the welfare of the animal and cost to the owner are also important considerations. It is inappropriate to embark on a prolonged and costly Caesarean hysterotomy (or fetotomy for that matter) if the prospects for survival of the animal are poor. Hopeless cases or cases beyond the expertise and capabilities of the attending veterinarian should be recognized before the procedure is started and either the animal should be humanely destroyed or expert assistance sought.

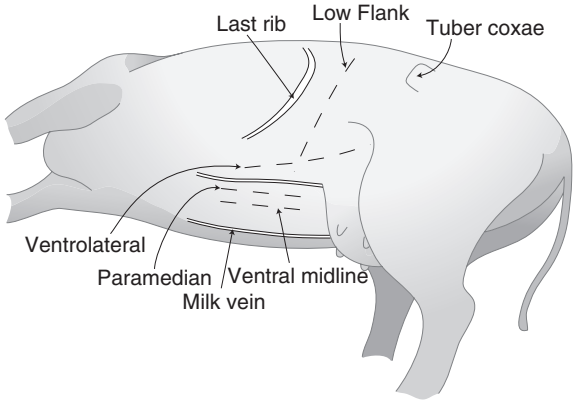
The most important rule in the management of an emphysematous fetus is not to panic. By the time the cow is presented, the question of how quickly the fetus is removed has little effect on the likelihood of the animal surviving. An emphysematous fetus is often associated with profound toxaemia and bacteraemia of the dam, resulting in fever, hypotension, dehydration, and shock. Therefore it may be necessary to first provide supportive treatment for cardiovascular stabilization and management of shock using intravenous fluids and NSAIDs.

In case of an emphysematous calf, exteriorization of the gravid uterine horn becomes crucial in order to avoid contamination of the abdominal cavity with infected uterine contents. In the standing animal, sufficient exteriorization is usually not possible and another approach (i.e., in the recumbent animal) should be used in which the uterus can be apposed more closely to the abdominal incision.

Recumbent Ventrolateral Approach

A ventrolateral incision is particularly indicated for the removal of an emphysematous fetus (Campbell & Fubini 1990). The gravid horn can be exteriorized more easily, but the incision may be difficult to close because of the tension on most tissue layers. Wound problems may also occur after surgery, such as breakdown and dehiscence or incisional hernia, because of the limited holding strength of the fasciae present in this part of the abdominal wall.

The cow should be cast in lateral recumbency with the pregnant horn nearest the incision. The hindlimbs are pulled caudally, and the upper hindlimb is abducted slightly to provide the best exposure to the incision site and more room in case the incision needs to be extended. An oblique abdominal incision in the lower flank, starting from the flank fold dorsal to the attachment of the udder, is continued cranially, parallel to the ventral border of the last rib; it more or less follows an imaginary line between the stifle and the navel (Fig. 16.17). In cattle with a large udder the incision can be extended caudally more easily than when a ventral midline or ventral paramedian approach is used. Therefore this ventrolateral approach may have particular value in dairy cows and older beef cows. Initially, the incision should be 30 to 40 cm long. When



• **Fig. 16.17** Alternative incision sites for Caesarean hysterotomy, all used in the recumbent animal and particularly suitable for extraction of an emphysematous fetus.

VetBooks.ir

necessary, it can be extended caudally towards the attachment of the hindlimb or cranially parallel to the subcutaneous abdominal vein (milk vein). As a precaution, this major vessel should be clearly identified and marked before the cow becomes recumbent, as it often collapses in recumbent animals.

The skin and external sheath of the rectus abdominis muscle are incised. The rectus abdominis muscle fibres are then bluntly separated in the direction in which they run. The internal rectus sheath is very thin, and its fibres are separated perpendicular to their orientation. The uterus lies directly underneath the incision, and an attempt should be made to exteriorize the entire gravid horn. If this is not possible, the abdominal wall should be pushed down and around the uterus. The uterus should be further isolated from the abdomen using drapes such as clean towels or plastic sheeting. The uterine wall is then incised and the emphysematous calf (with or without placenta) withdrawn from the uterus. After the removal of a grossly emphysematous fetus, the uterus is often noticeably ischaemic, of cardboard-like consistency, and totally atonic.

The uterine incision should be closed in a double layer, preferably using the Utrecht method, thus providing a secure closure, which is less likely to leak uterine fluids during contraction and involution of the uterus. The surface of the uterus (especially the suture line) should be thoroughly rinsed with an isotonic saline solution before returning it to the abdomen. The abdominal wall incision should be sutured in layers. The peritoneum and internal rectus sheath can be closed together. The rectus abdominis muscle is sutured (if possible) in a continuous pattern. The most important layer is the external sheath of the rectus abdominis muscle because it has the most tensile strength; it is best closed using a single interrupted or vertical mattress suture pattern. The skin is closed in a routine fashion. The integrity of the abdominal wall closure is less secure than that of either the ventral midline or ventral paramedian approach and therefore more prone to herniation (Schultz et al. 2008).

The advantages of the ventrolateral approach are that it gives good exposure of the uterus, even when it is friable, and that it minimizes the risk of uterine contents contaminating the abdominal cavity. However, repair of the abdominal muscle layers can be more difficult, particularly if the muscles are under tension, and sutures may tear through the tissues. A surgical drain may be inserted during repair of the wound.

Recumbent Ventral Midline Approach

The ventral midline approach (see Fig. 16.17) is not often used in the field because respiratory function may be compromised with the animal positioned in dorsal recumbency. Also, heavy sedation or general anaesthesia is sometimes necessary, and extra assistance will be required to cast and position the cow for this particular approach. Nevertheless, a midline incision provides excellent access to the uterus. Furthermore, the technique has the added advantage of the greater holding strength of the linea alba.

The cow should be positioned in dorsal recumbency, leaning towards the surgeon at a 30 to 45 degree angle, with both front- and hindlimbs secured to a post, gate, or wall. Such positioning is important because exteriorization of the pregnant uterine horn becomes difficult, if not impossible, if the cow is placed either in exact dorsal recumbency or leaning away from the surgeon. If the incision is properly made, the only body wall layers incised are the skin, subcutis, and the linea alba. When the peritoneal cavity has been opened, it may be necessary to pull the greater omentum cranially in order to adequately expose the uterus, after which the fetus is removed. Exteriorizing the uterus will be made easier by temporarily resting the hindlimbs flat on the ground, thus turning the abdominal incision closer towards the ground. After removing the fetus and suturing the uterus, the cow is returned into dorsal recumbency.

Closure of the abdominal wall is often problematic due to increased tension on the incision. Some surgeons prefer to close the linea alba in an everting, interrupted, horizontal mattress pattern using absorbable suture material such as polyglactin 910 (Schultz et al. 2008). Others choose to close the linea alba with braided, nonabsorbable suture material. Eversion of the linea alba allows the surgeon to oversew the linea with relative ease and safety. Other appositional suture patterns, including simple continuous and horizontal mattress, may also be used. No matter what suture material or pattern is used, the reliability of the abdominal wall closure is critical. Less than ideal closure may result in postoperative wound dehiscence, which has severe implications, including herniation or, in severe cases, evisceration. This approach should not be used when the large udder of older beef and dairy cows prohibits extending the midline incision sufficiently caudally to permit easier exteriorization of the uterus and when udder oedema and increased ventral vasculature make this particular approach more difficult.

Recumbent Ventral Paramedian Approach

In most aspects this approach is similar to the ventral midline approach (Turner & McIlwraith 1989). The abdominal wall incision is made parallel and approximately 5 cm lateral to the linea alba (see Fig. 16.17). However, the integrity of the abdominal wall closure may be less than that of the ventral midline approach, as neither the internal sheath of the rectus abdominis muscle nor the rectus abdominis muscle itself has substantial holding properties (Schultz et al. 2008). Also, closing a one-layer abdominal wall is easier and therefore preferable to a three-layer closure.

Recumbent Low Flank Approach

With the cow in left lateral recumbency, the incision is made from approximately 15 cm below the transverse processes of the lumbar vertebrae, extending down to just above the milk vein (see Fig. 16.17). The three abdominal muscles are sharply incised in the same direction. After the abdominal cavity is opened, the cow is pushed up into a near sternal position. Now, the pregnant horn is rolled out of the abdomen on to a large plastic sheet or apron, which had been sterilized or disinfected beforehand. The uterus is incised, its contents removed and the incision closed, using a double suture line. The flank incision is then closed as described for the left paralumbar fossa approach. Although this particular approach has not been tried and tested, it may be a useful alternative technique in the field for the surgical delivery of a grossly emphysematous calf.

Intraoperative Management

The emphysematous fetus presents an unavoidable risk of peritoneal contamination, not least because hair and hooves may already have been shed. In such cases, incision of the uterus is often followed immediately by the escape of gas and fetid fluid; parts of the fetus may be grossly swollen, dry, and crepitating on handling. The uterine wall is often tightly stretched, and intrauterine manipulation can be very demanding. Therefore it is essential to make the abdominal wall and uterine incisions of adequate length. Such a fetus often requires considerable traction, not only when using limb chains but also with sharp or blunt hooks applied in the orbits and at appropriate points on the trunk or upper limbs to secure additional purchase. Before

VetBooks.ir

removal is possible, it may be necessary to make several deep incisions at different sites over the fetal thorax and abdomen in order to release gas and, sometimes, to partially eviscerate the fetus. Incising the fetal abdominal wall may also be necessary in case of ascites. Sporadically, the fetus simply cannot be removed from the uterus because it is impossible to make a uterine incision of adequate length. In such cases a partial fetotomy through the laparotomy site may be attempted.

Success Rates and Complications of Surgery

Fetal survival after delivery by Caesarean surgery partly depends on the indication for surgery. However, Barkema et al. (1992) reported a calf mortality rate of 12% after Caesarean hysterotomy, compared with 5% for control calvings. In the study of Dobranic et al. (2001), the proportion of calves that were born alive was greater if the duration of dystocia was less than 12 hours.

Maternal survival rates after Caesarean hysterotomy are usually high; most surveys report 90% to 98% dam survival (Dehghani & Ferguson 1982, Cattel & Dobson 1990, Dawson & Murray 1992). Sellart and Campero (2008) reported a maternal survival rate of 97.4%. In a series of 1134 surgeries performed primarily for dystocia, Pearson (1996) reported an 88% maternal survival rate despite the fact that 37% of calves were dead at the time of surgery.

Cows that have emergency Caesarean hysterotomy are more likely to experience intraoperative and postoperative complications and are less likely to survive than cows that had an elective Caesarean (Newman & Anderson 2005). Thus, Bochard et al. (1994) found that the survival of the dam was influenced by the status of the calf: risk of maternal death was 63%, 21%, and 14%, respectively, if the calf was emphysematous, dead, or live. However, Vandeplassche (1963) reported that 80% of cows survived even when an emphysematous fetus was present. A more recent study of 103 cases of Caesarean hysterotomy performed in one predominantly dairy practice found that the 14-day cow survival rate was 80.6%, and of those surviving beyond this period, 55.4% carried another calf to term, 27.7% were culled due to infertility, and 16.9% were culled for other reasons (Lyons et al. 2013).

Complications associated with Caesarean hysterotomy are often due to difficulties encountered during rotation of the uterus, exteriorization of the pregnant horn, making the uterine incision, removing the calf, and suturing the uterine incision. Exteriorizing the uterus is the most common difficulty experienced during Caesarean hysterotomy: Hoeben et al. (1997) found that the uterus was difficult to exteriorize in 21% of surgeries and impossible to exteriorize in 6%. They also noted that the ability to exteriorize the uterus was associated with the experience of the surgeon. Failure to exteriorize the uterus is associated with reduced survival of the cow, especially if the fetus is dead.

Complications that have been reported to occur after Caesarean hysterotomy are:

Subcutaneous Emphysema

If the edges of the peritoneal incision are not fully apposed, air often leaks from the abdominal cavity into the subcutaneous tissues and muscle layers after surgery, causing emphysema (Sloss & Dufty 1977). In some cases it may extend as far as the shoulders. The condition is more common in animals that continue to strain after surgery, usually as a consequence of the dystocia. Although unsightly, it has no significant detrimental effect on the animal and treatment is not required. Usually, the gross appearance of the animal will return to normal in 1 to 8 weeks, depending on the amount of air that leaked into the tissues.

Metritis and Retained Fetal Membranes

Retention of the placenta occurs in 6% to 10% of cases of Caesarean hysterotomy. Dystocia, twins, uterine torsion, and fetal monsters are common indications for Caesarean hysterotomy; the procedure itself predisposes to retained fetal membranes. Removal of the membranes during surgery is rarely possible, but the placenta is normally expelled within 4 to 6 hours after surgery. However, if the membranes are still retained more than 24 hours after surgery, gentle attempts at removal can be carried out daily by exploration of the vagina only. The risk of retention of the placenta may be reduced by administering $PGF_{2\alpha}$ after removal of the calf (Stocker & Waelchli 1993). The intramuscular administration of antibiotics can be considered, although most literature recommends no treatment in uncomplicated cases. Once the membranes have been expelled, usually as a necrotic mass after approximately 7 to 11 days, gentle lavage of the uterine lumen with 5 litres of warm, normal saline can be carried out, using a sterile, wide-bore tube.

Adhesions

To date, no clinical research has documented any beneficial effect of prophylactic treatment, such as lavage of the uterus, NSAIDs, and intraabdominal antibiotics, to prevent adhesion formation in cattle. Still, it is not uncommon for adhesions to develop after Caesarean hysterotomy. Neither the suture pattern (i.e., Utrecht method, Lembert, or Cushing) nor the suture material (i.e., plain and chromic catgut, polyglycolic acid, and polyglactin 910) used to repair the uterine incision appears to be specifically important (Anderson 1998). However, the actual surgeon seems to have the greatest influence on the number and severity of adhesions that occur. The surgeon's speed, skill, and dedication are mentioned in the literature as being the best prevention against adhesion formation. Also, it is vital to obtain a good seal of the uterine incision, whenever possible, and to avoid excessive tissue handling, trauma, ischaemia, and haemorrhage.

The use of synthetic absorbable suture material, such as polyglactin 910 and polyglycolic acid, does not seem to offer any real advantage as far as the development of adhesions is concerned. However, from a surgical point of view, these materials have excellent handling qualities, are more pliable than catgut, hold knots well, and do not fray. They also have a higher guarantee of uniform material quality compared with a biological product such as catgut. Besides the high cost of synthetic suture materials, there is another important disadvantage. Their braided structure causes more drag as they pass through tissue, which may result in small tears, especially when the uterine wall is oedematous. Catgut, on the other hand, is more easily damaged by contact with the needle. This can cause the uterine suture to break, which would inevitably result in a severe peritonitis.

Nowadays, the trend among cattle surgeons is to use large-diameter (6 USP or 10 metric), plain catgut for closing the uterine incision. Although this material is more reactive than chromic catgut or the synthetic materials, it may actually result in fewer adhesions, possibly because of the associated time factor. Because of the abundant blood supply in the rapidly involuting uterus, the suture material is probably absorbed so quickly that adhesions have less chance to form compared with suture materials that remain *in situ* for longer periods of time. The knots are the last portion of the suture line to be absorbed, probably because

VetBooks.ir

cellular invasion is more difficult. Therefore burying the knots in folds of uterine tissue at both ends of the incision, as is achieved when using the Utrecht method, should always be the primary goal when suturing the uterus.

Peritonitis

Diarrhoea, pyrexia, inappetence, and abdominal pain are the common presenting signs of peritonitis after Caesarean hysterotomy. Fortunately, the omentum and/or the use of antimicrobial therapy often limit the spread of peritonitis within the abdominal cavity. In many instances, however, there are recurrent cycles of peritonitis and healing, leading to formation of extensive adhesions and chronic weight loss.

Inadequate repair of the uterine incision, particularly in the presence of a metritis, is the principal cause of postoperative peritonitis. However, in some cases, the peritonitis may already exist at the time of surgery. The incidence is increased in case of a dead or emphysematous fetus, after severe dystocia, rupture of the uterus, or presence of a fetal monster, and after spillage of infected uterine fluids into the abdomen during surgery. However, spilling small quantities of uterine fluid into the abdominal cavity during calf removal appears to be of little consequence to the outcome of the Caesarean hysterotomy no matter whether the fetus is alive or dead, but still fresh.

A variety of treatments have been suggested in case of peritonitis, including parenteral antibiosis, intraabdominal administration of antibiotics through the right flank, surgical lavage of the peritoneal cavity, and intravenous fluid therapy.

Wound Dehiscence

As many as 6% of animals may have complications related to dehiscence, abscess, or seroma formation around the abdominal incision (Dehghani & Ferguson 1982). Predisposing factors for wound dehiscence include inadequate asepsis, low abdominal incisions, overzealous handling of tissues during surgery, environmental contamination, tenesmus, and poor temperament of the animal after surgery. In addition, removal of skin sutures too early after surgery can lead to the incision line opening up; 3 weeks is a minimum period before removing sutures.

Serum-like fluid occasionally accumulates at the ventral aspect of the wound between the muscle layers if the dead space is not fully occluded; it usually resolves spontaneously or can be drained surgically.

In other cases, there may be formation of an abscess. In most instances, the abscess can be lanced, drained, and irrigated as a granulating wound, followed by second intention healing. Antibiotic treatment is usually not required but may be necessary if there is pyrexia.

Nerve Paralysis

Cows that are recumbent during surgery have the risk of temporary or permanent peroneal nerve injury. Animals that have been in lateral recumbency on a hard surface may suffer from radial paralysis. In addition, a number of cows may have sustained trauma to the obturator nerve as a consequence of dystocia before surgery. More often, however, femoral paralysis is encountered as a 'stretch injury' in large calves, mainly of beef breeds, after hip- or stifle-lock during parturition.

Fractures

The dam may sustain a fracture when attempting to rise after surgery. However, more common is for the calf to sustain a long bone fracture(s) or growth plate separation during attempts at correcting dystocia before surgery.

Postpartum Haemorrhage

Haemorrhage from the abdominal incision is usually limited, although dependent on the haemostatic concern of the surgeon. However, haemorrhage from the uterine incision can be considerable and in some cases fatal, especially when cotyledonary vessels are disrupted. Occasionally, the haemorrhage may be minimal during the surgical procedure, but may progress in the 24 hours after surgery. Furthermore, in sporadic cases the large vessels present in the broad ligaments may be damaged, causing considerable blood loss. Prevention of these causes of haemorrhage is by careful incision of the uterus (avoiding cotyledons), adequately supporting the uterus during surgery (especially when suturing the uterine incision), and close attention to haemostasis. Treatment of severe, life-threatening haemorrhage is by blood transfusion. In addition, 20 to 40 IU oxytocin may be administered repeatedly to stimulate uterine contractions in an attempt to reduce uterine haemorrhage.

Blackleg

Dehghani and Ferguson (1982) reported that 0.5% of cases died suddenly within 24 hours of surgery as a result of blackleg, with the muscle lesions located some distance from the surgery site.

Postoperative Fertility

Under normal circumstances the three main goals of the Caesarean hysterotomy in cattle are survival of the cow, survival of the calf, and maintenance of postoperative productivity, implying not only the maintenance of body condition and an acceptable level of lactation but also the ability to conceive again and sustain a developing fetus to term. Numerous data have been published on fertility rates after Caesarean hysterotomy, but their significance is qualified by the fact that many animals were culled without being inseminated or served again. In 10 such series, the percentage of cows that subsequently conceived postoperatively ranged from 48% to 80%, with a mean value of 72% for 2368 animals, compared with 89% for normal calvings (data cited by Boucoumont et al. 1978). Vandeplassche et al. (1968) reported that 60% of 1857 cows and heifers that had had Caesarean surgery were subsequently inseminated and 74% of these eventually conceived with an average of 1.8 inseminations per conception. However, there was an increased incidence of abortion, hydrallantois, and failure of the cervix to dilate at the next parturition, probably due to scar tissue in the uterine wall. Although the calving interval is increased in cows after Caesarean hysterotomy compared with normal calvings, the principal cause of economic loss is the higher culling rates (Barkema et al. 1992). Interestingly, in the latter study the calving-to-first-insemination interval was similar between Caesarean cows and control cows, but the calving-to-conception interval was 18 days longer. Lyons et al. (2013) reported a 14–day cow survival rate after Caesarean hysterotomy of 80.6%; of these, 27.7% were subsequently culled due to infertility. Reduced fertility may result as a consequence of increased incidence of retained fetal membranes and endometritis, uterine adhesions that hinder involution, adhesions that affect the ovary or uterine tube, and reduced competence of the endometrial tissue. In addition, there is an increased frequency of abortions during subsequent pregnancies, possibly as a result of scar tissue formation within the uterine wall, restricting the expansion of the uterus and/or nutrition of the fetus.

VetBooks.ir

Sheep, Goats, and Deer

Indications

The main indications for Caesarean surgery in the ewe, doe, and hind are similar to those in other species:

- Fetopelvic disproportion, particularly in primiparous animals with a single fetus
- Failure of the cervix to dilate (so-called 'ringwomb')
- Irreducible or severely traumatised vaginal prolapse
- Fetal emphysema after protracted dystocia

Less frequent indications are uterine torsion, vulvovestibular stricture, and faulty fetal disposition that cannot be corrected because of maternal immaturity or uterine contraction. Occasionally, a Caesarean hysterotomy is done to terminate pregnancy when the ewe suffers from pregnancy toxaemia. Vaginal prolapse should initially be treated conservatively by repositioning and inserting vulvar retention sutures in the hope that pregnancy will continue to term (see Chapter 10). However, many cases undergo early labour with incomplete dilation of the cervix. Unfortunately, lambs from such animals frequently die of prematurity, after showing characteristic convulsive limb movements and respiratory embarrassment. The success of Caesarean surgery in sheep is largely dependent on the early recognition of dystocia by the farmer. Sadly but not surprisingly, considering the economic value of most commercial ewes, the vast majority of Caesarean operations are carried out as a last resort. In the study by Brounts et al. (2004), over half (116 of the 201) lambs and kids delivered were dead or died shortly afterwards; this can be explained by the fact that 42 of the 65 dams had been in the second stage of parturition for more than 6 hours. In the authors' experience, however, ewe and lamb survival rates are high when surgery to relieve the dystocia is carried out promptly.

A common indication for Caesarean hysterotomy in deer is faulty fetal disposition that cannot be corrected by other means (e.g., lateral or ventral flexion of the head). Although fetotomy would be the preferred method to relieve this type of dystocia, this is not always possible.

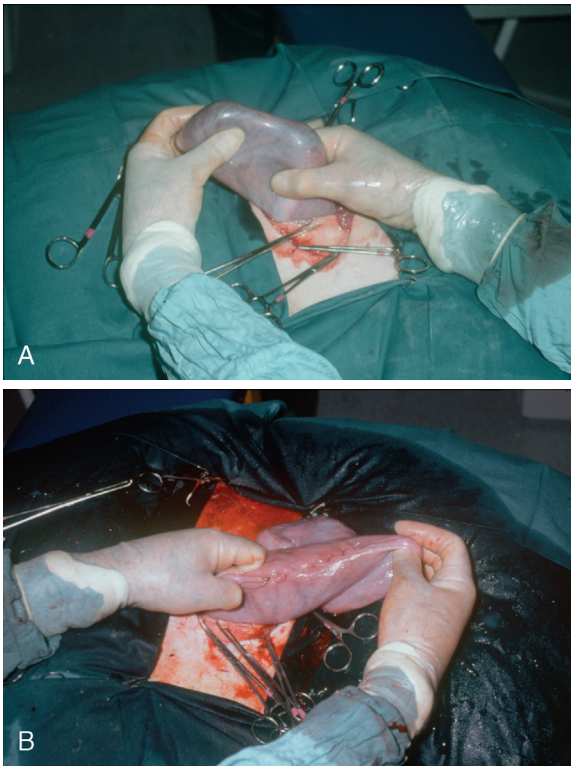
Anaesthesia

Hysterotomy is usually performed through a left flank incision under paravertebral, inverted-L nerve block or local infiltration analgesia with the animal positioned in right lateral recumbency, using 2% lignocaine. Caution is essential when inducing local analgesia in sheep because accidental intravenous administration or the injection of an excessive amount of lignocaine may cause convulsions. A lumbosacral epidural will also provide good anaesthesia, but one should be watchful for possible shock.

Operative Technique

The most commonly used surgical techniques are right lateral recumbency with a paralumbar incision, dorsal recumbency with a ventral midline or paramedian incision, and dorsal recumbency with a ventral abdominal incision located in the naturally denuded area above the udder. The first listed technique is the authors' preferred approach and is described later in this section. Using this approach, there is no depression of the fetus(es), and the ewe experiences less respiratory embarrassment than when positioned in dorsal recumbency. Some surgeons, however, favour the ventral abdominal approach because less wool needs to be removed from the surgical field (Ames 2014). In deer the authors' preference is for the right lateral recumbency approach with a mid paralumbar incision.

The ewe is positioned in right lateral recumbency with rope restraint. In case additional restraint is still needed, sedation with xylazine or diazepam can be used. The left paralumbar region is close-clipped and the skin prepared for aseptic surgery. In deer, it is best to remove the coarse hair with a pair of large animal clippers, as close shaving is difficult. The surgery site should be covered with a large, fenestrated, moisture-repellent drape. A vertical incision is made in the midparalumbar fossa, and the underlying muscles are incised in the same way as described previously for the cow. However, compared with bovine tissues, ovine tissues are more fragile and thin; they should be handled with care. In this context it is important to stress that the body wall is much thinner than in the cow, and thus care must be taken not to incise the rumen accidentally. With a high paralumbar incision it is also essential to identify the highly vascular mesometrial attachment to the parietal peritoneum. After brief exploration of the abdominal cavity to determine the number of lambs, a gravid horn is partly lifted through the abdominal incision. A fetal extremity, preferably the hock, is grasped through the uterine wall so that an incision can be made in the same way as that described for the cow (Fig. 16.18A). However, it is important to stress that more than a single fetus is likely to be the norm, potentially making identification of which extremity belongs to which fetus difficult. It is even more important to remember to explore the entire uterus, particularly the horn opposite to the one incised, to ensure that all lambs have been removed before suturing the uterine incision. Usually, it is possible to remove all lambs through a single uterine incision by manoeuvring the fetus(es) situated in the opposite horn around the uterine bifurcation.



• **Fig. 16.18** Caesarean hysterotomy in the ewe. (A) The exteriorized uterus over a fetal forelimb. (B) Hysterotomy repair with inversion sutures.

VetBooks.ir

The fetal membranes should be removed if they can be readily detached; if not, then the part(s) that cannot be returned to the uterine lumen, thus interfering with the closure of the uterine incision, should be trimmed off. The uterine incision is closed with a single, continuous inversion suture pattern, such as Utrecht's, Lembert's, or Cushing's (see Fig. 16.18B), using absorbable suture material, such as 0 USP (3.5 metric) or 1 to 0 USP (4 metric) plain or chromic catgut or a comparable synthetic suture, swaged on an atraumatic, round-bodied needle. After prolonged dystocia, oxytocin (3–5 IU) can be administered after uterine closure to promote contraction of the uterus and milk letdown. Each layer of the abdominal wall should be sutured in a continuous pattern with absorbable suture material. Skin closure is with a continuous interlocking or interrupted pattern using nonabsorbable suture material. Systemic antibiotics should be given as deemed prudent. Sheep, more than any other species, are highly susceptible to the toxaemic effects of intrauterine clostridial infection, and most deaths are due to this complication.

The techniques and approaches for Caesarean hysterotomy in goats and deer are comparable to those used in sheep.

Postoperative Fertility

Only scant information exists on the fertility of ewes and doe goats after Caesarean hysterotomy, because often ewes, and to a lesser extent does, will be culled either because they had the procedure done or because of the nature of the dystocia. Brounts et al. (2004) found that of the 16 ewes and does that were rebred (admittedly a very small percentage of the 110 that had Caesarean hysterotomy to relieve dystocia) all conceived, and none suffered subsequently from dystocia. This confirms the authors' experience with experimental ewes that fertility is not impaired to any extent, probably because of the seasonal pattern of reproduction with a long anoestrous period, allowing for adequate healing of the genital tract.

Horse

Casearean hysterotomy in the mare is still widely regarded as a serious and difficult procedure. Even so, the mare tolerates this surgical interference as well as most other species, and the recovery rates are generally good. However, there is little doubt that improved methods of general anaesthesia and postoperative care have greatly improved the chances of maternal recovery. Even in specialist equine hospitals in areas of high stud density, Caesarean hysterotomy is not a common procedure. Perhaps a reflection of overall improved anaesthetic and surgical techniques can be gleaned by comparing the observations of Vandeplassche et al. (1977), who commented that they performed 15 fetotomy procedures for every Caesarean, with those of Freeman et al. (1999a). In the latter study, performed at two university veterinary hospitals in the United States 22 years later, there were 66 Caesarean operations and 50 vaginal deliveries. This study indicated that Caesarean hysterotomy was preferable to delivery of the foal by controlled vaginal delivery under general anaesthesia in situations in which correction of the dystocia was difficult and prolonged.

If the foal is alive, the surgery should be carried out with minimum delay. If the fetus lies already in the maternal pelvic canal, it suffers fatal anoxia due to dehiscence of the allantochorion within 1 to 2 hours of the beginning of second stage labour. This observation is corroborated by the fact that 70% of foals born by hysterotomy at the University of Ghent were stillborn or died soon after delivery (Vandeplassche 1980). Resolute surgery in the field may therefore be more beneficial than referral to a specialist hospital setting. One particular complication of Caesarean hysterotomy in the mare is rupture of the uterine artery during manipulation of the gravid uterus (Threlfall 1997).

Indications

The range of indications is more limited than that in cattle. Cervical dystocia is not recognized in the mare, and fetomaternal disproportion and fetal monsters are less common than in other species. The major indication in the Ghent series, accounting for 39 of 71 cases, was bicornual pregnancy or transverse presentation, followed by other faulty fetal dispositions, complicated by injury, contraction, or infection (13 cases), and uterine torsion (10 cases). In a much smaller series of 34 cases at the veterinary school of the University of Bristol, uterine torsion was the most common indication.

With their considerable experience of equine dystocia, Vandeplassche et al. (1977) regard the following indications as absolute:

- Faulty fetal disposition that cannot be corrected by other means (e.g., transverse presentation)
- Vulvovaginal or uterine trauma
- Vaginal oedema
- Uterine torsion that is not correctable by a vaginal approach or by rolling the mare
- Severe congenital deformities (e.g., 'wryneck', ankylosed limbs, hydrocephalus)

In these forms of dystocia, Caesarean hysterotomy should be the primary method of delivery rather than a last resort.

Significantly, these authors also specify forms of dystocia that they consider as contraindications for surgery; these include lateral deviation of the neck, breech presentation of a dead fetus, twin dystocia, and prolapse of the maternal bladder.

Anaesthesia

Correction of preparturient uterine torsions can be carried out by laparotomy in the standing animal, using local analgesia or nerve block (Vandeplassche 1980). New and improved anaesthetic agents and better patient monitoring have significantly reduced the risk to the mare during Caesarean surgery performed at term. For details of anaesthesia in this species the reader is advised to consult a specialist textbook. It is important to stress that there may well be a conflict between the obstetrician and the anaesthetist because dorsal recumbency may induce 'supine hypotension' if the gravid uterus compresses the posterior vena cava, thus impeding venous return and reducing cardiac output. For this reason the mare should be placed in lateral or dorsolateral recumbency during preoperative preparation and retained in dorsal recumbency for as short a period of time as is appropriate for effectively carrying out the actual surgery.

Operative Technique

Potential surgical sites in the standing animal include right or left flank, using sedation and local anaesthesia. However, this approach is seldom used because of reduced exposure of the uterus, visible abdominal wall scarring, and the risk of animal movement during surgery (Threlfall 1997). The same flank approaches using general anaesthesia are also options, although some of the previously mentioned disadvantages (i.e., limited exposure and scarring) still remain. Possible surgical approaches in a recumbent animal include low incisions through either of the ventral flanks, the paramedian,

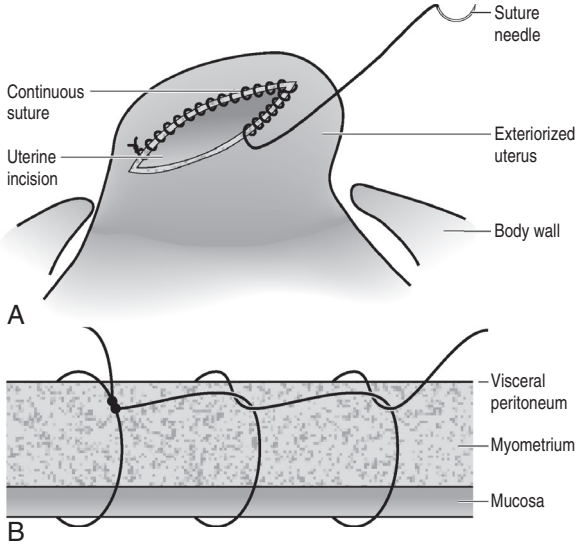
• **Fig. 16.19** The foal is removed from the uterus by the surgeon and assistant pulling on the hindlimbs.

• **Fig. 16.20** Physical separation of the allantochorion from the endometrium for several centimetres from the edges of the uterine incision.



• **Fig. 16.21** The use of a continuous lockstitch suture through the whole thickness of the uterine wall, from serosa to endometrial surface, as described by Vanderplassche (1973).

or ventral midline. The ventral midline incision is now widely adopted for gastrointestinal surgery. It is even more satisfactory for Caesarean hysterotomy because it provides excellent exposure of the uterus and considerably reduces intraabdominal pressure so the wound can be repaired easily without excessive tension on the suture lines. In addition, there is very little haemorrhage when this site is used. Sometimes, one or two large veins exist in this area, creating an anastomosis from the right to left subcutaneous abdominal veins (Threlfall 1997). If so, these vessels should be ligated before proceeding with the incision in the subcutaneous tissues. All other approaches necessitate muscle division, which results in greater operative haemorrhage and postoperative oedema. Provided that the midline incision is properly repaired, the risk of incisional hernia is negligible.

The mare's uterus is seldom so tightly contracted that a fetal limb cannot be grasped through the uterine wall and brought through the abdominal incision. For this reason a uterine incision of adequate length is easily made on the greater curvature of the gravid horn with little risk of tearing during manipulation of the fetus. The fetus is then extracted, making maximum use of joint flexibility, and gently supported outside the abdomen with its umbilical cord still intact (Fig. 16.19). The equine fetus is significantly less sensitive to 'pinching' stimuli *in utero* than the bovine fetus; therefore, fetal viability should be assumed until cord or heart palpation proves otherwise, unless the placenta has fully separated. If the foal is alive, the cord is left intact for several minutes until breathing begins. The cord is then ligated or preferably divided by stretching. If the foal is dead, the placenta may already have separated. It can then be easily removed through the uterine incision. In many cases, hysterotomy is followed immediately by profuse haemorrhage from the subendometrial plexus of arteries and veins, these being too numerous to ligate individually. As a means of controlling such haemorrhage, Vandeplassche (1973) recommended the insertion of a continuous suture through all layers of uterine wall along the edges of the uterine incision, immediately after the placenta has first been detached from the area near the incision (Figs 16.20 and 16.21). However, its value has been questioned and, in a study involving 66 mares in which the suture was used in 31 and not used in 35, the length of the surgical procedure was significantly shorter ($p < 0.05$) in the latter group, and there was no difference between the two groups for the numbers of mares that had anaemia after the surgery (Freeman et al. 1999b). Nevertheless, anaemia was found to be five times more common after Caesarean hysterotomy than after vaginal delivery. Therefore it is recommended that, if the suture advocated by Vandeplassche (1973) is not used, a full thickness simple continuous, continuous interlocking, or similar suture pattern is used that is sufficiently tight to compress the vessels in the uterine wall.

VetBooks.ir

If the placenta remains attached to the endometrium, it is better not to attempt manual separation because this procedure not only results in diffuse endometrial bleeding but also in the retention of microvilli, which predisposes to subsequent endometritis. The uterine incision is repaired using polyglycolic acid suture material in a Cushing pattern to invert the incision site. One or two rows are used, depending on whether the first row of suturing tears through the uterine wall, which is sometimes noticeably fragile. After the removal of clotted blood and other debris, a soluble antibiotic preparation may be sprinkled on the uterine incision.

The abdominal incision is easy to suture because of flaccidity of the stretched abdominal musculature. It is important to insert closely spaced sutures of appropriate material in a continuous or interrupted pattern. There is no need to stitch the peritoneum and layer of subperitoneal fat. The laparotomy repair is completed with a continuous subcutaneous suture and appropriate stitches in the skin.

Postoperative Management

After Caesarean hysterotomy, oxytocin should be administered to induce uterine contraction even if the placenta has been removed at surgery. In the study by Freeman et al. (1999a) the fetal membranes were retained in 65% of the mares, which included 22 out of a total of 116 that had a vaginal delivery to correct the dystocia; it was retained much longer in those mares that had elective surgery. Vandeplassche et al. (1971) recommend immediate oxytocin therapy followed by a supplementary slow intravenous infusion of 50 IU in saline if the placenta is not expelled within 4 hours. The latter method of administration probably has a more physiological effect. Experience suggests that oxytocin therapy in the mare is sometimes followed by excessively vigorous uterine contraction and eversion of the uterine horn into the vagina, threatening eversion through the vulva, even after the placenta has been expelled. Nevertheless, repeated administration of oxytocin (e.g., every 4 hours) is advisable to enhance uterine involution (Threlfall 1997). After oxytocin therapy, the placenta is usually expelled within 12 hours. In occasional cases it may separate but remain within the uterus and anterior vagina and is then easily removed through vaginal exploration. Nowadays, retention for longer than 24 hours is not regarded as an indication for immediate manual separation, provided that antibiotic therapy is maintained. However, removal may still be justified in draught-type mares, which are particularly susceptible to systemic reactions. Although intrauterine antibiotic administration may have a beneficial effect after removal of the placenta, more important by far is siphoning of any uterine fluid that accumulates, especially in mares that show signs of anaphylaxis or are not recovering satisfactorily. Vandeplassche et al. (1977) have commented on the 2- to 3-day delay in uterine contraction after Caesarean hysterotomy and recommend the breaking up of perimetrial adhesions per rectum at the end of this period.

In general, antibiotic therapy is provided pre- and postoperatively, especially if the foal has been dead for some time, which may have resulted in putrefaction.

Abdominal incisions in the horse are usually followed by local oedema of varying severity. After midline laparohysterotomy, diffuse subcutaneous oedema may extend along the ventral abdomen as far as forward as the presternal region; however, the swelling usually subsides slowly over a period of 7 to 10 days. The administration of diuretic agents appears to make the oedema disappear more quickly, but the necessity for such treatment is questionable. Wound infection is treated by removal of appropriate skin sutures to provide drainage.

Foal Survival, Maternal Recovery Rate, and Causes of Death

As has been mentioned previously, placental separation occurs rapidly in the mare; hence the delivery of a live foal from a Caesarean hysterotomy is uncommon unless it is elective surgery. Six out of 19 foals (Juzwiak et al. 1990) and 11 out of 102 foals were alive at the time of surgery, of which only five were alive at the time of discharge from hospital (Freeman et al. 1999a). Foal survival was much better after an elective Caesarean hysterotomy with a survival rate of 90%, although it fell to 38% if done concurrently with surgery to treat colic (Freeman et al. 1999a).

If the dystocia is of short duration, the prognosis for maternal recovery is good. In the Ghent series of 77 surgeries, 62 mares (81%) recovered (Vandeplassche et al. 1977). The Ghent data suggest that most deaths occur during or very soon after surgery and are attributable to shock caused by uterine haemorrhage or gross uterine infection. Haemorrhage can be largely prevented by haemostatic suturing of the uterine incision. The systemic effects of fetal emphysema and other forms of shock can be countered by intensive, intravenous fluid therapy during and after the surgery. Juzwiak et al. (1990) reported that 17 out of 19 mares survived postoperatively until the time of discharge, the most common complications being abdominal pain (13 mares), anaemia (10 mares), and retained fetal membranes (6 mares).

Because most deaths occur during the immediate postoperative period, the clinician is more likely to be worried by two particular complications that may develop within a few days after surgery. The onset of diarrhoea should be viewed with the greatest concern because body fluid loss is rapid and severe, and fluid reserves are soon depleted even if the mare continues to drink. The role of antibiotics in the pathogenesis of this disorder and their value in its treatment are unclear, but there is no argument about the necessity for immediate fluid replacement therapy to maintain hydration and normal electrolyte status. The other complication is laminitis, which has long been recognized as a sequel of placental retention in animals of the heavy draught breeds. The earliest sign of this supposedly anaphylactic reaction may be severe pulmonary oedema with dyspnoea and nasal regurgitation of fluids. Pedal pain is then manifested by reluctance to move or even stand, and without careful clinical examination the resultant recumbency during the early postoperative period may easily be mistaken for terminal illness justifying euthanasia. In such cases, accumulated uterine fluids should be removed immediately by careful siphoning. The use of diuretics is indicated for remedying severe oedema, whereas laminitis should be managed by dietary restriction and pain control.

Postoperative Fertility

Juzwiak et al. (1990) reported that 50% of mares bred after Caesarean surgery produced at least one other foal. Stashak and Vandeplassche (1993) found that, in a series involving 82 mares that had had Caesarean surgery, 34 (41.5%) were not bred again; of the 48 (58.5%) that were bred, 28 (58.3%) became pregnant. In the same study, of the 28 mares that became pregnant, 23 (82.1%) foaled at term; of those that did not, most aborted at various stages of gestation. Thus Caesarean surgery in the mare should not have too great an effect on subsequent fertility, provided it is performed

VetBooks.ir

quickly after the onset of dystocia and before there is heavy bacterial contamination of the uterus either from manual interference or from putrefaction of the foal. The report by Arthur (1975) of two mares that each conceived after two elective surgeries suggests that the hysterotomy per se is less important in this respect than the state of the fetus and the uterus at the time of surgery.

Pig

The sow, similar to the bitch, is a difficult obstetrical patient because it is not always possible to identify a particular cause of dystocia even after Caesarean surgery has been carried out, although the need for surgery may be quite clear. Under field conditions, Caesarean surgery is usually attempted after the sow has been in labour for at least 6 to 12 hours (Noordsy 1994). Generally, the prognosis for the dam and piglets becomes guarded to unfavourable in dystocias of 12 hours or more.

Indications

In a series of 57 surgeries reported by Renard et al. (1980), the major indications were: irreducible vaginal prolapse (32%); fetopelvic disproportion, including fetal emphysema (32%); secondary uterine inertia (23%); and, surprisingly, nondilation of the cervix (10%). Preparturient vaginal prolapse may be complicated by rectal prolapse and retroversion of the urinary bladder, and even of the gravid uterus. Such a prolapse has often undergone considerable trauma and marked oedematous swelling. A fresh prolapse at term does not necessarily interfere with parturition. However, in cases in which manual delivery is required, oedema rapidly develops and tissues tear readily. Uterine inertia of a primary or secondary nature is an important indication for surgery, and because of delay, the fetuses in such cases are often emphysematous. Primary inertia is frequently associated with 'deep-sided' sows and a hyperthermic environment (Noordsy 1994). Especially in cases of secondary inertia, it is not always easy to be certain that fetuses are still retained in the uterus. If they cannot be palpated or balloted through the uterine or abdominal wall and if fetal heart sounds cannot be detected, radiography or ultrasonography is advisable before surgery is undertaken. Less frequent clinical indications for Caesarean hysterotomy are maternal immaturity and pelvic deformity, torsion of one or both uterine horns, lacerations of the birth canal due to improper manual attempts to alleviate dystocia, and fetal deformities such as hydrocephalus or conjoined piglets. Preparturient elective hysterotomy is also performed as an alternative to gravid hysterectomy to obtain pathogen-free piglets, which are then fostered or reared artificially.

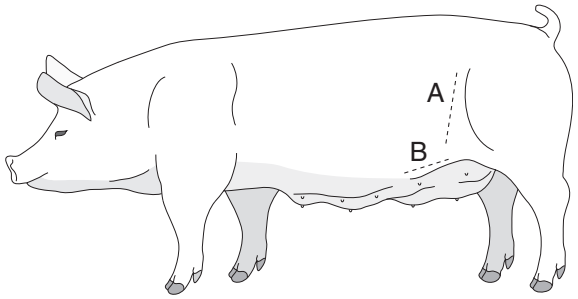
Anaesthesia

Because of difficulties in restraint, the surgery is generally performed using deep sedation and local analgesia or general anaesthesia. The best method under field conditions is a combination of azaperone (1.0 mg/kg) and ketamine (2.5 mg/kg) intramuscularly as a sedative, followed by intravenous ketamine (2 mg/kg) and midazolam (100 µg/kg) about 15 minutes later (Clutton et al. 1997). Once adequately anaesthetized, the sow can be intubated and the general anaesthesia maintained with oxygen/nitrous oxide/halothane. Alternatively, it is possible to perform the Caesarean surgery using local infiltration and the ability to 'top up' with further doses of the latter combination intravenously. Brodbelt and Taylor (1999) reported the use of two combinations of drugs injected intramuscularly, which is a much easier technique than the intravenous route. The combinations were azaperone (2 mg/kg), butorphanol (0.2 mg/kg), and ketamine (5 mg/kg) or detomidine (100 µg/kg), butorphanol (0.2 mg/kg), and ketamine (5 mg/kg). Although both combinations allowed endotracheal intubation, it is likely that Caesarean hysterotomy can be carried out with the use of local infiltration at the surgery site, i.e., without inhalation anaesthesia.

Renard et al. (1980) recommended the use of anterior (lumbosacral) epidural analgesia; however, they also reported a very high incidence of postoperative hindlimb paresis, which was attributed to lateral recumbency on a hard surface. Provided that the animal is adequately restrained under sedation, local analgesia or a paravertebral nerve block can also be successfully used, especially in toxic sows. However, it is important to avoid unnecessary struggle with hypotensive surgery subjects.

Operative Technique

Several different methods of restraint and approaches have been described, including right- or left-sided lateral recumbency restraint with either a vertical midparalumbar or horizontal low ventral incision (10–15 cm dorsal and parallel to the thickly developed mammary tissue), and dorsal recumbency restraint with a ventral midline incision (Noordsy 1994). A vertical paralumbar fossa or ventral flank incision on either side is the preferred site (Fig. 16.22). The choice between right or left side is that of the surgeon and is usually dictated by his/her dexterity. Anatomically, there is no obvious advantage for either side. The incision site should be clipped using a No 10 head set of small animal clippers and scrubbed for aseptical surgery. An adequate-sized, fenestrated, moisture-repellent drape is applied to the surgical area. A vertical incision is made in the midparalumbar region, large enough to allow easy insertion of the surgeon's arm. After cutting or spreading the muscle layers, the peritoneum will often bulge outward when exposed. It is grasped with forceps, punctured and then incised carefully because of its usually close contact with the underlying abdominal viscera (Noordsy 1994). Each gravid horn should be exteriorized in turn for incision outside the peritoneal cavity in order to minimize peritoneal contamination. A fetus is grasped within one of the uterine horns and brought through the abdominal incision (still enclosed in the uterus). The incision should be made longitudinally on the greater curvature of the uterine horn. If the fetuses are not emphysematous, it is usually possible to evacuate both horns through a single incision in the centre of each horn, with the piglets at the ovarian poles and the base of the uterine horns being squeezed down the horn and grasped through the incision. In cases in which the fetuses are emphysematous, multiple



• **Fig. 16.22** Position of skin incision for Caesarean surgery in the sow: (A) in the left paralumbar fossa or (B) ventral flank.

VetBooks.ir

incisions sited directly over or between them may be necessary. It is important to keep the uterine tissue moist during the surgery using a normal saline solution, with or without soluble antibiotics. The piglet's umbilical cord is long and, even without placental separation, forceps clamping or ligation is usually possible before division. Fetal membranes that have not separated should be left *in situ* and not forcibly removed by traction. Because the uterine horns are long, it is important to palpate the genital tract in its entirety to ensure that all piglets have been removed. The uterine incisions are repaired with inversion sutures, using 2 to 0 USP (3 metric) medium chromic catgut or a comparably sized synthetic, absorbable suture material, and a swaged, atraumatic needle. The sow's uterus, similar to the mare's, is apt to tear if the suture is pulled too tight, but this is of little, or no consequence if rapid contraction is induced by postoperative oxytocin therapy. Finally, the uterine horns are placed in the abdominal cavity in their normal position, making sure they are not accidentally crossed. Before closing the abdominal incision, Noordsy (1994) advises to administer intraperitoneal soluble tetracycline. The peritoneum and muscle layers are sutured separately, using a simple continuous suture pattern. Moderate tension should be placed on the muscle suture lines. The skin is closed with extra heavy, synthetic, nonabsorbable suture material (e.g., Supramid Extra), using a large, curved cutting-edge needle capable of easily going through tough pigskin without bending. An interrupted cruciate or a continuous interlocking suture pattern is appropriate, making sure to apply moderate to marked tension on the sutures. In addition to intramuscular antibiotics and oxytocin, it is recommended to administer NSAIDs in order to prevent possible shock.

Maternal Recovery Rate and Causes of Death

The maternal recovery rate after Caesarean surgery in the sow is usually quite good unless the fetuses and uterus are grossly infected. In a series of 78 unselected cases, Renard et al. (1980) reported a maternal recovery rate of 72%. Deaths are typically due to the combined effects of toxaemia and surgical shock and occur during the immediate postoperative period. Animals that are likely to die can often be identified as such before surgery because of a characteristic blotchy cyanosis of the limbs, ears, and udder. The adverse effects of peritoneal contamination are more easily avoided in the sow than in larger animals because the uterus can be exteriorized in its entirety during the surgery. Other frequent complications reported by Renard et al. (1980) include constipation, locomotion problems exacerbated by the sow's tendency to remain recumbent, and the mastitis–metritis–agalactia syndrome. Severe preoperative vaginal prolapse may recur after surgery and requires the insertion of a temporary retaining perivaginal suture.

Llamas and Alpacas

Nearly all information in this chapter relates to both the domesticated species of llama and alpaca. Differences are only the relative shorter normal gestation length of alpacas, and the smaller body size, birth canal, and term fetus (cria) of the alpaca (Johnson 1997). The birthing process in these camelids is quick and, compared with other farm animals, dystocia is an uncommon event. Studies in South America found that less than 2% of births required assistance and that 25% of these occurred in primiparous females (Bravo 2002). Caesarean surgery is indicated if labour has been protracted, fetal heart rate cannot be assessed, or the condition of the fetus or birth canal prohibits vaginal delivery. Unlike cattle, fetal maturity is highly variable in llamas and alpacas. For this reason, it is inadvisable to carry out an elective Caesarean operation in these species. If maternal conditions require surgical intervention (e.g., fractured pelvis), it is recommended to allow the dam to enter Stage I labour first.

Indications

The most common causes, and therefore indications, for Caesarean surgery in llamas and alpacas are in order of importance:

1. Faulty fetal disposition, with 70% of these occurring with the fetus in anterior presentation and 30% in posterior presentation (Bravo 2002)
2. Uterine torsion
3. Poor cervical dilation

Malpositioning of the fetal head (deviation to the side, to the back, or down) can be associated with rotation of the long neck, which is then commonly impacted into the pelvic inlet. Fetotomy or Caesarean surgery is needed to complete delivery of the fetus if this faulty disposition is further complicated by fixation of the cervical vertebrae ('wryneck'). Occasionally, Caesarean surgery may be necessary because of disparity between the dam's birth canal and the fetus. Most dystocias due to fetal malformation (e.g., schistosoma reflexus, ankylosis) require Caesarean hysterotomy.

Anaesthesia and Restraint

Because the majority (> 95%) of fetuses reside in the left uterine horn (Johnson 1997), restraint in right lateral recumbency and using a left paralumbar fossa incision seems appropriate. The ventral midline approach has also been recommended but is best carried out with the dam under general anaesthesia (Fowler 1998). With the dam sedated and restrained in right lateral recumbency, crias are likely to be more vital and maternal-neonate bonding also occurs more quickly (Anderson 2009).

Intravenous administration of butorphanol (0.03–0.1 mg/kg) will render most adult females very manageable. If necessary, based on maternal activity, xylazine (0.1–0.3 mg/kg) may also be used; this sedative can be readily reversed using tolazoline or yohimbine. In cases in which the animal is intractable, deep sedation may be necessary using a combination of ketamine (4.4 mg/kg) and xylazine (0.44 mg/kg), both given intramuscularly.

Operative Technique

The dam is haltered and positioned in right lateral recumbency, with the head and limbs safely tied to prevent unnecessary movement. After clipping and surgical preparation, lignocaine 2% is used to establish a line block at the site of the incision. It is important not to exceed 4 mg/kg total dose of lignocaine (1 mL/5 kg body weight) so as not to induce lignocaine toxicity (Anderson 2009). A 15-cm cranioventral (oblique) skin incision is made from approximately 8 to 10 cm cranial and ventral to the tuber coxae towards the last costochondral junction. After careful incising the three flank muscles, the peritoneum is pinched, lifted, and cut with scissors. With the left flank approach, compartment 1, spleen and left kidney are located against the abdominal wall and may be accidentally cut during entry into the abdominal cavity. The uterus is exteriorized through the flank incision and the fetus removed. In llamas and alpacas the uterine wall is surprisingly thin and care

VetBooks.ir

should be taken when opening the uterus so as not to cut into the fetus. Usually, the placenta is not easily removed and is best left in place to avoid excessive endometrial haemorrhage (Anderson 2009). A healthy uterus may be closed in a single layer with 0 USP (3.5 metric) plain catgut or a comparable synthetic suture material such as polydioxanone (PDS II suture). In case of an infected or otherwise compromised uterus, a double layer closure should be done to obtain an adequate serosal seal. Before returning the uterus into the abdominal cavity, any blood clots and fibrin are carefully rinsed off. Compared with ventral midline incisions, paralumbar incisions in llamas and alpacas carry a greater risk of postoperative incisional herniation. Therefore each of the muscle layers should be exactly restored with simple continuous suture patterns, using 1 USP (4 metric) polyglycolic acid suture (Anderson 2009). Chromic catgut or polydioxanone are good alternatives. Finally, the skin incision is closed in an interrupted or continuous, interlocking suture pattern, using 1 USP (4 metric) nylon or polypropylene suture material.

Broad spectrum antibiotics and NSAIDs should be routinely administered before surgery and continued for at least 3 days after surgery – longer if required. The use of oxytocin has been associated with abdominal pain in llamas and alpacas. Therefore caution is advised, and oxytocin should only be administered if the cervix is open (5 IU subcutaneously, every 2–4 hours, repeated 2–4 times).

Postoperative Fertility

Published information on success and fertility rates after Caesarean hysterotomy in llamas and alpacas is very limited. The rebreeding success rate is considered to be good, as long as the surgery is done early in dystocia and a sterile technique is used. Under these circumstances, Anderson (2009) expected that 75% of females that had had Caesarean surgery would return to normal breeding soundness.

Disorders of Parturition and the Puerperium in the Gilt and Sow

OLLI AARNO PELTONIEMI, STEFAN BJÖRKMAN AND CLAUDIO OLIVIERO

'Dystocia' or difficult birth is discussed across the species in Chapters 11 and 12, in which obstetrical terminology is defined, whereas the puerperium in all species is discussed in Chapter 7. The emphasis in both these chapters is on monotocous species, such as cattle and horses; the circumstances in polytocous species such as the pig are very different.

In the wild pig, which is considered to be the ancestor of present day farmed pig breeds, the duration of farrowing is short (1–1.5 hours), but the litter size is much small than that of the high prolific commercial sow lines used commercially today. In these, farrowing lasting longer than 5 hours is the norm (Björkman et al. 2017), whereas 10 years ago it was the upper limit for a normal successful farrowing (Oliviero et al. 2008).

Overview: Causes and Incidence Rates of Porcine Dystocia

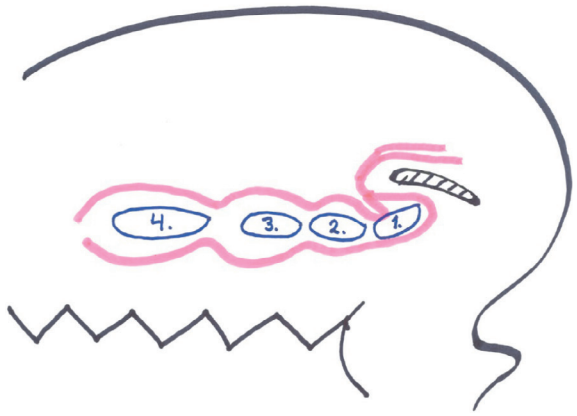
It is generally accepted that the shape of the porcine fetus and its small size in relation to the size of the pelvic inlet of the mother make the incidence of dystocia in sows lower than in other farm animals. Reports are: 0.25% (Jones 1966), 1% (Jackson 1972), 3 % (Randall 1972), and 5% (Waldmann 1993). A survey by Jackson (1972) showed that dystocia was of maternal origin in about 63% and of fetal origin in about 37% of the cases. Maternal causes were mainly uterine inertia (37%), obstruction of the birth canal (13%), and downward deviation of the uterus (9.5%). The relative incidence of the different forms of uterine inertia were: primary (20%), secondary (49%), and idiopathic (31%) inertia. Fetal causes were mainly faulty disposition (33.5%) and oversize (4%). Faulty disposition was caused by breech presentation (14%; faulty posture with both hindlimbs extended forward with the fetus in posterior longitudinal presentation), simultaneous presentation (10%), and postural defects in anterior presentation such as downward deviation of the head (3.5%). In another survey (Wehrend 2003) dystocia was 63% of maternal and 37% of fetal origin. Maternal causes were mainly due to uterine inertia (32%), oedema of the birth canal (9.5%), vaginal prolapse (7%), vaginal injuries (5.5%), obstruction of the birth canal (4%), uterine torsion (2.5%), and bladder flexion (1.5%). Fetal causes were mainly due to fetomaternal disproportion (26%) and faulty disposition (11%). Interestingly, a survey in Germany between 1982 and 1988 (Waldmann 1993) identified that dystocia was almost exclusively due to maternal causes: 78.6% of dystocias were caused by obstruction of the birth canal, 11.4% by prolapsed vagina, 4.2% by primary uterine inertia, 3.9% by uterine torsion, 0.7% by downward deviation of the uterus, and 0.5% by a prolapsed uterus; only 0.4% were caused by piglet oversize. In this survey, secondary uterine inertia was not considered as a cause. Another survey (Schulz & Bostedt 1995) showed that bladder flexion caused 3.1% and vaginal prolapse 6.3% of dystocias. Dystocia may also occur as a result of the use of prostaglandin F2α and oxytocin to induce or control parturition (see Chapter 8).

Dystocia Due to Obstructive Causes

Vaginal Prolapse. Vaginal prolapse (see Chapter 10) was the cause of dystocia in 11.4% of the cases in the study by Waldmann (1993), in 7% by Wehrend (2003), and 6.3% by Schulz and Bostedt (1995). In the latter study, 78.8% of vaginal prolapses occurred within 1 week before parturition and mostly in sows in their third or more pregnancy. In 21.2% of the cases there was concurrent rectal prolapse. The aetiology is not clear, but it is likely that hormonal imbalances, increased abdominal pressure, and/or very relaxed birth canal caused by instability of pelvic ligaments and/or connective tissue of the perineal area play a role. The vagina can be partially or totally prolapsed, which can be temporary or permanent. If the vaginal prolapse does not resolve spontaneously, treatment is indicated. Otherwise, swelling and oedema of the vaginal mucous membranes can stimulate further abdominal straining and therefore increase the risk of rectal prolapse and vaginal injury with subsequent infection.

Bladder Flexion. Jackson (1972) reported that bladder flexion can cause obstruction of the birth canal resulting in dystocia; he identified it in 13% of the cases. In the survey by Schulz and Bostedt (1995), bladder flexion was associated with 3.1% of dystocias and in the study by Wehrend (2003) with 1.5%. Bladder flexion occurs mainly in multiparous sows in their third or higher pregnancy (Schulz & Bostedt 1995, Jackson 2004) and within 1 week before parturition (50% of all bladder flexions in the survey by Schulz and Bostedt (1995)) or during parturition (Jackson 2004). It can be accompanied by rectal prolapsed, as it was the case in 31.2% of dystocia caused by bladder flexion (Schulz & Bostedt 1995). The aetiology of both disorders is similar. Jackson (1995) reported that it occurred in sows with a very relaxed birth canal and surrounding tissue, together with excessive straining.

VetBooks.ir



• **Fig. 17.1** Downward deviation of the uterus. The most caudal piglets *(piglets 1. and 2.)* create a bend in the uterine horn under the pelvic bone, creating a downward flexion of the horn and thus causing its obstruction.

The latter probably caused kinking of the urethra, resulting in urinary obstruction and bladder distention due the accumulation of urine. The distended urinary bladder was then further forced back into the pelvic cavity and thus ventral to the vaginal floor, causing it to be elevated and forming a 'mound', thereby obstructing the birth canal.

Downward Deviation of the Uterus. Downward deviation of the uterus occurred in 9.5% of dystocia cases (Jackson 1995) or only in 0.7% as in the study by Waldmann (1993). The incidence seems to be lower than that of both vaginal prolapse and bladder flexion, though it might be greater in modern highly prolific breeds. Affected animals strain vigorously despite an empty vagina, and at a point in front of the pelvic brim, the uterus deviates sharply in a ventral and caudal direction under the pelvic brim (Fig. 17.1). Affected sows are multiparous, with deep bodies and large litters (Jackson 2004). Causes may be primary uterine inertia and atony of the uterine muscle (Waldmann 1993).

Uterine Torsion. In a uterine torsion the uterus rotates on its long axis. No cases of torsion were reported in the study by Jackson (1972), but there were 3.9% and 2.5%, respectively, in the studies of Waldmann (1993) and Wehrend (2003). It appears to develop shortly before parturition (Waldmann 1993) and mainly in multiparous lean sows. The rotation can involve the uterine body, one uterine horn, or part of one uterine horn, thereby trapping a fetus or fetuses distal to the stricture. The torsion can be clockwise or anticlockwise, and the degree of torsion can be of 180 degrees to 360 degrees, although a complete torsion is very rare (Waldmann 1993). The uterine wall may rupture, and a fetus or fetuses may become pseudoectopic. Moreoften the torsion resolves spontaneously during parturition without any adverse effects.

Obstruction Due to Other Soft Tissue Abnormalities. Other obstructive causes are rare and variable. Furthermore, the precise classification is not always clear in published studies. Incomplete dilatation of the cervix during the first stage of labour seems to be uncommon. When it does occur, it may be the result of an antepartum infection of the placentae or the uterus. Incomplete dilatation at the end of the second stage of labour may become relevant in sows with prolonged parturition. Involution of the cervix can start 6 hours after the beginning of the second stage of labour. Although the cervix will be still open, the loss of elasticity, stretchability, and lubrication can lead to complications for the piglets entering and passing through the birth canal. Because in modern highly prolific sows the duration of parturition is on average 6 hours (Björkman et al. 2017), this cause of dystocia may now be more relevant.

Another soft tissue abnormality that may be increasingly relevant is severe swelling and oedema of the birth canal which can occur in prolonged parturitions, after an obstetrical examination, and/or piglet removal, particularly if the procedure is not done gently (Björkman 2017). The birth canal is very delicate, fragile, and susceptible to trauma. In cases in which there are a large number of piglets entering the birth canal simultaneously followed by manual extraction of piglets, the mucous membranes may react with increased swelling. Furthermore, the mucous membranes can be more easily damaged. Thus in sows with large litters and prolonged parturition, there is an increased need for manual interventions, and dystocia caused by swelling and oedema of the birth canal may be more relevant. In addition, there is evidence that sows with a large litter also have higher oestrogen concentrations in the blood (Edgerton et al. 1971, Kensinger et al. 1986), especially before parturition, resulting in severe oedema of the vulva (Waldmann 2009).

Obstruction Due to Bony Tissue Abnormalities. Obstruction caused by bony tissue abnormalities, e.g., pelvic constriction, are very rare and only cause dystocia when they occur in gilts which have been bred at a too young age (< 200 days) and a too low body weight (< 90 kg) (juvenile pelvis); they rarely occur in sows after fractures, in which there has been poor alignment of the pelvic bones. Gilts should be between 220 to 270 days old, and a body weight of 135 to 170 kg, a backfat depth of 12 to 18 mm, and a body condition of about 3, when they are bred for the first time (Rozeboom 2015). If these recommendations are followed, the incidence of dystocia due to a juvenile pelvis should be very low.

Obstruction Due to the Piglets. Jackson (1972) reported that 37.5% of dystocias were due to a fetal cause. These were due mainly to faulty fetal disposition (33.5%) and oversize (4%). In the study by Waldmann (1993) no fetal causes of dystocia was reported. 57% of the piglets were born in anterior longitudinal presentation, whereas 43% were born in posterior longitudinal presentation. Posterior presentation is not itself a cause of dystocia, unless the piglet is oversized. Currently, fetal causes of dystocia are minimal. It may occur in gilts bred at too young an age or with low body weight (see previous mention), or in which the litter is small. Infection, with porcine parvo virus, can cause small litters. In sows with large litters the smaller piglets can be expelled even when their fetal disposition is incorrect and as a result, simultaneous presentation of two piglets may become more frequent. Congenital abnormalities are very rare; they may include: arthrogryposis, hyperostosis, hydrocephalus, conjoined piglets, schistosoma reflexa, syndactyly, polydactyly, and micromelia (see Chapter 9). Arthrogryposis is characterised by ankylosis of various joints, in various degrees of flexion or extension, as well as the vertebral column resulting in lordosis, kyphosis, or scoliosis. Hyperostosis is stiffness of the forelegs, with enlarged elbow joints and cartilaginous thickening of proximal bones of the forelimbs.

Inadequate Expulsive Force

Primary Uterine Inertia. Primary uterine inertia is defined as the absence of or deficient myometrial contractions (see Chapter 13). Primary uterine inertia, which is the absence of or reduced contractility of the myometrium, was present in 7.5% of dystocias (Jackson 1972) and in 4.2% in Waldmann's study (1993). In toxaemic sows there may be signs of systemic illness before farrowing

VetBooks.ir

with a foul-smelling vaginal discharge, which is sometimes associated with infections such as porcine parvovirus. Nontoxaemic sows are usually healthy, with a dilated cervix and fetuses palpable within the birth canal but with the absence of contractions. It may be caused by hormonal abnormalities, such as an increased progesterone to oestrogen ratio, and/or deficiencies of oxytocin and prostaglandin secretion and/or their receptors, and nutritional factors, for example diets low in fibre and high in energy. Other less common causes, such as calcium deficiency, have been reported (Framstad et al. 1989). The inability of sows to be able to express normal nest-building behaviour may be an important primary cause of uterine inertia. It has been shown that lack of space and absence of available nest-building materials can be an important stressor in sows, thereby decreasing oxytocin secretion, and the resultant reduced uterine contractility will eventually increase the duration of farrowing (Oliviero et al. 2008).

Secondary Uterine Inertia. Secondary uterine inertia is more common than primary inertia, usually occurring as a result of another cause of dystocia, usually obstructive but also associated with a prolonged parturition particularly associated with a large litter.

Management

Inappropriate Use of Exogenous Oxytocin. Oxytocin is widely used to augment normal uterine contractions. Its uterotonic has been demonstrated by Mota-Rojas et al. (2005a), who showed that exogenous oxytocin increases the number, intensity, and duration of myometrial contractions. However, its use has been shown to have negative effects on the outcome of farrowing, for example increased incidence of intrapartum asphyxia and stillbirths (Mota-Rojas et al. 2002, Alonso-Spilsbury et al. 2004, Mota-Rojas et al. 2005b) and the duration of piglet expulsion. Several studies (Welp et al. 1984, Chantaraprateep et al. 1986, Dial et al. 1987, Alonso-Spilsbury et al. 2004) have shown that oxytocin can increase the frequency of dystocia and therefore the need for subsequent obstetrical assistance. However, most of the adverse effects have been associated with its use when not truly indicated, e.g., at the beginning of fetal expulsion when oxytocin concentrations and oxytocin binding sites in the endometrium and myometrium are high (Lundin-Schiller et al. 1996, Phaneuf et al. 2000). The time of administration is appropriate when the expulsion of the last piglet was at least 30 minutes ago, and if the obstetrical examination showed that piglets are still present within the uterus but none are within the birth canal. Furthermore, the birth canal should be fully dilated and unobstructed.

Body Condition. There is a negative correlation between the amounts of backfat and farrowing duration (Oliviero et al. 2010). The fatter the sow, the longer the duration of farrowing. The reason may be that increased backfat reflects the level of fatty infiltration of the tissues of the birth canal, resulting in a reduction in the diameter of the birth canal, as well as predisposing to secondary uterine inertia. Another reason may be that a higher level of fat is known to affect lipid-soluble steroids and may affect the progesterone to oestrogen ratio, a consequence of which is that it affects oxytocin receptor activation. Abnormalities due to oxytocin receptor activation may weaken the expulsive phase of parturition. This hypothesis is supported by the observation of Oliviero et al. (2008), who observed that fat sows had a delayed decline in peripheral progesterone concentrations beyond day 1 after parturition. Furthermore, Björkman et al. (2017) observed a negative correlation between backfat and the depth of the uterine wall antepartum, which could be the result of a delayed decline in progesterone or a higher progesterone to oestrogen ratio, which could impair the degree of myometrial hypertrophy during pregnancy and hence before parturition.

Constipation. There is a negative correlation between constipation and farrowing duration (Oliviero et al. 2010). The more constipated the sow, the longer the duration of parturition. The reason may be that constipation results in an accumulation of faeces in the rectum that causes a physical obstruction to the passage of the piglets, resulting in secondary uterine inertia. Another reason may be that constipation may result in impaired uterine contractions due to the effects of lipopolysaccharides. Lipopolysaccharides are endotoxins produced by Gram-negative bacteria that increase around the time of parturition and are associated with constipation. Endotoxins can be absorbed from the gut and influence the normal endocrine changes associated with farrowing, resulting in primary uterine inertia. A third explanation may be that the discomfort and pain associated with constipation may also influence the hormonal changes associated with parturition. Studies have found that opioids inhibit oxytocin during parturition (Bicknell & Leng 1982, Douglas et al. 1995. Brown et al. 1999). Therefore pain due to prolonged constipation could promote the release of opioids and, consequently, impair oxytocin secretion, thus reducing myometrial contractions.

Dystocia: Examination

History of the Sow. Before examining an individual sow with suspected dystocia, it is important to obtain details of her previous farrowing history, if appropriate, by examining her records for breeding and obstetrical history; these may be manually or electronically recorded. Details include general health, number of litters and their sizes, and duration of previous gestations.

Duration of Farrowing. The timescale before intervening in the process of parturition is critical. Knowing the normal physiology and behaviour of the particular sow and her immediate cohorts is important. Previous studies (Oliviero et al. 2008) have reported the average values for the duration of farrowing were 200 to 300 minutes, which were considerably longer than those reported earlier. However recent data suggests that with ever increasing litter numbers, there is a concomitant increase in the duration of farrowing. Björkman et al. (2017) have recently reported that in highly productive sow lines, the average duration of farrowing was 400 minutes, which was influenced by parity and number of stillborn piglets. Thus classifying a sow as suffering from dystocia according to the 5-hour principle as occurred 10 years ago is not applicable now. By providing the sow with an open farrowing pen and adequate amounts of suitable nest-building material, and dispensing with farrowing crates, reduces the duration of farrowing by approximately 90 minutes (Oliviero et al. 2008).

Inter Piglet Interval. The decision on when it is appropriate to intervene will depend on a number of factors, e.g., if the interpiglet interval is prolonged at the beginning and end of the second stage of parturition, if the piglet fetus is large, especially some males, and if it is dead.

General Examination. Frequent observations of the sow before farrowing should enable the signs of impending farrowing to be detected. General examination may include measuring body temperature; it normally increases above 39°C 24 to 48 hours before the birth of the first piglet and heart rate peaks before and during parturition. Nesting behaviour is greatest 6 to 12 hours before the first piglet is born. Palpation of the mammary gland for the composition and presence of colostrum, which normally runs

VetBooks.ir

freely during parturition, appearing first in the cranial pair of the mammary glands some hours before beginning of parturition. After the onset of the second stage of labour and as it progresses, the number of piglets born, as well as their vitality and uniformity, should be assessed (Oliviero 2010).

A lack of uniformity in the weight of new born piglets may be an indicator for a large litter; low piglet vitality may indicate a prolonged inter piglet interval. Large litters may result in uterine inertia, and prolonged interpiglet intervals may be indicative of endocrine imbalances or obstructive dystocia. Continuous straining by the sow without piglet expulsion, bleeding, or an abnormal vaginal discharge, including meconium staining of the piglet as well as loss of movement immediately after birth (see piglet vitality scoring later in this chapter) are indicative of disturbances of farrowing.

Intervention Criteria. As discussed previously, if the inter piglet interval is longer than 2 hours or the overall duration of farrowing is longer than 5 hours, it is indicative of dystocia. Although the criteria for intervention may have changed in recent years, intervention should always be based on the history and health of the sow and the piglets that have been born.

Obstetrical Examination

Rectal Palpation. This should be considered before the vagina is examined for number of reasons. Provided it is performed carefully, it is easily performed, using a gloved hand and plentiful lubricant, and safe. By performing the procedure, one of the potential causes of obstruction of the birth canal, namely a hard faecal mass due to constipation can be removed. It also reduces the likelihood of vaginal faecal contamination during subsequent vaginal examination. Rectal palpation has limitations because it is only possible to reach the body of the uterus and caudal parts of the uterine horns.

Vaginal Examination. This should be done carefully and cleanly using a gloved hand/arm and with plentiful amounts of lubricant. Once the hand is in the birth canal, the mucosa of vagina, cervix, and uterine body should be carefully palpated for any signs of possible damage, including swelling of the mucosa, which readily occurs after an obstructive dystocia. Cranial to the uterine body, the caudal parts of the both uterine horns should be palpated to determine the presence of downward, ventral torsion of uterine horns, which is typical in a sow with a large litter.

Ultrasonographic Examination. Real time transabdominal ultrasonography is very useful as part of an obstetrical examination to identify the number of fetuses present within the uterus, as well as detecting their heartbeats, thus indicating the number that are alive.

Dystocia: Treatment

Uterine Inertia. As described previously, this is the commonest cause of dystocia, occurring in over a third of cases. Clinical examination will show that no fetuses can be palpated in the birth canal, and uterine contractions cannot be detected. Initially, if possible, the sow should be encouraged to stand and move around even outside the farrowing pen. The sow should be treated with oxytocin at a dose of 5 to 10 IU i.m for a maximum of 2 to 3 times; the time interval between the successive injections should not be less than 30 minutes. As a last option, manual palpation of the cervix may be tried to stimulate the release of endogenous oxytocin.

Use of Oxytocin in Prolonged Farrowing. In prolonged farrowings, the overuse of oxytocin may expose those fetuses still within the uterus to hypoxia because oxytocin reduces blood flow through placenta and also increases the risk of a ruptured umbilical cord and thus the severance of blood supply to the fetus. It is well documented that piglets appear vulnerable to asphyxia during parturition, and the increasing litter size appears as a common denominator for this.

Downward Deviation/Torsion of the Uterine Horn. Large litters seem to predispose the sow to downward deviation/torsion of the uterine horn (Figure 17.1). In the sow, in contrast to other larger domestic species, the twisting of the caudal part of the uterine horn is due to the caudal fetuses becoming positioned ventral to the pelvic bone.

Prevention of Dystocia

As described previously, dystocia in sows is relatively rare compared with other multiparous species. Dystocia adversely affects piglets' survival, thus there is an increase number of stillborn piglets as well as those that are considered to be 'hypovital' (Alonso-Spilsbury et al. 2007). It also affects the survival of the sow (Sanz et al. 2007), as well as her subsequent fertility (Oliviero et al. 2013). For all these reasons, it is important to attempt to prevent dystocia throughout the course of pregnancy until the start of farrowing. For example, maintaining good body condition and preventing constipation are important. These factors, unlike mechanical and obstructive causes of dystocia, can be influenced to some extent by proper management and feeding strategies.

Endogenous Hormonal Balance at Farrowing

Modern housing and production systems have promoted the confinement of sows in crates during farrowing, whereby the sow's movement is severely restricted, and she is allowed limited bedding. As a consequence, nest-building at the best is limited or does not occur at all. The sow's innate behaviour of nest-building is induced by the decline in progesterone and the increase in prolactin prepartum (Algers & Uvnäs-Moberg 2007). As well as these endocrine changes, 6 to 12 hours before farrowing oxytocin increases before peaking at parturition to stimulate effective contractions of the uterus and, as a consequence, rapid birth of the piglets (Taverne et al. 1979, Lawrence et al. 1997). There are studies showing an increase in farrowing duration and stillbirth rate when innate behaviours, such as restricting nest-building by the absence or limited availability of the necessary materials, as well as limiting the mobility of sows by confinement and restraint by the use of the farrowing crate (Oliviero et al. 2008 and 2010, Gu et al. 2011). Allowing the sow to move freely before and during farrowing reduces the duration of farrowing by an average of 100 minutes, thereby reducing the risk of stillborn piglets. A combination of a free pen and the provision of abundant nest-building material increased the circulating level of oxytocin and prolactin before farrowing (Oliviero et al. 2008, Yun et al. 2015). Therefore it is recommended that sows are allowed to move freely to perform natural nest-building behaviour and to provide nest-building material such as straw, hay, sawdust, and paper sheets. This will help to ease the parturition process, reducing risks of prolonged farrowing that may have negative consequences for the sow and her offspring.

Feeding in Late Pregnancy

During late pregnancy, to ensure that sows receive enough energy to satisfy the demands of forthcoming milk production, sows

VetBooks.ir

are usually fed with high energy concentrated diets (Einarsson & Rojkittikhun 1993). Such concentrated diets, which have a much more limited amount of fibre than standard pregnancy diets, can promote obesity and constipation. These two conditions are associated with prolonged duration of farrowing and an increased stillbirth rate (Oliviero et al. 2010). Late pregnancy diets should contain up to 7% to 10% of fibre, in order to reduce constipation and excessive fat deposits (Oliviero et al. 2009). The use of high fibre diets appears to be a beneficial strategy to improve the health of the sow around farrowing (Peltoniemi et al. 2016). If the diet cannot be easily modified, a good fibre source can be provided by offering different types of roughage (straw, hay) or adding any other feedstuffs with high levels of fibre, such as sugar beet pulp (Quesnel et al. 2009). Offering roughage may not only be a way to increase fibre intake and alleviate constipation and obesity, but it can also serve as an appropriate material for nest-building. Preventing sows becoming excessively fat in the last part of pregnancy can be achieved by encouraging sows to be more mobile by allowing them more space, with strategic feed distribution and with provision of interactive substrates like straw or hay. A reduction in feed intake by the sow (up to 50%) may be implemented during the last week before farrowing, which also helps to prevent constipation, as well as other physiological and behaviour aberrations around the time of farrowing.

Disturbed Parturition and the Neonatal Piglet

Introduction

During the last two decades there has been emphasis on the development of highly prolific pig breeds in many countries, resulting in substantial increases in litter size (Bjerre et al. 2010, Paredes et al. 2012). In order to improve the productivity of sows, a better method would be to select breeding stock based upon the number of piglets weaned. However, due to the common practice of crossfostering small piglets at an early age of life, the total number piglets born has been the preferred method of selection (Su et al. 2007). Litters with greater than a total of 16 born piglets have been associated with higher stillbirth rates (1.5 piglets) compared with litters of 11 to 12 total born piglets (0.6 piglet), and piglets in larger litters also have lighter birthweights (Boulot et al. 2008). Comparing similar litter sizes, Canario et al. (2006) found the probability of stillborn piglets in large litters to be almost twice as high as in a reference litter. Large litters are also associated with longer farrowing times, a higher risk of fetal hypoxia during birth (Herpin et al. 2001), and higher within litter weight variation (Milligan et al. 2002). Piglets' mortality after birth and before weaning have ranged from 11% to 24% in several countries, and the mortality is mostly observed in the first 5 days of life (Pedersen et al. 2011, KilBride et al. 2012). The main causes of death included crushing, low viability, starvation, and diseases. These levels of preweaning mortality represent a challenge to modern pig production and also a concern for animal welfare.

Weak and Stillborn Piglets: Causes and Consequences

Different studies have reported that stillbirths rates vary between 3% to 10% of all pigs born (Borges et al. 2005, Cutler et al. 2006, Oliviero et al. 2010, Vanderhaeghe et al. 2010). According to the time of death, stillbirths can be classified into: type I, in which fetuses die before the end of gestation (antepartum or prepartum deaths), due to infectious causes; type II, in which piglets die during parturition (intrapartum deaths) due to noninfectious causes, such as intrauterine asphyxia and dystocia (Sprecher et al. 1974).

TABLE 17.1 Number of stillborn piglets according to housing type (n = litters)[a]

Housing	Number of Stillborn	Average Duration of Farrowing (min)	n
Pen	0.6 ± 0.8	208 ± 58	89
Crate	1.1 ± 1.1	297 ± 130	133

[a]Summary of three studies (Oliviero et al. 2008, 2010; Gu et al. 2011).

One cause of type II stillbirths is large litter size (> 16 total born piglets) as previously discussed. Another cause is housing. Both housing and stillbirth rate relate to farrowing duration (Table 17.1). Farrowing duration > 300 minutes was associated with a higher stillbirth rate, compared with the duration of farrowings of <200 minutes (Oliviero et al. 2008 and 2010, Gu et al. 2011). According to the review by Vanderhaeghe et al. (2013), large litter size, high parity, excessive thin or fat sow's body condition, and limited or no farrowing supervision/birth assistance seem to be the most relevant factors in increasing the stillbirth rate.

Thermoregulation is challenging for neonate piglets, and this competence is highly correlated with their vitality after birth. They are born wet, covered by fetal fluids that allows for heat loss by evaporation, so it is important that they quickly dry. They have very little pelage to insulate against heat loss, and they lack brown fat that could be metabolised to generate heat and balance their body temperature (Berthon et al. 1994). Thus newborn piglets are very vulnerable to the effects of environmental temperature and can only use metabolic responses to reduce heat loss if their body temperature is >34°C (Lossec et al. 1998). The main metabolic responses are mobilisation of free fatty acids, shivering, and a modest gluconeogenesis using their own liver's glycogen reserve. The latter is available and metabolised within a maximum of 15 to 20 hours in starving piglets (Svendsen & Bengtsson 1986, Lossec et al. 1998). Pedersen et al. (2011) found that piglets with a rectal temperature of 36.1°C, 2 hours after birth, had greater odds of being crushed by the sow, whereas in those with a rectal temperature of 38.6°C, the odds were reduced.

Herpin et al. (1996) demonstrated that piglets that suffered from hypoxia due to rupture of the umbilical cord or detachment of the placenta during parturition were less viable and needed more time to reach the sow's udder (120 ± 35 vs 25± 3 min). They also showed a reduced ability to maintain the body temperature (36.3 ± 0.9 vs 38.4 ± 0.1°C) during the first 24 hours of life. In contrast to older animals, the early neonatal piglet does not increase its energy intake in response to cold temperature. In fact, colostrum intake decreases by 36.8% during cold exposure (18° – 20°C) compared with piglets at an ambient temperature between 30° to 32°C, thus exacerbating the likelihood of starvation (Lay et al. 2002). Kammersgaard et al. (2011) found that a birth weight >1.1 kg was the most important single factor in successful recovery from postnatal hypothermia. In addition, Milligan et al. (2002) found that birth weight >1.3 kg was positively correlated with higher piglet preweaning survival. It has been shown that the birth process and individual characteristics influence the piglet's

VetBooks.ir

thermoregulatory mechanism. However, in the environment of a modern farrowing unit, with different zones at different temperatures, it is heat preservation rather than mere heat production that determines thermoregulatory success and recovery from postnatal hypothermia (Kammersgaard et al. 2011).

Assessment of Neonatal Vitality

Piglet vigour postpartum, in addition to birth weight, is crucial if the piglet is to acquire colostrum and preserve homeothermy (Baxter et al. 2008). Piglet vigour appears to be independent of birth weight, suggesting that small, but proportional, piglets that display high vigour can survive the vulnerable perinatal period (Baxter et al. 2008). The same authors propose the use of a categorical scale to visually assess and score the piglets' vitality immediately after birth (Table 17.2), which can be predictive of the survival rate of the neonate piglets after birth. In large litters, piglets can suffer from intrauterine growth restriction (IUGR) during uterine development. These piglets have a 'dolphin-like' head shape compared with 'normal' piglets (Fig. 17.2; Hales et al. 2013). Piglets with a 'dolphin-like' head shape ingest insufficient amounts of colostrums and hence have lower glucose levels at 24 hours. In addition, they have less glycogen reserves in the liver (Amdi et al. 2013). These factors combined suggest that if piglets are born with a dolphin-like head shape, they have a lower chance of survival. Identifying IUGR piglets on their head shape and evaluating the vitality score at birth can provide a rapid and simple method of deciding which piglets need extra support to maximise neonatal survival (Amdi et al. 2013, Baxter et al. 2008).

Management and Supportive Therapy of Neonates

Piglets should be quickly dried soon after birth and placed in a suitable environment to minimise their body heat loss. This can

TABLE 17.2 The vitality score of piglets immediately after birth

Vitality Score	Description
0	No movement, no breathing after 15 sec
1	No movement after 15 sec, piglet is breathing or attempting to breathe (coughing, spluttering, clearing its lungs)
2	Piglet shows some movement within 15 sec, breathing or attempting to breathe
3	Good movement, good breathing, piglet attempts to stand within 15 sec

Adapted from Baxter et al. 2008.

Individual physical characteristics of neonatal piglets affect preweaning survival of piglets born in a noncrated system. *J Anim Sci.* 91: 4991–5003.)

VetBooks.ir

be done using insulated nests, floor heating pads, heating lamps, or combinations of these. A second important step is to ensure that the whole litter has sufficient individual colostrum intake (200 – 250 g) within 12 to 16 hours from the beginning of parturition (Devillers et al. 2011). When possible, small and weak piglets should be assisted to suckle, by helping them to attach to the teat, thus ensuring that colostrum is ingested. It is important to remember that small piglets have difficulty in sucking from big teats, therefore the smallest functioning teats should be selected when assisting suckling. This procedure should be repeated 3 to 4 times within the first few hours if these piglets are not seen actively suckling. Additionally, weakly piglets can be hand fed with colostrum collected from their own mother, or other sows, within 6 to 12 hours from the beginning of farrowing. At this stage, milking by hand is relatively easy, due to the almost continuous (every 5–40 min) milk ejections (Algers & Uvnäs-Moberg 2007). Piglets can be hand fed using a feeding bottle with a suitable nipple or using a syringe connected to a soft silicone plastic tube (3–4 mm in diameter) that is inserted in the oesophagus and then stomach, and administering 20 to 25 mL of colostrum. The correct length of the tube can be assessed and subsequently marked, by measuring it against the piglet from the tip of its nose to the last rib. Great care is necessary to avoid intratracheal intubation insertion and injury to the larynx. Assisted suckling and hand feeding is appropriate in small or normal size litters when only one or two piglets require help. In large litters or when more piglets require assistance, a split suckling strategy could be more effective. In order to minimise the sibling competition for colostrum intake, the litter is split into two groups. The heavier and stronger piglets are kept in the creep area or in a separate box, allowing the smaller piglets to suckle for 60 to 90 minutes, and then the groups are switched. When separating the piglets, both groups should always have free access to a warm creep area. This can be easily achieved by using a box with an additional heat lamp for the separated group, which leaves the creep area accessible for the remaining group to suckle. If some small piglets are still unable to successfully suckle, assisted suckling should be combined with split suckling.

Colostrum Uptake

Because of the epitheliochorial nature of the porcine placenta (see Chapter 4), neonate piglets lack maternal IgG at birth. They must acquire maternal immunoglobulins from ingested colostrum for passive immune protection before they produce their own immunoglobulins at around 3 to 4 weeks of age (Rooke & Bland 2002). However, colostrum is produced only during the first 16 to 24 hours after the start of parturition, and even after the first 6 hours, the IgG content in colostrum is halved (Le Dividich et al. 2005). Acquiring adequate colostrum at the right time and in the required amount can be a challenge because of sibling competition, protracted farrowing, and reduced piglet viability. All these factors have a major effect in large litters (Devillers et al. 2007). The same authors found that individual colostrum intake ranged from nil to >700 g during the first 19 hours of life (450 g/kg birth weight), indicating that the capacity for colostrum intake can be high when its supply is unrestricted. In large litters, an ad libitum supply of colostrum is rarely available to all piglets, and probably 200 to 250 g intake per piglet provides sufficient protection. Devillers et al. (2011) found that the preweaning mortality rate was 7.1% when piglets ingested >200g of colostrums, and increased to 43.4% when intake was <200 g. Thus it is not the piglets' intake capacity that is the limiting factor in satisfying the passive immunity requirements, but the production of adequate colostrum by the sow. Colostrum yield is highly variable; it averages 3.3 to 3.7 kg, ranging from <1.5 kg to greater than 6.0 kg (Devillers et al. 2007, Quesnel 2011). However, Andersen et al. (2011) found that, without human assistance to piglets (such as drying, placing under a heat lamp, cross fostering, movement to a nurse sow, split- or suckling assistance), it can be difficult for many sows to adequately nurse more than 10 to 11 piglets. Furthermore, Quesnel et al. (2012) suggested that the genetic selection for higher prolificacy is one of the major causes for the increase in low birth weight of piglets and poor vitality. Insufficient colostrum production has been found to be associated with impaired hormonal status of the sow at farrowing. Abnormal high levels of circulating progesterone (< 4 ng/mL) in blood of sows at farrowing have been related to poor colostrum yield (Foisnet et al. 2010, Hasan et al. 2016a).

Evaluation of Colostrum Quality

Hasan et al. (2016b) have recently proposed the use of Brix refractometer to evaluate the IgG content of sows' colostrum content. Based on the study by Quesnel et al. (2015) and in the review by Hurley (2015), the IgG content in sows peaks within 2 hours after the start of farrowing, with a mean concentration of 64 mg/mL (range: 50–80 mg/mL), whereas it decreases to around 10 mg/mL at the end of colostrogenesis (24 hours after the start of farrowing). By using a Brix measurement on the farm, it might help to identify sows with an impaired IgG concentration and allow improved management of lactating sows and neonate piglets. This procedure should be done during early colostrogenesis (0–3 hours after start of farrowing), when colostrum is easiest to collect and when peak levels of IgG occur (Hasan et al. 2016). On the contrary, low IgG levels (10 mg/mL) are not expected to be found during early colostrogenesis. Taking the lower range of the peak IgG level as 50 mg/mL, it should be a fairly reliable point to assess that adequate levels of IgG are present at this stage. Table 17.3 shows a suggestion for the evaluation of the Brix refractometer results. Brix values <20% reflect very low levels of IgG, whereas values >25% reflect good or very good concentrations of IgG. Values between 20% and 24%, defined by the authors as borderline, should not be considered as being inadequate for the IgG content, especially if the Brix values are in the highest range (23% – 24%). Conversely, levels in the lowest range (20% – 21%) might be considered more critical. When borderline results are obtained, the authors suggest taking another sample within 1 to 2 hours, to evaluate if the development of the estimated IgG content is stable.

TABLE 17.3 Colostrum IgG content based on two methods of evaluation, and categories of estimation

Brix %	ELISA IgG 0–3h, mg/mL, average ± SEM	IgG estimation categories
< 20	14.5 ± 1.8	Poor
20–24	43.8 ± 2.3	Borderline
25–29	50.7 ± 2.1	Adequate
≥ 30	78.6 ± 8.4	Very good

Abnormal Parturition and Reproductive Health

Effect of an Abnormal Parturition on Health of the Uterus and Mammary Gland Postpartum

There is enough evidence which suggests that a prolonged or abnormal farrowing predisposes the sow to poor reproductive health during the puerperium. When parturition is prolonged, placental retention is more likely to occur with consequential metritis (Björkman et al. 2017). It is also known that, if there is dystocia or farrowing is prolonged, there is an increased frequency of constipation and decreased circulating oxytocin concentrations (Oliviero et al. 2008), both of which predispose to disorders such as postpartum dysgalactia syndrome (PDS).

Retained Fetal Membranes. The time interval between the expulsion of the first and last placenta (placental expulsion duration) has been reported in sows as 4 hours and 4.5 hours (Björkman et al. 2017), and 2.5 hours in gilts (van Rens & van der Lende 2004). Van Rens and van der Lende (2004) showed that an increase in the duration of farrowing was significantly associated with an increase in placental expulsion duration. Björkman et al. (2017) showed that the duration of placental expulsion was mainly affected by the use of exogenous oxytocin during parturition. If the latter was used, then the litter size had the main effect on the duration of placental expulsion, probably due directly to the actual number of placentae that need to be expelled, which increases with increasing litter size. If exogenous oxytocin was not used, the farrowing duration was associated with the placental expulsion duration, confirming the observations made by Van Rens and Van der Lende (2004). Nevertheless, this association was observed only in sows with a farrowing duration of < 700 to 800 minutes. If the farrowing duration was longer, placental expulsion was severely compromised, which occurred in about 6% of the sows. Fifty percent of these sows had a partial retention of their placentae due to either a delayed onset of placenta expulsion and/or an early abortion. Another 50% of them expelled no placental parts and therefore had total retention (Fig. 17.3.); in these sows the average duration of farrowing was 1000 minutes. The most likely cause of impaired placenta expulsion in sows with a prolonged farrowing is secondary uterine inertia. This is supported by the findings of Oliviero et al. (2008) and Castrén and colleagues. (1993), who showed that increased farrowing duration is associated with decreased oxytocin levels. In addition, it is also supported by the observation that moderate use of oxytocin towards the end of the second phase of the parturition had a significant effect on reducing the duration of placenta expulsion (Björkman et al. 2017). If retained placentae can be expelled later during the puerperium, or are absorbed within the uterus, or expelled at the subsequent oestrus is not known.

Delayed Uterine Involution. Initially, uterine involution is very rapid during the first week postpartum (Fig. 17.4) when the uterine weight is reduced by 65% (Palmer et al. 1965). Thereafter, uterine involution continuous progressively and uniformly and is completed during the third week postpartum (Palmer et al. 1965, Kudlac & Groch, 1979, Schnurrbusch 1998, Busch 2007). During the initial period, uterine weight loss is mainly due to atrophy and resorption of intraluminal fluid, whereas after the initial period, uterine weight loss is mainly due to changes in the myometrium, notably a reduction in cell numbers, cell size, and amounts of connective tissue; this has been described as 'reorganisation' (Busch 2007). Björkman (2017) showed that transabdominal B mode ultrasound can be used to assess the course of the initial stages of uterine involution, by assessing uterine size, echotexture, and content (Fig. 17.5). Schnurrbusch (1998) defined a uterine weight of 500 to 700 g as being indicative of the completion of uterine involution, though Kauffold et al. (2005) and Busch (2007) reported a uterine weight of 1.5 kg. However, although uterine weight is an indicator of the successful completion of uterine involution, it is not necessarily a good indicator for subsequent fertility (Kauffold et al. 2005).

During the third week postpartum, many authors reported an increase in uterine weight for the length of the uterine horns (Busch 2007). Busch (2007) interpreted the increase in length and weight of the uterus during week three postpartum as tissue proliferation due to increased oestrogen production by developing follicles and considered that it was a sign of completion of uterine involution. Delayed uterine involution may cause subsequent fertility problems if sows are bred after a short lactation of, for example, 3 weeks. Björkman (2017) reported that prolonged parturition, multiple stillborn piglets, obstetrical intervention, and retained placentae can delay uterine involution. On the other hand, exogenous oxytocin

hastens uterine involution (Björkman 2017). Compared with the uterus, involution of the cervix is very rapid and completed within 1 week (Busch 2007, Kudlac & Groch 1979).

Resumption of Ovarian Function. Weaning sows immediately after parturition (zero-weaned sows) or <3 weeks postpartum results in a higher incidence of anoestrus and a longer weaning-to-oestrus interval, ovulation failure, or a reduced litter size (Peters et al. 1969, Elliot et al. 1980, Varley & Atkinson 1985, Soede et al. 2009). Sows that fail to ovulate either show follicular regression, with a short/intermittent oestrus, or develop ovarian cysts. If sows are weaned >3 weeks, 98% of them show oestrus signs within a normal weaning-to-oestrus interval of less than 7 days, of which 98% ovulate (Knox & Rodriguez Zas 2001). Anoestrus and cystic ovaries in sows weaned at <3 weeks may be due to the lack of a preovulatory LH surge. The lack of the LH surge is believed to be due to high levels of corticosteroids observed in early weaned sows (Ryan & Raeside 1991) or an impaired responsiveness to a positive feedback of estradiol-17β at the hypothalamic–pituitary level (Soede et al. 2011). The impaired responsiveness may be related to depleted LH stores just after farrowing that will progressively restore during lactation (Crighton & Lamming 1969, Bevers et al. 1981). LH concentrations and the number of LH pulses remain low during days 4 to 14 and gradually increase thereafter (Stevenson et al. 1981, Shaw & Foxcroft 1985, De Rensis et al. 1993b). Besides the restoration of LH pulsatilty, follicular development during early lactation is suppressed and characterised by a large population of small-sized follicles (< 3 mm) and a small population of medium-sized follicles (3–4 mm) (Britt 1985). During the second week postpartum the number of small-sized follicles increases, and during the third week the overall number of follicles and the number of medium-sized follicles increases (Busch 2007). Nevertheless, a preovulatory LH surge will not occur before weaning because suckling and piglet proximity stimulates opioid release (De Rensis et al. 1993b). These opioids inhibit the GnRH pulse generator through neuroendocrine reflexes and therefore the LH secretion. If and how uterine involution affects the restoration of LH concentrations and pulsatility, and therefore follicular dynamics at the ovary, is not known. The restoration of LH-pulsatility and the shift in the follicular pool occur around the same time that uterine involution is complete – during the third week postpartum. Thus it is possible that uterine involution plays a role in the restoration of LH pulsatility and therefore follicular activity. Other factors that affect the degree of LH suppression are the suckling intensity and the energy balance of the sow (Soede et al. 2011).

Postpartum Dysgalactia Syndrome, PDS. PDS is the major puerperal disease in pigs. It affects both the sow and neonatal piglets during their first 1 to 3 days of life. It is characterised by insufficient colostrum and milk production by the sow and, as consequence, results in reduced intake by the piglets during the first days of their lives.

Martineau et al. (1992) listed the symptoms that may be present in the sow and the piglets, resulting in reduced herd productivity. In the sow the common general symptoms include fever (> 40°C), loss of appetite, and lethargy. The local symptoms are observed as inflammation of the mammary glands, dysgalactia, and metritis. In piglets < 1 week old, there is increased mortality, diarrhoea, and increased heterogeneity in the litter, and for those more than 1 week old, there is increased heterogeneity of the litter and low weaning weights. For the herd there is a reduced number of piglets/sow/year. PDS is considered to be a multifactorial disease involving different pathways.

The current hypothesis is that interactions between endotoxin produced by Gram-negative bacteria in the gut, mammary gland and/or uterus, and alterations in the immune and endocrine functions, play a central role in the development of PDS (Maes et al. 2010, Martineau et al. 2012).

In the study by Bostedt (1998), 24.4% of gilts suffered from a feverish puerperal illness; 24.4% exclusively showed signs of mastitis; in 29.5% there was a combination of mastitis and an inflammatory infection of the genital tract; 46.1% of the cases had only infection of the reproductive tract. Predominantly E. coli, followed by Staphylococcus spp. and Streptococcus spp., were isolated from the genital tract. The prominent role of E. coli has also been shown in puerperal mastitis, and therefore E. coli is considered the causative pathogen for agalactia in the majority of cases (Gerjets & Kemper 2009). This is supported by a study of Nachreiner and Ginther (1974) that challenged periparturient sows with lipopolysaccharide (LPS) endotoxin of E. coli and in which sows generated symptoms similar to postpartum agalactia.

There is actually little information available about if, and how, farrowing affects PDS. There seems to be a connection between a prolonged duration of farrowing and PDS. For example, both have common risk factors. These are: (1) constipation (Peltoniemi & Oliviero 2015, Hermansson et al. 1978, Martineau et al. 1992, Oliviero et al. 2009); (2) increased back fat (Göransson et al. 1989. Oliviero et al. 2009); (3) no farrowing supervision (Papadopoulos et al. 2010, Björkman et al. unpublished); (4) restricted space in farrowing crates (Bäckstrom et al. 1984, Cariolet 1991, Oliviero et al. 2008); and (5) farrowing induction (Papadopoulos et al. 2010, Smith 1982). Furthermore, associations between prolonged farrowing and general signs of PDS (Tummaruk & Sang-Gassanee 2013, Bostedt et al. 1998), such as fever, anorexia, and metritis (Björkman 2017) have been demonstrated. There seems to be an effect of farrowing duration on puerperal diseases. In a study by Tummaruk and Sang-Gassanee (2013), the percentage of sows with fever during the first 24 hours postpartum increased from 40% to 100%, when the farrowing duration increased from <2 to 4 to 8 h. Furthermore, until the third day postpartum, the percentage of sows with reduced appetite was higher than in sows with a farrowing duration 4 to 8 hours than in sows with <4 hours. A study by Bostedt et al. (1998), which examined gilts suffering from a feverish puerperal illness, found that the farrowing duration had a significant effect. Of the sows, 85.9% of sows with consequent puerperal illness had farrowing durations of >6 hours, whereas

VetBooks.ir

78.8% of control sows completed parturition in <3 hours. Other significant factors affecting the incidence of feverish puerperal illness were the frequency of obstetrical intervention and the stillbirth rate. The frequency of obstetrical intervention measured in the group of sows was 27%, whereas it was 9.5% in the control group. The stillbirth rate was significant higher in the ailing group than in the control group. Björkman et al. (unpublished) have linked exactly the same factors with puerperal metritis. When the birth canal was palpated and/or piglets removed manually, the incidence of puerperal metritis increased. The same association was found with the number of stillborn piglets. Furthermore, retained retention of placentae was shown to increase the incidence of puerperal metritis significantly.

Manipulative Delivery *per vaginum* in Dogs and Cats

GARY C. W. ENGLAND

Introduction

Faulty fetal disposition, together with a smaller number of cases of moderate fetal oversize, fetal malformation, and fetal death, account for approximately 25% of cases of dystocia in bitches and queens. There are breed differences in causes of dystocia (O'Neill et al. 2017), and in some breeds the morphological features of the fetus will certainly necessitate a Caesarean hysterotomy. Nevertheless, some cases of fetal dystocia may be amenable to vaginal manipulation and traction, depending on the cause where they obstruct within the birth canal. In some cases manipulation may be attempted as a first line before implementation of a Caesarean hysterotomy (Münnich & Küchenmeister 2009). There is, though, an important place for manipulative obstetrical procedures to treat dystocia, particularly simple ones that, when implemented, can be followed by normal expulsion of the remainder of the litter. Importantly, obstructive dystocia is frequently followed by secondary uterine inertia. Although this can be treated by the administration of oxytocin, if the number of fetuses yet to be delivered is large, this may require multiple doses and result in prolonged parturition, risking fetal death. In these cases, it may be simplest to revert to Caesarean operation to ensure the prompt delivery of the remaining fetuses.

For any cases of vaginal manipulation, it is essential to ensure appropriate restraint of the dam that may be anxious and difficult to examine. Attention should be paid to cleaning the vulva and to appropriate hand hygiene before conducting a digital examination. Copious lubrication with a water-soluble lubricant is helpful in cases of moderate fetal oversize or when the tract has become dry because of prolonged dystocia.

Digital Manipulations

As for evaluation of any parturient animal, it is best to assess the presentation, position, and posture of the fetus within the birth canal. This facilitates decision making about grasping the fetus, use of instruments, and direction of traction.

Before resorting to assistance using instruments, the use of fingers should be fully exploited because they are gentler and can be used more sensitively than instruments. This technique is valuable when parts of the fetus have passed through the pelvic inlet and are reliably palpated within the vagina. During all these manipulations, in small or medium-sized bitches, it is helpful to fix the position of the fetus in the uterus by gripping it with the other hand through the abdominal wall and to direct the fetus towards the pelvic inlet.

In these instances, if the fetus is in anterior presentation it is often possible to grasp it by inserting the index or middle finger over the occiput and placing the thumb into the intermaxillary space, or by hooking the index and middle fingers and placing them behind the head, thus trapping the neck (Fig. 18.1). This will be sufficient to allow redirection and traction (see later in this chapter). For fetuses in posterior presentation, the index and middle fingers can be used to hook cranially to the wings of the ilium and provide a firm grip on the fetal pelvis. For cases of breech presentation (posterior presentation with the limbs flexed cranially), it is generally possible to hook the fingers around the retained limbs and draw them upwards and backwards into the maternal pelvis.

Frequently, these manipulation result in eliciting Ferguson's reflex, such that there will be additional uterine contractions, supplemented by abdominal contractions.

Once parts of the fetus are protruding from the vulva, traction delivery is generally simple. For fetuses in normal anterior or posterior presentation with the fetus present within the vestibule, it is usually a relatively simple matter to insert the finger beneath the fetal chin or around the fetal pelvis and, by drawing it upwards, direct the fetus in line with the birth canal (Figs 18.2 and 18.3).

The Use of Instruments

When parts of the fetus have already entered the pelvic inlet and occupy the vagina, Hobday's vectis (see Fig. 18.8) is a useful instrument. The vectis is passed into the vagina and, according to the presentation, over the dorsal aspect of the fetal head or pelvis, and by pressure downwards is thus engaged behind the occiput or tuber coxae. The index finger is then introduced and pressed upwards into the intermaxillary space or in front of the fetal pelvis. In this manner the opposing forces of the vectis above and the finger beneath enable sufficient compression to 'trap' the fetus, allowing it to be grasped adequately for traction without injury (Fig. 18.4). The method may be successful in cases of anterior presentation in which the forelimbs are flexed caudally and cannot be corrected because they do not necessarily contribute substantially to the diameter of the fetus such that, with suitable lubrication, the fetus may be delivered with traction.

VetBooks.ir

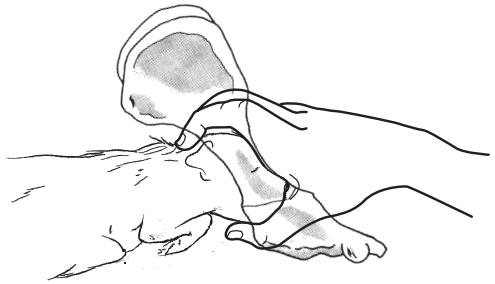

Fig. 18.1 Puppy is in normal disposition, but traction is applied by tightly grasping the head between the index and middle fingers.

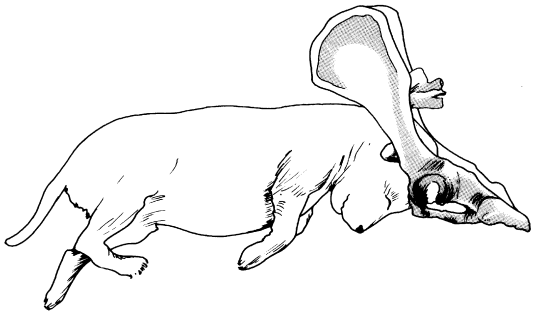
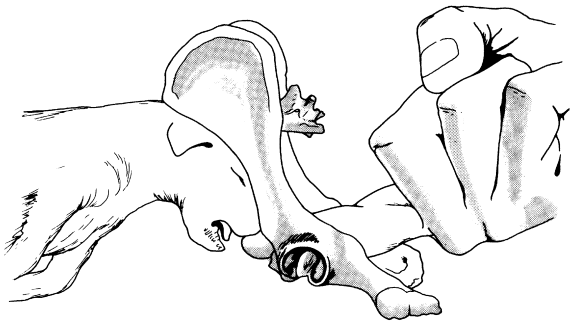
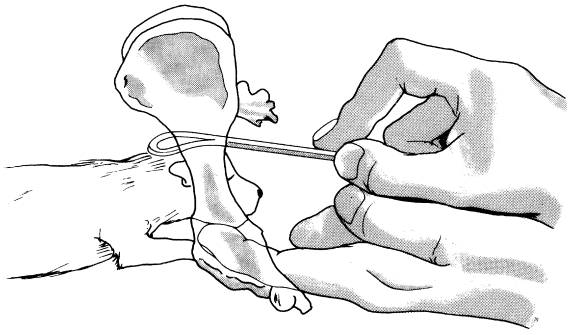


• **Fig. 18.2** Vertex posture ('butt' presentation) with bilateral shoulder flexion.

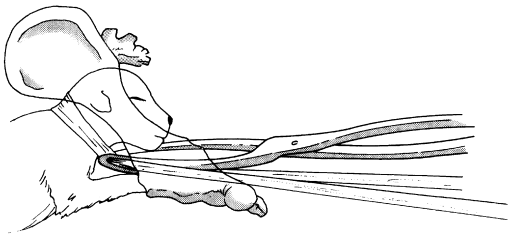


• **Fig. 18.3** Correction of the vertex posture with the finger.



• **Fig. 18.4** Traction applied to a puppy's head using the vectis and finger.

In cases of fetomaternal disproportion in anterior presentation, in which the fetus is entirely in the uterus and obstruction is caused by the size of the head, Roberts's snare forceps are of great value, particularly in small bitches and cats. Such cases may also be associated with retention of the forelimbs. Should the latter be the case, it is better to attempt delivery with the posture uncorrected, for the forelegs will cause no greater obstruction lying



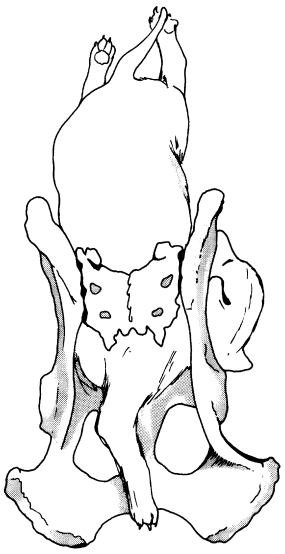
• **Fig. 18.5** Roberts's snare forceps applied to the fetal neck.

alongside the chest than they would if extended; moreover, the subsequent traction, applied as it is to the head only, may cause the elbows alongside the head to become impacted at the pelvic inlet. Snare forceps are used as follows: The fetus is fixed at the pelvic brim by holding it through the abdominal wall; the closed forceps carrying the snare are passed into the uterus and over the fetal head until they lie above the neck. The jaws are then opened as widely as possible and depressed downwards until they lie ventral to the neck and are then closed. In this way, an encircling noose has been applied. By traction on the free ends of the snare, the noose is drawn tight, and it is held in position by the forceps. Traction is then applied to the forceps and the free ends of the snare (Fig. 18.5).

If snare forceps are unavailable, it is possible to use Rampley's sponge-holding forceps (Freak 1948). These provide a suitable grip, but obviously the ratchet mechanism should not be used. In this manner, traction can be applied to a living fetus similar to previously outlined. Using the index finger as a guide to their application, the forceps are lightly fixed across the lateral aspects of the head, or to the upper or lower jaw, or even the whole snout. In the case of a posterior presentation, they may be applied to the upper portion of a hindlimb until the fetal pelvis is drawn into the maternal inlet and then a more secure hold is obtained. It is best not to grasp distal parts of the limb because these are easily traumatised resulting in lifelong damage.

Lateral deviation of the head and limbs displaced dorsally over the neck (nape posture) are abnormalities that require special consideration. These initially may be difficult to diagnose and do require correction to allow delivery of the fetus. In lateral deviation of the head, the forelimb on the side opposite to the neck flexion has generally passed through the pelvic inlet (Fig. 18.6). Thus the presence of a single forelimb in the cranial vagina indicates a likelihood of the condition. To verify the diagnosis and also to ascertain the side to which the head is deviated, the fetus must first be repelled cranially. A finger is then used, directed laterally towards the iliac shaft in order to detect the fetal occiput or ears. In the small bitch or normal-size queen, this may not be difficult, but in the large animal the length of the maternal pelvis and of the fetal neck are often such that it is impossible to make an accurate diagnosis, let alone correct the condition. In a protracted case, it may be impossible to obtain the space in front of the pelvis necessary for exploration with the finger. Rampley's forceps can be used as both an aid to diagnosis and to the correction of downward and lateral deviation of the head (Freak 1948). Once the fetus is grasped, it may be raised sufficiently into the birth canal to allow a more complete examination with the finger, when fetal ears may be recognised lying just below the pelvic brim. Using the forceps to anchor and provide retropulsion to the fetus, the operator's other hand is used to apply transabdominal pressure to lift the fetus further into the birth canal. Correction has to be undertaken in stages, obtaining a new grip on the head after each repulsion. When the head is

VetBooks.ir



• **Fig. 18.6** Lateral deviation of the head (shoulder presentation).

displaced laterally, the forceps are used to repel the fetus diagonally away from the side to which the head is flexed. It may be helpful to position the dam in lateral recumbency, with the side to which the head is turned being uppermost. In this manner, the repulsion is directed downwards, and the weight of the fetal head helps in its repositioning. Again, correction may be undertaken in several stages, with assistance derived from transabdominal manipulation.

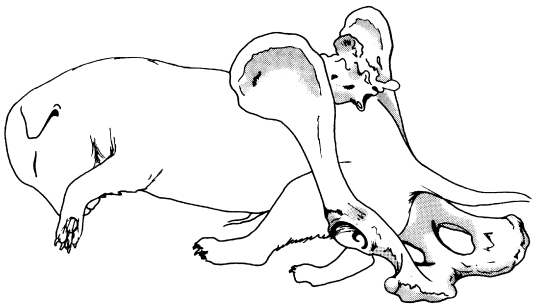
Delivery by Forced Traction

In most cases, traction is synchronised with the abdominal contractions of the dam, and the direction of traction follows a caudal and ventral direction to ensure minimal damage to the birth canal. In some cases, there may be absence of contractions from the dam, particularly in protracted cases of dystocia, with dead and emphysematous fetuses. Forceful traction should always be avoided in the case of a living fetus, for the grip of the forceps generally causes it severe injury. Hobday's forceps are generally employed.

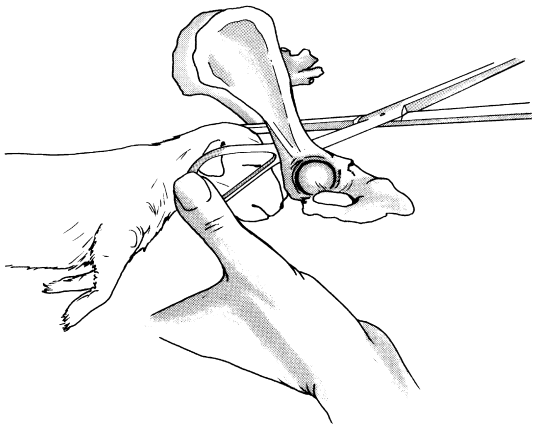
It should always be remembered that a Caesarean operation or, in the case of putrid fetuses, hysterectomy, will carry a better prognosis for the bitch or queen than prolonged attempts at forceps delivery.

In cases requiring traction, even when the fetus is dead, the presentation, position, and posture should be evaluated to enable correction before application of traction; this may necessitate initial repulsion (Fig. 18.7). The aim is to obtain a secure grip across the fetal cranium or pelvis, so that considerable traction can be applied. The application of the forceps to a limb or the lower or upper jaw is generally futile because the force that is necessary to be applied causes either the forceps to slip or the parts to be torn away.

Forced traction should be carried out under general anaesthesia and may be undertaken before a Caesarean if the dystocia affects only the last fetus. Forced traction is best undertaken with the dam in ventral recumbency. The position of the presented fetus is fixed by gripping it through the abdominal wall. The closed forceps are introduced into the vulva and directed at first upwards until they have reached the pelvic floor, then horizontally forwards through the pelvic canal, and finally slightly downwards and forwards into the uterus. Here, the fetal extremity will be felt and identified. The jaws of the forceps are now opened as widely as possible and again depressed downwards. On closing them, it becomes clear



• **Fig. 18.7** Bilateral hip flexion posture (breech presentation).



• **Fig. 18.8** Delivery of a puppy with retention of the forelimbs using Hobday's forceps. When the position of the fetus is fixed through the abdominal wall with the left hand, the forceps are applied to the skull with the right.

from the extent to which the handles are apart that the whole width of a fetal head or pelvis has been gripped. On no account should traction be applied until the operator is satisfied that he or she has a firm grip on the cranium or pelvis (Fig. 18.8). The operator is always fearful that vaginal wall has been trapped by the forceps in addition to the fetus. Fortunately, if the forceps are applied within the vagina as described previously, this is uncommon. Nevertheless, as soon as the secured part of the fetus has been retracted sufficiently caudally to a point that can be reached with a finger, the operator should ensure by palpation that the uterine wall is not trapped.

Steady traction is then applied, initially in a dorsal and caudal direction, to lift the fetus over the dam's pelvis into the birth canal. From this point, delivery is relatively easy. The direction of traction changes to a caudal and ventral direction to follow the anatomy of the birth canal. There is a limit to the amount of force that can safely be applied; severe traction may cause tearing of the vagina at the pelvic brim. In neglected cases in which the fetus is putrid, the application of traction may result in breakage of the fetus. Copious lubrication may help facilitate delivery and prevent breakage of the fetus.

After Delivery

After any cases of assisted vaginal delivery, the birth canal should be examined to ensure that there is no tearing or splitting of the vaginal or vestibular wall. Appropriate antimicrobial therapy is warranted in cases of manipulative delivery to reduce the risk of postpartum metritis.

VetBooks.ir

In cases of simple fetal dystocia corrected by vaginal manipulation, normal parturition may recommence. However, in many cases, secondary inertia will have ensued necessitating administration of oxytocin. Low dose oxytocin is most appropriate (0.04 IU/kg), administered every 30 minutes usually to a maximum of three doses.

Caesarean Hysterotomy in Dogs and Cats

GARY C. W. ENGLAND

Introduction

There are multiple indications for Caesarean hysterotomy in the bitch and queen. These include obstructive dystocia, primary and secondary uterine inertia, and increasingly, at least in the bitch, as an elective procedure in which fetal oversize is predicted, commonly in brachycephalic breeds. As a result, there may be a wide variation in the status of the dam, from being substantially compromised to clinically normal. Anaesthetic regimes therefore should be planned to allow for this variation in status of the dam.

A significant complication to the assessment of bitches with potential dystocia is the large variability in 'apparent' pregnancy length; the interval between mating and the onset of parturition can vary from 58 to 72 days. This is despite the 'actual' (or endocrinological) length of pregnancy having a more limited variation of 63 ± 1 days from ovulation to the onset of parturition (Concannon et al. 1983). The difference between actual and apparent pregnancy length is primarily a result of the timing of mating that may occur many days before or many days after ovulation; the dog is unique in domesticated species in being able to achieve pregnancy over a longer time period because of significantly longer time of sperm survival in the female tract and prolonged viability of ovulated oocytes respectively. The large variability in apparent pregnancy length, especially pregnancies that appear to be very long (associated with mating before ovulation), creates the specific challenge of differentiating this normal pregnancy from primary uterine inertia (which is the most common cause of dystocia seen in the bitch). In the queen the length of pregnancy is less variable at a mean of 67 ± 3 days from mating to parturition, with a range of 62 to 71 days.

Pregnancy Length and Predicting Parturition

Understanding of normal pregnancy length, particularly in the bitch, is important especially to allow the differentiation of a normal apparently long pregnancy from primary uterine inertia, and also for cases when elective Caesarean is planned so that immature fetuses are not inadvertently delivered.

Normal pregnancy in the bitch and queen appears to be terminated, as in other species, by fetal signalling that ultimately results in a cascade of events resulting in prostaglandin release (see Chapter 6). Plasma progesterone concentrations therefore decline, and there is then an increase in uterine contractions and softening of the cervix. In bitches the onset of parturition occurs 63 ± 1 days from ovulation. Normal pregnancy may be slightly longer when fetal number (litter size) is small and also in some breeds (e.g., German Shepherd dog).

The anticipated day of parturition in the bitch can be predicted from assessment of the time of ovulation made during the breeding oestrus (Kutzler et al. 2003) (for example, parturition occurs approximately 61 days after progesterone exceeds 32 nmol/l), or by measurement of fetal size or stage of development at the time of ultrasound pregnancy diagnosis (England et al. 1990), or by monitoring the bitch in the last few days of pregnancy. In the queen, ultrasound assessment of fetal size and appearance may similarly allow the prediction of the onset of parturition, and some of the features of impending parturition are also comparable to those noted in the bitch.

For the bitch in particular the normal sequence of events seen in late pregnancy are that vulval and perineal tissues relax as a result of increasing relaxin concentrations and progesterone concentrations decline (termed the Stage of Preparation); as a result, there is a significant decrease in rectal temperature, the volume of mucus at the cervix increases, and the cervix begins to open (this can be seen endoscopically).

Subsequently uterine contractions commence (termed First Stage parturition) and may be seen by careful observation of the flank or by the measurement of uterine electrical activity. These contractions are often associated with anorexia, shivering, nesting, and vulval discharge; they are followed by the onset of abdominal contractions (termed Second Stage parturition). Generally, the sequence of events follows the time course noted in Table 19.1.

In some species there are changes in the ionic composition of milk that can be used to predict parturition, but this does not appear to be the case at least in the bitch (England & Verstegen 1997).

Indication for Caesarean Hysterotomy

The decision to perform a Caesarean operation is commonly undertaken in one of three particular circumstances:

A. Obstructive dystocia with or without secondary uterine inertia

Caesarean hysterotomy is likely in the bitch or queen as a result of a clear indication of an intractable dystocia after a digital examination of the vestibule and vagina, or when secondary uterine inertia follows the correction of dystocia and: (i) there is inadequate response to oxytocin administration; (ii) there is a large litter size such that parturition will inevitably be prolonged; or (iii) there are signs of fetal stress (see later in this chapter).

VetBooks.ir

TABLE 19.1 Normal time sequence of prepartum events in the bitch

Parameter	Relation to Parturition
Initial abrupt decline in progesterone	Approximately 36 hours before parturition
Rectal temperature declines to less than 37°C	No more than 36 hours before parturition
Progesterone concentration decreases to less than 2.0 ng/mL (6 nmol/l)	No more than 26 hours before parturition
Onset of uterine contractions (First Stage)	No more than 24 hours before parturition
Mucus at cervix increases and cervix opens	No more than 12 hours before parturition
Onset of abdominal contractions (Second Stage)	No more than 2 hours before parturition

B. Primary uterine inertia

Primary uterine inertia accounts for more than 70% of cases of dystocia seen in bitches and queens. In these, the common sequence of events is that progesterone concentrations decline (Stage of Preparation), uterine contractions begin (First Stage commences) but may be weak, and then uterine contractions cease. There are usually no abdominal contractions (no Second Stage). Unless the owner is experienced, the initial signs may be missed, and the owner is therefore unaware that parturition is overdue because of primary uterine inertia until placental separation commences (commonly indicated by the presence of a green/brown vulval discharge associated with release of pigment (uteroverdin) from the marginal haematoma of the placenta). Fetal death occurs rapidly at this point. When the clinical history is not informative and it is not clear whether the bitch has primary uterine inertia or parturition is not yet due, measurement of progesterone concentrations (England & Verstegen 1996) may be informative; basal progesterone indicates parturition is overdue or imminent.

If detected early before placental separation, cases may respond to exogenous oxytocin administration. Many cases of primary uterine inertia are, however, associated with either a small litter size, large litter size, or a dam that is obese, aged, or debilitated. In these cases, undertaking Caesarean hysterotomy may be more appropriate than attempting oxytocin administration which may not be successful.

C. Elective Caesarean hysterotomy

Elective Caesarean surgery may be considered when there is expected fetomaternal disproportion, perhaps most commonly in dogs of the brachycephalic breed or queens in which there is narrowed birth canal as a result of a previously fractured pelvis. In these cases the challenge is identification of the optimal time of surgery, which can be difficult to predict if only the date of mating is known because of the large variation in apparent pregnancy length as described previously. Different approaches are taken to decide on which day to perform an elective Caesarean, with some practitioners waiting until the onset of clinical signs of the onset of First or Second Stage parturition, others relying on detection of the prepartum decrease in rectal temperature, and others monitoring the decline in plasma progesterone concentration.

Whenever the late pregnant bitch is examined, the key feature is always to consider whether there is a failure of the normal events of parturition to progress. This requires knowledge of the normal time sequence of events, which may be modified depending on the age and parity of the dam as well as the litter size. Measurement of plasma progesterone is a useful indicator of the stage of parturition (Table 19.1), but for accurate assessment repeated samples are required (Rota et al. 2015). Additional critical signs include the appearance of a green/brown/red coloured vulval discharge that is indicative of placental separation. The presence of placental separation may modify the clinical decision taken about a given case. Furthermore, ongoing monitoring of the fetus during late pregnancy and parturition may include attempts to detect fetal stress by assessment of fetal heart rate. Normal fetal heart rate at term is between 170 to 230 bpm (or 3–4 times maternal heart rate). The immediate response of a hypoxic fetus is a short-term increase in heart rate; however, the most common finding in veterinary practice is chronic fetal hypoxia detected by a decrease in fetal heart rate. Fetal heart rates less than 150 bpm indicate hypoxia (fetuses are stressed); fetal heart rates less than 130 bpm are associated with poor survival if delivery does not occur within 2 to 3 hours; fetal heart rates less than 100 bpm generally require immediate intervention to hasten delivery before demise of the fetuses.

Anaesthetic Considerations

Substantial physiological changes occur in late pregnancy. These include a reduction in functional residual capacity, and in the bitch, a substantial normochromic normocytic anaemia becomes maximal near to term and can involve a reduction of haematocrit to 30%. Pregnant animals are at risk of hypoxaemia and preoxygenation before induction of anaesthesia is indicated. Animals may also be debilitated and dehydrated if presented because of dystocia, and in these cases intravenous fluid therapy is mandatory.

It is not within the scope of this text to review anaesthetic regimes for the Caesarean hysterotomy; suffice to say, they should take account of the clinical presentation of the dam. A recent review of appropriate analgesia and anaesthesia regimes has been published by the WSAVA Global Pain Treatise and can be found at www.wsava.org.

Operative Technique

The surgical procedure is similar for both bitches and queens, although many variations in technique have been described (Traas 2008). It is common practice to undertake preparatory activities such as hair clipping and initial antiseptic scrub before induction of anaesthesia.

The female is placed into dorsal recumbency on a slightly tilted table such that the dam's head is highest as this may reduce abdominal pressure on the diaphragm. The surgical site is prepared and draped from the xiphoid to the pubis, and a ventral midline skin incision is made from just cranial to the umbilicus to just cranial to the pubis. Electrocautery may be useful to control skin and subcutaneous bleeding from vessels that may be enlarged associated with mammary development. The abdomen is opened in a routine manner to avoid possible penetration of the distended uterus lying immediately beneath. The common procedure is to carefully lift the gravid uterus from the abdominal cavity, ensuring no tearing of the uterus or of the broad ligament vessels. Moistened swabs can help support the uterus, prevent it from drying, and avoid contamination of the peritoneal cavity with allantoic or amniotic fluid. The number of fetuses present, the degree of coiling of the uterus, and the innate pressure within the uterus will influence

VetBooks.ir

whether the dorsal or ventral surface of the uterus is uppermost when exteriorised. Once exteriorised, it is likely that uterine blood flow is compromised, and so removal of the fetuses should be undertaken rapidly. If possible, a relatively avascular area of the uterine body is chosen for the initial hysterotomy incision. The incision is best made by lifting the uterine wall away from the fetus, making a small stab incision with a scapula and extending the incision in a longitudinal manner with scissors. The incision should be sufficiently long to allow manipulation and delivery of the fetus without risk of tearing of the uterus. The adjacent fetus is located, grasped by the surgeon through the fetal membranes, and extracted through the uterine incision. At this stage no attention needs to be paid to specific fetal membranes as they will be ruptured during removal of the fetus. Forceps are applied to the umbilicus, and the fetus is passed to an assistant to revive. Gentle traction should be applied to the remaining umbilical cord, and the placenta should be removed if it detaches easily from the uterine wall; otherwise it can be left in place. Remaining fetuses are manipulated by gently squeezing them to the hysterotomy incision and are removed in a similar way. In large breed bitches with many fetuses, it may be necessary to make secondary incisions within both uterine horns to facilitate rapid removal of all pups. The entire length of the uterus should be examined to ensure that no fetuses remain and special attention should be paid to the distal uterine body/vagina. Once all fetuses have been removed, the uterus normally starts to decrease in size quite rapidly. The hysterotomy incision is closed with a monofilament absorbent suture material with a continuous pattern using either a single inverting pattern or an initial appositional pattern followed by a second inverting pattern. After closure of the hysterotomy incision, if the uterus has not started to involute then it is appropriate to administer exogenous oxytocin at 0.04 IU/kg. The uterus is lavaged with saline, inspected for any tears to the uterine wall or broad ligament, and then replaced into the abdominal cavity. If the abdominal cavity has been contaminated, abdominal lavage should also be performed. Closure of the abdominal wall is routine except that many veterinary surgeons place subcuticular sutures to minimise interference from the neonates. Placentae that were not removed through the hysterotomy incision are normally expulsed over the first 48 hours after surgery. Bitches with retained placentae should be monitored to ensure that metritis does not develop.

In a small proportion of cases in which dystocia has been long-standing and especially if there are emphysematous fetuses, the uterus may be devitalised. Ovariohysterectomy may be required and is best performed with the fetuses in situ. This technique of en bloc ovariohysterectomy may also be performed when the fetuses are alive after a presurgical decision to perform ovariohysterectomy. The technique follows a similar approach with exteriorisation of the uterus as described previously. The broad ligament vessels are ligated and the broad ligament is transected. If a fetus is present within the uterine body, it is pushed cranially away from the cervix, and two pairs of forceps are placed across the uterine body. Two pairs of forceps are similarly placed across each ovarian pedicle. Transection between the pairs of forceps allows the uterus to be removed and passed to an assistant who removes and revives the neonates. The surgeon then ligates the uterine and ovarian stumps in the normal manner. This technique is not associated with reduced milk production from the dam.

Resuscitation of Neonates

With modern anaesthetic regimes, neonates are often not significantly depressed at the time of removal. However, they have not been stimulated by passage through the birth canal, and there has been no time for amniotic fluid to drain from the respiratory tract. The airway should therefore be cleared of fluid using a towel or suction, the chest should be dried with a towel, and the neonate assessed for respiratory and cardiac activity (ABC; airway, breathing, circulation). If spontaneous breathing is not present, then artificial respiration should be initiated. Transtracheal intubation can be particularly useful as a short-term measure. Similarly, cardiac massage should be initiated if heart beats are absent. Once each neonate is stable, it can be transferred to a warm environment to recover while the surgery is completed. After surgery the dam's nipples should be cleaned to ensure no residual antiseptic (which may deter neonates from sucking) before neonates are encouraged to suck. Milk let-down can be encouraged with exogenous oxytocin at 0.04 IU/kg. In dams with inadequate milk production, prolactin agonists such as metoclopramide (0.1–0.2 mg/kg given three or four times daily for 5 days) can be administered.

Injuries and Diseases Consequent Upon Parturition

TIMOTHY J. PARKINSON AND DAVID E. NOAKES

Trauma to the Birth Canal and Neighbouring Structures

There are numerous accidents and diseases that accompany or follow parturition. Some, such as prolapse of the uterus, retention of the fetal membranes, and puerperal infection, occur after the delivery of the fetus; the last two are considered elsewhere in the book. Traumatic lesions of the soft tissues of the genital tract or bony pelvis may lead to fatal haemorrhage or infection or to disability due to fractures, dislocations, or paralysis. Other complications of parturition include displacement, herniation, and rupture of the pelvic or abdominal organs. Parturition and the puerperium may also be complicated by metabolic diseases, particularly hypocalcaemia and, in adult cows, by displacement of the abomasum. A difficult foaling may be followed by laminitis or tetanus, and postpartum animals of all species may incur embolic pneumonia, toxaemia, septicaemia, and pyaemia as sequels to uterine infection. Endocarditis, unthriftiness, and sterility are possible later sequelae.

Although spontaneous injury may occur in unassisted deliveries, they are rare. The most frequent cause of parturient and postparturient disease is delay in giving obstetrical aid to dystocia cases, or bad and unsympathetic obstetrical practice, frequently by unskilled individuals. For this reason it is very important for the veterinarian attending dystocias to determine whether, and what, lay assistance has been given, both by questioning the person responsible for the care and by clinical examination of the genital tract. If skilled attention were to be provided at the correct time to animals with dystocia, the frequency and severity of postparturient disease would be markedly reduced.

Postpartum Haemorrhage

Bleeding from the maternal side of the placenta after natural separation of the placenta is only likely in carnivora, in which breakdown of the marginal haematoma is accompanied by a green or brown discharge of altered blood. If, however, premature dehiscence occurs when the afterbirth is removed during elective Caesarean hysterotomy, severe and even fatal haemorrhage may follow. In veterinary obstetrics the usual cause of serious haemorrhage is trauma of a uterine blood vessel by a fetal appendage, the application of forced traction before the cervix has fully dilated, or via an obstetrical instrument, of the hand of the obstetrician. After removal of the fetus, much blood may accumulate in the uterus before it begins to escape via the vagina; alternatively, blood may drain through a tear in the uterine wall into the abdomen.

When, after delivery of the offspring, there is a profuse haemorrhage from the vulva, the most likely source is the broken ends of the vessels of the umbilical cord which have recoiled into the vagina. This is likely to occur in uterine inertia in which, owing to poor uterine contractions, much of the blood from the fetal side of the placenta (allantochorion) is not expelled into the fetus during second stage labour. Similar bleeding from mares is seen when there is manual interference by unnecessary traction on the fetus resulting in premature rupture of the umbilicus; if this occurs, ligation of the cord as close to the fetal abdomen should be attempted. Such haemorrhage from the allantochorion does not affect the dam, but the neonate is thereby deprived of placental blood transfer, which can be a significant factor in causing cerebral anoxia in newborn foals (MacLeay 2000).

If profuse haemorrhage is occurring from a uterine laceration, prompt contraction of the uterus should be promoted by means of an injection of oxytocin. Next day, any blood clots should be manually removed. Haemorrhage associated with uterine rupture is managed when the uterine tear is repaired. When severe haemorrhage is occurring from a ruptured vaginal vessel, an attempt must be made to close the vessel. Ligation is usually not practicable, but artery forceps may be applied and left on for 24 hours. Where the vessel cannot be secured, an intravaginal pressure pack can be improvised with a large clean towel or by the insertion of a large role of surgical gauze or cotton wool. General symptoms of severe haemorrhage and shock can be counteracted by blood transfusion (4–5 litres) from a neighbouring animal or the use of blood volume expanders.

Fatal haemorrhage from vessels in the broad ligament can occur in the mare and cow. Ueno et al. (2010) reported 31 cases of fatal haemorrhage into the broad ligament of mares. Thirty of these had had over eight pregnancies and were over 10 years of age. The most common site of haemorrhage was the uterine artery (24 cases) and the internal pudendal artery (5 cases). They found that the smooth muscle of tunica media adjacent to the arterial ruptures showed atrophy and that there was fibrotic change of the tunica intima, together with disruption and/or calcification of the internal elastic lamina and proliferation of collagenous and elastic

VetBooks.ir

stroma. These lesions were most prominent in the uterine arteries of aged and multiparous mare, and were rare in mares that had not experienced such haemorrhage. The lumen of the proximal uterine artery of aged mares was sometimes dilated, forming small aneurysms. Reduced density of smooth muscle cells and fibrosis was present in the expanded wall of the aneurysm. Rooney (1964) recorded 10 cases of fatal haemorrhage in mares with similar pathology of the blood vessels. Ueno et al. (2010) considered that the most likely cause was age-related haemodynamic stress, although copper deficiency has also been suggested (McGladdery 2001). In mares the haemorrhage is sometimes contained within the broad ligament, with the formation of a large haematoma, which can be diagnosed by careful transrectal ultrasonography as a hyperechoic structure in the broad ligament. Attempts at surgical repair are rarely successful because stress-induced hypertension may exacerbate the problem (McGladdery 2001). A more cautious approach is preferable, such as sedation and the use of blood transfusions and blood volume expanders, with regular monitoring of blood values.

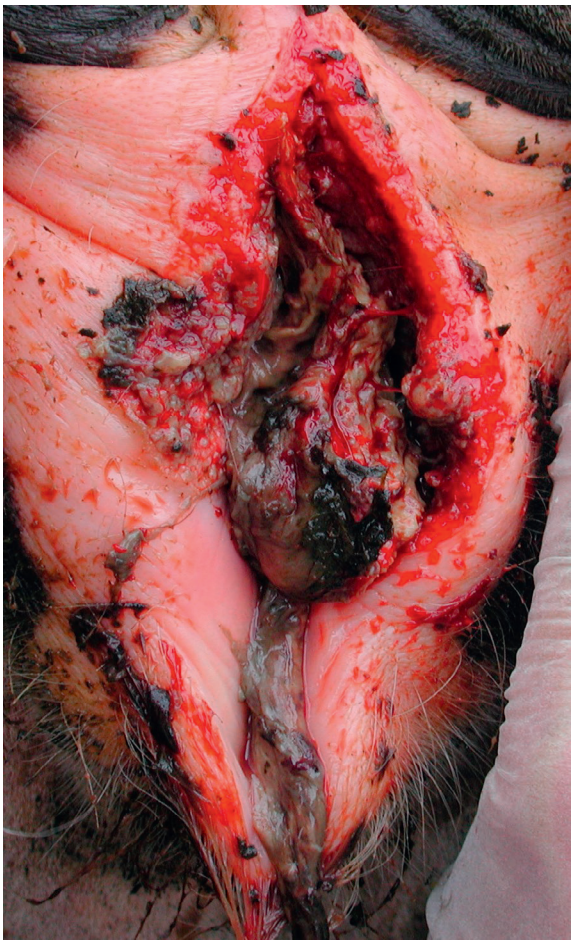
Lacerations and Contusions

Any part of the birth canal may suffer contusion during forcible extraction of the fetus, but the cervix and vulva are more likely to be lacerated than the dilatable vagina. The retroperitoneal fat surrounding the vagina of heifers of the beef breeds makes such animals particularly prone to vaginal contusion when the fetus is oversized. Infection with *Fusobacterium necrophorum* is then probable, and a severe necrotic vaginitis ensues. The condition is very painful and causes continuous, exhausting straining and marked toxaemia (Fig. 20.1). Pyogenic infection is also possible. All vaginal contusions and lacerations should be treated with mild emollient and antibiotic preparations; parenteral antibiotics should also be given. Caudal epidural anaesthesia, particularly when xylazine is used, gives temporary relief from straining (see Chapter 14). Lacerations, however modest in severity, can be a sign of more severe uterine disease or may predispose to it; in addition, they may have an effect on the return of subsequent ovarian cyclicity. Vieira-Neto et al. (2016) found that Holstein cows that had injuries to the vulva or caudal vagina 4–8 days post partum were more likely than normal cows to develop endometritis by 32 days. They were also slower to resume oestrous cycles and were less likely to conceive to their first insemination.

Rupture of the vagina should be repaired, if possible, by suturing, although access can be difficult. Infection after rupture may give rise to peritonitis, to severe cellulitis (which, if severe, can be accompanied by marked toxaemia and straining), or to abscess formation with subsequent vaginal constriction. Lacerations of the cervix may be sutured by applying vulsellum retraction forceps to the organ and withdrawing it to the vulva.

Wounds to the vulva and perineum are generally easily sutured, with any devitalised tissue, including any loosely attached portions of fat, being first removed. If lacerations of the vulva and perineum are left unsutured, scar tissue formation and distortion may impair the sphincter action of the vulva, with consequent aspiration of air, vaginitis, and metritis; a special, and much more difficult, operation is then required. When Caslick's operation to prevent vaginal aspiration has previously been performed in the mare (see Chapter 31), it should be resutured immediately after delivery. Repair of the vulva, perineum, and cervix may be conveniently carried out under caudal epidural anaesthesia.

In cows previously unsuspected organising haematomata of the vagina may suddenly prolapse from the vulva 4 to 6 weeks after parturition. These lesions resemble fibromata but are not neoplastic and are easily excised.



• **Fig. 20.1** Necrotic vaginitis, as a sequel to trauma of the birth canal during calving. (Courtesy Dr. Jakob Malmo.)

Haematoma of the Vulva

This is a sequel to contusion of the submucous tissue during delivery. One lip of the vulva is usually affected, and an obvious round swelling occupies the vulva orifice (Fig. 20.2). The condition may arise spontaneously in the mare, but in both cows and mares it is likely to follow assisted delivery in which considerable manipulation or forced traction was required. Haematoma of the vulva may be confused with prolapse, tumour, or cyst of the vagina. If left untreated, natural resolution usually occurs within a few weeks with resorption of fluid and regression of swelling; occasionally, pyogenic infection occurs and may be accompanied by fibrosis and distortion of the vulva with vaginal aspiration. If left for 3 or 4 days after labour, the haematoma may be safely incised and the clot removed without recurrence of haemorrhage. An abscess should be opened and drained.

Perineal Injuries at Parturition

Serious perineal injuries occur during the second stage of labour in both the cow and the mare, mostly in primiparous animals,

VetBooks.ir

• **Fig. 20.2** Vulva haematoma in the left labium.

and are often associated with poor relaxation of the vulva and perineum and/or unsympathetic forced traction. These injuries may be classified as first, second and third degree tears, and rectovaginal fistulae. Many heifers sustain slight superficial tearing of the upper commissure or other part of the vulva (first degree laceration) because of stretching during expulsion of the fetus; such lesions may heal satisfactorily by first intention without suturing, although it is preferable to do so whenever possible. Tears which extend more deeply into the perineum involving muscle (second degree laceration) destroy the sphincter effect of the vulva and lead to aspiration of air into the vagina, even though the integrity of the anus is not impaired. These require immediate surgical repair. With greater stretching and tearing during the second stage of labour, the wound may extend into and destroy the anal sphincter, thus creating a cloaca through which faeces fall into the caudal-most part of the vagina (third degree laceration) (Figs 20.3A and 20.4). Despite rapid epithelialisation, the abnormal communication between the terminal rectum and vagina persists, although its extent may be considerably reduced by wound granulation; complete surgical repair about 6 weeks after it occurred is required. In cattle, simple rectovaginal fistulae (Figs 20.5 and 20.6) without damage to the anal sphincter are uncommon spontaneous obstetrical injuries, although they occur as developmental anomalies in cases of anal atresia. They may also result from an unsuccessful attempted closure of a third degree perineal laceration in the mare.

In the mare the mechanism of perineal tearing is different. In this species, the initial injury is usually perforation of the roof of the vagina by a fetal forelimb, which may be pushed or reflected dorsally during the second stage of labour. As a result of sustained vigorous straining, the limb is then likely to perforate the rectum and be forced, possibly with the fetal head, through the anus, which in turn may be ruptured. Early recognition of the injury may allow repositioning of the fetal extremities and normal vaginal delivery, but deliberate incision of the perineum and anal sphincter is usually expedient if the rectum is already perforated, because a third degree defect is easier to repair surgically than a rectovaginal fistula, which would otherwise result. Mares in which a Caslick's closure of the upper vulval commissure has not been not reopened before foaling may sustain a similar injury in a slightly different way, with the tear extending dorsally from the vulva, as in cows. Records of cases presented for repair indicate that third degree tears are the most common perineal injury in the mare, but rectovaginal fistula formation is still more frequent in the mare than the cow. By contrast, second degree defects are rare in the mare but not uncommon in cows, simply because of the different mechanisms of tearing in the two species.

Perineal defects granulate and are epithelialised rapidly, but they are lacerated wounds with considerable tissue damage, and a degree of superficial sloughing is usual before granulation begins. The extent of inevitable tissue necrosis prejudices the likelihood of first intention healing after immediate suturing. It is nevertheless advisable to stitch deep perineal wounds that have not perforated the anal sphincter as soon as possible. Third degree tears with destruction of the sphincter and rectovaginal fistulae should be left to heal by granulation and surgical reconstruction can be undertaken later if necessary. The extent of such defects is considerably reduced by cicatrisation, and occasionally small, oblique fistulae in the mare close completely; however, in most cases a significant defect remains.

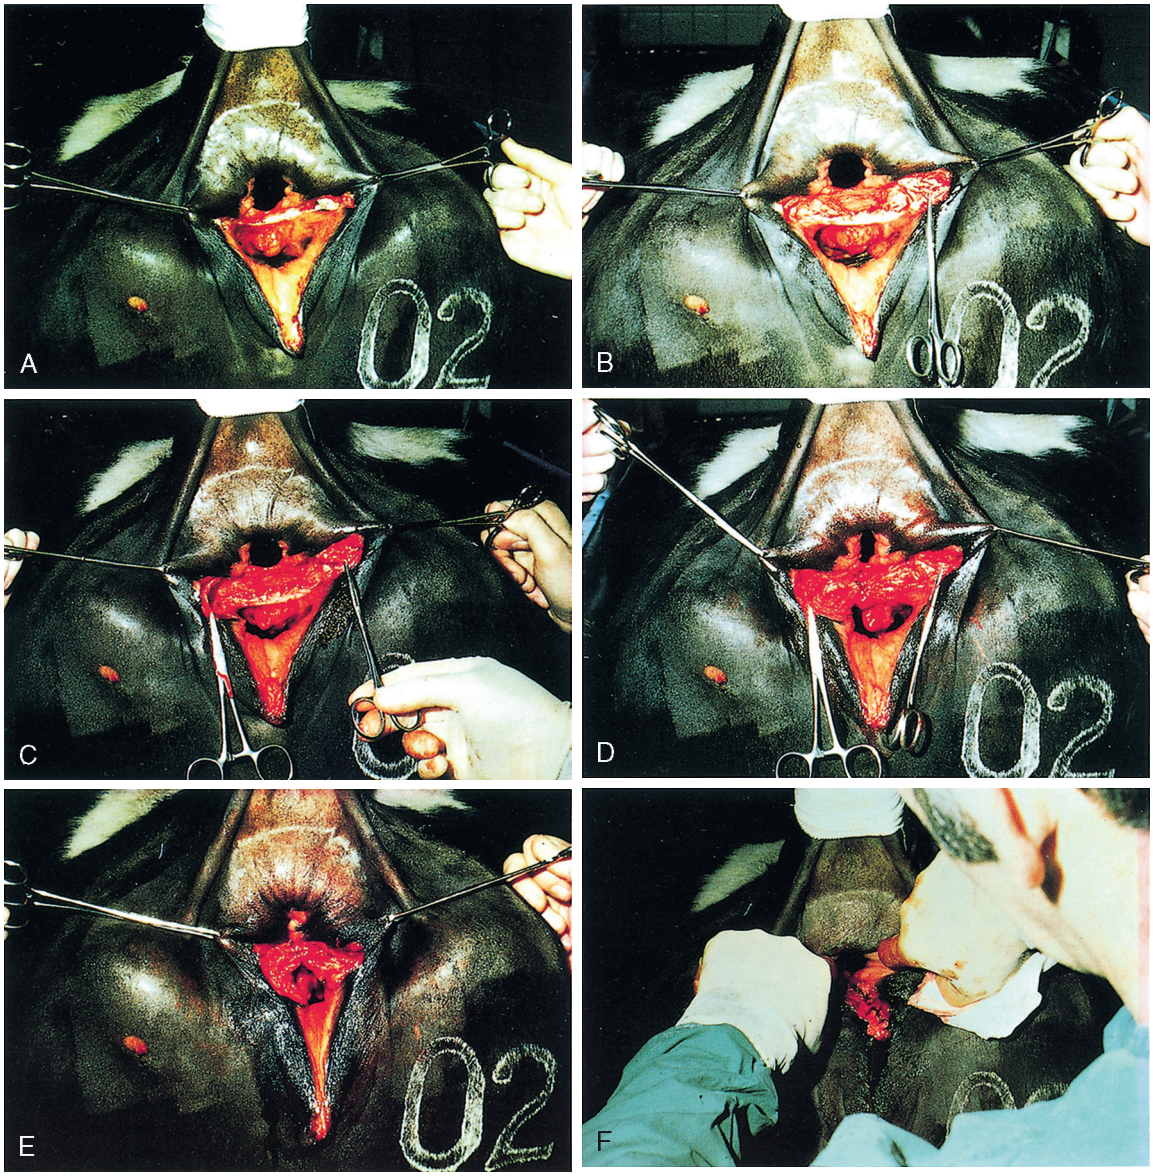
The clinical effects of a third degree defect are twofold: continuous aspiration of air into the vagina and contamination of the vaginal lumen with faecal fluids or, worse still, accumulation of faecal boluses in its terminal segment. Pneumovagina, in turn, by distorting the lumen, may lead to pooling of urine cranial to the external urethral meatus. Inevitably in both the cow and the mare, these factors result in gross bacterial contamination and ascending infection in the genital tract. In both species, therefore, sizeable cloacal lesions result in infertility, and affected mares are also aesthetically unsuited for other uses because of perineal incompetence. In cases of rectovaginal fistula, the degree of faecal contamination of the vagina depends on the extent of the fistula. The few animals that are able to maintain a normal pregnancy are generally found to have a caudally sited lesion of very small diameter.

Surgical intervention should be delayed until all tissue surfaces are covered by epithelium, which usually takes 6 weeks or so. In the mare the urinary bladder is sometimes everted soon after the injury occurs (Fig. 20.7), but it is easily replaced and retained if necessary with sutures. There is no need for other treatment during the intervening period except perhaps for tetanus prophylaxis.

Second degree defects can be satisfactorily obliterated by stripping the vaginal mucosa from the normal level of the upper vulval commissure dorsally on both sides and suturing the submucosal tissues as in a Caslick's operation.

One step and two step procedures for surgical reconstruction of the perineum were described by Götze (1938) and Aanes (1964), respectively. The main method in current use is a one-step procedure described by Stickle et al. (1979). The procedure is suitable for the cow or the mare: in the cow it should be performed under caudal epidural anaesthetic, and it is best to do so in the mare, although it

VetBooks.ir



• **Fig. 20.3** Repair of third degree perineal laceration in a Friesian heifer. (A) The perineal laceration is exposed with cow under caudal epidural anaesthesia. (E) Closure almost completed. (F) Restoration of a complete shelf of tissue between rectum and vagina; the dorsal commissure of the vulva will require further repair.

can be performed under general anaesthesia. Cows require no dietary preparation, but, in the mare, a laxative diet without roughage is advisable for 3 days beforehand, followed by overnight starvation. After proper cleansing of the site, the rectum is gently packed with towelling; if the mare is anaesthetised, the bladder is catheterised to divert urine from the operation site. In cows the defect is usually no more than 6 cm deep from the perineum, but in the mare it can be considerably longer and sometimes extends almost to the cervix. In both species tissue forceps are placed on the cutaneous borders of the cloaca down to the normal level of the upper vulval commissure and on the caudal edge of the residual shelf. Bridges of skin across the defect are removed, and it is then possible to see a sharp demarcation between the vaginal and rectal mucosae (see Fig. 20.3A–C). The first stage of the procedure is to separate the vaginal mucous membrane from the tissues which will subsequently be apposed to create a shelf. The dissection begins at the level of the normal upper commissure and is extended dorsally on the mucocutaneous border and then cranially on both sides along the junction of vaginal and rectal mucous membranes until the incisions meet on the caudal edge of the residual shelf. The final stage of dissection is the separation of vaginal mucosa for 4 cm cranial to the edge of the shelf (see Fig. 20.3B and C). It is essential that all the vaginal mucous membrane is removed from the tissues that are to be sutured. There is minimal haemorrhage during the procedure and no need for haemostasis. In some cases, cicatrisation results in considerable asymmetry of the cloaca which should be corrected before suturing is begun. The curtain of separated vaginal mucosa is then included in a purse-ring type of suture.

• **Fig. 20.5** Acquired rectovaginal fistula in a cow. Vulva dilated to vaginal opening to fistula.

• **Fig. 20.6** Acquired rectovaginal fistula in a cow, with a bandage passed through the fistula.

An absorbable suture material is used: the sutures are placed and tied serially from the depth of the wound outwards (see Fig. 20.3D and E). The method of suturing is illustrated in Fig. 20.8.

It is most important that the stitches tighten properly, because dead space predisposes to wound breakdown. The operation is completed with mattress sutures in the perineal skin (Figs 20.3F and 20.9). Further minor closure of the upper commissure may be necessary under local anaesthetic infiltration when the integrity of the repair has been properly tested a month or so later. It should be emphasised that, although this operation restores breeding ability, it does not prevent air movement through the incompetent anal sphincter, a consideration which may be important in mares that are to be used for other purposes. In such animals a second operation to strengthen the sphincter can be attempted later by stripping mucocutaneous tissues in the defective segment and suturing whatever muscle remnants can be identified. The horse's anus is normally somewhat lax, and minor incompetence is no great detriment. If attempted reconstruction is unsuccessful, the operation can be repeated, but the prognosis is then less good because of local fibrosis and reduced vascularity. Unless the vulval length is inadvertently shortened during reconstruction, subsequent parturition in both the cow and the mare usually occurs normally without the risk of vulval tearing or the need for episiotomy.

Paradoxically, a simple rectovaginal fistula is more difficult to repair than a third degree defect. Aanes (1964) recommended that such lesions should first be converted into a cloaca (as in a third degree laceration) and repaired as such after granulation stops. The deliberate destruction of perineum and anal sphincter can be avoided by adopting a different surgical approach to such lesions. Unless the fistula is deeply sited, it can be exposed satisfactorily by a dorsal commissure episiotomy that is extended cranially under the anal sphincter and rectal floor beyond the fistula (Fig. 20.10). The rectal mucous membrane lining the lesion can then be securely inverted with sutures placed in a transverse direction in the submucosal tissues before the episiotomy is repaired in the

conventional way. Perineal defects are usually obvious in mares but are nevertheless sometimes not noticed by unwary purchasers. They are less obvious in cattle, particularly if the anal orifice remains intact.

Rupture of the Uterus or Vagina

Rupture of the uterus may occur spontaneously, but faulty obstetrical technique is a more frequent cause. Spontaneous rupture is most likely to arise in association with uterine torsion or with cervical nondilation, but is also possibly due to the gross uterine distension that occurs with twins in one horn, with hydrallantois, or with excessive fetal size. The most likely time of spontaneous rupture is in late gestation or during labour. Hopkins and Amor (1964)

VetBooks.ir

remarked on the association of spontaneous uterine rupture and breech presentation; they encountered three cases and cited four other cases from the literature. The most common site of rupture was the dorsal aspect of the left uterine horn, with the tear extending caudally to involve the uterine body and cervix. Their hypothesis is that breech presentation predisposes to rupture because the breech of the calf fully occupies the maternal pelvic inlet and allows no egress for the fetal fluid when the uterine and abdominal contractions build up the hydrostatic pressure within the uterus. In a review of 26 cases of uterine rupture, 18 of which were heifers, Pearson and Denny (1975) considered uterine torsion and fetomaternal disproportion to be major predisposing factors. In that series, 14 of the 26 fetuses were mainly or entirely within the peritoneal cavity; four were still alive at the time of laparotomy. According to the size of the rupture – which may heal without incident or allow escape of the conceptus in the abdomen – and to whether or not infection occurs, there is great variation in the syndrome; from cases in which no symptoms are shown to others in which shock and fatal toxaemia soon supervene. Thus in some instances the owner is unaware of the accident, and the only evidence of it is the subsequent finding of a uterine adhesion or of a mummified fetus among the abdominal viscera – so-called extrauterine or pseudoectopic pregnancy. When rupture occurs during labour and the fetus passes into the abdomen, labour pains and straining cease and uterine inertia may be suspected until a uterine exploration proves otherwise. Alternatively, the dam's intestines may prolapse into the uterus and even protrude from the vulva; the condition may then be confused with dystocia due to schistosoma reflexus (see Fig. 14.37) in visceral presentation.

Accidental rupture of the uterus is likely to occur in the most difficult dystocia cases: those in which the initial disposition of the fetus is markedly irregular and difficult to rectify, and those in which there has been much delay in treatment with the development of unfavourable complications. Insufficient uterine space for the extension of a limb or head, inordinate traction on a wrongly disposed or oversized fetus, and excessively vigorous retropulsion are the immediate causes of uterine rupture. When the cervix is incompletely dilated, traction on the fetus may cause rupture of that organ. Careless use of the obstetrical forceps in the bitch is a potential cause of uterine rupture. Lastly, rupture of the uterus may be due to external violence as, for example, when the parturient dam falls heavily or receives a severe kick or horn-gore on its abdomen.

When making the initial examination of a dystocia case, the veterinarian should always explore the genital tract for traumatic lesions that may have been caused by unskilled lay interference or that, rarely, may have arisen spontaneously. If uterine rupture is found then or if it occurs during subsequent manipulations, the obstetrician must decide – largely on considerations of size and site of the lesion and the amount of manipulation or traction still required to effect delivery – whether to proceed with the delivery *per vaginam* or whether to perform a Caesarean hysterotomy and repair the uterine rupture from the laparotomy site after the removal of the fetus. Except where a small dorsal rupture is discovered and the amount of obstetrical interference still required is small, a laparotomy is indicated. The procedure then adopted is almost identical to that described for a Caesarean hysterotomy, the only complication being the difficulties of accessing the site of uterine rupture from the abdominal incision. The accidental rupture may be extended and the fetus extracted, or if the tear is difficult to access, another surgical incision must be made for delivery, and then both it and the rupture must be repaired. The tear in the uterus is much more accessible for suturing after the fetus has been removed.

Spontaneous rupture of the vaginal wall in late pregnant ewes was first described by White (1961); since then, it has been reported by others (e.g., Knottenbelt 1988, Mosdol 1999). The small intestine passes into the vagina and protrudes from the vulva; frequently the ewe will be found dead. The precise aetiology of the disorder is still unknown. Initially, it was generally believed to be associated with cervical vaginal prolapse (CVP), although Mosdol (1999) found evidence that uterine torsion during late pregnancy might be involved. In one case, which was considered to have a similar aetiology, Fox (1962) noted complete prolapse of the intact pregnant uterus through a tear in the dorsal wall of the vagina. O'Neill (1961) observed several parturient ewes that were unable to lamb in which rupture of the uterus was present. Prompt Caesarean hysterotomy and repair of the uterine tear gave good results.

Prolapse of the Bladder

Prolapse of the bladder through the urethra is most likely in the mare (see also Chapter 13). In this species the urethral opening is wide and parturient straining very forceful. The organ becomes everted during labour and may be injured during fetal expulsion. It should not be difficult to identify the everted bladder. It is pear-shaped and attached to the vaginal floor; urine drips from the two openings of the ureters, and the congested mucosa is apparent. Epidural anaesthesia should be induced. The bladder is first cleaned, and any lacerations are repaired by suture. The organ is then compressed between both hands and gradually forced back into the urethra. Further manipulation is then applied to the vaginal floor until the bladder is properly replaced. Antibiotic therapy lasting several days should be prescribed. Tetanus antitoxin should be given. Prolapse of the bladder occasionally occurs in cattle, but is rare.

Protrusion of the Bladder

Protrusion of the bladder through a rupture in the wall of the vagina may occur during or after parturition (see also Chapter 13, Fig. 13.2). The rounded organ protrudes from the vulva. The kink that forms in the urethra prevents micturition; thus the organ progressively distends with urine. The condition must be distinguished from prolapse of the vagina, cyst or tumour of the vagina, haematoma of the vulva, and prolapse of perivaginal fat. The surface of the bladder is cleaned, and the organ is punctured with a hypodermic needle to allow drainage of urine. It is then dressed with an antibiotic powder and gently pushed back into place through the vaginal rupture. The latter is then repaired. Epidural anaesthesia will greatly facilitate return of the protruded organ.

Prolapse of Perivaginal Fat

Prolapse of perivaginal fat is most likely in over-fat heifers of beef or dairy breeds and is a sequel to a rupture of the vagina, often a small one. The site of rupture is typically at the junction between the vagina and vestibule (Arbeiter & Mayer 1967). The fat should be carefully removed with scissors or an emasculator, and if possible, the vaginal tear should be sutured. Recently, Blaser et al. (2013) described an alternative method in which deep sutures are placed into the pedicle of the protruded fat, after which the fat is removed with an ecraseur. The defect in the vaginal wall is then closed with the previously placed sutures.

VetBooks.ir

• **Fig. 20.11** Infarction of the colon is a rare complication of prolapse of the rectum in the parturient mare.

Prolapse of the Rectum

Slight eversion of the rectum is a common accompaniment of powerful expulsive efforts, which usually recedes after delivery. Severe prolapse is likely only in the mare; if it is already present in a dystocia case when the veterinary surgeon arrives, an attempt should be made to reduce the prolapse, and an assistant should be instructed to maintain the organ in position by pressing a towel against the mare's anus. Epidural anaesthesia may be needed to replace the rectum. When the prolapse has been present for some hours before veterinary assistance is available and the organ has become markedly oedematous and contused or torn, it may be difficult or impossible to replace. Submucous resection under epidural anaesthesia or under a general anaesthetic must then be carried out. In the mare, parturient prolapse of the rectum, no matter how transient, may prove fatal because stretching or tearing of the colic mesentery can result in infarction of the terminal colon (Fig. 20.11). The affected segment of bowel becomes atonic, defecation stops, and the mare's condition deteriorates insidiously during the next few days.

Postparturient Prolapse of the Uterus

Prolapse of the uterus is a common complication of the third stage of labour in the cow and, less commonly, of the ewe. It occurs less frequently in the sow and is rare in the mare and bitch. In the ruminant species the prolapse is generally a complete eversion of the gravid horn, whereas in the sow and the bitch eversion is generally partial and comprises one horn only. Cases are on record in which the bitch has everted one horn before she has completely delivered the fetuses from the other. In the mare, the rare cases of prolapse are generally partial only.

• **Fig. 20.12** Uterine prolapse in a cow in lateral recumbency. The fetal membranes are still attached and there is a significant degree of rumen tympany. (Courtesy Dr. Jakob Malmo.)

Cow

The prevalence has been reported as ranging from 0.2% in range beef cattle in America (Patterson et al. 1979) to 0.3% in Scandinavian dairy cattle (Odegaard 1977, Roine & Soloniemi 1978) to 0.09% in dairy cows in California (Gardner et al. 1990). The occurrence seems to be affected by seasonal as well as regional factors, the condition being more common in the autumn and winter (Gardner et al. 1990) in some years and in some localities. Pluriparous animals of the dairy breeds are more prone to suffer from the disorder than are heifers, although in a study by Murphy and Dobson (2002) in the UK, the disorder was more prevalent in beef breed heifers than in cows. The highest incidence in dairy cows in New Zealand was in fourth parity animals (Oakley 1992).

In the majority of instances the prolapse occurs within a few hours (over 90% in less than 24 hours after calving; Gardner et al. 1990) of an otherwise normal second stage labour, although Gardner et al. (1990) reported that in their study, 47 out of 200 cases had received obstetrical assistance; similarly, Murphy and Dobson (2002) found that 33% of their cases followed an assisted calving. In some cases prolapse may be delayed for several days; these are generally associated with a grossly protracted and assisted labour. When delivery is achieved by heavy traction, the uterus sometimes prolapses immediately after the calf is withdrawn. Likewise, some cattle with extreme laxity of the perineum and vulva may spontaneously prolapse immediately after every calving.

The signs of this condition are obvious. As a rule, the affected cow is recumbent and if in lateral recumbency, rumen tympany can be prominent (Fig. 20.12); less often, the cow is standing with the everted organ hanging down almost to its hocks (Fig. 20.13).

Aetiology

Prolapse of the uterus occurs during the third stage of labour, normally within a few hours of the expulsion of the calf, and at a time when some of the fetal cotyledons have separated from the maternal caruncles. The aetiology of the condition is not fully elucidated but is clearly multifactorial (Dawson & Peter 2012).

• **Fig. 20.14** Uterine prolapse in which there has been haemorrhage from a torn uterine blood vessel into the everted organ. The prognosis for such cases is extremely poor. (Courtesy Dr. Jakob Malmo.)

Many of these factors relate to uterine inertia. Thus causes of primary inertia, such as hypocalcaemia, impairment of expression of prostaglandin or oxytocin receptors, and myometrial defects due to overstretching, contribute to primary uterine inertia, whereas exhaustion and dystocia contribute to secondary inertia. All of these contribute to the risk of uterine prolapse. Hypocalcaemia may also make the uterus atonic after the end of labour, resulting in delays to the involution of the cervix and uterus. Secondly, when tenesmus continues after second stage labour, there is increased risk of prolapse. Such situations include the aftermath of a dystocia, forced extraction of the fetus to resolve fetomaternal disproportion, retained fetal membranes, and laceration of the reproduction tract. Thirdly, prolonged recumbency, either due to paralysis or hypocalcaemia, is associated with the risk of prolapse, possibly due to the rise in intraabdominal pressure that is consequent upon being recumbent. High intra-abdominal pressure may also underlie the increased risk of prolapse in overconditioned or obese animals. Outbreaks of uterine prolapse have also been attributed to extreme weather, deficiencies of phosphorous or magnesium, or the presence of oestrogens in pasture. Finally, prolapse is more common in closely confined and highly fed cows rather than those at range.

Regardless of the predisposing factors, it appears that the onset of uterine inversion and prolapse occurs during or after third stage labour when a portion of detached afterbirth occupies the birth canal and protrudes from the vulva. Vandeplassche and Spincemaille (1963) were of the opinion that the pregnant horn does not undergo a progressive inversion from its anterior extremity; only the posterior two-thirds invert. The actual protrusion of this portion can occur very quickly in one bout of straining.

Prognosis

The prognosis will depend on the type of case, the duration of the condition before it is treated, whether the organ has sustained severe injury, whether haemorrhage has occurred from a major uterine blood vessel, and whether other organs (bladder, intestine) are involved in the prolapse. The mortality rate for a cow with an uncomplicated prolapse has been reported as 18% to 20% (Odegaard 1977, Gardner et al. 1990, Oakley 1992) within 24 hours of treatment; in addition, Oakley (1992) also found that a further 15% of animals died or were lost from the study during the course of the calving season. The prognosis for animals in which the prolapse has been long standing, in which there is intestinal or bladder involvement in the prolapse, or in which haemorrhage has occurred, is generally poor. Immediate recurrence occurs in a small proportion of animals: failure to completely extend the tips of the uterine horns is particularly associated with an increased risk of reprolapse.

Fertility of cows that survive uterine prolapse is reduced compared with normal cows. Patterson et al. (1979) reported that 40% of cows became pregnant after uterine prolapse. Murphy and Dobson (2002) found that only 55% of cows that had suffered from uterine prolapse were bred again, compared with 91.7% for unaffected cows; but, of the animals that were rebred, conception rates were satisfactory at 75% (versus 80.7%). Intercalving interval was extended in the studies of Jubb et al. (1990) and Oakley (1992) by 10 and 50 days, respectively. Loss of pregnancies in midgestation was also reported in the latter studies. Most cows that suffer a uterine prolapse calve subsequently without trouble. Murphy and Dobson (2002) reported only one recurrence at the next calving out of 77 cows that survived a prolapse, whereas Jubb et al. (1990) reported finding one cow that had prolapsed twice.

Haemorrhage is a serious potential complication of prolapse. Haemorrhage can occur when the uterine is prolapsed (Fig. 20.14) or, occasionally, after its replacement. Postmortem examination of such cases indicates that haemorrhage occurred due to the weight of the everted organ having torn the mesovarium and the ovarian artery.

VetBooks.ir

Treatment

The main difficulties in replacement of the organ are: (i) the almost continuous straining which manipulation of the uterus provokes; (ii) the pressure that has to be applied in an uphill direction; and (iii) the oedema/congestion of the uterus due to compression of the venous return.

Straining is prevented by the administration of an epidural anaesthetic. This also has the advantage that defecation is in abeyance during the operation. It is good practice to give a preliminary injection of calcium borogluconate (as for milk fever) and to relieve rumen tympany.

The need for uphill pressure can be managed by raising the hindquarters of a recumbent animal (e.g., by placing on a bale of straw or by using hip lifters), although the method described by Plenderleith (1986) is now almost universally used for recumbent cows. The cow is placed in sternal recumbency with both hindlegs pulled out behind her (weight therefore being taken on her stifles) (Fig. 20.15A and B; 'froglike position'). The assistant sits astride the cow, facing the rear, and holds the cow's tail up vertically. This manoeuvre causes the slope of the vulva to be upwards. The veterinarian then kneels between the cow's hocks and supports the weight of the prolapsed organ on his or her thighs. The weight of the uterus can be further supported by an assistant holding the corners of a towel, a plastic sack, or a piece of board. If the cow is standing, it is very helpful indeed to have to assistants holding the uterus above the level of the vulva by such means. If the fetal membranes are still attached, it is worth making an effort to remove them to reduce the weight of the uterus and reduce the risk of reprolapse. If the fetal membranes are already partially detached and their complete removal can be carried out easily and without injury to the caruncles, this should be done. However, if attachment is complete or when attempts at detachment are associated with haemorrhage, it is better that the organ be replaced with the membranes still adherent. (The subsequent management of the retained fetal membranes should be on the principles outlined in Chapter 23). The prolapsed organ should be palpated in order to detect the possible presence within it of a distended urinary bladder; if such is the case, the bladder should be emptied by the use of a catheter.

Wapenaar et al. (2011) obtained a consensus view of the management of uterine prolapse from a Delphi survey of expert opinion as follows. Before arrival, the uterus should be protected and supported by wrapping it in a moist towel or sheet, and the animal should be restrained where it is. Epidural anaesthesia should be administered plus a sedative if the animal is fractious. Assistance to restrain and support the cow and support the uterus should be sought. If possible, the cow should be standing, but if she is recumbent, she should be placed in the froglike position previously described. Lateral recumbency should be avoided; cows that are standing should be left standing, but those that are recumbent should be left recumbent. Recumbent cows that rise are at risk of rupturing uterine blood vessels as they move around, especially if they are uncoordinated due to early stage milk fever (Dawson & Peter 2012). In this context, it is worth noting that the prognosis for standing cows appears to be better than for recumbent animals: Ishii et al. (2010) reported a survival rate of 65% for standing cows versus 38% for recumbent animals. The uterus and perineum should be cleaned with warm, clean water, and the tail tied to one side. The uterus should be checked for lacerations: partial thickness lacerations should be sutured if they present a risk of haemorrhage or perforation but not otherwise. Full thickness lacerations should be sutured, but, if they are extensive and the cow's condition is poor, culling may be a better alternative. Lubrication is useful if the uterus is dry or oedematous, but the use of hygroscopic substances such as sugar or salt to draw out

• **Fig. 20.16** Diagram illustrating where pressure is applied to start the replacement of the prolapsed uterus.

oedema is not recommended. The fetal membranes should be removed according to the criteria described previously. Replacement should normally start at the vulva.

During replacement of the uterus, the veterinarian starts to replace the uterus little by little, starting with those portions that are nearest the vulval lips (Fig. 20.16). The nearest cotyledons are pushed into the vagina, taking care that the lips of the vulva remain well apart and do not become turned inwards. It is generally best to replace portions of the upper and lower surfaces alternately. When the last portions remain to be replaced, an assistant should press against these, using the palms of both hands, while the veterinarian endeavours to draw the lips of the vulva over the prolapse. As the mass disappears through the lips of the vulva, the veterinarian, using a clenched fist, should then continue to press it forward to the full length of the arm, ensuring that the uterus is pressed forwards beyond the cervical ring and to ensure that the horns are fully inverted. A bottle or blunt probang may be helpful with this step. It is worth taking time to ensure that the horns are fully inverted, as failure to invert the horns is significantly associated with the risk of re-prolapse. When this has been accomplished, the cervix should lie unoccupied at the level of the pelvic brim and, if the whole uterus has passed the cervix, it should regain its normal position. To ensure complete replacement of the uterus, it can be helpful if 9 to 14 litres of clean warm water are infused into the uterus by gravity feed and immediately removed by siphonage; the weight of water eliminating any remaining inversion of the horn.

After replacement, oxytocin should be given to help restore uterine tone and thus to prevent recurrence of the prolapse. It is generally held that preoperative treatment with oxytocin, although reducing the size of the prolapsed organ, increases the turgidity of the everted organ and makes replacement more difficult. However, a method of direct injection of oxytocin into the uterine muscle before attempting replacement has been described, which is said to make the process of replacement easier. Even if the animal shows no clinical signs of hypocalcaemia, IV calcium borogluconate therapy should be given, together with parenteral antibiotics and a nonsteroidal antiinflammatory agent. Intrauterine antibiotics are not generally found to be helpful.

A final advantage of caudal epidural anaesthesia is that straining will be prevented for an hour or so after replacement of the organ; the duration will be extended if xylazine is used as well. Some veterinarians choose to insert vulva sutures in a Buhner pattern to reduce the risk of reprolapse. This practice is controversial; many consider that it serves no useful purpose because prolapse should not recur if it has been replaced correctly. It may even stimulate the cow to strain, allowing the prolapse to recur within the animal and thus not be detected. Others consider that, provided the cow is reexamined 24 hours later and the sutures are removed, it can prevent the recurrence of a complete prolapse that will be much more difficult to replace a second time. In uncomplicated cases it is generally found that within 24 hours of replacement the degree of cervical contraction present is such that recurrence is very unlikely. Wapenaar et al. (2011) suggested that such sutures should be removed 4 to 5 days after replacement.

Amputation of the Uterus

Uterine amputation is a procedure for the salvage of the cow in which the uterus is necrotic or severely traumatised. The surgery can be performed using an open or closed approach. An open approach allows the identification and replacement of any viscera that are within the prolapse before the uterus is amputated, whereas the closed approach is rather simpler (Prado et al. 2016).

Dawson and Peter (2012) describe the open surgical procedure as follows. The uterine body is incised from the cranial cervix to the bifurcation of the uterine horns to expose the contents of the prolapse. Any abdominal viscera are returned to the abdominal cavity. The major uterine vessels are then located in the stretched broad ligament and are double ligated. The vessels are severed between the ligatures, and the mesometrium is incised and allowed to retract into the abdominal cavity. Next, a series of adjacent, slightly overlapping mattress sutures are placed across the uterine body just proximal to the cervix, after which the uterus is amputated 2 to 3 cm below this line of sutures. The stump is then sutured with a simple continuous pattern.

In the closed approach the entire organ is circumferentially tightly ligated near the vulva with surgical tubing, broad suture (umbilical tape), or elastic/rubber tubing. The uterus can either be allowed to slough over a period of 7 to 10 days or can be amputated straight away and the stump returned to the abdomen. If the uterus is allowed to slough, there is a risk of exsanguination due to the weight of the prolapse (Meisner 2009).

Postoperative treatment should include administration of tetanus toxoid, nonsteroidal antiinflammatory drugs, and appropriate antibiotics.

Sheep and Goat

The method of replacement is similar to that described for the cow (Figs 20.17–20.20), except that it is easier to perform because of the ease with which the hindquarters of the ewe or doe can be kept raised by an assistant; caudal epidural anaesthesia should always be used except in those situations in which a long delay may occur before it could be treated by a veterinarian. However, because of their different physical relationship to the caruncles, the fetal cotyledons cannot readily be detached, and rather than damage the uterus by persistent attempts to separate them, it is preferable to leave them attached and return them with the uterus; failure to detach them at this stage will not significantly affect the prognosis. Anaerobic infection should be anticipated and prophylactic antibiotic used. Murphy and Dobson (2002) noted that, among sheep farmers, there is a reluctance to retain a ewe for breeding that has suffered from prolapse for fear of it recurring.

Horse

Aetiology

The disorder is relatively uncommon in this species, but when it occurs, it can be life-threatening (Pascoe & Pascoe 1988). The condition is more common in older, pluriparous mares and in mares that have experienced prolonged dystocia and/or delivery of the fetus by traction (e.g., Hadiya et al. 2015). The condition is also related to partial or complete failure of expulsion of the fetal membranes (MacGillivray 2011). The membranes tend to separate from the endometrium in the uterine body more readily than at the tip of the uterine horns. The consequence of this is that, during the persistence of uterine contractions during third stage labour, the pull on the attached membranes at these points cause the eversion of the tip or tips of the horns. The continued uterine contractions and the subsequent straining as the mass of the fetal membranes enter the pelvis cause the whole of the uterus to be inverted and prolapsed. Mares that have to undergo Caesarean hysterotomy may also be at risk of uterine prolapse if the fetal membranes are accidentally sutured into the hysterotomy wound or if they remain attached at the tip of the uterine horn (Arthur & Allen 1971, unpublished). Hence it is important that, when closing the uterus, the allantochorion should be separated from the endometrium for some distance (see Chapter 16) around the site of incision. Some cases of uterine prolapse occur if retained fetal membranes are delivered by traction; eversion of the uterus at the point of attachment of the fetal membranes can be quickly converted into a prolapse when the mare strains. Thus in spontaneously occurring cases of uterine prolapse, the weight of the fetal membranes hanging from the vulva and the straining that occurs as a consequence of failure of passage of the fetal membranes are important causative factors in the development of uterine prolapse. In view of these observations, it is important that undue traction on the detached portion of the fetal membranes should not be applied when the more anterior retained portion is being freed. It is for this reason that the use of an oxytocin drip is the preferred method of treating retained fetal membranes in the mare (see Chapter 16).

Treatment

Diagnosis of a complete prolapse is straightforward. However, some mares have a partial prolapse of intussusception of a uterine horn, which is more difficulty to identify; these cases may present with persistent tenesmus, restlessness, colic, and tachycardia (Turner 2007) rather than overt uterine prolapse. The presence of lacerations, ischaemia, or necrosis of the uterus is associated with a poor prognosis for survival.

VetBooks.ir

The approach to replacement of the prolapse is broadly similar to that described previously for the cow. As soon as the condition is identified, the prolapsed tissue should be elevated/supported by two assistants to prevent the development of passive venous congestion and oedema. The mare must be adequately restrained to prevent trauma to the prolapsed organ and to prevent injury to the veterinarian. Sedation, IV analgesia, and caudal epidural anaesthesia (Chapter 14) are required in almost all cases; general anaesthesia may be required if the mare is fractious. Before replacement, an attempt should be made to remove the fetal membrane so long as the allantochorion can be readily separated from the endometrium without causing haemorrhage; if this is excessive, then as much as possible should be cut away before replacement. Also, the prolapse should be palpated to ensure that the bladder is not entrapped within it: if this has occurred, the bladder will need to be emptied via a catheter before the uterus is replaced.

The uterus should be replaced starting at the part adjacent to the vulva as described in the cow. The technique is easier than in the cow because of the absence of the caruncles; this tends to reduce the amount of haemorrhage. After replacement it is important to ensure that the organ is completely inverted; an intrauterine infusion of saline, with subsequent removal by siphoning, can be used, or a mare vaginal speculum can be inserted into the length of the uterine horn (Turner 2007). Once the organ has been replaced, the mare should be given oxytocin to restore tone to the uterus. Systemic antibiotics as well as antiinflammatory agents should be used, and there is a relatively high probability of laminitis occurring. Vulval sutures should never be used.

Pig

The consensus of veterinary opinion is that pigs are unable to tolerate uterine prolapse unless the uterus is replaced easily and quickly; frequently, by the time help is summoned, the sow will have died most probably due to a fatal haemorrhage after rupture of the uterine vessels or possibly shock. The degree of prolapse will vary from part of one horn at its simplest to both horns at its most extreme. The sow should be deeply sedated or preferably given a general anaesthetic and placed in an incline with the head facing downwards or suspended by her hindlegs. If the uterus is traumatised, then euthanasia is preferable, particularly in commercial pig units because there will be a delay before she can be served by the boar and become pregnant. An alternative procedure which merits a trial is to 'float' the uterus back into the abdomen with the aid of water pressure. The sow is placed on her side, head downwards, on a slope; the end of a soft tube of rubber or plastic, 2 cm diameter and 1.5 m long, is gently passed into the stoma of the prolapsed viscus and eased along as far as possible. Clean water is then allowed to flow into the prolapsed viscus. The weight of the introduced water gradually draws the prolapsed organ back into the abdomen; the tube is introduced further and more fluid infused. By this means the whole uterus is not only returned but completely replaced without manipulation. In the case of noncommercial pet sows, replacement can be attempted under general anaesthesia via a laparotomy (Raleigh 1977), as described later in this chapter for the bitch.

Dog and Cat

A laparotomy can be performed, and with simultaneous external manipulation and abdominal taxis, replacement can be attempted. It is more usual, however, to carry out 'external' hysterectomy on the prolapsed organ. The prognosis is favourable after amputation.

Parturient Recumbency

Recumbency, as a complication of parturition, is occasionally seen in all species but is most common and important in cattle.

Prepartum Recumbency in Cattle

The main causes of prepartum recumbency in cattle are nutritional: starvation ketosis (protein–energy malnutrition) and pregnancy toxaemia.

Starvation ketosis is used to describe inadequate supply of feed in terms of quantity, quality, or both. In such conditions of general underfeeding, the resulting protein and energy deficiencies cannot be strictly separated. The condition is commonly seen in heavily pregnant cattle on a poor plane of nutrition, particularly towards the end of the winter when fodder is scarce or poorly saved. Beef cattle on hill farms are at the highest risk of developing the condition. Affected animals are usually bright and alert and have normal appetites, and cardinal signs are generally normal; however, emaciation can be extreme. The onset of energy deficiency is gradual; thus neither ketone nor NEFA concentrations are particularly elevated (Malmo et al. 2010).

Animals that are recumbent generally have a poor prognosis and, in repunctuate animals that are in lateral recumbency, the prognosis is virtually hopeless. If treatment is attempted, it is based on providing additional feed, supplemented with propylene glycol, and attempts to lift the animal from recumbency. Premature induction of calving with corticosteroids can be attempted if the animal's condition is not too severe, but the stress of the induced calving can be fatal to more severely affected animals. Otherwise, in the interest of the animal's welfare, euthanasia should be performed, with salvage recovery of the calf (if it is likely to be viable) and measures taken to ensure that similar cases do not recur.

Pregnancy Toxaemia of Beef Cattle

Pregnancy toxaemia is most often seen in fat or very fat pregnant beef cows which are grazing marginal land or are provided with a much reduced plane of nutrition during the last 1 or 2 months of pregnancy. It can occur in animals carrying a single large calf or carrying twins. Growing heifers are particularly at risk due to the competing demands of pregnancy and growth. The resultant large scale mobilisation of body fat results in severe ketonaemia and fatty infiltration of the liver. Affected animals show signs of severe ketosis, including dullness, depression, inappetence, rapid weight loss, and, sometimes, recumbency. Blood concentrations of β–hydroxy butyrate and liver enzymes are typically high, and animals are hypoglycaemic. The response of severely affected animals to treatment is often poor, but less severely affected animals may respond to standard therapies for ketosis. Immediate removal of the calf by Caesarean hysterotomy may save a valuable cow (Malmo et al. 2010).

Postpartum Recumbency

Hypocalcaemia

Hypocalcaemia is the chief cause of recumbency in parturient and puerperal cows. It is a metabolic disease that is characterised

VetBooks.ir

by the development of paresis and severe hypocalcaemia near the time of calving. Clinically, it is characterised by weakness, recumbency, depression of consciousness, and, ultimately, death. Approximately 75% of cases occur within 24 hours of calving. Most cases occur within 48 hours of calving, but cases can occur several days before calving and up to 10 days after calving (Malmo et al. 2010). Parturient hypocalcaemia needs to be differentiated from other puerperal conditions, including acute coliform mastitis, calving paralysis, acute hypomagnesaemia, uterine disorders such as puerperal metritis, uterine rupture or retention of the fetus, or generalised peritonitis. Reference should be made to standard textbooks of bovine medicine for a full description of the condition.

Puerperal Metritis and Toxaemia

Puerperal metritis usually follows dystocia and is often accompanied by retention of the afterbirth. There is a fetid vulval discharge and diarrhoea; straining is frequent, and there is an expiratory grunt. The pulse rate is elevated, but the temperature, although at first raised, may be falling in a case of advanced toxaemia. A physical examination should verify the suspicion of metritis as a cause of recumbency. The clinical signs and treatment of puerperal metritis are described and discussed in Chapter 23.

Puerperal Laminitis

Puerperal laminitis is a troublesome complication of puerperal metritis. It is essentially an equine condition, but the other farm animals are occasionally affected. In the mare the condition is a likely sequel to retention of the fetal membranes. Two to 4 days after foaling the typical stance of laminitis is seen, the hindlegs being placed well forward to ease the weight on the more severely affected forefeet. It is a most painful condition and causes rapid loss of weight. Owing to the prolonged periods of recumbency and diminution in milk secretion, the foal may require artificial feeding. Avoidance of puerperal laminitis lies in preventing metritis by treating cases of dystocia promptly and carefully and by the appropriate treatment of retained fetal membranes.

Hypocalcaemia of Sows

True hypocalcaemia occurs occasionally in sows, but the most likely cause of postparturient recumbency is toxaemia due to metritis or mastitis. Incomplete parturition with retention of a fetus or a portion of the afterbirth should always be suspected. Failure of milk secretion is one of the symptoms of toxaemia and hypocalcaemia; it sometimes results from lack of the 'let-down stimulus'. So-called agalactia of sows is thus not a specific syndrome but merely a symptom common to several quite different affections.

Physical Inability to Rise

Physical inability to rise may be due to muscular weakness or to lesions of the locomotor system. Locomotor lesions that may occur during labour and cause recumbency include: dislocations of the hip and of the sacroiliac joints; fracture of the pelvis, femur, or vertebral column; rupture of the gastrocnemius muscle; and paralysis of the obturator or gluteal nerves. When a large fetus is forcibly drawn into the maternal pelvis, the lumbar nerves, which pass over the lumbosacral joint to form the anterior part of the lumbosacral plexus, may be damaged; paralysis of the gluteal, sciatic, or obturator nerves is a possible result. This is particularly likely when an oversized fetus becomes impacted in a state of 'hiplock' (see Chapter 14), the nerves being trapped between the lumbosacral promontory of the mother and the iliac bones of the calf. In addition, the obturator nerve, as it passes down the inner surface of the iliac shaft, may be damaged by an oversized fetus.

A diagnosis of disease of the locomotor system depends on a methodical clinical examination with a view to eliminating the several possibilities. The degree and form of the disability and the manner of the unsuccessful attempt to rise often give a strong indication of the cause. The examination includes the manipulation of the hindlimbs to determine the presence of excessive mobility or crepitus; it is combined with a rectal examination of the pelvic bones. Regional absence of peripheral sensation may verify nerve paralysis, including paraplegia associated with vertebral fracture. In cases of recumbency due to physical inability or pain associated with attempts to rise, the affected animal is usually bright, its appetite is good, and, when undisturbed, its temperature and pulse are unaffected. Each case must be treated on its merits.

When no cause of recumbency can be found in an animal that appears normal in other respects, tissue swelling, oedema, or haemorrhage in the vicinity of nerves is possible. If such were the case, the normal recovery processes would diminish pressure on the nerves, and this would be reflected in progressively better attempts to rise. However, if a cow is still unable to rise after being recumbent for a week, the prognosis is grave. Slings, hoists, and other devices are sometimes used to encourage the patient to stand, but in general they are of limited use. The best contribution that can be made to a recovery is the provision of first class nursing. This comprises placing the recumbent animal on ample, soft, clean bedding that overlies a dry floor and that is frequently changed. The patient is turned from side to side as often as possible, with concurrent massage of the limb muscles. Meanwhile, close veterinary attention is paid to the health of the cow's uterus and udder.

Gluteal Paralysis

Gluteal paralysis is seen in the mare and cow; in the mare it occurs after a spontaneous birth. It is recognised when the dam is found to have difficulty in rising and when she walks with 'weakness of the hindlimbs'. Later, atrophy of the gluteal muscles is apparent. Prognosis is favourable, the disability usually disappearing in a few weeks, although occasionally complete recovery may take months. In warm weather, the affected animal should be placed in a paddock which is free from ditches and obstacles; here a firmer foothold for getting up is more likely than in a barn or loose box. The animal may be helped to rise by lifting on its tail and then steadying its hindquarters. In order that the mare may suckle the foal and also rest on its feet, slings may be usefully employed. If the mare or cow cannot get up within a few days of parturition the prognosis is grave.

Damage to the Sciatic Nerve and Its Branches

In the cow, damage to the sciatic nerve is associated with intrapelvic pressure damage during calving that occurs when the sixth lumbar nerve is compressed against the ridge on the sacrum before it joins the first two sacral roots to form the sciatic nerve (Vermunt et al. 2010). Animals with damage to the entire sciatic nerve typically stand with the fetlock knuckled over and the hock dropped (Fig. 20.21). When paralysis is complete, the limb is dragged and advanced by flexion of the hip only; weight may be borne on the dorsal aspect of the fetlock. Femoral and peroneal paralysis is not usually direct sequelae of birth; damage to the femoral nerve can occur when a recumbent cow struggles to rise when its limbs are

VetBooks.ir

retracted caudally, whereas the peroneal nerve can be damaged by prolonged recumbency.

Obturator Paralysis

Obturator paralysis is more frequent in cows than mares. Obturator paralysis commonly occurs with the delivery of an oversized calf, causing compression of the nerve roots of L5 and L6 or compressing the obturator nerve as it courses down the medial shaft of the ilium (Vermunt et al. 2010). The obturator nerve supplies the adductor muscles of the thigh, thus paralysis results in abduction of the affected limb(s) (i.e., the animal is unable to bring the affected leg under the body, so it pushes out sideways; Fig. 20.22). When both nerves are damaged, the legs will be splayed, and the cow is unable to rise. If the cow is helped to its feet, the legs slide out laterally (in a characteristic 'froglike' position on its ventral abdomen with the hindlimbs flexed but abducted. When paralysis is one-sided, the cow generally requires assistance to rise, but, provided the affected leg is prevented from sliding outwards, it can usually remain standing. If the cow falls, there is a risk of limb fracture or dislocation of the hip joint. When there is complete and bilateral paralysis, prognosis should be guarded; when it is unilateral and the animal can walk with assistance, the outlook is favourable. If the limb is 'spread eagled', there is usually more severe damage than a simple obturator paralysis (Fig. 20.23). Such cases rarely recover (Vermunt et al. 2010). A significant proportion of cases show improvement within a few days and progress to a complete recovery, provided that they are provided with adequate nursing care and further damage to the limb is prevented. Hobbling together of the hindlegs with a strap applied above each fetlock prevents excessive abduction and secondary tearing of the adductor muscles or fracture of the femoral neck during attempts to stand. The cow must be assisted and maintained on her feet for milking

• **Fig. 20.23** Animals that are recumbent in a spread-eagled position have usually sustained more damage to the limb(s) than a simple obturator paralysis. (Courtesy Dr. Jakob Malmo.)

or suckling and as often as possible at other times. Necrosis of the muscles of the hindquarters must be prevented by the animal being turned from side to side, the hindquarters massaged, the bedding frequently changed, and the cow's rear and udder kept clean and dry. The frequent, careful, use of hip-lifters or a suitable sling can help maintain the circulation in the extremities and reduce the risk of muscle damage, although overuse can result in serious damage to the cow. Hip clamps should only be used if the animal can support its own weight on its hindlegs. Placing a rope under the brisket enables the cow to stand with greater comfort and for longer periods than if supported by clamps alone (Malmo et al. 2010). Slings are occasionally employed for cattle. Unless there is marked improvement within a fortnight, recovery is unlikely.

Castration and Cryptorchid Surgery

NEAL ASHTON

Castration of the Male Horse

Indications for Castration

Removal of the testes (also referred to as gelding, cutting, orchiectomy, orchidectomy) is routinely performed on male horses not intended for breeding purposes. The primary reason is to prevent stallion behaviour, which is generally regarded as inappropriate for most equestrian disciplines. In the wild, stallions organise into two distinct social groups: the harem bands that have one stallion and several mares, and the all male bachelor bands. Stallions can remain manageable if they remain in bachelor mode; however, interaction with other horses frequently results in harem band behaviour with increased aggression and reproductive drive (Klingel 1982). The average age that colts reach puberty is 69 weeks (range 55–101) (Cornwell et al. 1973). Stallions can be safely castrated at any age; however it is mostly undertaken at 6 months to 2 years of age. Some owners prefer to delay castration until after puberty to allow masculine features such as a crest or increased muscle mass to develop. In cattle, castration before puberty results in an increase in adult height due to delay in long bone growth plate closure (Shahin et al. 1992). It is possible that this also happens in the horse, but it is not documented or a reason for requesting castration by owners. Recently, there appears to have been an increasing tendency to castrate older animals once they have become unmanageable or once they have failed to perform to a level that justifies their use for breeding.

The anatomy of the reproductive organs, in particular the penis of the stallion, is shown in Fig. 21.1 and a diagram of the testes Fig. 21.2.

Surgical Techniques

Careful consideration of the age breed and type of horse, the premises at which the surgery is to be performed, and the methods for analgesia/anaesthesia should be made before selecting the surgical technique to be used. There are two broad surgical techniques, namely: (a) open castration (Fig. 21.3A–I) or (b) closed castration. An additional technique can be used in which an open castration is performed, and is subsequently closed; this prevents the possibility of postoperative herniation of abdominal viscera (Fig. 21.4 A–I). For an open castration, the vaginal tunics are incised, allowing direct visualisation of and access to the testicular vessels and the ductus deferens, which may then be ligated and crushed or solely crushed with an emasculator; the tunics are left open after removal of the testes (see Figs 21.3 A–I). For a closed castration, the vaginal tunics are not incised, with haemostasis ensured by placing ligatures around the spermatic cord (or transfixing ligatures); in this way no opening is created into the peritoneal cavity. For the open and subsequently closed technique (see Figs 21.4 A–I), the following procedure is performed: after opening the tunic, the blood vessels and ductus deferens are ligated and transaction, and the vaginal tunic and skin are subsequently closed.

Standing Castration

Standing castration (see Figs 21.3 A–I) can be undertaken in any colt that has normally descended testes, is large enough in height to enable the surgeon to access the scrotum by reaching underneath the abdomen, and has been well-handled with an amenable temperament. Owners should be warned about the risk of complications as they have been reported to occur in up to 60% of cases (Rosanowski et al. 2018).

The technique is traditionally used in thoroughbred racehorses in the UK but is less popular in sports horses and warm bloods. There is anecdotal evidence that warm bloods are more prone to scrotal hernia, and this may be the reason for this difference. Standing castration is generally performed using the open technique using emasculators and without placing ligatures across the vessels and ductus deferens. The major disadvantage of this technique is the possible risk of uncontrolled haemorrhage occurring and that it does not prevent the risk of evisceration of abdominal contents through the inguinal canal because the vaginal tunic is left open. However, the internal and external inguinal rings are not in alignment in the standing horse, and so the risk appears to be less compared with when the procedure is performed in the recumbent anaesthetised animal, when herniation may occur as the animal rises to a standing position.

The colt is first sedated, commonly using an α-2 adrenoceptor agonist (such as detomidine HCl) in combination with butorphanol tartrate; this results in profound sedation (Fig. 21.3A). The handler and surgeon remain on the left side of the colt, and the animal is made to stand against a wall on its right side. The surgeon approaches the scrotum from the horse's shoulder to reduce the chance of being kicked if the colt/stallion suddenly and unexpected kicks out with his left hind leg. The right (furthermost) testis is grasped in the left hand so that it is pushed down firmly into the scrotum. An 18-gauge 40 mm needle is advanced in one swift

VetBooks.ir

movement perpendicular to the skin of the scrotum directly into the testis to the level of the needle hub. Once the needle is in position, a 30 mL syringe containing the local anaesthetic agent is attached, and 20 mL of lignocaine HCl is injected into the testis. The needle is then retracted, and the remaining 10 ml is injected subcutaneously; then the needle is withdrawn (see Fig. 21.3B). The process is repeated for the left testis. Remarkably, this is well tolerated in the vast majority of animals. The scrotal skin can now be aseptically prepared. It is mandatory to wait after this; at least 10 minutes is allowed to elapse so that the local anaesthetic will have its maximal effect. Before commencing surgery the level of sedation should be assessed, and a further incremental dose of sedation may be required to ensure that the colt remains adequately restrained for the entire procedure.

The surgeon again grasps the left testis firmly against the scrotum, and a bold paramedian incision is made through the whole thickness of the scrotal wall (scrotal skin and vaginal parietal vaginal tunic) in a cranial to caudal direction, thus resulting in the 'open' castration technique. The incision is made large enough to allow the testis to be completely exposed. Gentle traction is then applied to the testis so that the 'opened' emasculators can be placed around the spermatic cord and testicular vessels with the cutting surface directly adjacent to the testis and the crushing surface positioned towards the direction of the spermatic vascular and not adjacent to the testis (the butterfly nut must be directed towards the testis (the so called 'nut to nut' orientation). The Serra emasculators are firmly closed at right angles to the spermatic cord, and the testis is removed. The emasculators must be closed completely, although this can require considerable force if the colt is large and the emasculators are not sharp. In these cases it may be best to first sever the caudal ligament of the epididymis with a scalpel, which allows the spermatic vessels and ductus deferens to be separated allowing the emasculators to be placed across the vessels and ductus separately (see Fig. 21.3 D). Once closed, the emasculators should be left in place for at least 5 minutes. During this time the procedure for removal of the left testis can commence. After removal of both testes, the scrotal incision is first inspected and if necessary manipulated to cover any protruding tissue; occasionally protruding connective tissue requires excision.

Routine perioperative antibiotics are administered systemically, along with non-steroidal antiinflammatory drugs. Procaine penicillin should not be used in horses likely to compete within 6 weeks; this mainly applies to race horses. Fly control is mandatory in the summer months to repel the attention from flies and prevent myiasis and other forms of wound contamination; many practitioners prefer to perform routine castration in the spring and autumn.

It is normal to advise that exercise is initially restricted for the first 36 hours postoperatively to only 'walking in hand', followed by a progressive return to exercise. Some trainers like to allow horses to swim shortly after castration, but although it may control swelling, this cannot be recommended due to the risk of wound contamination and even peritonitis.

Field Castration

Closed castration can be undertaken in the field or in a cleaner environment (e.g., a hospital induction box), or the open and subsequently closed method can be used. These methods are usually performed under dissociative anaesthesia and are appropriate for colts of 6 months to 2 years irrespective of temperament. It may also be used in mature stallions in which there are financial constraints when an increased risk of herniation has been identified.

The technique described here is that which is used routinely in the authors' hospital because this appears to address the most significant complications and has been associated with very low complication rates.

VetBooks.ir

Although premedication with acepromazine is slightly controversial due to the risk of priapism, the risk is outweighed because it helps to reduce anxiety and improves handling and anaesthetic induction. After this, the colt is then sedated with an α-2 adrenoceptor agonist (such as romifidine) with butorphanol. It is important to increase the dose if the animal is fractious because an adequate level of sedation is required before induction of anaesthesia.

Before induction, palpation of the scrotum and inguinal region is performed to ensure that both testes are descended and that there is no scrotal hernia. Anaesthesia is normally induced with ketamine, and the horse is then positioned in dorsal recumbency. It is often helpful for an assistant to straddle the horse across its thorax while holding the forelimbs to balance the horse in dorsal decumbency. Lignocaine HCl (20 ml) is injected into each testis, and a further 10 ml is injected subcutaneously into the scrotal midline. The scrotum is aseptically prepared for surgery, and a fenestrated drape is placed.

The surgeon kneels on the colt's right side. The left testis is grasped with the left hand and pushed against the scrotum; the median raphae of the scrotum are readily identified as a distinct line. A skin incision parallel to the median raphe is made over the left testis, 1 to 5 cm from midline and of appropriate length, depending on the size of testicle. A second incision is then made in the vaginal tunic and the testis exteriorised. Traction is applied to the testis to tense the epididymal ligament, which is then sectioned with a scalpel. Forceps (Lane, Aliss, or Babcock) are applied to the vaginal tunic, and it is bluntly separated from the cord and spermatic vessel by traction. Serra emasculators are then applied to the vessels and ductus deferens and the testis removed. The emasculators are left in place for 3 to 4 minutes depending on the size of the colt. After removal of the emasculators, the spermatic vessels are inspected to ensure adequate haemostasis. A swab is then used to bluntly dissect the vaginal tunic from the associated scrotal connective tissue to the level of the external inguinal ring. The amount and texture of connective tissue varies considerably between breeds and types of horses, often being substantial in native ponies and cobs. The vaginal tunic is again grasped with forceps at the site of the incision and twisted to ablate the lumen down to the level of the external inguinal ring. The forceps are handed to an assistant to apply traction as the surgeon places a transfixing ligature of 5 M Polyglactin 910 through the vaginal tunic at the level of the external inguinal ring; this is hand tied on either side of the fixation. The emasculator is then applied to the vaginal tunic distal to the transfixing ligature, and it is removed; the emasculators should be left in position for 2 minutes to ensure adequate haemostasis of the cremaster muscle vasculature. The process is repeated on the right side, although it is quicker to remove both testes first, leaving emasculators attached on the right testis while closing the left vaginal tunic.

After removal of both testes, the two parallel scrotal incisions are joined, and the median raphe of the scrotum is dissected out with scissors. This provides adequate drainage of the subcuticular dead space. The wound is inspected and the scrotum stretched to ensure that no connective tissue can prolapse through the incision; any tissue that may do so is removed. The horse is placed in lateral recumbency for recovery. As noted previously, this is the routine procedure used by the authors; however, in many circumstances, particularly when there is greater risk of wound contamination, the surgeon may elect to perform a closed castration whereby the vaginal tunic is not opened.

Postoperative management is as for standing castration.

Theatre-Based Castration

This technique, although the ideal procedure, is usually reserved for mature stallions due to cost. The aim of the surgery is to ensure a high level of sterility during the procedure and to close the skin incision after completion of the castration.

There are some variations in technique depending on the preferences of the surgeon (Kummer et al. 2009); the authors recommend the following technique.

Under routine general anaesthesia the urethra is catheterised, and the prepuce is temporarily closed with a continuous suture of 3 M nylon. The scrotum and inguinal region is aseptically prepared for surgery. A disposable impervious drape is applied, and an approximate V-shaped section of the drape is excised to expose the scrotum and the inguinal region while leaving the prepuce covered. An iodine impregnated adherent drape is then applied. A parainguinal incision is made midway between the external inguinal ring and the scrotum; care is taken to avoid large subcuticular vessels. The subcuticular fascia is incised, and then blunt dissection is used to expose the vaginal tunic. The tunic is grasped with Allis forceps, selecting a site where the cremaster muscle is not attached. The tunic is excised using a scalpel, and the incision extended with scissors to allow extraction of the testis by finger traction; the ligament of the epididymis is then transected. The ductus deferens and testicular vessels are ligated using a single 5 M polyglactin 910 suture. The spermatic cord and associated vessels are then severed with an emasculator distal to the ligature. A 'graft passer' is used to place a ligature around the vaginal tunic close to the external inguinal ring; this technique allows for minimal dissection, reduced chance of haemorrhage, and smaller dead space. The subcutaneous tissues are closed with 3 M polyglactin 910, and the skin with 2 M polyglactin 910 placed intradermally. The process is repeated on the contralateral testicle.

After recovery from general anaesthesia, postoperative management for the horse is as described later in this chapter for standing castration, apart from the use of antibiotic medication which is not required because of the high level of asepsis.

Laparoscopic Castration

Routine castration can be undertaken laparoscopically in the standing horse by ligating and transecting the vasculature and ductus deferens intraabdominally. In most animals the testes will undergo avascular necrosis. However, in 3.4% of stallions, a testis does not become necrotic due to the establishment of an alternative blood supply from the cremaster muscle and/or the external pudendal artery (Voermans et al. 2006). Laparoscopic techniques have also been combined with open surgery (Rijkenhuizen & van der Harst 2017).

Complications

Eventration

The most common severe complication of equine castration is eventration, the protrusion of small intestine through the inguinal canal (so called 'indirect herniation'). This can lead to trauma of the exposed bowel and is rapidly fatal. Eventration is prevented by techniques that either do not open the vaginal tunic or open it but after removal of the testis is subsequently close (as described previously). The risk period for herniation is within the first 36 hours of surgery. When eventration occurs, it is not possible to replace the herniated loop of small intestine into the abdomen. Therefore initial treatment requires protection of the exposed bowel and prevention of further herniation. If there is a relatively short

VetBooks.ir

loop of small intestine involved, it can be treated as an essentially 'first aid' measure by just suturing the scrotum to contain it in order to facilitate transport of the affected individual to a surgical facility. If the loop of exposed bowel is substantial and/or it is damaged, immediate field-based general anaesthesia may be required to facilitate replacing the exposed intestine into the scrotum and retaining it by suturing the scrotal incision. Sometimes resection of the traumatised intestine is required, and the bowel clamps on the transected stumps are then sutured within the scrotum to enable transport for surgery. All cases will require general anaesthesia and a laparotomy to enable hernia reduction and facilitate resection and anastomosis of the affected bowel. The prognosis is good in peracute cases; however, in chronic cases, cardiovascular compromise and endotoxaemia will reduce the prognosis.

Herniation of omentum is a much less serious complication, and generally the only indication is presence of the omentum protruding from the scrotal incision with no other clinical signs. Treatment involves applying gentle traction to expose a section of clean omentum, then simply excising the exposed tissue. If the amount of tissue is large, then ligation should be undertaken first; it is prudent to undertake a rectal examination to palpate the internal inguinal ring and thus ensure that no bowel appears to be entrapped. In simple cases the prognosis is good.

Haemorrhage

Bleeding from the scrotum, cremaster muscle and subcuticular vessels is generally self-limiting and not significant, although it can be alarming to owners.

Bleeding from the testicular vessels is potentially serious. This can be common particularly after standing castration, especially when ligation has not been performed. Many clinicians regard the presence of blood dripping from the scrotum for up to 24 hours after surgery as acceptable, but it can be avoided. Minimal but persistent bleeding is frustrating for the veterinarian because it may result in owners requesting often unnecessary repeat visits. Generally, this can be avoided by placing good quality emasculators correctly and leaving the emasculators in place for at least 5 minutes as described previously.

If the bleeding is continuous rather than intermittent dripping or has persisted for over 24 hours, then ligation may be necessary. The cardiovascular status of the horse should be assessed clinically and a packed cell volume (PCV) value obtained before treatment.

In cases with cardiovascular compromise or if the bleeding is minimal, the scrotum can be packed with gauze swabs in an attempt to apply pressure to the stumps of the cords; these can be sutured in place with heavy catgut. The gauze is removed 2 days later by breaking the catgut suture by a sudden pull on the gauze (Schumacher 2012).

In cases in which there is severe haemorrhage without cardiovascular compromise or corrected haemorrhagic shock, short general anaesthesia may be required. The stump of the cord can be located and religated using a 5 M polyglactin 910 ligature and repeat emasculation. In addition, gauzes can be sutured in place with heavy catgut as described previously.

Intraabdominal haemorrhage has been anecdotally reported postcastration; occasionally there is continued bleeding despite repeated attempts to ligate the stump. In such instances, standing laparoscopic ligation may be indicated (Trumble 2000). Using the author's field anaesthesia technique (described previously), the vaginal tunic is ablated by twisting. The author has used this technique with concurrent laparoscopic visualisation of the internal inguinal ring; the spermatic cord stump does not retract into the abdomen. Because it is not present in the resected vaginal tunic, the stump must remain in the region of the external inguinal ring. In the authors' experience, intraabdominal haemorrhage has not occurred using this technique.

Infection

Bacterial infection most frequently results from contamination of the scrotal wound after surgery and therefore cannot be prevented at the time of surgery. Attempts should be made to reduce contamination, especially in the first 36 hours postoperative, when the animal is confined; the bedding must be clean, of adequate depth, and a faeces removed frequently. Straw or paper bedding is preferable to shavings, especially in young animals that are more likely to lie down; deep litter systems are not appropriate. After this period, increased exercise is important to reduce swelling and oedema and to promote drainage. In young animals, free paddock exercise is appropriate. Consideration of the timing of surgery is important as in summer months fly-borne contamination is difficult to prevent. In winter, very low temperatures can hamper scrotal healing. In older horses, controlled exercise may be more appropriate; hand walking, a treadmill, walker exercise, or leading are all suitable. A significant period of walking exercise is recommended: 45 minutes three times daily. Some trainers favour swimming during this period; although this is very effective at reducing swelling and oedema, it cannot be recommended due to the potential risk of an ascending infection through the inguinal canal and subsequent peritonitis.

Scrotal Infection

In techniques without scrotal closure, subcutaneous scrotal infection is self-limiting because in most cases there is adequate drainage. Removal of the median raphe of the scrotum (as described previously) to create a single subcutaneous space further enhances drainage.

If the scrotum is closed, contamination of the sutures may result in bacteria tracking into the subcutaneous dead space and the creation of a scrotal abscess. If scrotal drainage is inadequate in open scrotal techniques, the skin may heal and trap infection subcutaneously, again resulting in a scrotal abscess.

Treatment primarily depends on establishing adequate drainage; with the horse adequately restrained, sutures must be removed and the scrotal incisions reopened. Local anaesthetic is injected into the abscess before reopening the incision, and this can almost always be achieved by blunt dissection, either digitally or using scissors. In extreme cases, general anaesthesia and surgical excision of the scrotum and removal of the median raphe may be appropriate. Exercise to reduce swelling and oedema is important; animals turned out may be inactive due to pain caused by the infection. Nonsteroidal antiinflammatory medication is important to reduce pain and swelling and facilitate exercise. Bacterial culture and sensitivity is appropriate but not always necessary. Broad spectrum antibiotics should be administered, although culture and sensitivity should be considered in serious cases in which longer course antimicrobial therapy may be necessary.

Scirrhous Cord

Chronic micro pyogranulomatous infection of the stump of the spermatic cord is a more serious complication caused by bacterial infection. The source of infection is either contamination at surgery or, more commonly, secondary to scrotal infection. Techniques that do not close the vaginal tunic increase the risk of the development of a scirrhous cord secondary to scrotal infection. Horses with this condition will have a chronic purulent discharge from the scrotum.

VetBooks.ir

Palpation reveals a firm thickening of one or both of the spermatic cord stumps. Because the infection is pyogranulomatous with multiple microabscessation, antibiotic treatment alone is unsuccessful and inappropriate. Appropriate treatment is by surgical resection, performed under general anaesthesia. There is frequently substantial highly vascular fibrosis and adhesion formation around the stump, which needs to be dissected by both sharp and blunt techniques from the surrounding tissues. The spermatic stump is freed up to the level of the external inguinal ring and then transected with emasculators at the level of the external inguinal ring; in most cases, this is proximal to the thickened infected stump. However, on rare occasions the thickened stump continues into the inguinal ring, in which case laparoscopy may be indicated to facilitate transection of the stump proximal to the infection. Despite the potential risk of peritonitis, in the authors' experience, this is extremely rare. The scrotum is left open for drainage. Appropriate antibiotics are administered based on culture and sensitivity, and the open scrotal wound is managed with appropriate exercise and frequent lavage. The prognosis with appropriate treatment is excellent; however, it is important to emphasise that even in cases in which there are financial constraints on the cost of treatment, surgery is necessary because attempts to treat with antibiotics alone will be unsuccessful and merely add to the cost.

Peritonitis

Peritonitis is a rare but serious complication of equine castration. Animals presenting with any of the following signs postoperatively should be considered at risk: pyrexia, inappetence, colic, lethargy, and/or weight loss. Diagnosis is made after the analysis of peritoneal fluid obtained by abdominocentesis. Gross examination reveals a turbid and cloudy fluid. Laboratory investigations usually demonstrate an elevated total nucleated cell count and elevated protein concentration, and in a cytological examination, there are degenerate neutrophils and bacteria. The sample should be submitted for culture and sensitivity. Aggressive antimicrobial therapy, along with appropriate management of the scrotal wound/scrotal abscess and/or scirrhous cord is required; in severe cases, peritoneal lavage may be necessary. The prognosis with appropriate management is good, although adhesion formation as a cause of colic after castration-induced peritonitis has been observed.

Postoperative Swelling and Oedema

Swelling and oedema of the scrotum and prepuce are commonly seen over the first 5 days after castration but generally resolve by 2 weeks. An appropriate exercise regime should help to prevent the early closure of the surgical incision and thereby reduce swelling. Swelling that is severe or persists beyond this period should increase the suspicion of the presence of infection (see previous mention).

Cryptorchid Surgery in the Horse

Aetiology

Failure of one or both testes to descend into the scrotum is relatively common in the horse. The retained testis or testes may be present within the inguinal ring or in the abdomen. In some cases the gubernaculum and/or epididymis are present within the inguinal canal, although the testis/testes remain within the abdomen. Abdominal testes are most frequently located close to the internal inguinal ring but may be situated anywhere between the inguinal ring and the kidney.

It is noteworthy that anorchidism (congenital absence of the testes) and monorchidism (only a single testis present) are extremely rare, and so most cases seen in primary care practice will be either unilateral or bilateral cryptorchids.

Investigation of Cryptorchidism

Careful palpation of the inguinal region under sedation may reveal the presence of an inguinal testis. Ultrasonography undertaken at the level of the inguinal ring enables an inguinal testis or an abdominal testis positioned close to the internal inguinal ring to be identified. Rectal palpation of the inguinal region may also be helpful.

In horses of unknown history that exhibit stallion-like behaviour but in which no scrotal testes can be palpated, endocrine investigations are required to confirm the presence or absence of retained testes. This can be undertaken using an hCG stimulation test (in which elevated testosterone concentrations after administration is diagnostic) or measurement of basal oestrone sulphate (in which elevated concentrations are diagnostic). In these cases, careful visual examination of the scrotum for scarring from previous surgery may also be helpful.

Surgical Technique

Cryptorchidectomy can be carried out by laparotomy, using an inguinal, parainguinal, suprapubic midline, or flank approach. Laparoscopic cryptorchidectomy is widely used in hospital practice; however, recent studies have found an increased complication rate compared with traditional techniques (Cribb et al. 2015).

Inguinal Exploration

In cases in which an inguinal testis can be palpated or identified on ultrasound examination, surgical inguinal exploration is indicated. This can be done with the animal standing after administration of local anaesthetic into the scrotal and inguinal regions but is easier under general anaesthesia.

After routine aseptic skin preparation, a scrotal incision is made parallel to the midline. Blunt finger dissection is used to expose the inguinal region. The gubernaculum and/or the epididymis and/or the testis may be palpable. If not, then direct visualisation may reveal a white structure with a smoother, almost shiny, appearance compared with the local fatty connective tissue. This tissue is likely to be the gubernaculum and can be grasped with appropriate Lane, Babcock, or Allis forceps. Traction on the gubernaculum will often deliver the inguinal testicle into the surgical incision, and a routine castration can then be performed. Care should be taken to ensure that a testis is present because occasionally only the epididymis can be exteriorised because the testis is too large to pass through the internal inguinal ring and remains in the abdomen; rarely the epididymis is mistaken for a testis and is removed, thus leaving the testis *in situ* within the abdomen.

Parainguinal Exploration

If the testis is abdominal or inguinal, a parainguinal approach is preferred. In bilateral abdominal cryptorchids, both testes can usually be retrieved from a unilateral parainguinal incision. Rarely, bilateral parainguinal incisions may be required for bilateral abdominal cryptorchids; this is still preferred to a midline approach.

A skin incision is made centred on the cranial boarder of the inguinal ring, 3 to 5 cm from the midline. Using blunt dissection, it is continued through the subcutaneous tissue to expose the

VetBooks.ir

aponeurosis of the external abdominal oblique muscle, taking care to avoid damage to any blood vessels. This fibrous structure is incised with a scalpel, then the internal oblique and rectus muscle fibres are separated by blunt dissection between their fibres to produce a grid approach, which exposes the peritoneum. The peritoneum is then penetrated with a finger. The incision only needs to be large enough to allow access of two fingers. The first and index fingers are then placed through the incision and angled laterally towards the internal ring. The abdominal testis can frequently be grasped between the fingers and exteriorised by traction. If unsuccessful, the incision can be extended to allow the insertion of a hand and, if necessary, an arm into the abdomen. A systematic search of the abdomen is then undertaken starting at the internal inguinal ring to confirm the absence of any structure including a previously severed spermatic cord passing into the inguinal ring. The examination should then logically progress towards the bladder neck, along the bladder, and up to the kidney. Occasionally, an abdominal testis is situated caudal to the inguinal ring and is found within the pelvis. Familiarity with the feel of the tubular nature of the epididymis and more homogeneous and slightly firmer texture of the testis, compared with the abdominal viscera, is helpful. Rarely, the testis is not identified using this approach; one of the authors' first surgical mentors then claimed 'if all else fails opening the palm of the hand in the abdomen and *thinking testis* sometimes results in the offending structure being identified'.

In bilateral cases, both testes can usually be removed from a single parainguinal incision; occasionally bilateral incisions are necessary when the spermatic cord is too short on the contralateral side. A midline approach is not recommended as the spermatic cord may be too short to enable the testis to be exteriorised. A parapenile midline approach can be used in bilateral cases but requires more dissection than the parainguinal approach. A direct approach through the inguinal ring is not recommended due to the increased risk of subsequent inguinal herniation.

After emasculation and removal of the testis, the wound is closed with a single suture placed through both deep muscle layers to close the grid, followed by simple interrupted closure of the aponeurosis, using 5 M polyglycolic acid 910. The subcutaneous tissue is closed with 3.5 M polyglycolic acid 910, followed by 3 M polyglycolic acid 910 intradermal sutures.

Laparoscopic Exploration

Ultrasonographic examination of the abdomen is very important before attempting laparoscopy because it often enables the identification of the approximate location of the testes and therefore assists with planning of the laparoscopic approach.

Standing Laparoscopy

Standing laparoscopic cryptorchidectomy is a very elegant technique for the well-behaved and easily handled mature horses (Hendrickson & Wilson 1997). It is performed via two paralumbar portals, employing similar techniques to those used for ovariectomy (see later in this chapter). In bilateral cryptorchid cases the procedure can be repeated on the contralateral side. In unilateral cases, castration of the descended testis can be carried out at the same time, although ligation and transaction of the spermatic cord and vessels can still be done laparoscopically (Sassot et al. 2017).

Laparoscopy Under General Anaesthesia

Laparoscopy under general anaesthesia may be appropriate for young and unhandled horses and ponies. An operating table capable of tilting into the Tredelenburg position is required. The laparoscope portal is placed cranial to the umbilicus; two instrument portals are placed either ipsilaterally or contralaterally in the caudal abdomen. After insufflation of the abdomen, the table is elevated into the Tredelenburg position so that the parts of the colon are displaced cranially to reveal the inguinal rings. Abdominal testes can be removed after transaction and ligation using a 'ligasure', via extension of the laparoscopic incision.

Laparoscopy Complications

The most serious complication of the laparoscopic castration is penetration of viscera, when inserting the laparoscopic and instrument portals; this risk can be minimised as described for laparoscopic ovariectomy (see later in this chapter). In a recent review (Crib et al. 2015), it was found that horses undergoing laparoscopic cryptorchidectomy had increased surgical preparation times, increased surgery and anaesthesia times, and greater postoperative complications, compared with horses undergoing open cryptorchidectomy. Laparoscopy may be advantageous for a second attempt at cryptorchidectomy or if the testis location is unknown before surgery (Crib et al. 2015).

Castration (Ovariectomy of the Female (Mare) Horse

Indications

Routine ovariectomy of the mare is indicated to reduce unwanted 'mare-like' behaviour and prevent oestrus. It is likely that prevention of inappropriate aggressive and dominant behaviour is most effective if ovariectomy is carried out in young mares soon after the behaviour becomes apparent. However, the effects of ovariectomy on mare behaviour have not yet been fully investigated. Prepubertal ovariectomy of mares to prevent inappropriate behaviour is not currently undertaken, and its effectiveness has not been investigated. Ovariectomy is also indicated in cases of ovarian pathology, most commonly a granulosa cell tumour in which the mare may demonstrate a broad range of clinical signs, and there is commonly substantial enlargement of the ovary.

Historical Perspectives

In the late 19th and early part of the 20th century, ovariectomy of mares was commonly performed in France and the UK; it was routine in the British military. The surgical technique employed was a transvaginal colpotomy, using chain ecraseurs to transect the ovarian pedicle and oviduct. Ironically, this was in some way an extremely modern technique, performed in the standing horse via a natural orifice approach. The practice fell out of favour as the horse became less essential for the armed forces. As the availability of hormonal methods of controlling ovarian activity increased and because simple suitable routine surgical methods were not applicable, there was a decline of routine mare ovariectomy by the mid to late 20th century. Nowadays, particularly in sports horse competitions, the gelding rather than the stallion or mare is preferred, as most riders regard the former as more predictable and trainable. Consequently, ovariectomy of fillies and mares appears to be becoming more popular (despite the legalisation of progesterone therapy to suppress oestrus for mares under FEI regulations). Recently, several minimally invasive laparoscopic techniques, either via a flank or vaginal approach, have been described. In the sport and leisure horse, the practice is gradually becoming more popular.

VetBooks.ir

However, evaluation of the benefits of mare ovariectomy and the most appropriate timing of the procedure need to be investigated so that mare owners can be advised correctly.

Surgical Technique

Routine Ovariectomy

A variety of techniques for ovariectomy are currently in use. The most common is a laparoscopic technique using three portals per side. The ovarian pedicle is sealed and transected using a ligature; the ovary is then removed by joining the two instrument portals using a blunt grid approach through the abdominal muscles. This results in the creation of a 20 cm long flank wound. Colpotomy techniques have also been reported; the challenge with using this technique is ensuring adequate sterility and closure of the vaginal incision. There have been other approaches advocated, including pararectal, hand-assisted laparoscopic, and trochar techniques.

In the authors' practice, a laparoscopic technique using a morcelator (Lund et al. 2014) is used. This involves two laparoscopic portals on each side of the animal. The ovarian pedicle is anaesthetised by the injection of lignocaine, and then the pedicle is sealed and transected using an electrosurgical ligating and cutting device, in a caudal to cranial direction, leaving the ovary suspended by the final 5 mm of cranial ovarian pedicle. The morcelater is then introduced through the instrument portal, and the ovary is removed. The two paired portals are closed with absorbable sutures in the muscle, and intradermal skin sutures. The mare can resume exercise 10 days later. It is likely that, with the continued development of safe elegant cost-effective techniques, routine ovariectomy of mares will once again become a commonly performed procedure in equine hospital practice.

Removal of Granulosa Cell Tumours

Granulosa cell tumours are benign ovarian tumours; they vary in size from little more than that of a normal ovary to over 50 cm in diameter in the most extreme cases. Removal by laparoscopic transection and ligation using an electrosurgical sealing and cutting device in the standing horse, as described previously, is now routine. Alternatively, laparoscopic stapling devices or ligatures can be used.

Removal of the ovary can be undertaken in several ways. The technique used should be selected based on three factors: the size of the mare, the size of the ovary, and the depth of extra peritoneal fat. Granulosa cell tumours are multilocular and fluid filled; therefore the size of tumour can be significantly reduced by aspiration of the fluid. Relatively small tumours, especially in large lean mares, can be removed via a flank incision. The instrument portals are connected, and the skin incision is enlarged to an appropriate size for the ovary. The fascia and external oblique muscles are transected, and the incision is enlarged using a blunt finger grid dissection through the internal oblique and the transverse muscles; the peritoneum is also bluntly opened. The ovary is elevated into the incision by traction on the grasping forceps. With a portion of the tumour exposed, a stab incision is made into it, which enables a suction catheter to be introduced so that fluid can be aspirated to reduce the tumour size. Once flaccid, the mass can be exteriorised through the flank incision, and the wound is then closed. In all but the largest wounds, closure of the deeper layers is not necessary. The external oblique and fascia is closed using a simple continuous pattern with 5 M polyglycolic acid 910; the subcuticular layer is closed using a simple continuous pattern with 3 M polyglycolic acid 910, followed by intradermal sutures using 2 M polyglycolic acid 910. Alternative techniques for flank removal include intraabdominal needle aspiration and the use of endobags, with and without morcellation.

For large or moderate sized tumours in small or obese horses and ponies, it is preferable to remove the mass in a second procedure under general anaesthesia. With the horse or pony in dorsal recumbency, a midline laparotomy incision is made, at least large enough for the insertion of the surgeon's arm. A 50 × 50 cm disposable drape is placed into the abdomen. The ovary is placed onto the drape, and the drape carefully opened out. The four corners of the drape are then grasped by the surgeon and pulled out of the incision so that the ovary is pulled up into the incision. A stab incision is then made in the ovary to enable a suction catheter to be pushed into the mass to aspirate as much fluid as possible. When the mass is more flaccid, it is exteriorised through the incision by traction on the drape; the celiotomy incision can be extended if necessary. The wound is then closed routinely, and the horse recovered.

Complications

Before the advent of laparoscopic techniques, the complication rate after open surgery was high. This is because the ovarian pedicle is relatively short and difficult to access, thus increasing the potential for inadequate ligation of the pedicle, leading to a high risk of potentially fatal haemorrhage. Traction on the ovary causes pain, which often necessitates increasing the depth of anaesthesia, and thus possible anaesthesia complications. Current laparoscopic techniques have resolved these issues. The pedicle is routinely anaesthetised by visually directly injecting local anaesthetic and then effectively ligated without the use of excessive tension. The main complication results from the risk of inadvertent visceral or splenic penetration when placing the first laparoscopic portal. This can be reduced by careful preoperative planning, including rectal palpation to assess the position of the colon, spleen, and caecum. The introduction of air into the abdomen via a Varres needle or teat cannula before the placement of the first trochar and cannula is also helpful. Guarded sharp trocars are also frequently used and are quite satisfactory. However, the threaded trocar further reduces the risk of visceral penetration as there is no forward stabbing force required for its insertion, and the peritoneum is incised in parallel plane. In most cases of inadvertent caecum or large colon penetration, the cannula remains in the viscera. This enables the surgeon to extend the incision so that the bowel and cannula can be carefully exposed and elevated by placing stay sutures either side of the penetration. The abdomen can then be packed-off with sterile saline–soaked, gauze swabs. The cannula can then be removed from the bowel, and the incision closed with a continuous double layer of inverting sutures, with 2 M polyglycolic acid 910 on a round body needle. If the bowel separates from the trocar, then significant faecal peritoneal contamination will occur, leading to rapidly fatal peritonitis. Conversion to a ventral midline laparotomy under general anaesthesia may be required to facilitate closure of the colon penetration followed by abdominal lavage.

Large flank incisions are associated with higher morbidity rates due to seroma formation; they are also unsightly and may leave significant scarring. The complication rate is very low for an elective midline laparotomy. This technique should always be considered when the tumour is large, especially in small or fat animals, and when a good postoperative cosmetic result is important, such as in show animals.

Infertility in the Cow Due to Functional and Management Deficiencies

TIMOTHY J. PARKINSON

General Considerations

Fertility is one of the key determinants of the lifetime performance of a cow. For beef cows and for pastoral dairy cows, it is necessary for a calf to be produced every 365 days. For intensively managed dairy cows, which can maintain long periods of high lactational yield, the need to produce a calf each year is less of an imperative (Dijkhuizen et al. 1985); yet, even for these animals, regular calving is necessary for the establishment of lactation and breeding of herd replacements.

Regular breeding depends on the normal function of the reproductive system. In order to breed regularly, the cow has to have functional ovaries, display oestrus behaviour, mate, conceive, sustain the embryo through gestation, calve and resume oestrous cycles, and restore uterine function after calving. Management, disease, and the genetic makeup of the animal can affect each of these aspects of reproductive function. Sterility, meaning an absolute inability to reproduce, is rare, but reduced fertility, referred to as subfertility, is common.

Prevalence and Cost of Infertility

Prevalence

Evidence for the decline in fertility of high yielding dairy cows has been steadily accumulating over about the last 50 years. Over that period, first service conception rates and pregnancy rates have decreased, and intercalving intervals and the proportion of cows culled for infertility has increased.

The decline in first service conception rates has been extensively reviewed. For example, Butler (1998) showed a decrease of first service conception rate from 65% to 40% between 1951 and 1996. Lucy (2001) and Mann (2004; Fig. 22.1) showed similar trends in the literature over the same period. First service conception rates of 40% to 45% (e.g., Bousquet et al. 2004) and pregnancy rates (defined as number of cows pregnant/number of insemination) of 27% (Cook & Green 2016) have been reported. Dubuc and Denis-Robichaud (2017) reported first service conception rates of (25th quartile) 24%, (50th quartile) 40%, and (75th quartile) 45% for lactating Holstein cows in Canada.

This decline of conception and pregnancy rates has been reflected in changes in culling rates. In the 1950s and 1960s, culling rates for infertility were around 5% (e.g., Gracey 1960, Leech et al. 1960). Today the figure is around 20% in the UK (Forbes 2000, Esslemont 2003), with similar rates reported from North America (Milian-Suazo et al. 1988, Ribeiro et al. 2003) and Europe (Frerking 2003, Bagnato 2004). Adamczyk et al. (2017) reported that 40% of Polish Holstein–Friesians were culled for infertility and reproduction problems. Involuntary culling for failure to conceive and other fertility-related culling is one of the most common causes of removal of cows from dairy herds (other important causes of culling are for lameness and mastitis) (Gardner et al. 1990, Miller & Dorn 1990, Forbes 2000) and, in consequence, there is relatively little opportunity to cull for other production-related traits. Unfortunately, not all cows that are culled as being 'infertile' actually are; abattoir surveys of cows that have ostensibly been culled for fertility consistently record that a significant proportion of animals are pregnant (Singleton & Dobson 1995, Sheldon & Dobson 2003), sometimes even in the third trimester of pregnancy.

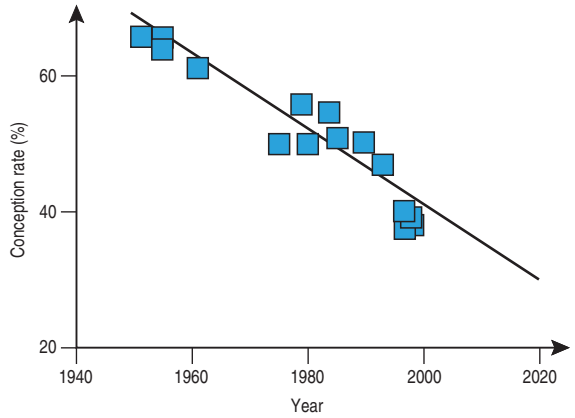
Likewise, calving interval has increased over a similar period. Hare et al. (2006) showed a progressive increase in calving intervals for first parity (Fig. 22.2) and second parity Holsteins in the US. Similar trends were shown for other major dairy breeds. In the UK the average calving interval for Holstein–Friesians was reported (Gates 2013) as 428 days, with the figures for the 75th quartile and 90th decile being 463 and 546 days, respectively.

Infertility is a considerable problem in beef herds, although relatively few data exist detailing its prevalence. Nevertheless, postpartum and lactational anoestrus are significant problems in beef herds, which, if animals are culled on the basis of calving pattern, can lead to significant losses of animals due to conception failure. New Zealand data indicates that between 7% and 11% of beef cows fail to conceive (Morris & Cullen 1998). Under the range conditions of northern Australia, 75% pregnancy rates are frequently achieved, although this can drop to as low as 15% (O'Rourke et al. 1991). However, for feedlot and intensively managed beef cattle, pregnancy rates of up to 98% have been reported (e.g., Warren et al. 1988), with first service conception rates of between about 75% and 80% (Brown et al. 1991, Mann et al. 1998).

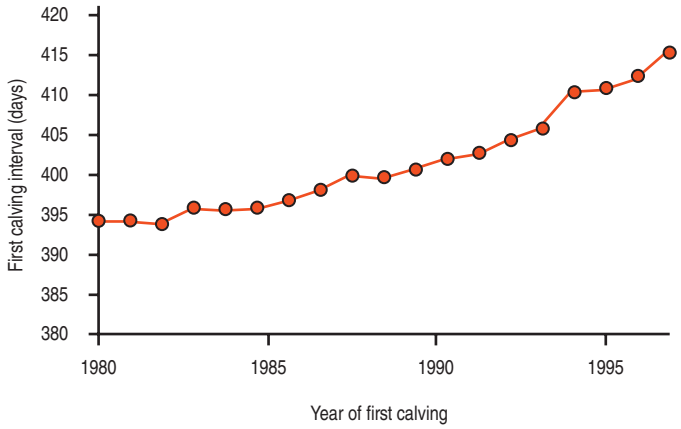
Economic Consequences of Infertility

Bozworth et al. (1972) stated that 'infertility is one of the important economic losses in high producing herds and…modern feeding and management practices in large herds may accentuate the problem'. This comment is equally true today.

VetBooks.ir



• **Fig. 22.1** Changes in conception rate of cattle in the literature between 1950 and 2020. (Adapted from Mann 2004.)

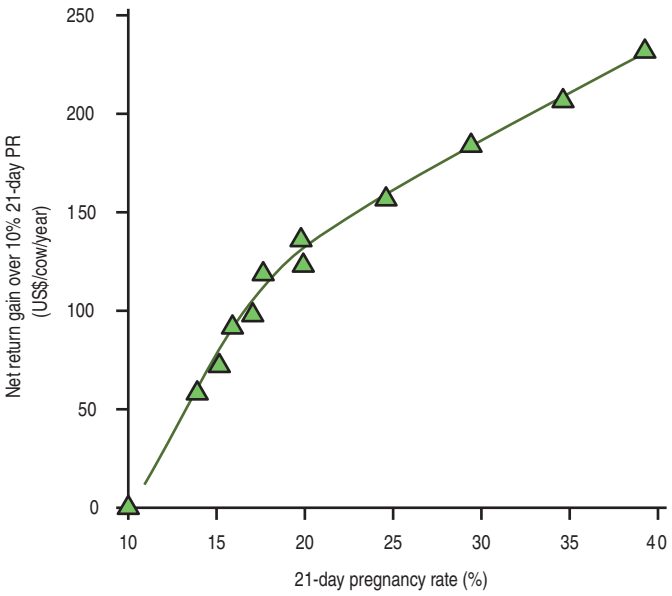


• **Fig. 22.2** Trend in calving interval between first and second parities by year of first calving for Holstein cows. (Adapted from Hare et al. 2006.)

Studies of the consequences of the losses due to infertility among dairy herds have attempted to quantify its effects on production and financial performance. All agree that infertility is expensive, although also highly dependent on the production system. Infertility leads to a loss of milk production, a loss of income from calf sales, and an increase in the replacement rate of cows with first-calving heifers. Its effects may, to some extent be mitigated by the income that is derived from cull animals, although this mitigation is largely a matter of perception rather than actuality because the costs of replacing mature cows with first-calving heifers are substantial.

In the early 1990s, US data suggested that the total cost of breeding problems was $24 per cow per year, compared with $36 for mastitis (Kaneene & Hurd 1990). In the UK, Esslemont (1992) calculated that for dairy herds, at 1992 prices of milk, feed, calves, replacement heifers, culled cows, and so forth, the cost to the farmer for each day's extension of the calving interval beyond 365 days was approximately £3.50. Estimates from the US also suggested that a 1% increase in conception rate was worth up to approximately $7.50 per cow per year (Pecsok et al. 1994a). Improvements in oestrus detection rates have also been associated with improved herd economic performance: Pecsok et al. (1994b) considering that an improvement from 60% to 70% detection efficiency was worth $6 per cow per year.

By the early 2000s an estimate of the costs of subfertility to the UK dairy herd (Esslemont 2003) had increased substantially to around £180 for every cow in the national herd. More recently,



• **Fig. 22.3** Approximate economic net return gain (US$/cow/per year) of improving reproductive efficiency by 10 percentage points of a 21-day pregnancy rate (21-d PR). (Based on Cabrera 2014.)

Cattaneo et al. (2015) estimated costs of infertility in Argentine dairy cows as being US$183, $358, $520, and $770 per cow per lactation for involuntary days open periods of 0 to 30, 30 to 60, 60 to 90, and 90 to 120 days, respectively. Laven (2017) suggested that the cost of culling a cow due to poor fertility was between £1000 and £1200, resulting in a net loss of £13,000 to a 100–cow farm with an involuntary culling rate of 19%. Cabrera (2014) examined the costs of infertility in cows in TMR systems and related the proportion of cows that conceive per 21-day period (21-day pregnancy rate) to the economic performance of the herd (Fig. 22.3): increasing the pregnancy rate by one percentage point increased the economic net return (US$/cow per year) by $14, $10, $7, $5, $4, and $3 when the 21-day pregnancy rate increased within 10% to 15%, 15% to 20%, 20% to 25%, 25% to 30%, 30% to 35%, and 35% to 40%, respectively. Similarly, Shalloo et al. (2014) estimated the costs of increasing replacement rate in a pasture-based dairying system, showing that farm profitability decreased by €6840 and €12,470 for a 100–cow herd when replacement rate increased from 18% to 23% and 23% to 27%, respectively; each 1-day increase in mean herd calving date reduced profitability by €3.86/cow/day.

Various tools have been devised to give farmers a better understanding of the costs of fertility. For example, Kossaibati and Esslemont (1997) developed the Fertex Score, which places an economic value on various aspects of reproductive performance such as days open, involuntary culling services per conception, and the effects of changing voluntary wait periods. Similarly, the Australian InCalf programme (InCalf 2000) also identified the areas in which the greatest losses due to infertility occur.

Overview of the Causes of Infertility

Domestic cattle are not a particularly fertile species. Per-service conception rates are rarely over 55%, and in dairy cattle they can be very much lower than that. Whether this is a consequence of domestication has been widely debated; certainly, wild Bovidae have much better fertility than domestic cattle, but they are also

VetBooks.ir

under much less demand for production. For domestic cattle, there are many factors that impinge upon fertility. These include the following:

- Congenital and acquired lesions of the genital tract (structural causes)
- Ovarian dysfunction
  - anoestrus
  - expression of oestrus
  - follicular or luteal dysfunction
  - age- and breed-related effects
- Stockmanship and management
  - oestrus detection
  - nutritional management
- Infections
  - metritis complex/retained fetal membranes (Chapter 23)
  - venereal diseases (trichomonosis, campylobacteriosis, ureaplasmosis; Chapter 24)

The most serious impairment of fertility is seen in dairy cows. There is now no doubt that reproduction is adversely affected by high yield, as a result of metabolic stress, feed imbalances, and negative genetic relationships between yield and reproduction. As a result, nearly all aspects of dairy cattle reproduction are affected, ranging from the expression of oestrus, to mechanisms related to follicular and luteal function, to uterine environment, to embryonic development. Concurrently, the stockmanship of the labour that is available to dairy farms is declining throughout much of the developed world. In consequence, oestrus detection rates are declining, often necessitating the use of automated detection systems or pharmacological interventions to maintain acceptable conception rates.

One of the consequences of the decline in fertility of dairy cows is the realisation that, for a dairy industry to be sustainable, fertility must be maintained at an acceptable level. This has led to the recognition that because fertility has declined through a negative genetic relationship with selection for milk yield, the potential exists for it to be improved though genetic selection. Hence, many cattle-breeding organisations are now including breeding values for fertility and longevity alongside yield, which appears to be halting (or perhaps even starting to reverse) the decline in the genetic components of fertility. It has also created opportunities for veterinarians to work alongside the dairy industry, not just to apply 'quick fixes' for subfertility but to become more deeply involved in the management of fertility (with consequent involvement in feeding, housing, labour skills, etc.), in order to ensure that fertility is maintained at a level at which the industry itself is sustainable.

Structural Causes of Infertility in the Individual Cow

Both congenital and acquired abnormalities of the genital system can influence fertility. Congenital abnormalities are much less common than those that are acquired; Kessy (1978) found that, in 2000 genital tracts that were examined from abattoirs, only six specimens (0.3%) had evidence of congenital abnormalities compared with 194 (9.65%) with acquired lesions. Similar patterns have been demonstrated by Al-Dahash and David (1977a). Anatomical abnormalities usually affect individual cows or heifers and are therefore unlikely to have a major influence on fertility in a herd. Most of the acquired lesions are identified in tracts from parous cows, emphasising the importance of conditions that occur during pregnancy, parturition, and the puerperium. However, heifers also display many similar lesions, some that would usually be associated with pregnancy (Herenda 1987). The results of Al-Dahash and David (1977a) and Herenda (1987) are summarised in Table 22.1.

TABLE 22.1 Incidence of reproductive abnormalities in cattle

	Al-Dahash & David (1977a)	Herenda (1987)
Number of Non-pregnant Tracts	6186 (Mixed Ages)	5800 (15–30 Months Old)
Abnormality	% of Non-pregnant Tracts	
Cystic ovaries		
• Uncomplicated	3.23	12.2
• With corpus luteum	1.52	0.76
• With mucometra	0.22	0.98
Ovarian bursal adhesions	2.39	5.38
Ovarian tumours	0.23	0.06
Hydrosalpinx	1.05	0.22
Salpingitis		0.68
Mucometra	0.23	5.00
Metritis		1.23
Pyometra	1.10	0.18
Non-involuted uterus	2.20	0.07
Segmental aplasia	0.05	0.04
Double cervix		0.26
Freemartin		0.06
Mummified fetus	0.36	0.13
Macerated/emphysematous fetus	0.13	
Uterine adhesions/abscess	0.31	0.06
Segmental aplasia of the vagina		0.44
Fibropapilloma		0.04

From Al-Dahash & David (1977a) and Herenda (1987).

Lesions of the Ovaries

Congenital Lesions

Congenital lesions of the ovaries are rare. A few reports exist of instances in which one or both ovaries are absent (ovarian agenesis), accompanied by an infantile genital tract and an absence of cyclical behaviour. Fincher (1946) saw an apparently hereditary condition of 'virtual absence of ovaries' in three maternal half-sister heifers.

Ovarian Hypoplasia

Ovarian hypoplasia is a little more common than ovarian agenesis. One or both ovaries are small, functionless, and composed of largely undifferentiated parenchyma. Oocytes and follicles are virtually absent. Ovarian hypoplasia is generally a sporadic condition, except in the gonadal hypoplasia syndrome of the Swedish Highland breed.

VetBooks.ir

A high incidence of gonadal hypoplasia was recognised in males and females of this breed: Lagerlöf (1939) found an incidence of 13.1% of ovarian hypoplasia among 8145 cows. When both ovaries were hypoplastic, the genital tract was infantile, and oestrous cycles did not occur. Eriksson (1943) concluded that the condition was inherited as an autosomal recessive with incomplete penetrance. There was a marked association of gonadal hypoplasia with white coat colour. By the adoption of a vigorous control programme in which veterinary examination of breeding cattle led to the recognition and culling of cases of unilateral hypoplasia, the incidence of gonadal hypoplasia in Swedish Highland cattle was reduced from 17.5% in 1936 to 7.2% in 1952 (Lagerlöf & Boyd 1953). Nonetheless, the disorder is still present in the breed; Settergren (1997) described cases of partial or complete hypoplasia in 18 Swedish Highland heifers.

Ovarian hypoplasia also occurs as an occasional finding in most breeds of cattle, including *Bos indicus* (Abalti et al. 2006). No inherited basis for the condition has been demonstrated in these animals, although, interestingly, Arthur (1959) reported a small number of cases in white Ayrshire heifers, which were acyclical and had hypoplastic ovaries.

Acquired Lesions of the Ovaries

Cystic ovarian disease is the most common of the acquired lesions of the ovaries. It is considered to be a functional disturbance of ovarian function and is described later in this chapter, in 'Cystic Ovarian Disease.'

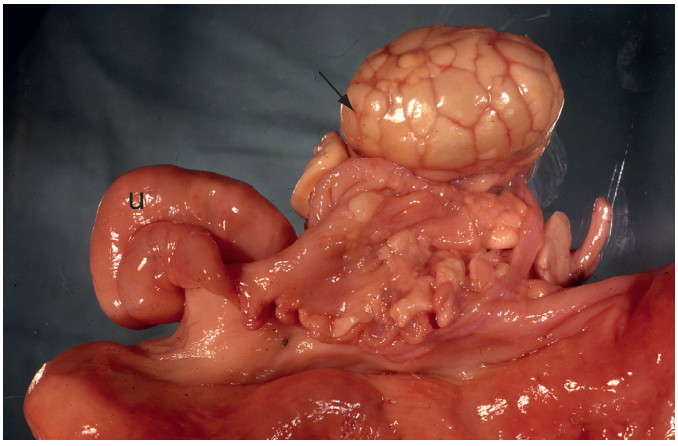
Oophoritis

Ovaritis (oophoritis; see Fig. 22.4) is a very rare lesion of the ovary, usually seen as adventitious findings at postmortem examination. McEntee (1990) described cases of tuberculous oophoritis, brucella-induced oophoritis, and ovarian abscessation in animals that that have had generalised pyaemia. He further suggested that enucleation of the corpus luteum (CL) could be a cause of ovarian abscesses, possibly when it has been undertaken in cows suffering from perimetritis.

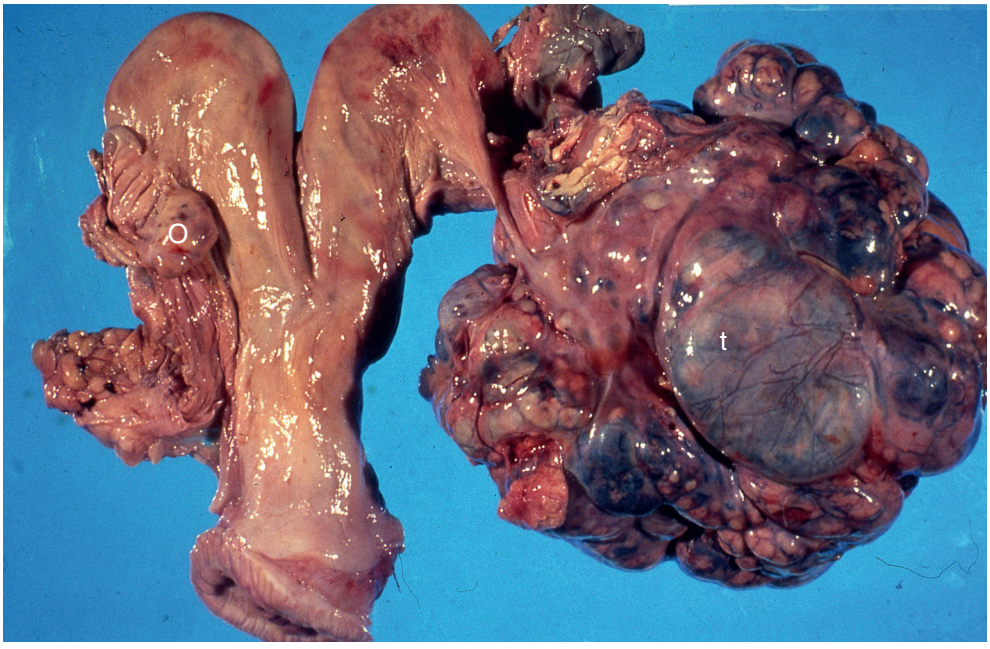
Neoplasia

Neoplasia of the bovine ovary is rare. The tumours most frequently encountered are granulosa cell tumours (Fig. 22.5) and fibromas. Lagerlöf and Boyd (1953) found three granulosa cell tumours and one fibroma in a survey of over 6000 bovine reproductive tracts; Al-Dahash and David (1977a) found seven fibromas and two granulosa cell tumours among 8000 tracts; and Hatipoglu et al. (2002) found three granulosa cell tumours among 1100 tracts. Most granulosa cell tumours are reported from nonpregnant cattle, although the tumour can also occur in pregnant animals. Lagerlöf and Boyd (1953) also found three carcinomas in their survey.

Granulosa cell tumours can produce any of the main ovarian steroids, although reports of oestrogen or androgen production are the most common in the literature (McEntee 1990). Tumours that secrete oestrogens cause animals to display persistent oestrus behaviour, at least in the early stages of the tumour. In long-standing cases, virilism may occur. Progesterone- or androgen-secreting tumours are more commonly associated with anoestrus.

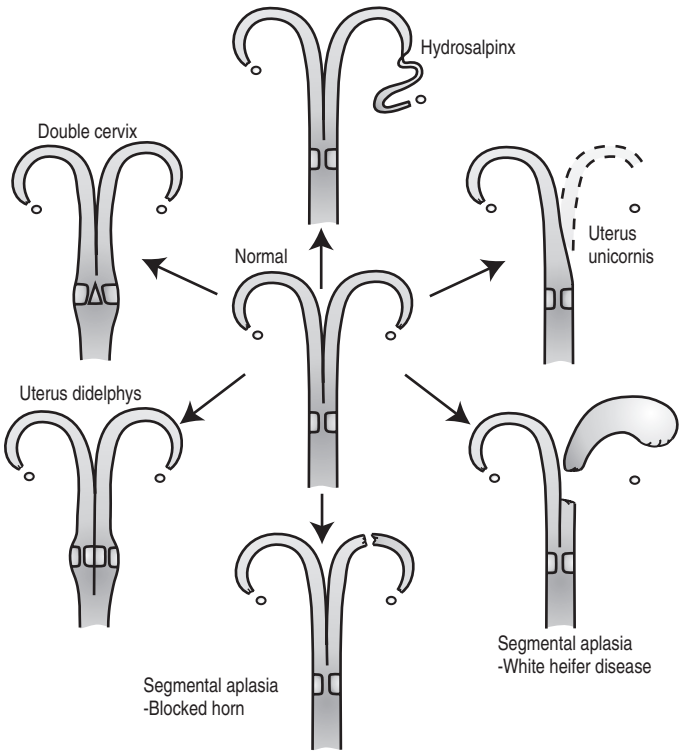


• **Fig. 22.4** Infection and inflammation of the ovary (oophoritis; *arrow*) of an infertile cow. The horn of the uterus is marked 'u'.

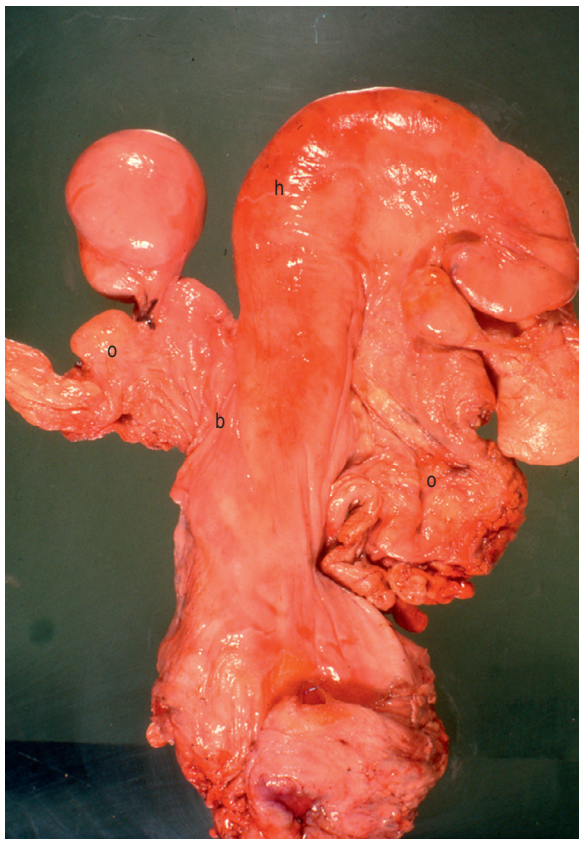


• **Fig. 22.5** A granulosa cell tumour (t) involving the right ovary. The left ovary (o) is normal.

VetBooks.ir



• **Fig. 22.6** Manifestations of the syndrome of uterine segmental aplasia, sometimes known as 'white heifer disease'.



• **Fig. 22.7** Uterus unicornis. Note normal left and right ovaries (o) and complete right horn (h). The left horn comprises a flat band of tissue with no lumen (b) and a blind residual segment.

The unaffected ovary is typically regressed and inactive, although Roberts (1986) reported that conception had occurred in a cow with a unilateral, non-steroidogenic tumour. Granulosa cell tumours are generally regarded as benign, although, in one series, 9 of 13 tumours had metastasised (Norris et al. 1969). McEntee (1990), on the other hand, considered metastasis to be very uncommon. These tumours can become massive: one Friesian cow is reported with a granulosa cell tumour that weighed 24 kg.

Other tumours of the bovine ovary have occasionally been reported. These include carcinomas, fibromas, thecomas, and sarcomas; these tumours are generally benign and are often massive in size. One such cow had an ovarian carcinoma that had enlarged to occupy the caudal third of the abdomen and had metastasised widely throughout the mesenteries.

Abnormalities of the Genitalia

Segmental Aplasia of the Paramesonephric Ducts

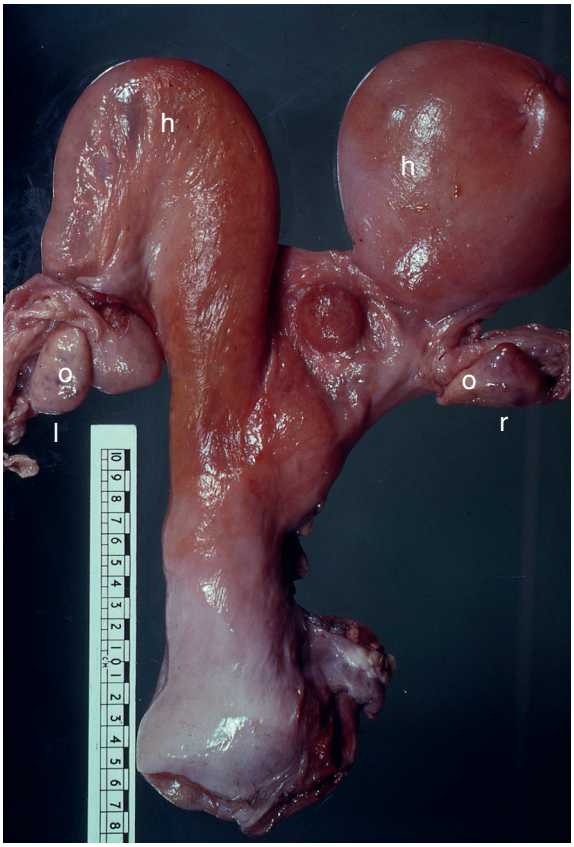
Developmental defects of the paramesonephric (Müllerian) ducts lead to a wide range of anomalies of the vagina, cervix, and uterus (Fig. 22.6). Depending on the site of the aplasia, the cow may be subfertile or sterile. However, the ovaries develop normally, and, consequently, affected animals show relatively normal cyclic behaviour. Moreover, because the ovary produces normal levels of steroid hormones, there is a significant level of secretory activity within the tubular parts of the genital tract. Hence when a developmental obstruction of the tubular tract occurs, cyclical secretions can distend the lumen of the isolated portion of the tract.

Aplasia of each part of the tubular genitalia has been reported. In some cases, the whole of the vagina, cervix, and uterine horns may lack patency. In these cases, as in the freemartin, the genital tract is difficult to locate by rectal palpation, but unlike the latter, the ovaries are normal. More commonly, partial or segmental aplasia of the paramesonephric ducts occurs. Youngquist & Braun (1993) identified the uterine tube as the site most often involved; unilateral aplasia was identified in 0.1% of the specimens and segmental aplasia in 0.05%. Herenda (1987) also identified segmental aplasia in 0.04% of 5800 specimens.

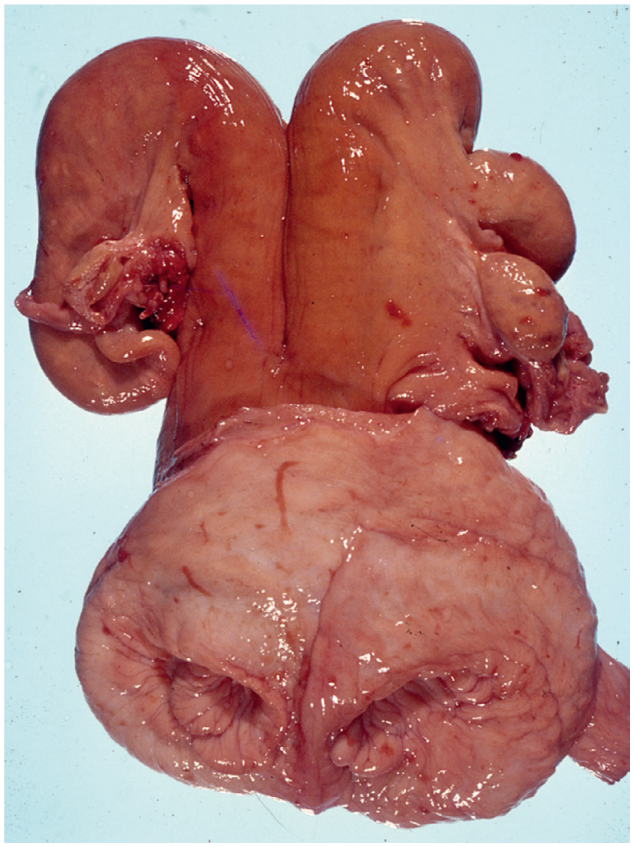
In the case of uterus unicornis, only one uterine horn has a lumen with the other appearing as a narrow, flat band (Fig. 22.7); it is more common for the right horn to be absent than the left. Provided the remainder of the genital apparatus is normal, these animals may conceive to ovulations from the intact side. A more serious type of aplasia occurs when isolated sections of uterine horn are present. Uterine secretion accumulates and causes sac-like dilatation of such isolated portions of the tract. These can become very large and can be confused with early pregnancy during manual examination *per rectum* (Figs 22.8 and 22.9). Animals with this deformity are sterile.

Abnormalities of the cervix also occur, usually as a result of fusion of both paramesonephric ducts. In the condition of uterus didelphys (Figs 22.10 and 22.11), failure of fusion is complete, so there is a double cervix, and each uterine horn connects with the vagina by a separate cervical canal. There is often also a division of the cranial portion of the vagina, as this is also derived from the paramesonephric ducts. Such animals may conceive, providing that insemination takes place into the horn ipsilateral to the ovulation; and a number of reports exist of them carrying calves to term and giving birth normally. A more common lesion is partial duplication of the cervical canal, often with a single internal ostium

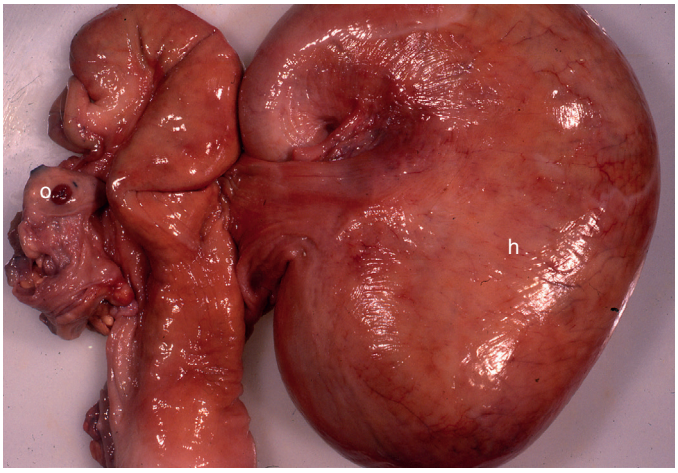
VetBooks.ir



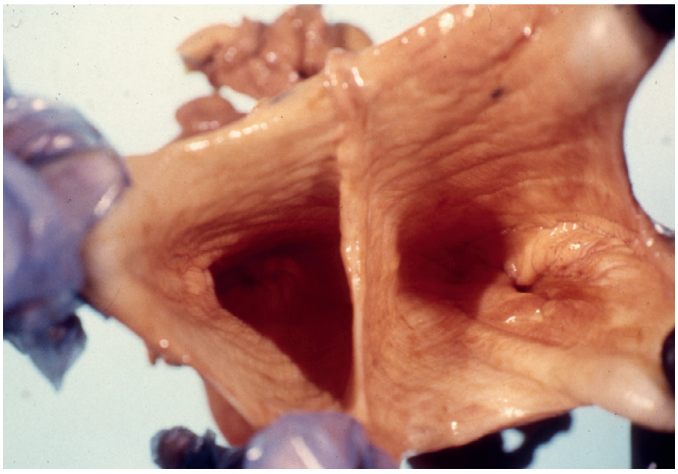
• **Fig. 22.8** Genital tract from a heifer with 'white heifer disease'. Note that both ovaries (o) are normal with a corpus luteum present in the right (r), and the uterine horns (h) are distended with accumulated fluid.



• **Fig. 22.10** Uterus didelphys showing two completely separate cervical canals.



• **Fig. 22.9** Genital tract from a heifer with 'white heifer disease'. Note normal left ovary (o) and isolated portion of the right horn (h) greatly distended with accumulated fluid.



• **Fig. 22.11** Double external os cervix showing two completely separate cervical canals.

and double external ostia. Affected animals conceive normally but may show dystocia due to fetal limbs entering both cervical canals; the expulsion of the afterbirth may also be impeded. A similar complication may arise in cattle showing a dorsoventral post–cervical band.

A further developmental aberration of the female tubular genital tract involves a variable degree of persistence of the hymen. This may appear as a vaginal constriction in front of the urethral opening, as a partition with a central aperture, or as a complete partition between the vulva and vagina. The first type is likely to be discovered at parturition, when it causes dystocia. The second and third types are likely to be found when investigating heifers that either strain forcibly after service or cannot be inseminated artificially. When hymenal obstruction is complete, there is an accumulation of secretions cranial to the obstruction. This may be present on rectal palpation as a fluctuating swelling of variable size or, in more extreme cases, may protrude from the vulva as

VetBooks.ir

a white, glistening, fluid-filled mass. After service, this retained secretion may become infected by pyogenic organisms. The less severe forms of hymenal obstruction may be rendered suitable for breeding by making cruciform incisions into the partition. Heifers with complete obstruction that are ill because of retained pus can be relieved by trocar and cannula and then fattened for slaughter. However, it should be noted that, in view of the probable hereditary origin of these developmental defects, surgical intervention in order to make breeding possible is not advisable. The genital organs of most heifers with hymenal constriction are otherwise normal, but occasionally segmental aplasia of other parts of the tubular organs or ascending infections of the urinary tract are present.

The aforegoing developmental anomalies may arise in all breeds of cattle. Historically, segmental aplasia was particularly common in the Shorthorn breed, in which it was associated with white coat colour. Hence syndromes associated with segmental aplasia are sometimes referred to as 'white heifer disease'. Originally, 'white heifer disease' was used to describe the syndrome of straining and illness after service in animals with retention of the hymen. Segmental aplasia of the paramesonephric ducts in the Shorthorn is due to a sex-linked recessive gene with linkage to the gene for white coat colour. In other breeds, developmental defects of the paramesonephric ducts are probably also due to either sex-linked or autosomal recessive genes; consequently they are likely to appear when inbreeding is practised. For example, Fincher and Williams (1926) reported that 56% of heifers were affected among the progeny that resulted from the mating of a Friesian sire with his daughters. The disease still occurs; Riley et al. (2007) reported 17 cases of the disease in Holstein–Friesian cattle.

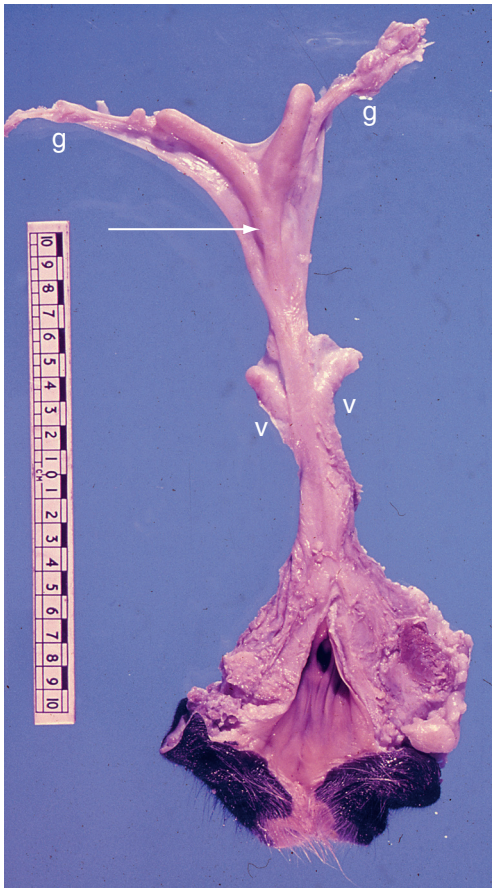
Parovarian Cysts

Parovarian cysts are remnants of the mesonephric ducts that are sometimes present in the mesosalpinx of cows. Tiny parovarian cysts of a few millimetres in diameter are common incidental findings in slaughtered cattle. Larger cysts of between 1 and 3 cm in diameter may be discovered during manual or ultrasound examination of the tract *per rectum* when they may be confused with ovaries. Parovarian cysts are of no consequence to the reproductive performance of the animal except in the rare instances when they impinge on the uterine tube and reduce its lumen.

Freemartinism

Freemartinism (Fig. 22.12) is a distinct form of intersexuality that arises as a result of a vascular anastomosis of the adjacent chorioallantoic sacs of male and female fetuses in multiple pregnancies (see Padula (2005) for review). The majority (~95%) of female fetuses in male/female twin pregnancies are affected (Biggers & McFeely 1966, Zhang et al. 1994). Because vascular anastomosis occurs as early as 30 days of gestation, it is possible for single-born freemartins to occur if there is death of the male twin of a heterozygous pair after the time of vascular fusion with the other being carried to term. This has been demonstrated as a cause of infertility in heifers with apparently normal external genitalia but with sex chromosome chimerism (Wijeratne et al. 1977).

The external genitalia of freemartin heifers may appear relatively normal, although the clitoris is characteristically enlarged and prominent, and coarse hairs are present at the ventral commissure of the vulva (Fig. 22.13). The internal genitalia are grossly abnormal. The gonads are typically vestigial, although they undergo masculinisation in a minority of cases. The structures derived from the paramesonephric ducts are almost entirely absent or are grossly hypoplastic. In animals that have undergone a significant degree of masculinisation, the gonads resemble testes to the extent that their parenchyma contains recognisable tubules and interstitial tissue. Development of the mesonephric (Wolffian) ducts is related to the degree of masculinisation of the gonad. In extreme cases there are well developed epididymides, vasa deferentia, and vesicular glands (Short et al. 1969). More typically, the vestigial gonads of freemartins are devoid of oocytes and follicles and have parenchyma that consists largely of degenerating sex cords. Occasional animals may have some oocytes present in their gonads and may even have small follicles and luteal-like tissue (Rajaoski & Hafez 1963). In some least affected cases, the female genital tract may be small, with a persistent hymen and hypoplastic ovaries (Wijeratne et al. 1977). Presumably the degree of masculinisation/aplasia of the female genitalia can be related to the time at which vascular fusion occurred.

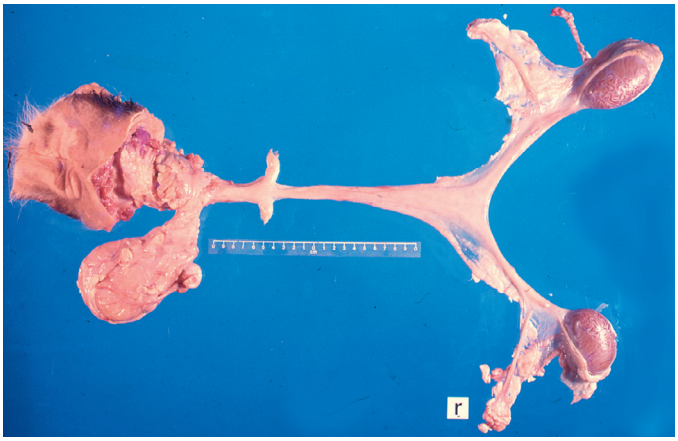


• **Fig. 22.12** Reproductive tract from a freemartin heifer. Note the vestigial gonads (g), underdeveloped structures derived from the paramesonephric ducts (arrow) and rudimentary vesicular glands (v).

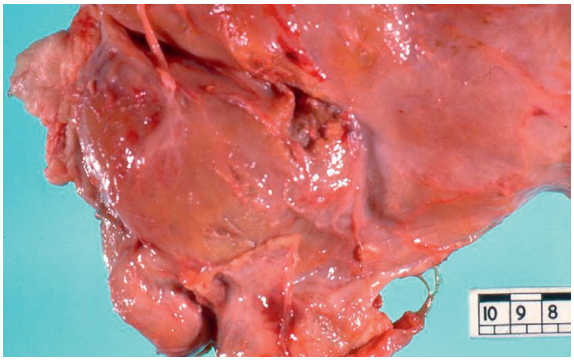
The newborn freemartin can sometimes be recognised by its prominent clitoris and tuft of hair at the ventral commissure of the vulva, although these signs are not always reliable. Freemartins can be identified on the basis of the length of the vagina and the absence of the cervix. In the adult the vagina is normally 30 cm in length compared with 8 to 10 cm in the freemartin. Rectal palpation will fail to identify the cervix. In calves of 1 to 4 weeks of age the vagina is normally 13 to 15 cm in length compared with 5 to 6 cm in a freemartin. Diagnosis at this age can be made using a blunt probe, which should be inserted initially at an angle of 45 degrees below the horizontal for 5 cm and then angled downwards

VetBooks.ir

• **Fig. 22.13** Vulva of a freemartin heifer showing the prominent clitoris and coarse hairs at the ventral commissure.



• **Fig. 22.14** Sex reversal in a Hereford cow. The vulva and vestibule have the phenotypic appearance of a normal female, but the structures derived from the paramesonephric ducts are absent. The gonads resemble testes, and epididymis-like structures are present. The mesonephric ducts are largely undeveloped, although vestigial vesicular glands are present.



• **Fig. 22.15** Ovariobursal adhesions. Note that the ovarian bursa has completely enveloped the ovary.

to avoid impinging on the hymen (Long 1990). It is easier when comparisons can be made among a number of animals.

The most accurate method of diagnosis, although not absolute, is the demonstration of sex chromosome chimerism in cultured lymphocytes. Heifer calves that are born cotwins to males and show morphological changes in their reproductive tracts invariably show sex chromosome chimerism in blood and blood-forming tissues. Unfortunately, the distribution of male cell percentages in freemartins appears to be random; thus animals with low male percentages in the blood are as common as those with high male percentages (Wilkes et al. 1981). More recently, diagnosis by a polymerase chain reaction (PCR) test for the presence of Y chromosomes in blood cells or hair has been described (Plante et al. 1992). This is a definitive test for the presence of the Y chromosome but does not provide an absolute differentiation between freemartinism and other abnormalities of sex differentiation in which a Y chromosome is present.

The economic importance of early diagnosis of freemartinism has been shown by the survey of David et al. (1976), who found that a large number of heifers that were sold for breeding in markets were freemartins. Very high incidences of freemartinism can sometimes be found therefore in herds of heifers – most commonly those of heifer rearers – that are purchased from markets. This could also become important if induction of twinning by superovulation or embryo transfer becomes popular. Increased emphasis on animals being sold on the basis of being 'fit for purpose' is putting pressure on farmers to declare if a heifer was born cotwin to a bull to avoid subsequent litigation.

Very occasionally, other forms of intersexuality are found. A few cases of pseudohermaphroditism have been reported, as have rare cases of XY sex reversal (Fig. 22.14) and true hermaphroditism.

Atresia of the Vulva

An abnormally small vulva has been described as a cause of dystocia in Friesian and Jersey heifers. In such cases episiotomy or Caesarean operation may be required to allow delivery. The defect has been seen to affect many of the progeny of a particular Jersey bull (Hull et al. 1940), indicating that it is likely to be of hereditary origin. It is occasionally seen in newborn calves in conjunction with atresia ani (Wamaitha et al. 2015).

Ovarian Bursal Adhesions

Acquired lesions of the uterine tubes and adnexa are common in cattle. One of the most frequently observed lesions of the bovine reproductive tract is adhesion between the ovary and the ovarian bursa (Fig. 22.15). The incidence of ovarian bursal adhesions ranges from 0.43% (Summers 1974; Australia), 0.97% (Lawton et al. 2000; New Zealand), 1.83% (Al-Dahash & David 1977a; UK), to 5.38% (Herenda 1987; Canada). The condition is uncommon in heifers, but its incidence increases with the age of the cow.

VetBooks.ir

Much variation exists in the extent of the adhesions that are present, ranging from fine, web-like strands in the depth of the bursa, which do not involve the uterine tube, to intermediate cases with fibrinous or fibrous strands of varying thicknesses connecting the fimbriae or bursae to the ovary, to complete envelopment of the ovary within a closely applied fibrous bursa. Infections of the ovarian bursa also occur, which are invariably accompanied by large-scale adhesions between the ovary and bursa, often in association with metritis or salpingitis. Ovarian bursal adhesions are also associated with cystic ovarian disease, although it is not clear which lesion is causal. In such animals regressed luteinised follicles from past cycles may be present in the same ovary. Strand-like adhesions arising from scars of old CLs (which more commonly affect the right ovary) may be regarded as physiological hazards that originate as slight haemorrhages from the site of ovulation. It is possible that a proportion of ovarian bursal adhesions occur as a result of rough palpation of the ovaries, particularly if a CL is accidentally enucleated or an ovarian cyst is burst. Other causes of ovarian bursal adhesions include salpingitis, metritis, or local or diffuse peritonitis (including tuberculous peritonitis). Indeed, the most likely cause of ovarian bursal adhesions in the pluriparous cow is puerperal infection, which arises from ascending infection of the uterus.

Minor, web-like adhesions are unlikely to interfere with fertility but, of the remaining more severe types, between 25% and 50% are bilateral and likely to interfere with ovulation or to impede sperm or egg transport through the uterine tube. Of the unilateral cases, the right side is more frequently involved. Conception is unlikely to occur to ovulations from the affected side. When the bursa is diffusely adherent to the ovary, ovulation is prevented and luteinisation of the follicle occurs, with the orange rim of the follicle being several millimetres thick. Intraovarian and periovarian abscesses have also been seen (Arthur & Bee 1996) in association with ovarian bursal adhesions.

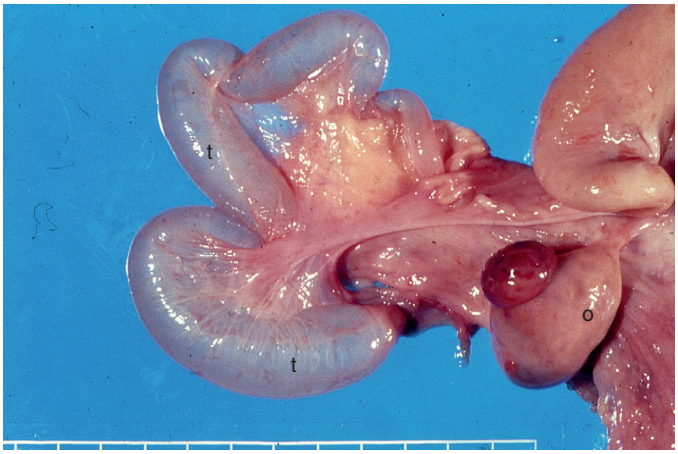
There is no doubt that ovariobursal disease is one of the major causes of individual cow infertility characterised by regular return to oestrus. There is no satisfactory treatment for the condition, although prompt attention to cases of dystocia with a view to preventing puerperal metritis would also reduce the incidence.

Lesions of the Uterine Tube

Occlusion of the lumen of the uterine tube results in an accumulation of secretions, resulting in thinning and distension of the wall, which is described as hydrosalpinx (Fig. 22.16). The accumulation of fluid is often a result of adhesions occluding the lumen, but it may also occur as the result of congenital stenosis or infection. Gross infection of the uterine tube, known as pyosalpinx, may occur as a result of a super infection of a hydrosalpinx with *T. pyogenes* or may be the result of ascending infection from the uterus. Most of such cases are the result of severe metritis or perimetritis, although cases have been reported in association with the presence of pyometra or of a macerated fetus (Kessy 1978). Pyosalpinx can often progress to pyobursitis. Because infection can be forced up the uterine tubes during irrigation of the uterus (e.g., in an animal with metritis), care should be exercised during this procedure.

Salpingitis and ovarian bursal adhesions can also be caused by *Mycoplasma* and *Ureaplasma* infections (Yaeger & Holler 2007). Ovariobursal adhesions are a feature of the viral epididymovaginitis of cattle in east Africa.

Several other acquired abnormalities of the uterine tubes can also cause infertility. A condition described as pachysalpinx has been identified in three genital tracts from parous animals (Kessy 1978). The gross appearance of the tube resembles hydrosalpinx or pyosalpinx, but no fluid is contained within the lumen; instead there is a mass of connective tissue. Enlargement and distension of the uterine tube can also occur as a result of the presence of multilocular mucosal cysts containing PAS-staining gelatinous material.



• **Fig. 22.16** Hydrosalpinx. Note distended ampulla of the uterine tube (t). The ovary (o) is unaffected and contains a corpus luteum.

Diagnosis of Ovarian Bursal Disease and Occlusion of the Uterine Tubes

Diagnosis of ovarian bursal adhesions in the live animal is difficult. As a consequence, only about one-third to one-half of the lesions that cause infertility are diagnosed by rectal palpation. In the more severe cases of ovarian bursal adhesions, the periphery of the ovary loses its clear definition, the ovarian outline is more bulky and irregular, and the ovarian mass lacks mobility. In occasional difficult cases, laparotomy with direct vision or endoscopic examination of the ovaries may be used. Rectal palpation of distended uterine tubes is usually indicative of the presence of advanced lesions of hydrosalpinx or pyosalpinx; ultrasonography has also been used to diagnose more advanced lesions (Pereira et al. 2015). However, most cases of occlusion of the uterine tubes can only be determined by undertaking tests of their function.

A fairly simple test is available to assess the patency of the uterine tube. Speck (1948) first demonstrated that if phenolsulphonphthalein (PSP) was placed in the uterine lumen, it was not absorbed, but if the uterine tubes were patent, it passed along them into the peritoneal cavity from where it was readily absorbed into the circulation. The PSP was then excreted by the kidneys into the urine, where it produced a red or pink colour if alkaline. If the uterine tubes were occluded**,** there was no passage of dye and hence no discoloration of the urine. The test involves the infusion of 20 mL of a 0.1% sterile solution of PSP into the uterine lumen, using a Nielson catheter. This has to be done carefully so as to avoid any trauma to the endometrium enabling absorption to occur. The bladder should then be catheterised, a small sample of urine is kept for a control, and a further urine sample is then collected 30 to 60 minutes later. The urine is made alkaline by the addition of 0.2 mL of 10% trisodium orthophosphate buffer to 10 mL of urine. In the presence of PSP, the liquid becomes red or pink; in its absence the urine remains the same colour as the control. The test should be performed during the luteal phase of the cycle, preferably about Day 10, because false negatives can be obtained during the follicular phase. False positives can arise if

VetBooks.ir

• **Fig. 22.17** Mucometra as a consequence of long-standing, untreated cystic ovarian diseases. Note the thin wall of the uterus and the presence of an ovarian cyst.

there is endometrial erosion due to infection and inflammation; it is not very effective in differentiating between bilateral and unilateral patency (Kessy & Noakes 1979a, b).

A more accurate method of evaluating the patency of each uterine tube separately has been described by Smith (2004). A Foley catheter is introduced into one horn, the cuff is inflated, and a small volume of dye is infused into the tip of the horn. If the tube is patent, the dye will pass via that uterine tube to the peritoneal cavity and hence to the urine (the cuff prevents reflux of the dye to the other side). The procedure is repeated on the other side several days later.

The prognosis for the condition is, at best, guarded. In cases of bilateral occlusion of the uterine tube the animal is normally irreversibly sterile. Various methods of restoring patency to the uterine tube have been described, but they appear to be of negligible therapeutic value.

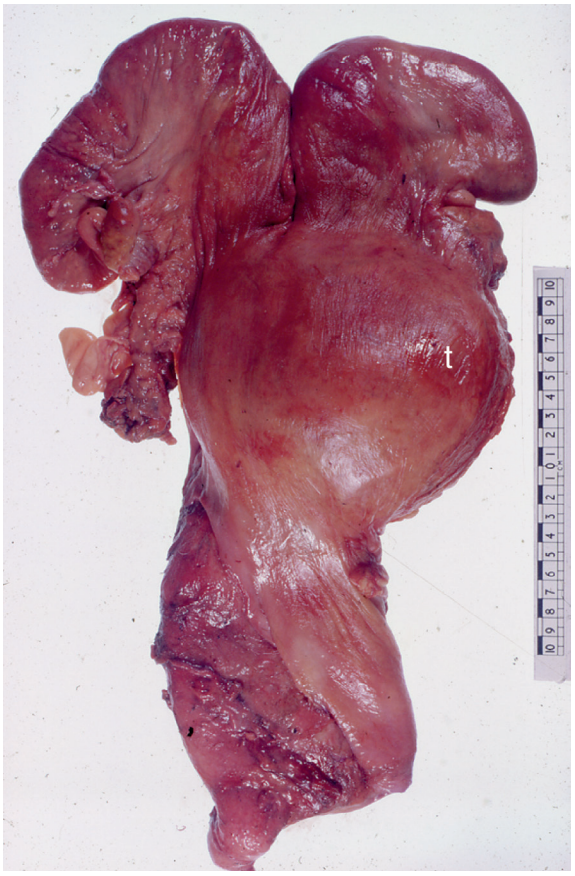
Mucometra

Mucometra is a rare sequel of untreated cystic ovarian disease. In this condition the uterus fills with a mucoid fluid, accompanied by a marked thinning of its wall and degeneration of the endometrium (Fig. 22.17). The enlargement of the uterus is bilateral, but is typically asymmetrical, so care is needed to differentiate the condition from a Week 9 to 11 pregnancy on rectal palpation. The ultrasonographic appearance should be easy to differentiate from pregnancy. Affected cows are most unlikely to be able to conceive.

Uterine Tumours

Tumours of the uterus are rare in cattle. Of those that do occur, benign tumours of mesenchymal tissues are the most common. Leiomyomas and fibromyomas have been described in cattle from many countries, and there have been significant numbers of reports of lymphosarcomas of the uterus of cattle in North America. In a meta-analysis of abattoir surveys of reproductive abnormalities, Roberts (1986) found that leiomyomas, fibromyomas, and fibromas accounted for 77% of tumours. These benign tumours are often incidental findings at the time of slaughter, although they affect fertility if they occlude or occupy a significant proportion of the uterine lumen. Very occasionally, the presence of a tumour may be found in a pregnant uterus. Such tumours are often large (Fig. 22.18) and can potentially be mistaken for the presence of a mummified fetus on palpation *per rectum*. Occasionally, the tumours are massive.

However, other series of cases have reported adenocarcinoma and lymphosarcomas to be the most important tumours of the bovine



• **Fig. 22.18** Fibroma (t) involving the base of the uterine horns and body.

uterus (Brandley & Migaki 1963, Smith 1965). Adenocarcinomas present as moderately enlarged, firm, constricted lesions of the uterine wall (McEntee 1990) and have a high rate of metastases to the lung and abdominal structures. Affected animals often present clinically as having chronic wasting disease. These tumours are very rare in Europe; most cases have been reported from North America.

Uterine Adhesions

Uterine adhesions are a common sequel of perimetritis. Adhesions may be present as fibrinous tags over the surface of the uterus (Fig. 22.19), adhesions that involve the ovarian bursa, or adhesions to other pelvic/abdominal viscera. A similar lesion may follow uterine rupture or retention of the fetus after dystocia. A troublesome sequel to Caesarean hysterotomy is adhesion of the uterus to the omentum, intestines, or abdominal wall, or ovarian bursal adhesions that occur when infected uterine fluids contaminate the bursa during surgery. Such lesions are frequently associated with sterility.

Lesions of the Cervix

The role of the cervix as the main barrier between the uterine lumen and the external environment makes it vulnerable to both infections and to trauma. Inflammation of the cervix is likely to follow obstetrical trauma incurred during the relief of a difficult dystocia. The most common congenital lesions of the cervix are those that occur as part of the 'white heifer' syndrome.

Cervicitis almost invariably accompanies puerperal metritis, and is common in cases of delayed involution of the uterus and/or retention of the afterbirth. The organisms present in such infections are those normally found in the caudal vagina, including *Escherichia*

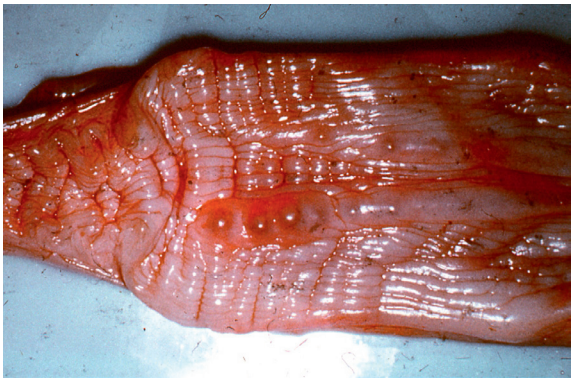
• **Fig. 22.20** Fibroma of the cervix (the cervix is *arrowed*).

coli, streptococci, staphylococci, and *T. pyogenes.* The latter organism is most prominent in established infections. Rarely, parturient laceration of the cervix is followed by fibrosis and obstruction of the cervical canal, resulting in infertility. Fibrosis of the cervix may very occasionally prevent its normal dilatation at the next parturition. Although prolapse of one or more of the cervical folds is commonly seen in the plurigravid cow, it is a hazard of parturition rather than a cause of infertility.

Tumours of the cervix (Fig. 22.20) occur very occasionally. Leiomyomas and, to a lesser extent, fibromas are the most common of these lesions, whereas adenocarcinomas (the most common human



• **Fig. 22.21** Cystic dilation of Gartner's glands.

cervical tumour) are very rare indeed. The benign tumours of the cervix are only of clinical significance as space-occupying lesions or when they cause mechanical interference.

Mummified and Macerated Fetus

These conditions are described in Chapter 9.

Conditions of the Vagina, Vestibule, and Vulva

Cysts of Gartner's Canals

Cysts in linear series, which may be 6 to 8 cm in diameter, often occur on the floor of the vagina (Fig. 22.21). They can be easily punctured and are not a cause of infertility.

Obstetrical Damage to the Vagina

Parturient trauma of the tubular genital tract is a frequent consequence of dystocia. Fetomaternal disproportion is the most common cause of dystocia in cattle, particularly in the Holstein–Friesian breed, and, as a consequence, delivery of large calves by forced traction can damage the birth canal to such an extent that the animal is rendered sterile. Obstetrical contusion of the vagina, especially in fat heifers of the beef breeds, is particularly likely to be followed by necrotic vaginitis associated with *Fusobacterium necrophorum* infection. Likewise, in other instances involving the removal of dead, emphysematous calves in unhygienic circumstances, parturient trauma may be followed by severe toxaemia due to invasion by anaerobic bacteria. Treatment of such animals requires the use of parenteral broad spectrum antibiotics and, in severe cases, supportive fluid therapy. Some practitioners have found that local emollient creams are also helpful. Because vaginitis causes persistent straining, particularly if severe, caudal epidural anaesthesia will provide temporary relief.

Other sequelae of dystocia include laceration or bruising of the vulva, which may be followed by cicatrisation and distortion, with imperfect closure of the vulval sphincter and aspiration of air. These sequelae are similar to, but less severe than, those of rupture of the perineum. Some of these cows are infertile to natural service but conceive to intrauterine insemination. At subsequent parturition, dystocia owing to fibrosis of the vulva may arise. Gross fibrosis of the vagina may also follow pyogenic infection of lacerations, causing a narrowing of the birth canal and dystocia; Caesarean surgery may then be required at subsequent births.

Obstetrical Damage to the Perineum

Lacerations of the perineum can also result in impaired fertility of affected cows. Second degree perineal lacerations may give rise to a

VetBooks.ir

pneumovagina; if the conformation of the vulva is compromised, surgical correction is possible by performing Caslick's operation.

A third degree perineal rupture may occur at calving, usually as a result of dystocia and severe calving trauma. In this situation the whole thickness of the vagina and rectal wall ruptures so that the rectum and vagina are confluent (i.e., the cow has a cloaca). Third degree perineal tears do not heal, thus air and faeces are aspirated into the vagina, inevitably resulting in vaginitis, cervicitis, and metritis. Affected cows have a chronic mucopurulent vulval discharge, but their general health is not impaired; normal cyclic behaviour resumes, but conception does not occur because of the metritis (see later in this chapter). The condition can be cured only by surgical reconstruction of the perineum. Rupture of the perineum may be prevented by sound obstetrical technique, including episiotomy.

These conditions are discussed in detail in Chapter 20.

Urovagina

An increasing number of cows are being diagnosed as having vaginal urine pooling or urovagina. In such animals, urine accumulates in the anterior vagina, where it impinges upon the cervix and causes inflammation of both cervix and vagina; the inflammation then extends into the uterus, causing endometritis. There seems to be a greater prevalence in certain breeds, particularly Charolais and Holsteins. The cause of the condition is not known, although stretching of the suspensory apparatus of the genital tract as a result of several pregnancies may be a factor. Surgical treatment has been described (Hudson 1986), although the procedure is far from straightforward.

Tumours of the Vagina and Vulva

Fibropapillomas of the vagina and vulva of cattle are not uncommon. They do not cause infertility but may interfere with birth. They are usually pedunculated and may be removed surgically. It is likely that there is one form of vaginal fibropappiloma which is of viral origin and is transmitted venereally; it occurs in young cattle and undergoes spontaneous resolution.

All other tumours of the vagina and vulva are rare. A squamous cell carcinoma of the vulva occurs in unpigmented areas of the skin of cattle that are exposed to high levels of solar radiation (McEntee 1990). Lymphosarcomas have also been occasionally found in the vagina.

Functional Infertility

Anoestrus

Anoestrus may be due to:

- Pregnancy;
- Anovulatory anoestrus;
- Cystic ovarian disease, which can result in anoestrus, or other abnormal patterns of reproductive behaviour; and
- Prolongation of the life span of the corpus luteum. This most commonly occurs as a consequence of endometritis, but can occur spontaneously (Kafi et al. 2012) as a result of embryonic death after the maternal recognition of pregnancy.

Pregnancy

It is remarkable how often pregnant cows, many in advanced gestation, are presented for examination for the cause of anoestrus. Most commonly, this occurs when dates of artificial inseminations or natural service matings are not recorded; but accidental situations, such as the bull that breaks through a fence or animals that have not been castrated, are by no means rare. Hence whenever anoestrus cows are examined, the possibility of pregnancy should not be overlooked however adamantly the herd manager protests the impossibility of its occurrence.

Anovulatory Anoestrus

Oestrous cycles, which cease during pregnancy, do not resume immediately after calving. The high concentrations of progesterone that have been present during pregnancy cause negative feedback suppression of the hypothalamo–pituitary axis, with the result that follicular activity in the ovaries of full term pregnant cows is minimal. A period of restoration of both gonadotrophin secretion and ovarian follicular activity occurs during the postpartum period before oestrous cycles are resumed, and a period of postpartum anovulatory anoestrus is a normal aspect of bovine reproduction (see Chapter 7). However, anoestrus becomes a problem when it extends into the period when animals need to be rebred. When this occurs, it is considered to be pathological and needs treatment. At the herd level, it is both the duration of anoestrus in each individual cow and its prevalence within the herd that determine the significance of the problem for the maintenance of regular calving patterns.

The clinical syndrome of anoestrus most frequently manifests as a prolonged period of postpartum anoestrus. Some other cows resume oestrous cycles at the normal time after calving but later relapse back into anoestrus. Other cows will start to have cycles, be inseminated, fail to conceive, and thereafter relapse into anoestrus. These animals are associated with significant economic losses, as their failure to return to oestrus may well be regarded as a sign that they have successfully conceived (Cavalieri & Macmillan 2002).

Prevalence

True anoestrus is most frequently diagnosed in high yielding dairy cows, first-calf heifers that are still growing, and beef suckler cows. Observed frequencies of anovulatory anoestrus are dependent on the presence or absence of the factors that predispose to the development of the condition. Thus a generalised figure for prevalence is of limited value because it depends entirely upon both the type of cattle and the management system. Even within a single system, the occurrence of anoestrus varies from region to region, season to season, and, especially from year to year. Interactions between nutrient availability, climatic conditions, and the establishment of lactation are responsible for enormous fluctuations in the incidence and depth of anoestrus.

Pathogenesis

Anovulatory anoestrus is a multifactorial problem, which occurs in response to a range of management or nutritional deficiencies. Major predisposing factors include:

Breed. The time taken for reestablishment of oestrous cycles after calving is generally longer in beef breeds (36–70 days) than in dairy breeds (10–45 days). The delayed resumption of oestrous cycles in beef cows is due to the combined effects of suckling and nutritional status (Sinclair 2008).

Season. The season undoubtedly affects the prevalence of anoestrus, although its effects vary by geographical location, depending on the interaction between climate, day length, state of nutrition, and the characteristics of the breed being studied. For example, in the temperate climate of Flanders, Opsomer et al. (2000) reported the lowest prevalence of anoestrus in high yielding dairy cows that calved in September (autumn) and the highest in April (spring),

VetBooks.ir

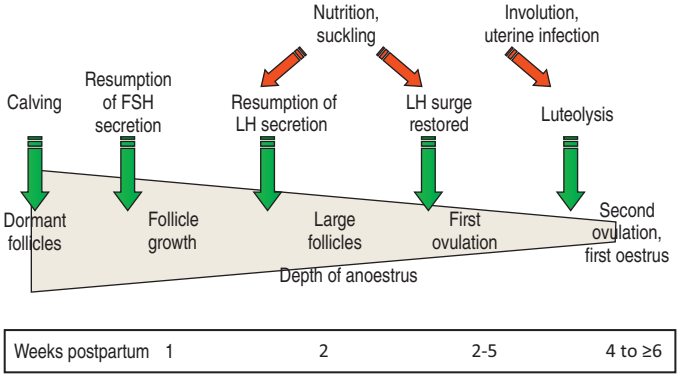
whereas in Iraq, the proportion of Holstein cows that were anoestrous was higher in winter than in autumn (Omran & Al-Saffa 2011).

Nutrition. Imbalances between the energy requirement for lactation and the energy available in feed are probably the main cause of anoestrus. Protein is less commonly limiting, unless gross deficiencies occur. Energy-related metabolic disorders, such as fat cow syndrome, fatty liver, and ketosis, are also related to anovulatory anoestrus. Very high metabolic workload, such as that which occurs in high yielding dairy cows, is also associated with anoestrus, even when the energy and protein requirements of the cow are fully met (Muller et al. 1986, Rind & Phillips 1998). Trace element deficiencies (notably magnesium, phosphorus, copper, cobalt, and manganese) are commonly associated with anoestrus. Sometimes these are causal; others may be reflective of, or additive with, an inadequate supply of energy (McClure 1994).

Stress. Social stresses produced by group and space management of animals are widely considered to be a significant contributor to anoestrus (Platen et al. 1995, Albright & Arave 1997). Physical stressors such as transport (Nanda & Dobson 1990), temperature, and handling (Thun et al. 1996), have also been implicated as limiting factors to reproduction in cattle, as have the stresses of pain and intercurrent disease.

Lameness. Lameness predisposes cows to anoestrus because of its effects upon nutrition and via the stress produced by chronic or unrelieved pain. Lame cows have longer intervals from calving to first service and from calving to conception, and have lower conception rates (Lucey et al. 1986), lower submission rates, and lower final pregnancy rates (Morton 2000a). Lame cows usually have subnormal feed intakes, so they often lose weight rapidly. Hence when lameness occurs during early lactation, affected cows are in negative energy balance for a long period of time. It is likely that there are also corticosteroid-mediated effects on the reproductive endocrine axis (Ley et al. 1994).

The endocrine mechanisms which are involved in restoration of normal cyclic activity of the reproductive system after calving are summarised in Fig. 22.22 (and see Chapter 7). The process is initiated by the hypothalamus regaining the ability to produce GnRH, as the negative feedback effects of the high progesterone and oestrogen concentrations in late gestation are withdrawn. There is a rapid increase in follicle-stimulating hormone (FSH) concentrations between approximately 7 and 14 days postpartum, resulting in the emergence of the first follicular wave. Whether the first dominant follicle ovulates depends on the growth and development of the follicle and the ability of the pituitary to sustain both an adequate luteinising hormone (LH) pulse frequency for preovulatory



• **Fig. 22.22** Sequence of event during the restoration of the reproductive endocrine axis during the postpartum period.

growth and an LH surge to cause ovulation (Roche 2006). The postpartum elevation of FSH secretion is largely independent of nutritional factors, so the extent to which follicular growth is adequate is largely determined by the systemic concentrations of the metabolic hormones, insulin, and insulin-like growth factor (IGF)-I (Butler & Smith 1989, Lucy 2001). Hence situations in which low IGF-I concentrations are present (underfeeding, Holstein genetics) impede follicular growth and reduce the chances of ovulation of the dominant follicle (Roche 2006).

Restoration of pulsatile LH secretion and the LH surge mechanism takes rather longer than that of FSH. In the early postpartum period, the anterior pituitary is virtually refractory to stimulation with GnRH, with progressive increases in responsiveness taking place over the period between approximately 14 and 28 days after calving (Lamming et al. 1979). However, negative energy balance reduces LH pulsatility (Beam & Butler 1999, Butler 2000) through effects of central hypoglycaemia (McClure 1994, Funston et al. 1995), excess concentrations of products of tissue lipid mobilisation (Zaaijer & Noordhuizen 2001), low circulating insulin concentrations (Grummer et al. 2004), and low concentrations of IGF-I (Lucy 2001). If the LH pulse frequency is adequate, the increase in oestradiol concentrations necessary to induce positive feedback and ovulation will occur. If not, the dominant follicle will undergo atresia, and a new follicular wave will be initiated. Hence the interval between calving and the resumption of normal pulsatile LH secretion is a key determinant to regaining the ability to ovulate (Lamming et al. 1981) and the resumption of oestrous cycles.

In beef cows, suckling contributes to the duration of anoestrus. There is much evidence that this is mediated by a reduction in the secretion of LH and consequent failure of follicles to ovulate (Sinclair et al. 2002). It was originally thought that this suppression of LH secretion in suckled animals was due to the raised concentrations of prolactin that are found in animals that are being suckled (Karg & Schams 1974), and there is evidence for such an effect in the effects of dopamine (= prolactin inhibiting factor) agonists and antagonists upon LH secretion (Peters & Lamming 1990). However, prolactin concentrations are not particularly well correlated with the resumption of cyclical activity (Wheeler et al. 1982), so other factors, such as endorphins/opioids, have been suggested as an alternative mechanism (Yavas & Walton 2000). Sinclair (2008) suggested that the inhibitory effects of suckling are mediated through an increased sensitivity of GnRH secretion to oestradiol negative feedback which, in turn, is mediated through central effects endorphins/opioids and insulin upon the hypothalamo–pituitary axis. Thus there appears to be a unifying mechanism for the effects of poor body condition, low plane of nutrition, and suckling in terms of the central effects of insulin upon the reproductive endocrine axis.

Stress contributes to the development of anovulatory anoestrus primarily through its effects upon gonadotrophin secretion. The effects of stress are initially mediated primarily through corticosteroid-mediated pathways (Smith & Dobson 2002), acting through Type II glucocorticoid receptors (Breen et al. 2004). Not all the effects of stress are corticosteroid-mediated, inasmuch as the impairment of reproductive function that is induced by stress persists after adaption and reduction of corticosteroid concentrations towards resting values (Smith & Dobson 2002). Corticosteroid-mediated pathways inhibit LH pulse frequency via a reduction in GnRH pulsatility (Smith et al. 2003) and a reduction in the response of the pituitary to GnRH (Breen et al. 2005). Consequently, there is impaired preovulatory follicular growth and oestradiol synthesis,

VetBooks.ir

and a delay or block in the development of the LH surge. There are also a number of corticosteroid-independent mechanisms that inhibit LH pulsatility, including opioids, corticotrophin-releasing hormone (Smith et al. 2003), endotoxin-mediated (Debus et al. 2002), and other mechanisms that potentiate the negative effects of hypoglycaemia upon the central neuroendocrine axis.

Clinical Findings

The clinical history is normally either of an animal that: (1) has not been seen in oestrus since the time of calving; (2) started having oestrous cycles but has subsequently ceased; or (3) is presented for pregnancy diagnosis but is found to be non-pregnant. The latter cows may have relapsed into anoestrus, but some will have a persistent corpus luteum or endometritis. Cuttance and Mason (2015) found an equal proportion of such cows with inactive ovaries or persistent corpora lutea.

On examination *per rectum,* the ovaries of the majority of affected cows are small, quiescent, flat, and smooth. This is especially so in first-calved heifers. A small proportion of anoestrous cows have larger follicles (up to a prematuration size of 1.5 cm) present. Depth of anoestrus can be estimated by the size of the ovaries and the degree of development of the structures within them (Nation et al. 1998). Thus cows with very small, inactive ovaries that are devoid of any significant structures (i.e., no palpable follicles or luteal structures) are likely to be in a greater depth of anoestrus than those with larger ovaries containing palpable follicles.
