Differentiation must be made from other causes of anoestrus and from ovaries that are functioning normally but are at a phase of the oestrous cycle that does not have prominent ovarian structures. The presence of a mature corpus luteum is generally associated with pregnancy, endometritis, or pyometra, whereas the presence of cystic ovarian disease is also characterised by enlargement of the ovary. Old cows frequently have roughened, irregular ovaries because of the presence of old corpora albicantia. Corpora lutea are difficult to palpate or to visualise by ultrasonography in the early postovulatory period, and the ovary of the freshly ovulated cow can be difficult to differentiate from an inactive ovary (although the presence of uterine tone and vaginal mucus should make the differentiation clear). Milk or blood progesterone can help to determine whether active luteal structures are present, with the development of 'cowside' ELISA tests giving the potential for this to be done when the cow is being examined (Bajema et al. 1994).

Management

In the long term, a high incidence of anovulatory anoestrus in a herd is best managed by identification and correction of the predisposing factors. For example, feeding could be improved, micronutrient deficiencies corrected, and stress reduced. In the short term, affected animals can be treated with reproductive hormones in an attempt to 'restart' the reproductive endocrine system. Even though such hormonal treatments are to a greater or lesser extent successful, they can rarely be relied upon to fully resolve a situation of anovulatory anoestrus at the herd level, unless attention is also paid to alleviating the predisposing factors.

The most common causes of anovulatory anoestrus that can be managed at a farm level are those relating to nutrition and stress. When micronutrient deficiencies exist in the absence of significant underfeeding, correction of the deficiency can produce a relatively rapid response. More commonly, effects of trace element deficiency are compounded with energy deficiency and, when energy deficiency is the primary cause of anoestrus, it is unlikely that a rapid response will be achieved by suddenly increasing energy intake (Rhodes et al. 2000). Stimulation of ovarian activity usually requires 3 to 4 weeks of improved feeding before a response occurs. When poor responses are obtained, it is normally possible to identify a time when feeding was suboptimal.

Hence, improvement of overall energy levels in the diet usually has to be part of a long-term strategy for the farm. Management of the dry period has to be improved so that cows calve in the optimum condition score. Management of the transition cow has to be improved so that she does not suffer from hypocalcaemia, and her rumen is prepared to respond to postcalving changes in nutrition. Management of feeding has to be improved, ensuring that supplies and requirements are as closely matched as possible, that feeding regimens are used that will ensure maximum dry matter intakes, and that all age groups of animals have equal (or, in the case of first-calvers, preferential) access to food. Most of these principles apply equally to dairy and beef cows, although the opportunities for modifying feed management practices of dairy cows are usually much greater than for beef suckler cows. In beef suckler cows, temporary weaning and restricted suckling, together with the use of progestogens (see later in this chapter) during the time of calf removal have resulted in reducing the time to the first ovulation postpartum.

Alleviation of other predisposing factors, such as stress, can be difficult. Avoiding mixing groups of cows at critical times seems obvious, yet management of high- and low-yielding groups of cows can make this difficult to achieve in practice. Provision of adequate feeding space is more easily achievable, but reducing group sizes to numbers in which cows can establish normal social hierarchies can be very difficult to achieve. The effects of climatic stress can be reduced by the provision of shade to cows that are heat stressed. Provision of shelter to cows that have to stand around in cold, draughty collecting yards can also be remarkably effective. The incidence of lameness can be almost entirely attributed to management practices, so anoestrus due to this cause should be regarded as being due to poor management rather than an inherent pathological problem.

Hormonal Treatment

The principles of the hormonal treatments for the management of anoestrus are described in Chapters 8 and 22.

Many different hormonal treatments have been given to anoestrous cattle in attempts to cause a resumption of cyclic activity. The main regimens that have been developed are based either on progestogens, relying on the so-called 'pituitary rebound' effect to restart the cycle, or upon drugs that either cause the release of gonadotrophins or have direct gonadotrophic actions themselves. The principles that underpin successful treatments for anoestrus (Wiltbank et al. 2011) are to:

1. Ensure that cows are cycling at the end of the voluntary wait periods or at the start of the breeding season, to maximise the chance of a timely conception;
2. Control ovarian follicle wave development to ensure that the ovulatory follicle is mature but not atretic;
3. Control the timing of ovulation to allow the use of fixed time AI or to maximise the opportunities for effective detection of oestrus; and
4. Ensure that the induced corpus luteum is functionally normal in terms of the duration of its persistence and the magnitude of its progesterone secretion.

There are currently four major methods of treating anoestrus:

- Ovsynch (GnRH–$PGF_{2\alpha}$–GnRH) (see Chapter 8);
- Ovsynch plus intravaginal progesterone;

VetBooks.ir

- Intravaginal progesterone plus eCG (and/or GnRH, $PGF_{2\alpha}$); and
- Oestradiol plus intravaginal progesterone plus (and/or GnRH, $PGF_{2\alpha}$).

These regimens meet the four principles for controlling ovulation in anoestrous cows. The first administration of GnRH or oestradiol esters causes ablation of dominant follicles, either by ovulation or luteinisation *in situ* (GnRH) or regression (oestradiol). Thereafter, a new follicular wave starts, in response to the FSH surge that is elicited by the administration of GnRH and/or the loss of the dominant follicle. Progesterone, which in dairy cows is most conveniently administered by the intravaginal route (but can be administered as an implant in beef animals), has two effects: suppression of ovulation of the growing follicular wave and accumulation of LH within the pituitary. Withdrawal of progesterone and/or administration of $PGF_{2\alpha}$ causes regression of the CL and permits ovulation. The final GnRH ensures synchronous ovulation. In animals that are deeply anoestrous, eCG can be given at the time of progesterone removal as a means of augmenting the growth of the preovulatory follicle (Bryan et al. 2013). Although eCG has long been used in deeply anoestrous beef cows, it is now increasingly also being used in dairy cows. Treatment regimens that use oestradiol cannot be used in the EU or in animals supplying food products to the EU, but oestradiol can still be used in many other areas, including North and South America. Fixed time insemination is used in nearly all anoestrus treatment regimens in order to obviate the need for oestrus detection and, more importantly, because the majority of cows either do not display oestrus at all or do not do so in close association with the optimal time for insemination. Several studies have shown better conception rates to fixed-time insemination than to detected oestrus. These regimens are summarised in Fig. 22.23.

Many studies have shown that the responses to any of the foregoing regimens are better in animals that are well fed rather than poorly fed. Most evidence shows that the response is better in animals whose plane of nutrition approaches equilibrium rather than being in energy deficit (e.g., McDougall et al. 2005).

Resynchronisation programmes are sometimes used as a means of managing the cows that fail to conceive after treatment for anovulatory anoestrus, but then relapse into anoestrus. The latter cows are frequently assumed to be pregnant. These cows, together with cows that spontaneously relapse into anoestrus, sometimes called 'phantom cows' (Cavalieri et al. 2000a, b), present considerable problems for herd managers as they either fail to conceive or have a very long open period. Management of such animals is aimed at preventing their relapse into anoestrus from going undetected. A further placement of intravaginal progesterone-releasing inserts after breeding (various studies have replaced them 12–16 days after breeding) will allow positive identification of cows that have failed to conceive.

Cystic Ovarian Disease

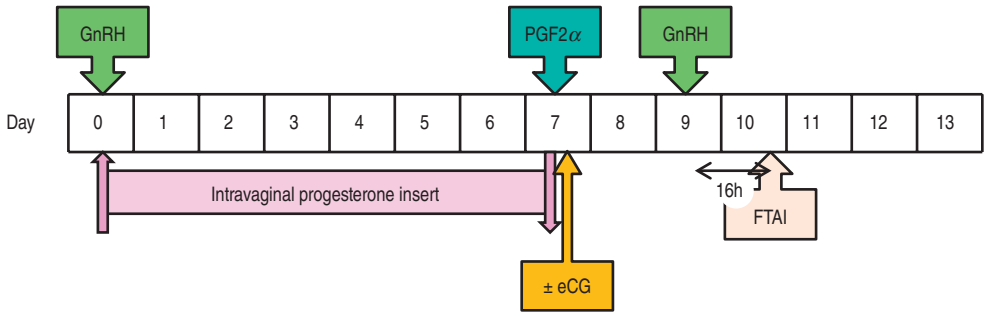
Ovarian cysts are follicular structures resulting from ovulation failure that are frequently larger than normal and persist within the ovary for longer than normal follicles, resulting in aberrant reproductive function. A cyst is defined as being larger than 25 mm in diameter if single (Al-Dahash & David 1977b), but, when multiple cysts are present, they can be smaller (> 17 mm diameter) (Garverick 2007). The definition normally requires the absence of a functional CL (Youngquist 1986).

In the normal postpartum cow, follicular waves start soon after calving, with ovulation of the dominant follicle of one of the early waves. Cystic ovarian disease (COD) is the clinical manifestation of dysfunction of this process, arising as a result of anovulation of a dominant follicle. Sakaguchi et al. (2006) suggested that the development of cysts is symptomatic of a more generalised disturbance of ovarian function, which ranges from a series of anovulatory follicle waves of normal duration, through temporary appearance of anovulatory cystic structures that develop and regress in a cyclical manner, to anovulatory cysts that persist in the ovary for extended periods of time (Fig. 22.24). Hence, many cows develop large, fluid-filled structures in the ovaries during the immediate postpartum period. These normally regress spontaneously but present as a clinical problem when they cause aberrant behaviour or alterations of the oestrous cycle.

Prevalence

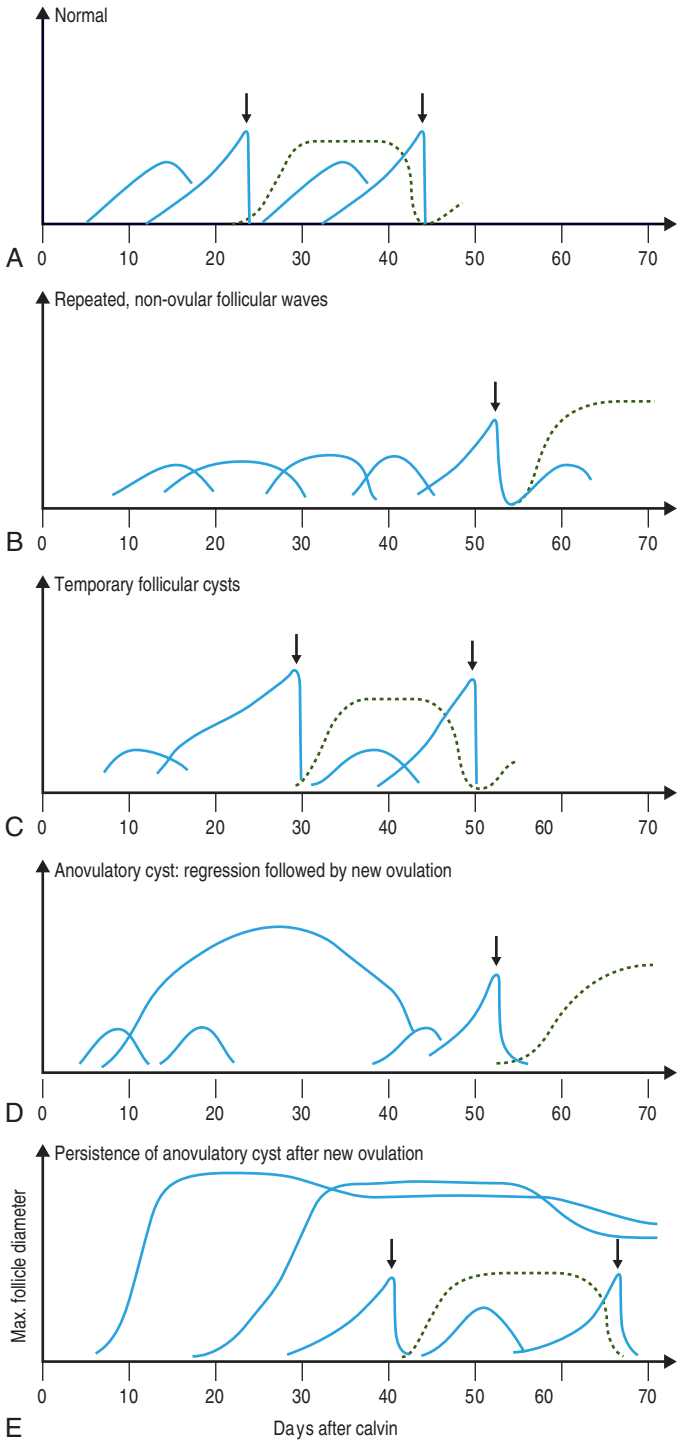
Surveys of the prevalence of cystic ovarian disease (or COD) need to be interpreted with some caution because information on the effects of the cysts upon reproductive function is usually absent from abattoir surveys, whereas in herd studies, cysts should only be regarded as pathological if they persist into the breeding period. Frequencies found in abattoir surveys range from 0.5% (Australia: Summers 1974) to 18.5% (Japan: Fujimoto 1956). Al-Dahash and David (1977a) found a prevalence of 3.8% in a British abattoir survey.

Figures for the prevalence of COD ranging from 6% to 19% per lactation were reported from the United States (Day 1991), 5% from Canada (Bigras-Poulin et al. 1990), and 7% to 8% from the UK (Watson 1996). Youngquist (1986) estimated the incidence at between 10% and 20% but considered that, if the cysts that occur before the start of the breeding season are also taken into account,



• **Fig. 22.23** Basic treatment regimen for treating anoestrus. The basic GnRH–$PGF_{2\alpha}$–GnRH is augmented with intravaginal progesterone and, sometimes, with eCG. Insemination is at a fixed time after the last GnRH (FTAI).

VetBooks.ir



• **Fig. 22.24** Sequences of postpartum follicle growth in a cow that (A) is normal; (B) has repeated non-ovulatory follicles; (C) has short-term follicular cysts; (D) has cystic ovarian disease; and (E) has persistent ovarian cyst after new ovulation. (Adapted from Sakaguchi et al. 2006.)

the incidence is about 30%. Anecdotal evidence has frequently suggested that cystic ovarian disease is increasing in incidence, but this is difficult to quantify from the literature.

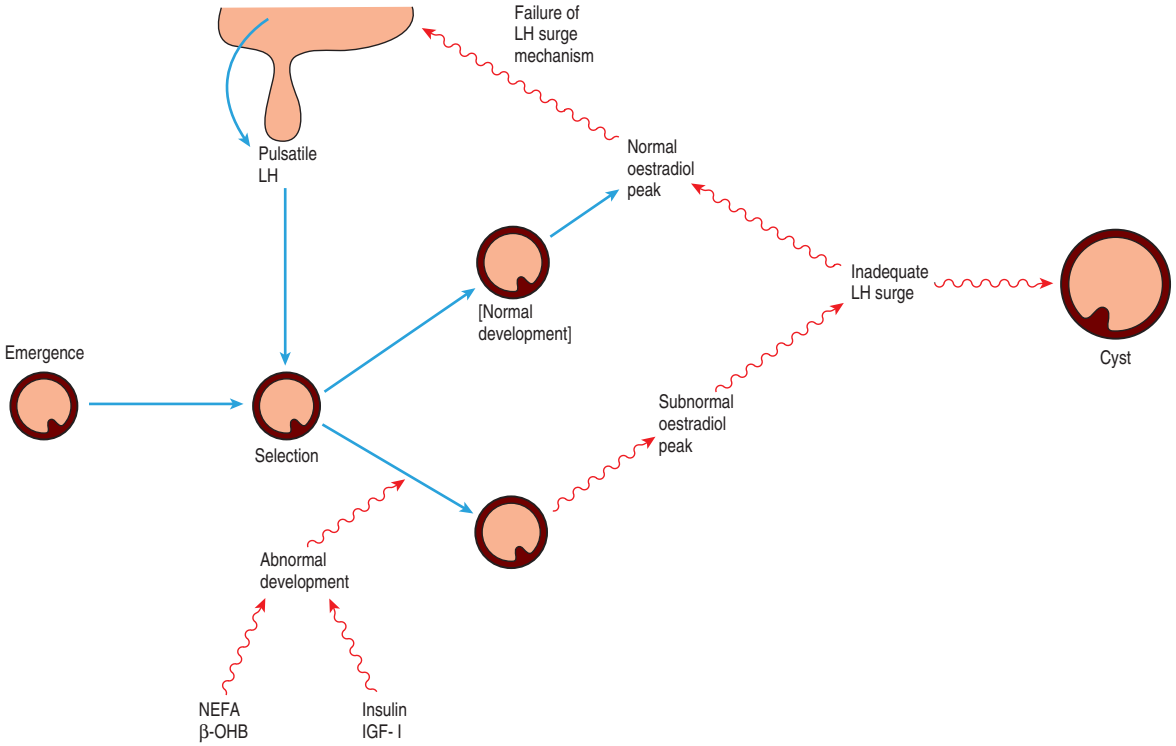
Aetiology and Pathogenesis

In cows with COD the preovulatory LH surge is absent or attenuated (Peter 2004), resulting in failure of ovulation of the dominant follicle. The consequence of failure of ovulation is that the follicle persists as a cystic structure, either with maintenance of the granulosa ('follicular cyst') or with luteinisation *in situ* in the absence of ovulation ('luteal cyst').

After calving there is a progressive restoration of the ability of the hypothalamus to generate an LH surge in response to oestradiol (Kesler & Garverick 1982), as a part of the normal process of resuming oestrous cycles. Cows with COD have a partial or complete failure of oestradiol to elicit a normal, positive feedback, LH surge (Nanda et al. 1991). Thus there is a lack of sensitivity of the hypothalamic surge-generating centre to oestradiol (Garverick 2007) and a failure of GnRH release. On the other hand, there is no lack of hypothalamic GnRH content, nor a lack of pituitary LH content, nor a lack of pituitary responsiveness to LH (Vanholder et al. 2005). Abnormalities of FSH secretion do not appear to be involved in the disorder (Hamilton et al. 1995). There are several factors that contribute to the lack of sensitivity to oestradiol. First, if a GnRH/LH surge occurs at a time when no follicle capable of ovulation is present, the hypothalamus becomes unresponsive to the positive feedback effects of oestradiol (Gülmen et al. 2002), which also occurs if there is no rise in progesterone after an ovulation. Responsiveness of the hypothalamus has to be restored by progesterone (Gülmen & Wiltbank 2005). Second, the LH surge mechanism can be attenuated by stress. Inhibition of ovulation and cyst formation (Liptrap & McNally 1976) and an impairment of the LH surge mechanism, similar to that in cows with COD (Dobson et al. 2000), can be produced experimentally by exogenous adrenocorticotrophic hormone (ACTH) or hydrocortisone. These changes can also be induced by stresses that activate the hypothalamo–pituitary–adrenocorticoid (HPA) axis (Nanda & Dobson 1990). Third, Diaz et al. (2015) have found that it is possible to replicate the condition of COD by maintaining progesterone concentrations slightly above baseline for 5 to 15 days after the expected time of ovulation. Because the inhibitory effect of elevated concentrations of progesterone on the LH surge is well-recognised, subluteal concentrations of progesterone could well be involved in the pathogenesis of COD.

The second major factor in the development of COD is alterations in the biochemical activity of the follicle. First, there is evidence (Kawate et al. 2004) of a reduced population of LH/chorionic gonadotrophin receptors (LHCGR) in the granulosa of cysts compared with normal follicles, which may be attributed in part to the effects of the HPA axis, because ACTH administration impairs steroid synthesis and LH expression within the dominant follicle (Biran et al. 2015). There is also a reduced concentration of oestrogen receptors in the granulosa cells of cysts (Salvetti et al. 2007) and alterations in postreceptor regulators of steroidogenesis (Ortega et al. 2015). Other recent research has identified differences in several autacoids or locally active hormones between normal and cystic follicles. Diaz et al. (2016) found differences in expression of bone morphogenetic proteins (BMP4 and BMP6) and the BMP receptor 1B (BMPR1B) between cystic and normal follicles (BMP4 and BMP6 are important regulators of steroidogenesis and mitosis in granulosa cells) that may contribute to follicular persistence and disruption of local hormone production. Expression of cytokines such as Interleukins (IL-6 and IL-8) and tumour necrosis factor–α (TNFα), all of which have roles in steroidogenesis and ovulation, differ between normal and cystic follicles (Stassi et al. 2017). Likewise, expression of transforming growth factor–β (TGFβ), a regulator of cell replication and steroidogenesis within the ovary, also differs between normal and cystic follicles

VetBooks.ir



• **Fig. 22.25** Schematic representation of the pathogenesis of ovarian cysts. (Redrawn from Vanholder et al. 2005.)

(Matiller et al. 2014). All of these differences in autacoid activity may contribute to follicular persistence and ovulation failure.

Negative energy balance is associated, at an epidemiological level, with COD, and there may be direct negative effects of elevated non-esterified fatty acids (NEFAs) upon follicular function. High yielding dairy cows have, as a result of genetic selection and metabolic load, low concentrations of insulin and IGF-I, and there is considerable evidence that these may contribute to the development of COD through an impairment of follicular cell proliferation and steroidogenesis (Vanholder et al. 2005). Rodriguez et al. (2017) also found alterations of the IGF system, such that cystic follicles had greater expression of IGF receptor 1 (IGFR1) and IGF binding protein 4 (IGFBP4) than normal follicles.

A scheme for the aetiology of COD based on that proposed by Vanholder et al. (2005) is shown in Fig. 22.25.

Cows with COD also have a higher frequency and amplitude of LH secretion during cyst growth than do normal cows (Cook et al. 1991). It was originally suggested that these abnormal patterns are causal of COD (Farin & Estill 1993), but current opinion is that, although such patterns of LH secretion are effective at maintaining a cyst once it has developed (Hampton et al. 2003), they are not required for the formation of cysts. On the other hand, it has been suggested that the abnormalities of tonic LH secretion are a reflection of the presence of progesterone concentrations that are marginally above baseline values (Vanholder et al. 2005).

Predisposing Factors

Cystic ovarian disease arises as an interaction between a hereditary predisposition, stress, milk yield, age, and plane of nutrition.

- **Hereditary predisposition:** There are differences in incidence of COD between breeds and between families and sires within a breed, which indicate the likelihood of an inherited predisposition. Estimates of heritability are variable but generally low (Zwald et al. 2004a, b). Because of the familial basis of the condition, its incidence can be dramatically reduced within a breed by avoiding the use of cows that have had COD as bull mothers and by avoiding the use of bulls that have bred daughters that have the disease as bull sires (Bane 1964, Kirk et al. 1982).
- **Breed:** COD is more common in Holstein–Friesians than in other dairy breeds. It is rare in beef breeds.
- **Age:** The incidence of COD is greatest in animals between 4 and 6 years of age (Roberts 1986). It has traditionally been regarded as being uncommon in animals in their first lactation, although Watson (1998) showed that the incidence in first lactation animals was similar to that in second and third lactations.
- **Yield and nutrition:** Many studies have linked COD to milk yield (e.g., Ashmawy et al. 1992). However, the relationship with yield is complex, as it involves the extent of negative energy balance, the genetic potential of the cow (see previous mention), and the metabolic load of lactation. Thus milk yield per se may not be as significant a cause of cystic ovarian disease as is the genetic potential for high yield (Zulu & Penny 1998, Hooijer et al. 2001). Body condition at drying off has also been associated with the disease (Gearhart et al. 1990), presumably through effects on postcalving fat mobilisation. Excessive dietary protein may also have a direct effect on the incidence (Ashmawy et al. 1992). Hooijer et al. (2001) found that there was a genetic correlation between COD and milk production of 0.34 and between COD and milk protein production of 0.44.
- **β-carotene:** It has been suggested that β-carotene may reduce the incidence of COD (Lotthammer 1979). However, this has

VetBooks.ir

not been supported by the work of others (Folman et al. 1979, Marcek et al. 1985), who found no benefit from such supplementation of cows' diets.

- **Season:** Some studies have found that COD is more common in autumn and winter than at other times of the year (Nelson et al. 2010, Cattaneo et al. 2014).
- **Intercurrent disease:** Ketosis, dystocia, stress, twin births, RFM, milk fever, and postpartum uterine infections have also been considered risk factors (Hardie & Ax 1981, Roberts 1986. Bosu & Peter 1987, Laporte et al. 1994).

Clinical Presentation

Cysts may be present in one or both ovaries (Table 22.2). More cysts are identified in the right ovary than in the left, reflecting the relative activity of the two ovaries. Solitary cysts are more common than multiple cysts, although the proportion of cows reported with solitary cysts varies widely (75%: Elmore et al. 1975; 53%: Al-Dahash & David 1977b). The majority of cysts are between 2.5 and 3.0 cm in diameter, with very few larger than 5 or 6 cm.

TABLE 22.2 Distribution of ovarian cysts and their association with corpora lutea

Type of Cyst	Number of Cysts	PERCENTAGE OF CYSTS: No Corpus Luteum Present	PERCENTAGE OF CYSTS: Corpus Luteum Present	Total (%)
Thin-walled	Single	16.9	18.9	80.2
	Multiple	40.3	4.2	
Thick-walled	Single	10.2	7.7	19.8
	Multiple	1.9	0	
Total		69.3	30.7	

From Al-Dahash & David (1977b).

Follicular cysts are two or three times more common than luteal cysts (Leslie & Bosu 1983).

Ovarian cysts can be classified as either follicular or luteal. Follicular cysts are thin-walled, fluctuating structures that can be single or multiple (Fig. 22.26A). Luteal, or luteinised, cysts (see Fig. 22.26B) are thick-walled and are usually single (Table 22.3). Identification and differentiation by ultrasonography (Fig. 22.27A and B) is generally more accurate than by manual palpation (Douthwaite & Dobson 2000). Although useful, this binary classification does not account for the many cysts that are partly luteinised or for changes in the extent of luteinisation over the lifespan of a cyst, so care is needed in interpreting clinical findings. There are a number of other fluid-filled structures that may be present on the ovary and need to be differentiated from cysts. The corpus haemorrhagicum, adjacent luteal and follicular structures, non-ovarian cysts (e.g., parovarian cysts, hydatids of Morgagni), abscesses, and tumours can also be confused with cysts (Farin & Estill 1993). The type of cyst that is present can be confirmed by measuring peripheral progesterone concentrations; blood or milk progesterone concentrations: higher than 2 ng/mL in milk or higher than 1.0 ng/mL in plasma/serum (Carroll et al. 1990, Farin et al. 1992) are considered to be indicative of a luteal cyst.

Cysts can be present concurrently with a corpus luteum (Table 22.2; Al-Dahash & David 1977b, Roy et al. 1985, Carroll et al. 1990), so the absence of a corpus luteum needs to be confirmed. However, in cows that also have a corpus luteum, any cysts that are present are likely to be hormonally inactive (Al-Dahash & David 1977c) because of loss of the granulosa cells and so are considered as anatomical remnants rather than active structures.

Clinical Signs

The main clinical signs of COD in cattle are persistent oestrus, anoestrus, or masculinisation; it was first discovered as a result of investigations of persistent oestrus behaviour in cows. Roberts (1955) described 'nymphomaniac' cows as displaying excessive, prolonged signs of oestrus, with oedematous swelling of the vulva, frequent and copious discharge of clear mucus, and a shortened interval between successive heats. In neglected cases, there is nervous

behaviour, depressed milk yield, loss of bodily condition (even emaciation), sinking of the sacrosciatic ligaments, and upward displacement of the coccyx (Fig. 22.28). Affected cows attempt to ride other cows and will stand to be mounted by other cows. Because of their excessive sexual activity they have a generally disruptive effect upon the rest of the herd, making accurate oestrus detection difficult. Occasionally, cows with long-standing COD will become virilised (Arthur 1959).

Most cows with COD are, however, anoestrous. Watson (1998) found that only 2% of cows with COD were presented for frequent, irregular display of oestrus, compared with 74% that were presented as being anoestrous. A further 12% were found during routine prebreeding examinations, and 12% were found in cows that were non-pregnant at pregnancy diagnosis. Likewise, in the series of cases reviewed by Roberts (1986), 63% to 85% of animals were anoestrous. The behaviour of cows with cysts is largely unrelated to peripheral steroid concentrations (Roberts 1986); cows with follicular cysts have blood oestrogen (Kittock et al. 1973, Dobson et al. 1977) and testosterone (Eyestone & Ax 1984) concentrations that are not greatly dissimilar from those of normal cows.

Sequelae

Spontaneous recovery from cystic ovarian disease occurs frequently in the early postcalving period, although it is difficult to estimate this figure accurately in the light of the data, which show that cysts can be short- or long-term structures (e.g., Sakaguchi et al. 2006; Fig. 22.24). Reported self-cure rates vary from 5% to 30% of cases (Garverick 1997, Peter 2004) within 45 days of calving. If divided into cysts that arise from the first dominant follicle versus those that arise from subsequent waves, the self-cure rates are 50% and 20% respectively (Kesler & Garverick 1982). Neglected cases of COD can result in mucometra, in which there is distension of the uterus with mucoid fluid and thinning of the uterine wall (Fig. 22.17; Al-Dahash & David 1977a).

Cystic ovarian disease results in an extension of the calving interval. Cows with follicular and luteal cysts had calving to conception intervals of 274 and 408 days, respectively, compared with 115

VetBooks.ir

days in unaffected animal (Chamba et al. 2017). Pregnancy rates of cows with COD (67%) are also lower than in normal cows (89%) (Cattaneo et al. 2014). Hence, cows with COD show decreases in lifetime milk yields and increases in the involuntary culling rate, and are more likely to become repeat breeders (Moss et al. 2002). Nonetheless, in both the field study of Watson and Cliff (1996) and the computer modelling of Scholl et al. (1990), it was found that, although COD has a major effect upon reproductive outcomes of individual animals, the condition was not of major significance in determining the reproductive performance at the herd level. Thus Watson (1998) calculated that the net effect of COD within a herd was to increase the mean calving to conception interval by approximately 2 days and the number of serves per conception by 0.1 to 0.2 serves. For the individual animal, treatment is economically worthwhile; de Vries et al. (2006) calculated a net benefit of approximately US$80 of treatment with a progesterone insert compared with no treatment.

Treatment

Physical Methods. It is generally advocated that cysts should not be manually ruptured per rectum, as this can cause trauma, haemorrhage, and/or ovariobursal adhesions (see Nanda et al. 1989). Despite the known risks and limited efficacy of manual rupture, Watson (1998) reported from a survey of field practice that nearly 35% of cysts were 'treated' by manual rupture (although half of these also had hormone treatment). More recently, aspiration of the contents of ovarian cysts has been suggested as a treatment (Amiridis 2009), but this does not seem to offer much advantage over hormonal treatments.

Hormonal Programmes. Most cysts are treated using reproductive hormones. The choice of hormonal treatment regimen depends largely upon the type of cyst that is present. Follicular cysts are usually treated with either gonadotrophic hormones (i.e., hCG or GnRH) or progesterone, whereas luteinised cysts can be treated with luteolytic substances.

Follicular Cysts. Follicular cysts can be treated with hCG or GnRH. These hormones do not cause ovulation of the cyst; rather, they cause ovulation of new follicles (Jeffcoate & Ayliffe 1995), which develop into corpora lutea. Treatment may also cause luteinisation of the cyst *in situ.* Lower doses of GnRH (100–250 μg) probably cause luteinisation of the cyst (Kesler et al. 1981); higher doses (e.g., 0.5–1.0 mg GnRH or 10 μg buserelin) probably cause ovulation of new follicles and formation of a corpus luteum (Bertchtold et al. 1980). The result is an increase in progesterone concentration, which causes negative feedback on LH secretion and resets the sensitivity of the pituitary to oestradiol (Gülmen et al. 2002). Thus LH concentrations decline, and there is a decline in follicular steroid synthesis, leading to lowered oestradiol–17β concentrations (Kesler & Garverick 1982). The luteinised structures produce progesterone for 15 to 18 days (Garverick 2007) so that there is a return to normal oestrus in approximately 3 weeks.

Resumption of normal oestrous cycles occurs within 3 weeks in 65% to 90% of cows after treatment with GnRH (Dobson et al. 1977, Probo et al. 2011), and in 75% of cows after treatment with hCG (Dobson et al. 1977). Conception rates to the next oestrus range from 37% to 55% (Ijaz et al. 1987). However, when the response to treatment, proportion of cows inseminated, and the conception rate to AI are considered together, the response to treatment is relatively poor. Probo et al. (2011) found that these figures were 71%, 70%, and 40%, respectively, giving a pregnancy rate after treatment of only 20%. Cysts recur in 8% (Nanda et al. 1988) to 16% (Watson 1998) of cows after treatment.

Once luteinisation has occurred, the interval to the next oestrus can be shortened by giving $PGF_{2\alpha}$ (Garverick 2007). Thus, Kesler et al. (1978) and Garverick (1997) suggested giving GnRH on the day of diagnosis of the cyst and $PGF_{2\alpha}$ 9 days later. However, studies (e.g., Archibald et al. 1991) of subsequent fertility compared with that achieved after using GnRH alone did not show any benefit of the addition of $PGF_{2\alpha}$. Ismail et al. (2017) found that a greater proportion of cows exhibited oestrus after GnRH + $PGF_{2\alpha}$ than after GnRH alone (87% versus 70%) but that the final pregnancy rate after three insemination cycles was identical (63% and 65%).

GnRH–$PGF_{2\alpha}$–GnRH ('Ovsynch', 'GPG') regimes (see Chapter 8) have been used to treat COD (Ambrose et al. 2004, Garverick 2007). Gundling et al. (2015) compared the results of a standard ovsynch protocol (Day 0: GnRH; Day 7: $PGF_{2\alpha}$; Day 9: GnRH) with a modified protocol (Day 0: GnRH + $PGF_{2\alpha}$; Day 14: $PGF_{2\alpha}$; Day 16: GnRH), finding that the reproductive performance of cows treated with the modified protocol was similar to that of unaffected controls in terms of display of oestrus, first service conception rate, and final pregnancy rate, but the standard ovsynch protocol gave significantly poorer results over all of those parameters. They calculated an economic benefit of the modified protocol of €132 over the standard ovsynch regimen. Similarly, Freick et al. (2012) found that only 19% of cows with COD became pregnant after a standard Ovsynch protocol, whereas 35% became pregnant after a similarly modified protocol. Thus there appears to be limited benefit to the more expensive ovsynch regimen over a simple GnRH or GnRH + $PGF_{2\alpha}$ protocol, but the modified programme may be cost effective in terms of reproductive outcomes.

Alternatively, follicular cysts can be treated with intravaginal, progesterone-releasing inserts (Nanda et al. 1989, Calder et al. 1999). Increased peripheral progesterone concentrations result in a lowering of pulsatile LH secretion and a restoration of the ability of the hypothalamo–pituitary axis to generate an LH surge in response to oestradiol (Gumen & Wiltbank 2002, Todoroki & Kaneko 2006). Signs of persistent oestrus abate within 24 hours of PRID (progesterone releasing intravaginal device) insertion, the cysts gradually regress and, after removal after 9 to 12 days, there is oestrus with ovulation and corpus luteum formation. Treatment of cows with follicular cysts with PRID alone resulted in similar calving to conception intervals to untreated cows without COD, although 40% of treated cows were eventually culled for failure to conceive (Douthwaite & Dobson 2000). Several reports have found progesterone alone to be a relatively ineffective treatment for luteinised cysts (e.g., Douthwaite & Dobson 2000, Todoroki et al. 2001), so there needs to be careful differentiation of the type of cyst before initiation of treatment or incorporation of a luteolytic agent into the programme. Mollo et al. (2012), on the other hand, found similar results after GnRH, hCG or progesterone treatment of cows with COD, regardless of whether they had follicular or luteal cysts. A comparison of the responses to GnRH, PGF, and intravaginal progesterone is given in Table 22.4 (Watson 1998).

Luteinised Cysts. The most logical way to treat a luteal cyst is the use of $PGF_{2\alpha}$. A consistent response was obtained by Dobson et al. (1977): 26 of 27 cows showed regression of the cyst, the majority came into oestrus in 3 to 5 days, and 56% of the cows conceived, at a mean treatment-to-conception interval of 27 days. Jackson (1981), in a survey involving several countries, reported over 80% response with disappearance of the cyst and oestrus within 3 to 5 days, with at least 60%, and in most cases over 90%, of these cows conceiving. Many similar reports exist in the

NQ, not quoted.
Derived from Watson (1998).

literature (see Ijaz et al. 1987). Indeed, failure of cows with supposed luteal cysts to respond to $PGF_{2\alpha}$ therapy is most commonly due to misdiagnosis.

Prevention

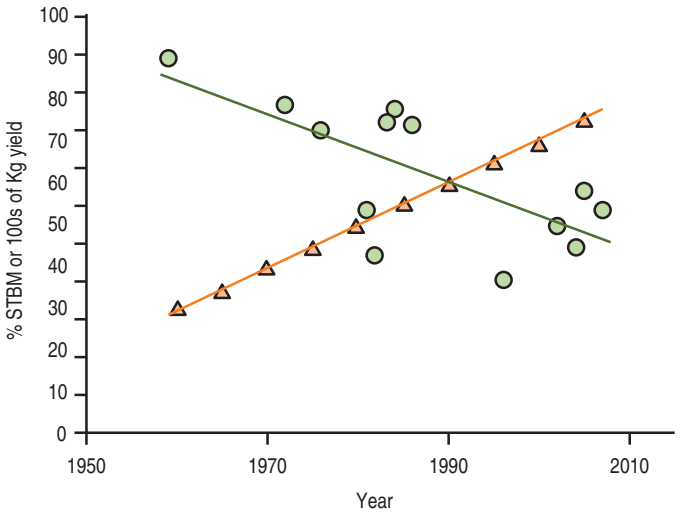
By careful genetic selection, improvements have been made by eliminating bulls that have sired daughters that have subsequently suffered from COD. Ideally, cows should not be treated for cystic ovaries, and their progeny certainly should not be used for breeding. Unfortunately, this places the herd manager and the veterinarian in a dilemma because, frequently, those cows that are affected are the highest yielders.

Prophylactic use of GnRH (e.g., 100–200 μg of GnRH 12–14 days postpartum; Kesler & Garverick 1982) has shown some success in reducing the prevalence of cysts in herds (Zaied et al. 1980). However, Noseir et al. (2013) found no difference between treated and untreated cows in terms of conception rates, services per conception, and calving to first service interval.

Expression of Oestrus

Cows display oestrus behaviour in the absence of a bull by mounting and standing to be mounted by other sexually active cows (see Chapter 1). The relatively short duration of oestrus is one of the main reasons that observation has to be undertaken both regularly and frequently. Early reports indicated that oestrus can last for 18 to 20 hours (Tanabe & Almquist 1960), but most studies have found it to last no more than 15 hours (Esslemont 1974, Albright & Arave 1997), and that 20% of cows are in oestrus for less than 6 hours. Until recently, the consensus view has been that most normal cows exhibit oestrus behaviour at the appropriate stage of the cycle and that, provided appropriate observations were undertaken, oestrus detection rates in excess of 90% should be achievable (Williamson et al. 1972).

More recently, there has been evidence for a decline in the intensity of oestrus behaviour in high yielding dairy cows, with a general decline in the number of mounts, the duration of each mount, and the length of time over which mounts occur. Dobson et al. (2008) reviewed literature on the duration and intensity of oestrus, showing that the proportion of cows that stand to be mounted has declined from nearly 90% in the 1950s to around 50% in the 2000s (Fig. 22.29). This decline in intensity of oestrus display has been accompanied by a reciprocal increase in the proportion of cows having 'silent heats'. The assumption that 100% of cows in physiological oestrus will show the classic behavioural signs of standing to be mounted during oestrus therefore no longer appears to be true for high yielding dairy cattle. In the study of Kerbrat and Disenhaus (2004), in which continuous video monitoring of cows was compared with milk progesterone profiles (as an indicator or physiological oestrus), only 8 of 15 cows ever stood to be mounted during the periovulation period. Other recent studies have confirmed that the reduction in intensity and duration of oestrus behaviour has resulted in low detection rates using standard observational techniques. van Vliet & van Eerdenburg (1996) only observed standing oestrus in 37% of cows, whereas Dransfield et al. (1998) recorded that 24% of cows had an oestrus period that was of low intensity and short duration, compared with only 8% with an oestrus of high intensity and long duration. Sveberg et al. (2015) compared the duration and intensity of oestrus in Holstein versus Norwegian Red cows, showing that the Norwegian Red cows



• **Fig. 22.29** Percentage of animals standing-to-be-mounted (STBM ◯) and average milk yield (△) in Holstein–Friesian dairy cows reported for 50 years to 2008. (Based on Dobson et al. 2008.)

VetBooks.ir

displayed more oestrus behavioural episodes, had a longer duration of oestrus, and were associated with 'sexually active groups' (SAGs) for longer than Holstein cows. Interestingly, in that study, the reduction of oestrus behaviour was an effect of breed rather than of yield per se, inasmuch as the yields of the Holsteins and Norwegian Reds were identical.

The reduced intensity of oestrus behaviour is explained in part with reference to preovulatory oestrogen concentrations. Although Glencross et al. (1981) considered that intensity of oestrus behaviour was unrelated to oestrogen concentrations, more recent studies (e.g., Lopez et al. 2004) have found that preovulatory oestrogen concentrations are lower in high yielding than low-yielding cows and that the intensity of behaviour is related to those oestrogen concentrations (Lymio et al. 2000, Lopez et al. 2004). In other words, high yielding cows have a lower oestrogen concentration and a reduced intensity of oestrus behaviour. The extent to which lower oestrogen concentrations are due to insulin- and IGF-I–mediated deficiencies of follicular growth (Butler & Smith 1989, Lucy 2001) or to the increased metabolism and clearance that occurs in cows with a high metabolic load (Sangsritavong et al. 2002) is yet to be established. There may also be changes in the central nervous system that are unrelated to altered steroid profiles (Mayne 2007).

Follicular or Luteal Dysfunction

Inadequate luteal function, although not a cause of anoestrus, is an ovarian dysfunction that results in a reduction in fertility. Many aspects of early embryonic development are progesterone dependent, such that inadequate progesterone concentrations are associated with impeded embryonic development. Thus, for example, inadequate expansion of the trophoblast can result in failure of maternal recognition of pregnancy, and hence luteolysis occurs. Furthermore, some cows can undergo premature luteolysis before the time of maternal recognition of pregnancy (Meier et al. 2009).

Persistent Corpus Luteum

Anything that interferes with the production or release of prostaglandin $F_{2\alpha}$ will result in a persistent corpus luteum (CL). Pregnancy is the condition that most frequently results in persistence of the CL. However, as previously described, in the presence of uterine infection and inflammation of the tissues, there is interference with the production or the release of $PGF_{2\alpha}$ (Seguin et al. 1974). This condition can be self-perpetuating because progesterone domination of the uterus reduces its resistance to infection, and prevents a return to oestrus (with its associated increase in uterine immunity). There is, however, evidence that persistence of the CL can occur in the absence of uterine lesions. Lamming and Bulman (1976) identified that 2% of cows have milk progesterone concentrations that are elevated for more than 30 days. Others have associated luteal persistence with failure of ovulation or follicular development.

If it is considered that a persistent CL is present, it can be readily treated with $PGF_{2\alpha}$ or a synthetic analogue, provided, of course, that the clinician is confident that the cow is not pregnant.

Ovulatory Defects

Ovulation in the cow normally occurs 25 to 35 hours after the onset of behavioural oestrus and 18 to 26 hours after the ovulatory LH peak (see Chapter 1). Extended intervals between the onset of oestrus and ovulation ('delayed ovulation') of up to 48 hours have been reported in dairy cows: typical incidences range from 2% to 5% (Erb et al. 1976, Roelofs et al. 2005). Concentrations of oestradiol and LH in the preovulatory period of such cows may be lower than in the normal follicular phase (Bloch et al. 2006). Conception rates of cows with delayed ovulation are generally low.

Some studies have associated delayed ovulation with subnormal progesterone concentrations in the after luteal phase (Bloch et al. 2006). On the other hand, some cows apparently have a prolonged follicular phase of the oestrous cycle, as determined by the presence of low progesterone concentrations in blood and milk (Erb et al. 1976, Bulman & Lamming 1978), that is not due to delayed ovulation but to delayed onset of progesterone secretion by the CL.

Stockmanship and Management

Oestrus Detection

The use of AI as the main method of breeding dairy cows means that the primary responsibility for oestrus detection falls upon the staff who manages the herd. Oestrus detection is therefore a critical aspect of dairy herd management for, although good oestrus detection does not necessarily guarantee good reproductive performance, poor oestrus detection makes poor performance hard to avoid.

Whether or not the behavioural signs of oestrus are observed depends on many factors (Table 22.5), and, notwithstanding the changes in the expression of oestrus that are occurring in high yielding cows, there is much that can be done at a management level to optimise the efficiency and accuracy of its detection. For example, the timing and duration of observations can be optimised and the signs that are indicative of oestrus behaviour can be recorded (Heres et al. 2000, Kerbrat & Disenhaus 2004), and technological aids can be used to improve the efficiency of oestrus detection. As difficulties in detecting oestrus have increased, the use of whole-herd synchrony techniques, which bypass the need for human detection of oestrus, has increased (see Chapter 8). Conversely, in herds that are naturally mated, the importance of oestrus detection is less critical, largely being confined to ensuring that adequate non-return rates occur after service.

Herd Size and Calving Pattern

In order for effective display of oestrus, there must be cows that are prepared to mount as well as cows that are prepared to be mounted. Cows that mount are generally those that are coming into or going out of oestrus, and these, together with the cows that are in oestrus, associate together in a sexually active group (SAG). Cows that are in dioestrus or anoestrus are not generally present in the SAG.

It is clear that the duration and intensity of oestrus increase as the number of animals in the SAG increases (Hurnik et al. 1975, Esslemont et al. 1980, Kilgour & Dalton 1984), making oestrus detection easier in a larger group. Systems that have strongly seasonal calving and mating patterns generally have much larger SAGs than year-round-calving herds and, consequently, better oestrus detection. In year-round-calving herds, only approximately 2% of the cows calve within any given week. In consequence, there will be times when the sexually active 'group' consists of a single cow, making oestrus detection very difficult indeed (van Vliet & van Eerdenburg 1996, van Eerdenburg et al. 2002, Kerbrat & Disenhaus 2004).

Herd size affects the detection of oestrus in two main ways. First, as herd size (and concentration of calving pattern) increases, the size of SAGs increases, making oestrus detection easier. On the other hand, there is a reduction in the accuracy and efficiency of oestrus detection associated with increased herd size (Esslemont

Can cows that are not in oestrus avoid being ridden?
Identification and Records
Can cows be identified accurately?
Are cows observed for returns to oestrus after artificial insemination?
Aids
Tail paint, heatmount detectors, electronic aids, etc.?
Relative reliance placed on aids and primary observation?

1974, Wood 1976). Negative effects of increasing herd size are that the herd manager has to look after more cows, so cows tend to lose their individual identity and, consequently, are neither so accurately identified nor so closely observed (Waiblinger & Menke 1999). Likewise, there is evidence for impaired display of oestrus in herds that are too large or have groups that change too frequently for a stable social hierarchy to develop between individual cows.

Time and Place of Observation

There are times and situations when cows exhibit few or no signs of oestrus behaviour and others when the display of oestrus is more likely to occur. Cows are unlikely to display oestrus behaviour when being held in collecting yards, during milking, when feeding, or when moving along races or tracks. Crowded collection areas and confined spaces may not permit the ready grouping of sexually active individuals. Conversely, cows are more likely to display oestrus in cubicle yards, in feeding or 'loafing areas', or when at pasture (Williamson et al. 1972, Esslemont & Bryant 1976, Pennington et al. 1985, 1986).

Tie-stall housing has a significantly adverse effect upon the display of oestrus (Unal et al. 1986, Felton et al. 2012), such that fewer oestrus periods are detected, although with no diminution upon accuracy of detection. Systems in which cows are continuously in tie-stalls through all or part of the year (e.g., Scandinavian herds: Refsdal 1999; small-holder herds in developing countries: Abeygunawardena et al. 2000) are therefore at particular risk of poor oestrus detection.

Several studies have reported that the floor surface is of importance in the display of oestrus behaviour. Concrete surfaces are more slippery than dirt surfaces and hence less conducive either to mounting or to being mounted (Britt et al. 1986; Vailes & Britt 1990), and individuals that have previously slipped on concrete may be unwilling to attempt to mount in the future (Albright 1994). Thus the majority of mountings take place in conditions that have the best footing and are less crowded (Albright & Arave 1997, Pennington et al. 1985). The detection of oestrus is better in cows that are pastured than in those that are housed (Palmer et al. 2010), regardless of whether visual observation or automated detection methods are used.

It has long been considered that cows are more likely to display oestrus behaviour during the night than during the day. Curiously, when video or radiotelemetry have been used to determine patterns of mounting, this nocturnal pattern has not been evident (Amyot & Hurnik 1987, Nebel et al. 2000). Indeed, Albright and Arave (1997) concluded that the results of studies of the timing of oestrus behaviour were inconsistent with simple diurnal patterns and probably should be explained in terms of the periods of time for which cows were left undisturbed by other farm activities. Slightly more ovulations occur at night than during the day (56% versus 44%: Kahn 1992), but relatively few between 0900 and 1500 hours. Perhaps these data could be interpreted to mean that the prevalence of ovulations and oestrus behaviour that occurs during the night may simply be an indication of the time when there is least other activity on the farm (see also Williamson et al. 1972, Hurnik et al. 1975, Esslemont & Bryant 1976).

Esslemont (1973) examined the effect of the use of a rigid regimen, involving three or four periods of observation for 15 or 30 minutes, upon oestrus detection efficiency. With three 15-minute periods of observation (0800, 1400, and 2100), a detection rate of 69.6% was achieved. Increasing the duration to 30 minutes improved the rate to 81.2%, and four 30-minute periods of observation (0800, 1400, 2100, and 2400) produced the best result of 84.1%. The absolute times of observation are not critical and can be varied to suit the timetable of the farm. van Vliet and van Eerdenburg (1996) suggested that, if oestrus is observed when cows are in a space in which they can form sexually active groups and when they are undisturbed (i.e., after completion of milking and feeding undisturbed), at a time when dioestrous cows are resting and cudding, two observations of 30 minutes per day would result in a detection efficiency of 74% and an accuracy of 100%.

Identification

It must be possible to readily identify the individual cow from any position so that the herd manager can then record the animal number immediately and permanently. Good freeze branding on the rumps, together with numbered collars or large ear tags, should preferably be used for identification. Even in small herds, whose stock managers think that they know the cows as individuals, many mistakes are made through misidentification or misrecording. When observation is made of housed cows, provision of adequate lighting is required for cows to be seen showing behavioural signs and for their accurate identification.

VetBooks.ir

Environmental Factors

Patterns of oestrus behaviour vary with environmental temperature, with the frequency of mounts, and with the repertoire of activities differing between hot, moderate, and cold conditions (Pennington et al. 1985). In cold conditions, mounting behaviour was much less between 1800 and 0600 than at other times of day, whereas in hot conditions it was least during the hottest part of the day. Also, the duration of oestrus was reduced to 8 to 10 hours under extreme climatic conditions. Certainly, where autumn calving and winter mating is practised (as in the UK), a shortening of the duration of oestrus and a reduction in the intensity of oestrus behaviour are widely recognised as problems of mating management of such herds.

Human Factors

Despite the importance of good oestrus detection to the economic performance of the dairy herd, it is often regarded as a 'chore' that has to be fitted in between the many other tasks that have to be done. Therefore perhaps it is not surprising that, in many situations, oestrus detection efficiency is poor. On the other hand, when oestrus detection is regarded as a priority task and is undertaken by highly motivated farm staff under ideal conditions for observation, oestrus detection rates can be remarkably high. An important prerequisite for effective oestrus detection is therefore the provision of enough time to do the job properly (O'Connor 2007).

With the general decline in numbers of staff working on dairy farms and the difficulties in getting junior staff that have any experience of working with livestock, there is often a dearth of personnel who are capable of accurate oestrus detection. O'Connor (2007) emphasised the importance of making sure that one person is assigned responsibility for oestrus detection and ensuring that the person is adequately trained to do so. The importance of having staff who are trained to identify oestrus correctly was shown by Esslemont (1974), who found that there was a significantly higher oestrus detection rate by trained staff compared with untrained staff. The importance of having staff who 'fully understand the signs of heat and are fully committed to heat detection in an optimal management' (Becker et al. 2005) has not diminished with the passing of time. When there is a defined breeding season, it is possible to use the detection of early (preseason) oestrus periods both as a means of retraining staff in the skills of oestrus detection and of ascertaining which cows are still anoestrous. Prebreeding oestrus detection also allows prediction of the timing of the first oestrus of the mating period. Recent changes in the intensity of behavioural oestrus implies that personnel need to be able to recognise a range of relatively subtle behaviours, as well as the classic sign of standing to be mounted (Heres et al. 2000, Lyimo et al. 2000, Kerbrat & Disenhaus 2004).

The length of the breeding season affects the ability of herd managers to detect oestrus. When there is a short breeding season, detection rates can reach 90% or more, because of a combination of a concentration of staff effort on detection of oestrus and large SAGs. In year-round calving herds, the dispersal of effort and the small SAGs mean that oestrus detection rates are rarely better than 60%, and in many cases, they are often much less than that.

'Silent' Ovulations

Most cows do not display oestrus at the time of their first postpartum ovulation because of a lack of progesterone priming (King et al. 1976). For the reasons discussed previously, it is increasingly common for cows to have low intensity of oestrus behaviour over a short period of time, which may not include standing to be mounted. Hence these cows may also be considered to have 'silent ovulation', even though at least some behavioural signs associated with oestrus will generally have been displayed.

Other causes of inadequate display of oestrus behaviour include heat stress (Gwazdauskas et al. 1983). Cows suffering from ergotism ('fescue toxicity') may become suboestrous, whereas a number of nutritional deficiencies, including β-carotene, phosphorus, copper, and cobalt, are also said to cause suboestrus.

However, the most common cause of 'silent ovulation' is a failure of oestrus detection. Hence, once convinced that cows are not suffering from anovulatory anoestrus and that there are no pathological causes of suboestrus, herds with a high incidence of 'silent ovulation' generally benefit from either a thorough review of oestrus detection procedures or the use of detection aids such as are described here.

Aids to the Detection of Oestrus

There are several methods available that can be used to improve the oestrus detection rate. Traditionally, these have been regarded as 'aids', inasmuch as they have been adjuncts to human observation of oestrus behaviour. With the difficulties presented by reduced intensity of behavioural oestrus display and the declining pool of labour with livestock skills, recent research has concentrated on attempting to fully automate detection aids, with the intention of obviating the need for human detection. Some of the aids to oestrus detection are summarised in Table 22.6.

Detection of Mounting

Detection of mounting can be achieved by marking the tailhead with paint so that when the cow is mounted the marking is disturbed, or by placing a pressure-sensitive device on the tailhead to record the act of mounting.

Tail Painting

The technique of tail painting was developed in New Zealand (Macmillan & Curnow 1977) to improve oestrus detection rates. A brittle, high gloss, enamel paint is placed as a thick layer in the midline over the sacrum and base of tail (Fig. 22.30A), preferably applied using a brush against the line of the hair to ensure good adhesion, before smoothing in the direction of the hairline. There should be regular inspection of the paint so that repainting can be done if necessary. When a cow is mounted by other cows, the paint is abraded and removed (see Fig. 22.30B). Submission rates of over 90% and pregnancy rates of up to 60% can be obtained after AI after observation of the condition of the tail paint. Some inaccuracies (positive or negative) of detection occur when between 25% and 75% of paint remains (Kerr & McCaughey 1984), although these can be minimised by concurrent direct observation for behavioural signs of oestrus. At the time of writing, the use of tail paint is almost ubiquitous in Australia and New Zealand. Tail paint has been used in the UK but has proved to be of little overall benefit to oestrus detection rates. This may be because of the small SAGs that occur in non-seasonal herds.

Heatmount Detectors

Simple mechanical heatmount detectors such as the Kamar or Bulling Beacon can be used. These consist of a soft, translucent plastic dome attached to a rectangle of canvas in which there is placed a soft plastic vial of red dye that is fixed with adhesive just cranial to the base of the tail (Fig. 22.31A). When a cow is mounted and the vial is subjected to sufficient pressure (i.e., at

VetBooks.ir

TABLE 22.6 Aids to the detection of oestrus in cows

Method	Use	Advantages	Disadvantages
Based Upon Mounting Behaviour			
Tail paint	Paint applied over the tailhead is removed when cows are mounted by each other	Improves results from visual detection alone	Needs considerable experience to decide if cows with partially removed paint are actually in oestrus
Heat mount detectors (e.g., Kamar, Bulling Beacon)	Capsule applied over the tailhead is broken when the cow is mounted, turning the capsule red	Gives a more clear cut result than tail paint in cows that are only mounted a few times	Capsule can burst by rubbing, or if a cow is unable to avoid a single mount when she in not in oestrus
Oestrus detection patches (e.g., Estrotect)	Patch applied over tailhead; removal of surface layer reveals a bright under–colour when the cow is mounted.	Gives a more clear-cut result than tail paint, but fewer false positives than capsules	Missed oestrus events can occur when devices are not checked or are rubbed in cubicles.
Electronic heatmount detectors (e.g., Heat watch)	Applied over tailhead; records mounts electronically	Accurate provided cows stand to be mounted	Relatively expensive, as it requires specialised equipment
Teaser bulls	Chin bull marker shows which cows have been mounted	Positive indication of oestrus	Presence of intact bulls in the herd, bulls become disinterested with time, small risk of spreading venereal disease
Based Upon Increased Activity			
Pedometers	Increased walking activity is measured as an indicator of oestrus	Improves results above that commonly achieved by visual detection	Relatively expensive, as it requires specialised equipment; moderate sensitivity and specificity
Neck-mounted activity monitors (e.g., Heatime) (Aungier et al. 2012)	Increased movement activity is measured as an indicator of oestrus	Improves results above that commonly achieved by visual detection	Relatively expensive, as it requires specialised equipment; moderate sensitivity and specificity
Based on Physiological Changes			
Method	**Use**	**Advantages**	**Disadvantages**
Milk progesterone	Monitor cycle and do fixed time AI when concentration falls	Very accurate if done carefully	Expensive; inaccurate if not done carefully
Vaginal mucous resistance	Daily monitoring of vaginal resistance	Independent of behavioural signs	Invasive
Milk composition and temperature	Inline measurement during milking	Fully automated, so minimises requirement for human observation	High capital input; validation of results is not complete

Based on Parkinson et al. (2010).

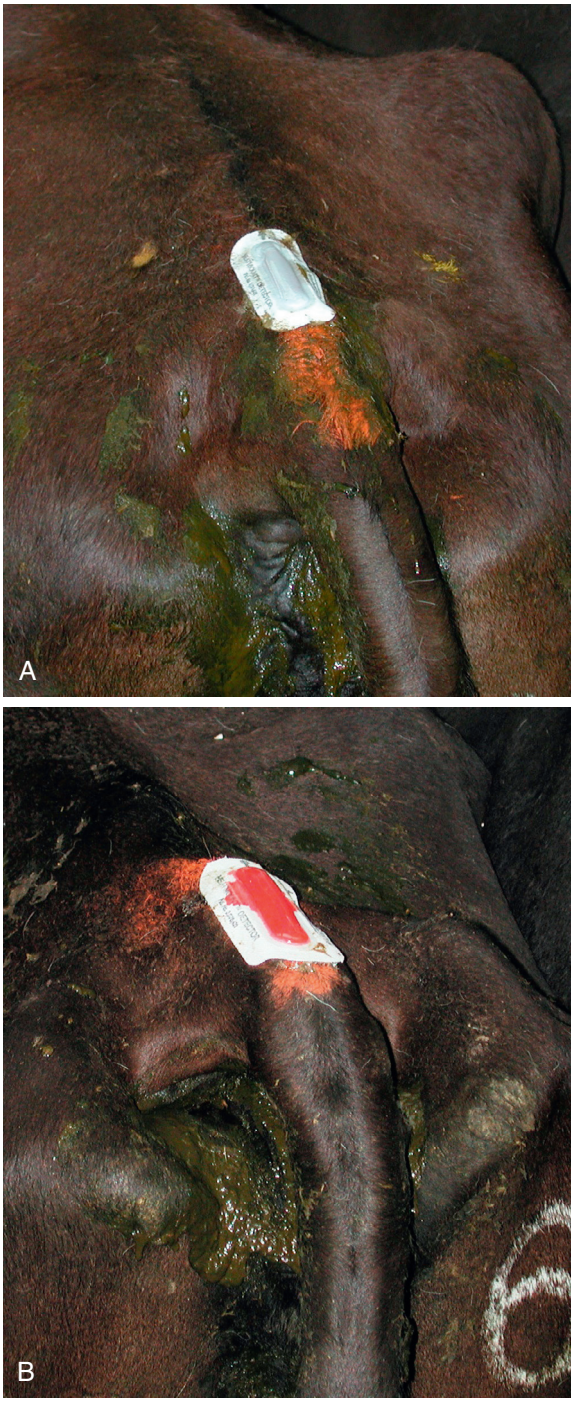
VetBooks.ir



• **Fig. 22.31** Kamar heatmount detector attached to the sacrum of a cow (A) before activation and (B) after activation. (Courtesy Dr. Jakob Malmo.)

standing oestrus), it is compressed, the dye escapes, and the dome becomes red (see Fig. 22.31B). False positives can occur when the detector is activated by a cow rubbing the underside of a rail, or in crowded collecting yards when a cow that is not in oestrus cannot escape the attentions of mounting cows. Detectors can also become detached when placed on wet coats or when the winter coat is being shed. Despite these caveats, however, heatmount detectors are widely used, with first-service conception rates of more than 60% having been reported (Phatak & Touchberry 1988). Holman et al. (2011) showed that the sensitivity of oestrus detection by Kamars alone was identical to that achieved by farm staff observation, but that the sensitivity was increased when the two methods were combined, with the sensitivity increased to 76%. There is some evidence to suggest that heatmount detectors have benefits over tail paint when the intensity of oestrus behaviour is low (i.e., as tail paint relies on multiple mountings for its removal).

Alawneh et al. (2006) reported the use of a novel oestrus detection strip that consists of a reflective material covered by a low sheen, black acrylic paint. The strip is applied to the sacrum, and when the cow is mounted, the black covering is rubbed off. The reflective strip can then be observed via an overhead camera. First-service pregnancy rate was approximately 70% in cows in which the detection strip was used versus approximately 40% in cows in which oestrus detection was by observation plus the use of tail paint. Various commercial variations on this method (e.g., Bonato et al. 2012) have produced similar results. A comparison of such 'scratch cards' with visual observation and other forms of heatmount detectors is given in Table 22.7.

Radio–telemetric heatmount detectors are available as an alternative to visual inspection of heatmount detectors (e.g., HeatWatch, ShowHeat). In such systems, an electronic pressure-sensing system is linked via a radio–telemetric link to a computer data analysis system, which sorts the information by cow and generates activity lists (e.g., oestrus, possible oestrus, etc.) (Nebel et al. 1995, Walker et al. 1995, Dransfield et al. 1998). Oestrus detection rates of more than 90%, with accuracies of approximately 95%, have been recorded using this system (Albright & Arave 1997, Cavalieri et al. 2000a), a figure that is as good as the best that can be achieved by behavioural observations and is very much better than national averages for oestrus detection. Timing of insemination may need to be altered after the use of heatmount detectors (i.e., compared with timing after direct observation). Dransfield et al. (1998) suggested an optimal interval of 4 to 12 hours after the first mounting episode, with a significant diminution of pregnancy rate after 16 hours.

Activity Monitors

Cows' movement and locomotor activity increases during oestrus, which can be used as the basis for its detection (Kiddy 1977, Schofield 1990).

Pedometer devices typically contain a mercury switch that is activated by the movement of the cow. They are attached either to one hind leg or, more recently, to the neck. The locomotor activity of individual cows depends not only upon the stage of the cycle but also upon the size of the SAG (Varner et al. 1994), with the result that pedometer systems are more accurate at detecting oestrus in groups of animals than in individuals (Roelofs et al. 2005). The accuracy is also affected by the interface between the pedometer and the data analysis system, because infrequent extraction of data from the pedometer (e.g., twice a day at milking time) is less effective than real-time acquisition of data (Lyimo et al. 2000, Nebel et al. 2000). Thus the accuracy of pedometers is greatest when activity data is interpreted by a computer algorithm in relation to the 'background' level of activity of the individual animal (Eradus & Braake 1993). Felton et al. (2012), however, found that the benefits of pedometers are very much reduced in cows housed in tie-stalls compared with those that have freedom of movement. Saint-Dizier and Chastant-Maillard (2012) therefore concluded that the performance of pedometers for oestrus detection may be affected by the environmental conditions, particularly as walking activity of dairy cows varies according to the type of housing and the herd management system. In pasture-based systems, in which

cows walk different distances on different days due to pasture rotation, the interpretation of pedometer data requires different parameters to those for housed cows.

Collar-mounted activity monitors (e.g., Heatime) assess the movement of the head and neck and are being used to detect oestrus. The system consists of an acceleration sensor, microprocessor, memory, infrared detection unit, and central computer processor. The central processor compares the current average activity level to baseline activity levels to identify increases in activity. Significant increase in activity (e.g., 5 x s.d. above baseline) is interpreted that the individual cow is in a preovulatory follicular phase, but the detection accuracy depends on appropriate setting of duration and activity thresholds. Saint-Dizier and Chastant-Maillard (2012) reviewed the relationships between increased activity, time of ovulation, and fertility. Ovulation takes place on average 29 to 33 hours after the onset of increased activity and 17 to 19 hours after the end of increased activity in lactating Holstein cows (Roelofs et al. 2005, Hockey et al. 2010). Aungier et al. (2012) optimised the interpretation of data from spontaneously cycling cows, to give 87.5% correct identifications of oestrus and 21.3% false positive identifications (see also Table 22.7). However, insemination to oestrus detected by activity monitors did not a give better conception rate in a Presynch–Ovsynch protocol than fixed-time AI (Burnett et al. 2017); however, the proportion of cows detected in oestrus by activity monitoring was substantially greater than that detected by visual observation (Gaude et al. 2017).

Conductivity of Vaginal Fluids

At oestrus the resistance of vaginal mucus falls in association with the rise in oestrogen concentrations. Various attempts have been made to use this as a means of predicting oestrus, although with generally disappointing results (Foote et al. 1979, Cavestany & Foote 1985). The variability in the measurements may well be related to the fact that the tip of the probe with its associated electrode is not in contact with vaginal mucus. Kitwood et al. (1993) reported that the position of the probe within the vagina affects impedance readings. When regular examination of cows can be backed up with a computer-based data-logging and analysis system, results are better than when 'one-off' measurements are made because, although most cows exhibit decreases in resistance at oestrus, most individuals differ in their baseline resistance during dioestrus. Hence the measurement of relative changes in resistance may be more useful than measurement of absolute values. Rezac et al. (1991) found that lowest impedance values could occur on Day –1, 0, or +1, relative to the day of oestrus (Day 0), although HongXiang et al. (2017) were able to predict the timing of the onset of oestrus and of ovulation with reasonable accuracy from the nadir of vaginal mucous resistance.

The main practical limitation to the use of vaginal probes is that it is labour intensive, requiring daily probing of each cow and cleaning and disinfection between cows. Experimental implantation of sensors beneath the vulval mucosa has been attempted to circumvent these problems (Lewis et al. 1989) but, although results appear promising, no further development of this technique has been reported.

'The Mechanical Nose'

Development of gas-sensing systems and work on the identification of pheromone-secreting cells in the perineum of oestrous cows (e.g., Blazquez et al. 1994, Lane & Wathes 1998) make it possible that direct electronic sensing of the odours of oestrus pheromones, perhaps as cows pass a detector during milking, may be feasible within the foreseeable future. At present, difficulties of sampling appear to be the main factor limiting the adoption of such technology.

Inline Progesterone Measurement

The decline in blood and milk progesterone concentrations at the end of the luteal phase precedes ovulation by a relatively constant interval. Milk progesterone concentration is therefore a reasonably good indicator of impending oestrus. Non-automatic progesterone measurement is not readily amenable to continuous monitoring of concentrations, but automatic systems have been developed. Delwiche et al. (2001) reported successful use of an in-line biosensor to measure milk progesterone concentrations

VetBooks.ir

as an indicator of oestrus, and, subsequently, automated systems have become available (e.g., Herd Navigator, DeLaval, Sweden) which measure progesterone concentrations at every milking. In addition to predicting oestrus, inline progesterone measurement can be used to assist with pregnancy diagnosis, detecting embryo losses and the presence of ovarian cysts (Friggens & Chagunda 2005, Bruinje et al. 2017). Birgersson (2013) studied the effects of the Herd Navigator system upon the fertility of Swedish and Dutch dairy herds: there was a significant reduction in the calving to first insemination interval, and a trend towards shorter calving interval. In addition, farmers found that the system reduced the time that needed to be spent undertaking oestrus detection.

Indirect Detection

Use of Teaser Bulls, Androgenised Steers or Cows

Vasectomised or other sterile entire or androgenised steers can be used, either equipped with some form of marking device (e.g., a chin-ball marker) or in association with 'heatmount' detectors. Gordon (2006) found that the use of vasectomised bulls increased the submission rate for AI from 61% to 69%, and reduced the calving-to-first service and calving-to-conception intervals (74 versus 85 days and 115 versus 120 days, respectively) while having no effect on conception rate. Despite these benefits, vasectomised bulls have not been very popular in the UK, largely because of perceived difficulties of managing bulls that are running loose with the herd. Furthermore, when venereal diseases are present, they represent a major health hazard because of their ability to transmit such diseases.

Penile deviation can also be used as a means of preparing sterile bulls. For this, the preputial orifice is freed from its normal attachments and is relocated some distance from the midline. Although this procedure is not permitted in the UK, it is considered to be an effective aid to the detection of oestrus in many other countries. Its disadvantages include those common to the use of gonad-intact bulls. Moreover, some bulls learn how to serve despite the penile deviation, whereas others desist from mounting at all. These and a number of other surgical procedures for creating marker bulls are described by Morgan (2007).

Androgenised cows can also be effective for detecting oestrus (Britt 1980). By administering testosterone propionate in oil by intramuscular injection every week for 3 weeks, a suitable teaser is prepared, which can be used from about 2 weeks after the last injection. Maintenance of sexual activity requires repeat treatment at intervals, but these androgenised cows have distinct advantages because they are safer and do not transmit venereal disease.

Video Monitoring

Continuous video recording can be made of the areas where cows are housed, which, so long as there is adequate lighting and good animal identification, can be used to identify cows that are in oestrus. Although the results of continuous video monitoring can be very good indeed, a means of automating the recognition of oestrous cows needs to be used (Roelofs et al. 2005) for significant time savings to be achieved.

Accelerated viewing or observation of only those cows which are moving may be methods to improve the speed of reading image data. Bruyere et al. (2012) described the use of conventional and infrared cameras, which were linked to computer analysis to record only those periods in which cows were moving. Using this system, the oestrus detection rate was greater than for visual observation (80% versus 69%), with similar positive predictive values (93%–94%).

Use of Oestrus Synchronisation and Induction Programmes

Because of the difficulties of maintaining effective levels of oestrus detection, whole-herd oestrus synchronisation programmes have been developed as a means of circumventing the need for human observation. These programmes, whether based on sequential administrations of prostaglandin $F_{2\alpha}$, GPG programmes, or more complex presynchrony–synchrony–resynchrony regimens, all aim to replace insemination to detected oestrus with fixed-time insemination, although resynchrony programmes also aim to ensure that cows that have not conceived are reinseminated in a timely manner. These methods are described in full in Chapter 8.

Use of Bulls: 'Throwing in the Towel'?

A response of some farmers to all the foregoing difficulties, which is increasingly evident in the lay or farming press, is to retreat from the use of AI back towards the use of bulls. Advocates of this idea argue that it is better to have a cow that is pregnant to a mediocre bull than to have a cow that fails to conceive to a high-breeding-value bull. Likewise, they argue that it is better to breed cows by natural service than to require expensive pharmacological regimens whose outcomes in terms of per-service conception rates and of numbers of cows involuntarily culled for failure to conceive give no better results than natural service.

The main counterargument to this approach is the cessation of genetic advancement or even the loss of genetic merit for key productivity traits. It is also important to ensure that bulls are healthy (in terms of venereal disease, bovine viral diarrhoea, etc.), fertile, and managed safely.

Timing of Insemination

Faults of Detection

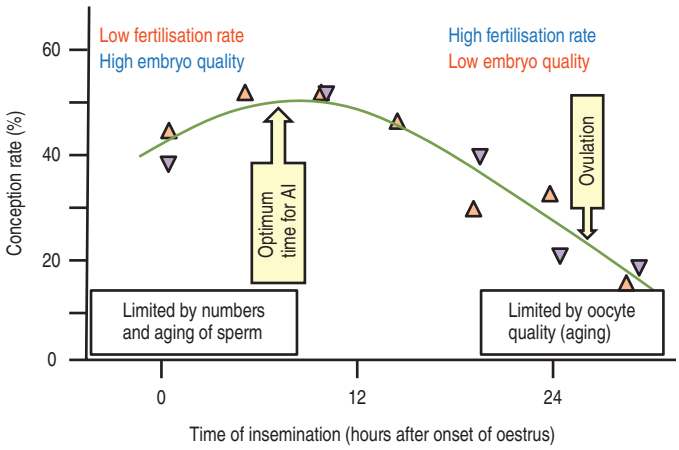
Milk progesterone profiles have been used to show that between 10% and 15%, or perhaps even 22%, of cows are inseminated during the luteal phase of the oestrous cycle (Hoffmann et al. 1974, Appleyard & Cook 1976). Clearly, such animals will fail to conceive. However, these figures do not include those animals that are inseminated during the follicular phase of the cycle at times that are not optimum for good conception rates. For example, Bulman and Lamming (1978) found that 15% of cows were inseminated during the luteal phase, but a further 15% were inseminated during inappropriate stages of the follicular phase.

The main reasons for these errors are incorrect identification of animals that are in oestrus and failure to appreciate the true signs of oestrus. Frequently, when large numbers of cows are inseminated at the incorrect time, the oestrus detection rate is poor, thus generally reflecting a poor standard of herd management. In such circumstances, some of the methods described previously should be used to improve the oestrus detection rate in the herd. In seasonally calving herds, the emphasis that is placed upon attaining high submission rates during the first few weeks of the mating period is such that many cows are presented for insemination that are not in oestrus. However, most of these cows are correctly identified a few days later, so the effect upon pregnancy rates is far less significant.

Optimal Timing of Artificial Insemination

Oestrus is short in the cow, with ovulation occurring 10 to 12 hours after the end of oestrus. During the next 6 hours the oocyte travels about a third of the way down the uterine tube, during which time fertilisation occurs, about 30 hours after the onset of oestrus (Robinson 1979, Roelofs et al. 2005). This figure has

VetBooks.ir



• **Fig. 22.32** Optimal timing of insemination in cattle derived from observations of the onset of oestrus (Trimberger 1948 ▽; Saacke et al. 2000 △) and as a theoretical compromise between fertilisation rate and embryo survival rate.

remained remarkably constant in view of the changes in oestrus behaviour that have occurred over the past 30 years, although some cows do exhibit significant prolongations of the interval between the onset of oestrus and ovulation (Bloch et al. 2006).

The best conception rates occur if insemination is carried out in the middle to the end of standing oestrus, i.e., 13 hours before to 8 hours before ovulation (Saacke et al. 2000, Nebel et al. 2000; Fig. 22.32). Traditionally, the recommendation for the timing of insemination has followed the a.m.–p.m. guideline, which is that cows observed in oestrus in the morning should be submitted for AI in the afternoon and cows observed in oestrus during the afternoon should be submitted for AI the next morning. Cows may conceive if they are inseminated at the beginning of oestrus or even 36 hours after the end of oestrus, but conception rates are reduced; if late insemination is undertaken, there is an increased risk of embryonic death. Nebel et al. (2000) suggested that, if the time of onset of oestrus is not precisely known, insemination should take place within 6 hours of its initial observation.

Nutrition

Nutrition and reproduction are highly interrelated. Plane of nutrition and growth rate exert substantial effects upon the onset of puberty, energy and protein feeding, and body condition are crucial in the resumption of oestrous cycles after calving, and there are a plethora of minerals, trace elements, and micronutrients that can have adverse effects on reproduction when they are deficient.

Puberty and the Rearing Period

Puberty, as determined by the appearance of the first oestrus, occurs between 5 and 20 months of age. It is considered that body size (rather than age), condition score, and plane of nutrition are the main factors that determine the age of puberty (Ducker et al. 1985, Spitzer 1986). In order to attain puberty, beef heifers should have reached 50%, and dairy heifers 35% to 45%, of their mature weight. Thus typical weights at puberty are 240 to 260 kg for Friesians, 270 to 300 kg for Herefords, and 230 to 250 kg for Angus. Within a group of cattle, however, puberty occurs at different body weights; for example, 50% of Hereford heifers exhibit oestrus at 272 kg body weight, whereas Charolais have to reach 308 kg for the same proportion of animals to be pubertal. For 90% of animals to be pubertal, the weights are 318 kg and 352 kg bodyweight, respectively (Spitzer 1986).

In most farming systems, it is preferable for heifers to calve for the first time at close to 2 years of age. For beef heifers, many studies from both the US and UK have found that beef breed heifers that first calve at 2 years of age are more profitable than those calving at 3 years (e.g., Nunez-Dominguez et al. 1991). In the study of Pinney et al. (1962), animals first calving at 2 years old produced 0.8 more calves per cow at 10% less cost over their entire production life than those first calving at 3 years old. Similarly, for dairy cows, the ideal age for first calving is approximately 24 months, as first lactation yield decreases rather than increases if the time of first calving is delayed (Spain et al. 2007). For seasonally calving dairy cows, both the age of first calving and the date of first calving are critical. Animals must calve right at the start of the season, which may mean that some calve at 23 or even 22 months of age. Attaining maximal growth rates during the rearing period is critical to achieve this (MacDiarmid 1999), both in terms of achieving adequate body size and ensuring that the youngest heifers have attained puberty at the start of the breeding season.

Age at puberty is therefore highly dependent on growth rate during the rearing period, which requires that animals be maintained on a high plane of nutrition. Gerloff and Morrow (1986) showed that the age at puberty of Friesian heifers decreases by 0.77 days for each additional 0.45 kg body weight at 6 months and by 0.36 days for each additional 0.45 kg body weight between 6 and 12 months of age. On the other hand, excessive growth rates of dairy heifers before puberty is associated with impaired development of the mammary epithelium and, as a consequence, reduced first lactation milk yields. Thus Foldager and Sejrsen (1982) suggested an optimal growth rate for Holstein heifers of approximately 600 to 700 g/day over the range 150 to 300 kg live weight. After puberty the effect of growth rate on mammary development is markedly lessened (Drew 2004).

These results demonstrate the importance of adequate feeding during calfhood to ensure the early onset of puberty. The aim should be to have calves that are healthy, with regularly monitored growth performance (Table 22.8) (McNeil et al. 2003, Schouten 2003), with planned growth rates to meet the target live weights at different stages of growth (Drew 2004). Generally, animals should have reached approximately 65% of their adult body weight at the start of the mating season in order to be pubertal and having regular oestrous cycles. Continued planned growth is then required to ensure that heifers have attained adequate body weight by the time of their first calving (Fig. 22.33). Heifers that have reached these targets should be able to reach their genetic potential for milk production in their first lactation, provided, of course, that their subsequent metabolic needs throughout pregnancy are not neglected. Live weight at calving has a significant effect upon subsequent reproductive performance: heifers that are underweight at their first calving have much lower conception rates and are more likely to be culled for infertility than those that are well grown (Table 22.9).

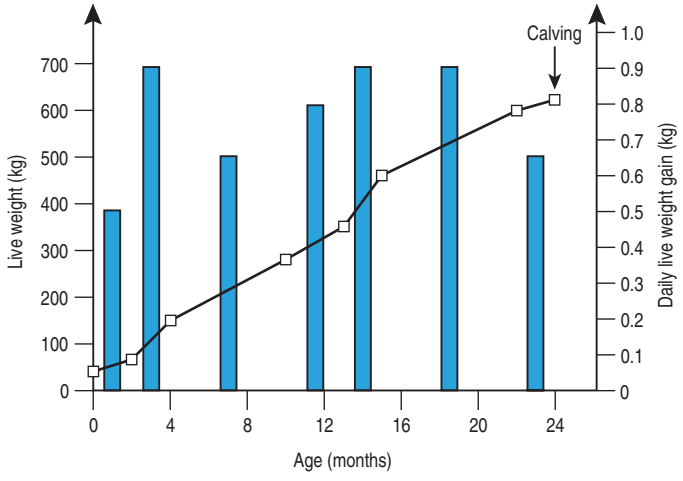
Nutrition and Reproduction in the Dairy Cow

Recent years have seen a dramatic decrease in the fertility of dairy cows. Many surveys have shown an inverse relationship (Fig. 22.1; Mann 2004) between fertility and yield (e.g., Nebel & McGilliard 1993, Washburn et al. 2002, Royal & Flint 2004, Butler 2005), which is generally considered to have resulted from: (i) selection for cows with the genetic potential for very high yields; and (ii) the metabolic demands of lactation. As a result, there has been an

VetBooks.ir

TABLE 22.8 Managing Heifer calves

Preweaning
Meticulous management of colostrum intake
Ensure good preweaning growth through well-managed milk feeding
Promote early development of the rumen by maximising early intake of concentrate feeds, provision of high quality roughage
Effective prevention of diarrhoea, respiratory disease, and navel ill
Postweaning
Weigh regularly to monitor growth rates adjust feeding as appropriate
Maintain high intakes of highly digestible forages
Avoid 'nutrient gaps', e.g., in dry summers or wet winters
Monitor regularly for trace element status
Effective parasite control
Effective vaccination programme (e.g., leptospirosis, bovine viral diarrhoea, infectious bovine rhinotracheitis)
Premating
Ensure adequate live weight at the time of mating (at least 65% of mature body weight)
Maintain a high plane of nutrition around mating; vital that weight is gained rather than lost
Mating to calving
Ensure adequate growth rates to achieve at least 85% of mature body weight at first calving (Fig. 22.33)
Reduce growth rate in the last 2 months to reduce the risk of dystocia



• **Fig. 22.33** Live weight (line graph) and daily liveweight gain (bars) of heifers. (Adapted from Drew 2004.)

upsurge of interest in the relationship between nutrition and fertility, especially in regard to the marked changes that have occurred in the metabolic endocrine system of dairy cows as a result of genetic selection for increased lactation performance.

Of course, nutrition has always been recognised a key determinant of reproductive performance, not only in dairy cattle but also

TABLE 22.9 Effect of live weight of Holstein Heifers at first calving on subsequent in-calf rates (at 6 and 21 weeks) and conception rates during their first lactation

in beef animals. The increase in energy demands that is associated with the onset of lactation is not immediately matched by an increase in feed intake, and there is a lag of several weeks between peak lactation and peak feed intake. Hence early lactation is usually characterised by a period of negative energy balance when tissue is mobilised to meet the demands for lactation that are not being supplied through feed. Negative energy balance is at its worst 1 to 2 weeks after calving, but it can persist well into lactation (Dillon et al. 2003), beyond the period of maximum yield (Hattan et al. 2001). In high yielding cows, appetite may not be able to satisfy energy requirements, even when using energy-dense diets, until yields have started to decline (Beever et al. 2001), well into the period when it would be appropriate to start serving cows. For high yielding cows that have a standard 305-day lactation, precalving body condition may not have been reached by the time of drying off (Beever et al. 2004).

Animals have a clear prioritisation for energy when in negative energy balance, such that maintenance and lactation take precedence over growth and reproduction: i.e., when negative energy balance exists, there is a consequential impairment of reproductive performance (Bauman & Currie 1980). Cows that are in negative energy balance during early lactation are at greater risk of becoming anoestrous than those that are in energy equilibrium (Zulu et al. 2002a). Likewise, cows that are in negative energy balance are more likely to remain in anoestrus until equilibrium is restored (Butler & Smith 1989), which is probably the reason that the persistence of lactation in Holstein cows is negatively associated with reproductive performance (Buckley et al. 2003). Conception rates and embryonic mortality rates are also adversely affected in animals that are in negative energy balance (Gossen et al. 2006, Grimard et al. 2006, Roche et al. 2007).

Maintaining body condition score (BCS) in cows that have been genetically selected for high yield is particularly challenging, especially in systems that are forage- or pasture-based. Roche et al. (2006) found that North American Holstein cows fed pasture plus concentrates lost approximately 65 kg live weight (compared with ~35 kg in New Zealand Friesian cattle) over the first 2 months of lactation. Holsteins receiving 6 kg of concentrates per day did not achieve precalving body weight until more than 200 days into lactation, whereas those on lower levels of concentrates had not

From Morton (2000b).

returned to precalving body weights by 300 days into lactation. It is interesting to note that, when BCS rather than live weight is assessed, Holsteins require an even longer period of time to return to precalving values (Roche et al. 2006), probably because changes in gut fill with advancing lactation contribute substantially to changes in live weight (Beever et al. 2004). The net result of these changes in live weight and BCS is that significantly more Holstein than Friesian cows (30% vs 3%; Kolver et al. 2006) failed to conceive by the end of the mating period. Fahey et al. (2005) also found that Holstein cows fed pasture plus limited concentrate supplementation had a longer anoestrous period than adequately fed animals. Taken together, these studies show that both excessive BCS loss (Chapa et al. 2001, Gossen et al. 2006) and the depth of the BCS nadir (Buckley et al. 2003, Roche et al. 2007) appear to be the main determinants of the degree to which reproductive performance (e.g., the duration of anoestrus, first-service conception rate, calving-to-conception interval) is impaired.

There is, however, a complex relationship between the effects of BCS at calving and energy balance during the postcalving period. Reasonable body stores of fat at the time of calving can provide a store of energy that can mitigate the effects of undernutrition. Thus whereas BCS loss in the postcalving period is negatively associated with the duration of anoestrus and conception rates (Roche et al. 2007), optimal BCS at calving is associated with better reproductive performance than low BCS (Patton et al. 2007). The InCalf survey of Australian dairy cattle (Morton 2000b) clearly illustrates this pattern (Table 22.10). Conversely, calving in too high a condition score also adversely affects reproductive performance. Cows that are fat at calving (Ohgi et al. 2005, Gossen et al. 2006) or have been fed excessively during the precalving period (McNamara et al. 2003) have higher live weight loss due to lower postcalving feed intake (Butler 2005). Consequentially, such animals have increases in NEFAs and β-hydroxybutyrate (βOHB), decreases in glucose, and increases in indicators of hepatic dysfunction due to lipid infiltration of the liver (Zulu et al. 2002a). There are strongly negative relationships between elevated blood NEFA/βOHB concentrations and reproductive outcomes, particularly in relation to ovarian follicular development (Marr et al. 2002) and oocyte competence (McEvoy et al. 1997). As a result, conception rates and pregnancy rates are likely to be significantly depressed; Samarutel et al. (2006), for example, found that no cows with a BSC of greater than 3.75 (1–5 scale) conceived to their first insemination. On the other hand, significant loss of live weight over the dry period is also associated with metabolic disorders and impaired reproductive performance in the postcalving period (Ill-Hwa & Gook-Hyun 2003).

Thus reasonable body stores of fat at the time of calving can provide a store of energy that can mitigate the effects of undernutrition, whereas excessive mobilisation of fat from overweight animals is undesirable, especially if there is a significant degree of underfeeding postcalving. However, if it is possible that energy demands of the freshly calved cow can be substantially met, calving with only a moderate condition score can be preferable to calving with excessive stores of fat. Hence, within each farming system, practices have been empirically developed that best approximate the type and amount of feed that is available for the nutrient requirements of lactation in order to minimise the duration/incidence of anoestrus. In traditional British dairying systems the preferred option has been for cows to calve in a moderately fat condition, because the grass silages and cereals available to British dairy farmers were of inadequate quality to fully feed freshly calved cows. More recent British practice has followed that of North America, in which the dairy cows hold relatively small reserves of body fat but whose appetite is capacious and, when given high quality forages and energy-dense cereals, can approximately match output by intake. Pastoral dairying cannot fully feed cows in the early postcalving period, so tries to find an equilibrium point of calving condition score that allows enough fat reserves to meet the energy deficit while not being so fat that appetite is limited. Farm advisors, nutritionists, and veterinarians who operate within these systems become adept at optimally balancing these factors in order to both maximise lactation yields and minimise postcalving anoestrus.

Nutrition and Reproduction in the Beef Suckler Cow

Similar relationships between BSC loss and fertility occur in beef cows. Losing weight is associated with poor fertility, whereas gaining weight is more likely to be associated with better fertility. Any postcalving loss of more than 5% is likely to be a cause for concern (Morris 1976). In a meta-analysis of the responses of beef suckler cows to oestrus synchronisation, Stevenson et al. (2015) found that parous cows with BCS of 5 or higher (1 (worst) to 9 (best) scale) had the highest conception rates and the lowest levels of embryonic loss, whereas primiparous cows with BCS lower than 5 performed the most poorly for these traits. Soca et al. (2014a) also found substantially poorer reproductive performance in beef cows that were in low BCS (<3.5; 1–8 scale) at calving than in those in moderate BCS (≥4); the postpartum anoestrous interval was 119 versus 94 days, and the probability of an early pregnancy was 0.46 versus 0.84.

These effects of BCS are additive with the effects of suckling. Suckling inhibits the release (but not synthesis) of GnRH, resulting in suppressed follicular development particularly in the early postpartum period. The mechanism for this suppression has long been held to be a prolactin-mediated inhibition of the reproductive neuroendocrine axis, but the literature review by Yavas and Walton (2000) suggested that this is not the case. Rather, they suggested that oxytocin and endogenous endorphins are likely mediators, although there are concurrent effects upon IGF-1, which may underpin the suckling–nutrition interaction that occurs in beef suckler cows. Suckling restriction over the start of the breeding period, even without complete calf removal, improves reproductive performance (Quintans et al. 2010). Even those suckler cows that do ovulate when being suckled are prone to irregular oestrous cycles, which may be due to oxytocin-mediated premature luteolysis

VetBooks.ir

of corpora lutea (Martin et al. 2010). On the other hand, restriction of suckling has been reported to increase concentrations of IGF-1 (Soca et al. 2014b), which may promote the development of follicles to the preovulatory stage.

Energy Metabolism and Reproduction

The last few years have seen the recognition that the fertility of dairy cows has been declining (McGowan et al. 1996; O'Farrell et al. 1997; Dillon & Buckley. 1998). This decline was initially attributed to the many changes in the husbandry and management of dairy cows that have occurred over the past couple of decades, but more recently it has been recognised that the intensive selection for high milk yield that has taken place (particularly in the Holstein–Friesian breed) has been associated with a parallel, unintentional, selection for worsening fertility.

Genetics and Heritability

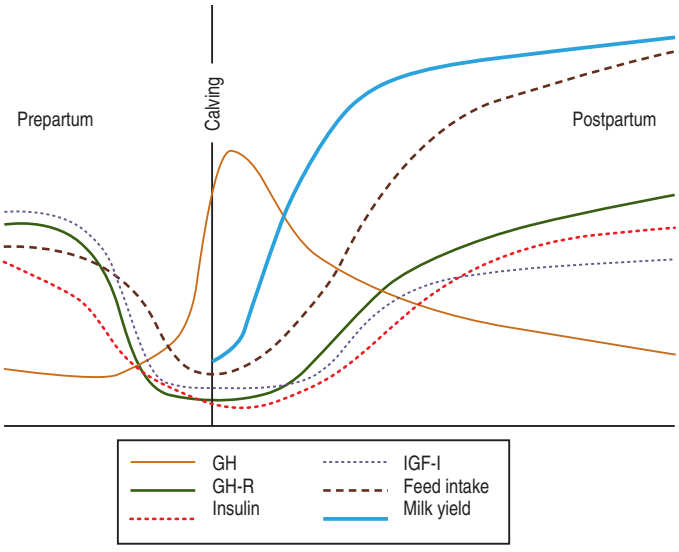
The traditional view has been that the heritability of fertility traits is very low and the magnitude of any genetic correlations between production and fertility traits so marginal that any genetic effect of selection for high yield upon fertility traits would be negligible (Raheja et al. 1989, Weller 1989, Mantysaari & van Vleck 1989, Arendonk et al. 1989). More recently, this opinion has changed. Many studies (e.g., Boichard & Manfredi 1994, Hoekstra et al. 1994, Dematawewa & Berger 1998) recorded genetic relationships between fertility and production traits in US Holsteins that were high and negative. Even in the Swiss Simmental, often regarded as a dual purpose rather than a dairy breed, a negative genetic association was found between yield and fertility (Hodel et al. 1995). As a result, it has now become widely accepted that there is an inverse genetic relationship between yield and fertility that is manifest most strongly in the North American Holstein and animals derived from it. Flint (2006) even refers to infertility as an 'inherited disease' of cattle. Heritability of binary traits such as conception to first service remains relatively low but, by linking yield to fertility through continuous variables such as interval to first luteal activity (Royal et al. 2002), embryonic mortality (Grimard et al. 2006), dairy conformation (Royal et al. 2002, Berry et al. 2004, Dechow et al. 2004), and proportion of Holstein genetics (Wall et al. 2005), more useful heritabilities have been identified. Indices based on BCS have also been explored: some studies have not considered them valuable (e.g., Banos et al. 2004) whereas others have come to the opposite conclusion (e.g., Royal et al. 2002, Berry et al. 2004).

In consequence, there has been a progressive trend to incorporate fertility and longevity traits into selection indices (Mantysaari & van Vleck 1989, O'Farrell 1998, Burton & Harris 1999), as a means of preventing a further decline in fertility or even of reversing the trend. Most studies of the relationship between fertility and yield have recorded a cohort of cows that have both high yield and acceptable fertility: identification and selection of such individuals is advocated as a means of improving fertility without compromising yield (e.g., Kadarmideen & Wegmann 2003). The use of genomic, rather than phenotypic, selection processes for dairy cows appears to be having some success in this, not least because it circumvents some of the problems caused by inability to directly assess fertility traits versus the direct assessment of production. A major thrust of selection for fertility has therefore been centred on the use of quantitative trait loci (QTLs) associated with a female fertility index (FTI), which is a composite of various parameters of fertility (Hoglund et al. 2015), or which are associated with functional longevity (Punsmann & Distl 2017). Use of QTL technology has also allowed the identification of genetic parameters associated with individual parameters of reproductive performance (Carthy et al. 2015), some of which have proved to be closely identified with physiological parameters such as steroidogenesis (Ortega et al. 2016). García-Ruiz et al. (2016) considered that, in the 7 years since genomic selection was introduced for US Holsteins, selection has improved for low heritability fertility characteristics such as daughter pregnancy rate and productive life.

Energy Metabolism

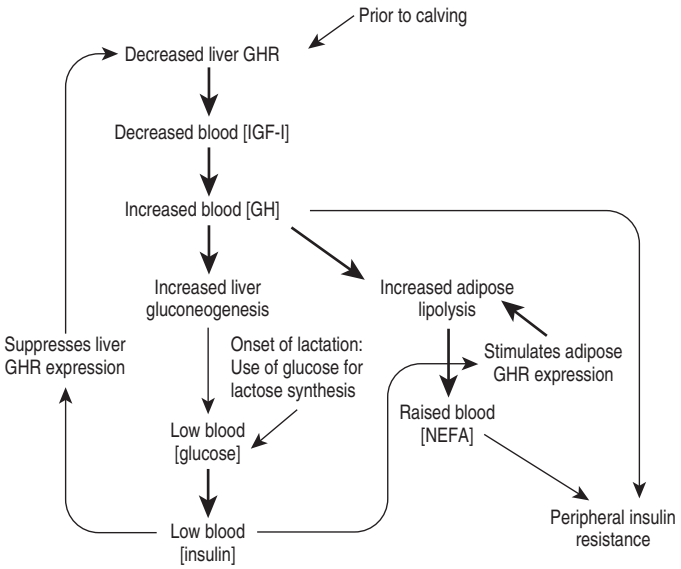
Cows that have been genetically selected for high yield have a number of differences in the activity of their metabolic endocrine system from cows with a lower genetic potential, which appear to be of importance in the mechanism of their subfertility. Growth hormone (GH) is the chief hormone responsible for nutrient partition in dairy cows. Cows that are genetically selected for high yield have higher blood GH concentrations than lower-yielding and beef cattle, whereas administration of bST (i.e., GH) is a pharmacological stimulus to greater lactational yield.

Growth hormone acts through receptors in liver and adipose tissue to regulate the supply of glucose and fatty acids to the mammary gland (Lucy 2006). The liver also produces IGF-I in response to GH, with a negative feedback loop between hepatic IGF-I and hypothalamic GH releasing hormone (GHRH) (and hence pituitary GH) secretion. Liver GH receptors (GHR) decrease abruptly just before calving, resulting in reduced IGF-I secretion (Lucy et al. 2001, Zulu et al. 2002b). Loss of the negative feedback regulation of GH by IGF-I means that its concentrations rise (Fig. 22.34), resulting in gluconeogenesis in the liver and lipolysis in adipose tissue. Hence there is a net decrease in IGF-I concentrations and a net rise in concentrations of NEFA and other products of lipolysis in the postpartum period. Insulin appears to be a key mediator in this process (Fig. 22.35). High yielding cows have lower insulin concentrations and a much greater degree of peripheral insulin resistance than lower yielding cows (Wathes et al. 2007), and the massive drain on blood glucose into the mammary gland means that insulin concentrations are maintained at low values. Low insulin concentrations, in turn, continue to suppress hepatic

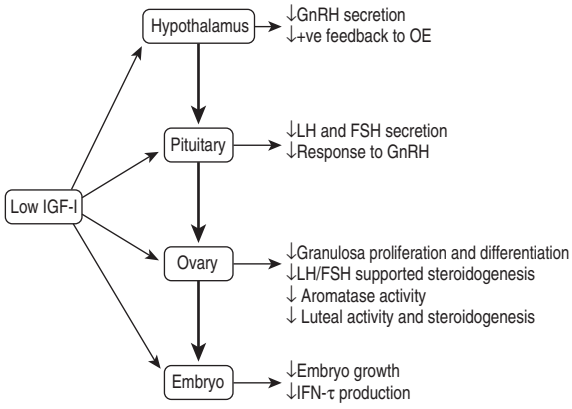


• **Fig. 22.34** Sequence of changes in concentrations of key metabolic hormones and metabolites during the pericalving period and the onset of lactation. (Adapted from Lucy et al. 2001.)

VetBooks.ir



• **Fig. 22.35** Interrelationships between GH, IGF-I, insulin, and negative energy balance in the postpartum, high yielding dairy cow. (Based on data in Lucy 2006.)



• **Fig. 22.36** Effects of low circulating IGF-I concentrations on the reproductive system. (Adapted from Zulu et al. 2002a, b, and Butler 2005.)

GHR expression, resulting in the maintenance of the catabolic state. Once glucose supply starts to exceed demand, the situation becomes reversed.

Strategies to increase glucose supply include modifying rumen fermentation to increase the supply of propionate or to directly supply gluconeogenic substrates (Patton et al. 2004). Thus feeding monensin (Hixon et al. 1982), monopropylene glycol (Tunon et al. 2006), or increasing the starch component of the diet have all been associated with improved reproductive outcomes.

In the underfed cow (Lucy et al. 2001, Wang et al. 2003), there is also a decline in liver GHR and IGF-I concentrations, leading to sustained GH secretions and the consequent stimulation of lipolysis. The effects of impaired or altered energy nutrition upon reproduction are therefore largely the result of the interaction of low concentrations of IGF-I (Fig. 22.36), insulin, and glucose and high concentrations of NEFA and βOHB with the reproductive endocrine axis.

Low blood glucose and elevated βOHB and NEFA concentrations result in impaired GnRH and/or LH secretion (Butler & Smith 1989, Beam & Butler 1999) with consequent effects upon follicle growth and ovulation. This is particularly noticeable in cows with fatty liver, in which basal, pulsatile, and preovulatory LH are abnormal (Reid 1984). Second, both IGF-I and insulin are important growth factors for the growth and development of follicles (Simpson et al. 1994, Armstrong et al. 2002, Zulu et al. 2002a). The actions of IGF-1 are primarily mediated through granulosa cell proliferation (Wathes et al. 2003) and enhanced responsiveness to gonadotrophins (Zulu et al. 2002a), whereas insulin primarily affects oestrogen production (Wathes et al. 2003). There is also some stimulation of aromatase activity by IGF-I. Low IGF-I concentrations are therefore associated with underdevelopment of follicles in underfed cows (Webb et al. 1997), whereas cows with short postpartum anoestrous intervals (Thatcher et al. 1996) and normal ovarian function (Zulu et al. 2002b) have higher IGF-I concentrations than do those with delayed or abnormal ovarian activity. Third, there is evidence that negative energy balance has deleterious effects upon the oocyte (Kruip et al. 1998, Butler 2005), primarily due to the effects of raised NEFA concentrations (Kruip et al. 2001). These effects are not limited to the duration of elevated NEFA concentrations, however, and may persist well into lactation (Snijders et al. 2000). Even when insulin concentrations are elevated through concentrate feeding, residual adverse effects upon the oocyte persist (Garnsworthy 2006).

Steroidogenesis in the CL is impaired in the absence of adequate concentrations of insulin or IGF-I (Liebermann et al. 1996). Conversely, luteal cells have receptors for GH (Wathes et al. 2003), so the relationships between high yield, negative energy balance, and progesterone synthesis are relatively complex. On the other hand, progesterone concentrations in high yielding cows are reduced by its increased metabolism in the liver (Lucy & Crooker 2001, Sangsritavong et al. 2002). Thus regardless of whether the cause is impaired luteal synthesis or enhanced metabolism, high yielding cows and animals in negative energy balance generally have lower circulating progesterone concentrations during the luteal phase or early pregnancy than other animals. Low progesterone concentrations are associated with a reduced probability of pregnancy, at least partly due to retarded embryo development and a consequent inadequate production of IFN-τ to prevent luteolysis (Mann et al. 2006).

Protein

High yielding dairy cows require around 18% to 19% crude protein (CP) to sustain lactation (Kung & Huber 1983). Degradable protein and non-protein nitrogen sources that are incorporated into microbial protein are able to maintain moderate yield, but, in order to meet the nutrient demands for high yields, sources of undegradable protein are also needed. In terms of maintaining normal reproductive function, however, high protein levels are not needed, with a number of studies suggesting that approximately 16% is adequate for the maintenance of reproductive activity (Jordan & Swanson 1979, Ferguson & Chalupa 1989). Protein undernutrition (<16% CP) has, however, been associated with impaired reproductive function in some (Jordan & Swanson 1979, Fekete et al. 1996) but not all (Edwards et al. 1980) studies. One mechanism by which protein deficiency may affect reproductive activity is via a decrease in GH receptor expression in the liver (Breier 1999) and a reduction in IGF-I release in response to exogenous GH (McGuire et al. 1992, Lucy et al. 2001).

The effect of high levels of dietary protein upon conception rate has been the subject of long-standing controversy: many studies show an adverse effect of high protein levels upon fertility, whereas many others show no effect (Lean et al. 1998).

VetBooks.ir

The potential for high levels of protein to affect fertility has to be considered in terms of the overall metabolic effects of excess protein. These effects are well recognised:

- When energy supply is limiting and the rate of ammonia production from dietary CP exceeds the ability of the rumen microbes to convert it into microbial protein, excess nitrogen will be absorbed as ammonia (Wathes et al. 2003). This is particularly a feature of diets that are deficient in readily fermentable carbohydrates and have a significant excess of degradable protein (e.g., spring pasture).
- Excess ammonia has to be converted to urea by the liver. This has two consequences. First, there is an energy cost associated with the synthesis of urea, which can be an additional drain on the energy resources of an underfed cow (Roche 2006). Second, blood urea concentrations rise, with potentially negative consequences on a number of aspects of reproductive activity.

The energy cost of metabolising the ammonia that is liberated from excess protein is generally accepted to be such that excess degradable protein may exacerbate negative energy balance during early lactation and thereby reduce fertility (Butler 1998). There are a number of possible routes by which urea might affect reproduction:

- Abnormally high concentrations of urea and ammonia may be present in the uterus (Jordan et al. 1983), which may be toxic to spermatozoa (Jordan & Swanson 1979), oocytes, or embryos (Ferguson 1990, Elrod & Butler 1993, Robinson & McEvoy 1996), or adversely affect uterine function (Elrod 1992, Butler 1998, Rhoads et al. 2004).
- High circulating concentrations of urea may also have an effect upon the hypothalamic–pituitary axis, particularly LH (Jordan & Swanson 1979, Blauwiekel et al. 1986).
- There may be an impairment of luteal progesterone synthesis, resulting in reduced circulating concentrations (Larson et al. 1997), although others (Ferguson & Chalupa 1989) have found no effect of high CP inclusions on progesterone concentrations.
- There may be adverse effects of urea upon hepatic clearance rates of reproductive steroids (Lean et al. 1998).
- High dietary CP may be associated with an increased incidence of retained fetal membranes, dystocia, and postpartum metritis (Anderson & Barton, 1987).

Meta-analyses of field trials (Gerloff & Morrow 1986, Lean et al. 1998) concluded that a marginal depression of conception rate occurs at CP levels of 16% to 18% and that the reduction is significant at higher than 19% CP. Laven et al. (2007), on the other hand, came to the conclusion that cattle can tolerate high nitrogen intakes without their fertility being adversely affected, probably because of their ability to adapt to high blood urea concentrations (Dawuda et al. 2002). They concluded that the effect of excess dietary nitrogen upon reproduction is primarily a function of the interval between the timing of the increase in nitrogen intake relative to fertilisation or ovulation (i.e., with a shorter interval increasing the likelihood of an effect) rather than to CP or rumen degradable protein (RDP) contents per se. Hence the effects of excess nitrogen are more likely to be related to acute increases in blood ammonia (and hence follicle, oocyte, and intrauterine ammonia) in the preadaptation period than to those of urea (which represent a postadaptation situation). However, when excess nitrogen causes a significant drain on the energy resources of cows that are already in negative energy balance, this may impair reproduction via energy-mediated pathways.

Interestingly, a number of studies have shown that small improvements in the UDP content of the diet improves fertility, or at least mitigates the effects of high levels of RDP (Armstrong et al. 1990, Staples et al. 1998a). This may, as suggested by McClure (1994) and Webb et al. (1997) improve the availability of gluconeogenic substrates. However, the most common source of high grade, undegraded protein for such trials is fish meal, a feedstuff that also contains unique fatty acids that can affect not only carbohydrate metabolism but also prostaglandin and steroid metabolism (Staples et al. 1998b, Meier 2000, Verkerk 2000), so the effects are not necessarily a direct effect of UDP.

Minerals and Micronutrients

Effects Upon Fertility

Although it is generally agreed that micronutrients can affect fertility of cattle, there are conflicting opinions about the significance of apparent deficiencies. This is because of the inherent difficulties of accurately determining nutrient requirements, because of lack of knowledge of the interaction of micronutrients in the alimentary tract, and because many of the studies that determined nutrient requirements were done 40 or more years ago when yields were much lower. McClure (1994) also pointed out that many older studies attributed beneficial effects of micronutrient supplementation upon fertility to comparisons of reproductive performance before and after supplementations, a technique that is now considered to be invalid. Most micronutrient deficiencies exert their effects upon reproduction through (i) depression of the activity of rumen microflora, (ii) reduction in enzyme activity affecting energy and protein metabolism and the synthesis of hormones, (iii) integrity of rapidly dividing cells within the reproductive system, and (iv) the role of micronutrients as antioxidants, which are responsible for protecting cells from the effects of free radicals.

Cobalt

Cobalt deficiency occurs in pastures of Australia, New Zealand, Florida, Kenya, and Scotland (McClure 1994). Deficiency occurs when diets contain less than 0.07 mg/kg dry matter (DM) cobalt and is due to the failure of vitamin B_{12} synthesis, which is an essential cofactor for carbohydrate metabolism. Deficiency usually causes anaemia, inappetence, poor bodily condition, ill thrift, and loss of condition. Poor fertility (non-display of oestrus, irregular interoestrus intervals, and poor pregnancy rates) may be present at the same time as these obvious signs of deficiency. Sometimes poor fertility in apparently normal cows can be corrected by cobalt supplementation.

Diagnosis can be confirmed by measuring liver cobalt or vitamin B_{12} concentrations. The concentration of cobalt in the liver of cattle is sufficiently responsive to changes in cobalt intake to make it a useful aid in the diagnosis of cobalt deficiency in the field. Similarly, the responsiveness of vitamin B_{12} concentrations to suboptimal cobalt intakes makes it a useful diagnostic aid. Blood concentrations of cobalt or vitamin B_{12} can also be used.

The mode of action of vitamin B_{12} in carbohydrate metabolism is well-recognised, but it is less clear whether it has direct effects upon the reproductive system. Gagnon et al. (2015) showed that vitamin B_{12} supplementation was associated with the activation of a range of genes in dominant follicles, resulting in larger follicles than in untreated animals.

Copper and Molybdenum

Hypocuprosis can be either direct or indirect. Direct copper deficiency, due to an absolute deficiency of copper in the diet,

VetBooks.ir

TABLE 22.11 Diagnosis of copper deficiency: lower limits of 'marginal' bands[a]

Criterion[b]	Diet	Sheep and Cattle[c]	Interpretive Limits
Diet Cu:Mo	H	**1.0**–3.0	Diet S >2g kg^{-1} DM
	F	**0.5**–2.0	Diet Mo <15 mg kg^{-1} DM for cattle
Diet Fe:Cu	H	50–**100**	
Diet Cu (mg kg^{-1} DM)	H	**6**–8	Diet Mo <1.5 mg kg^{-1} DM
	F	**4**–6	
Liver Cu (µmol kg^{-1} DM)[d,e]	H or F	**100**–300	
Plasma Cu (µmol l^{-1})[e]	H or F	**3**–9	Diet Mo <15mg kg^{-1} DM for cattle: no acute phase response; age >1 week
Blood Cu (µmol l^{-1})	H or F	**6**–10	
Hair or wool Cu (mg kg^{-1} DM)	H or F	**2**–4 (sheep)	Clean sample, recent growth
		4–8 (cattle)	

[a]Means within marginal band indicate a probability of CU-RD that increases with proximity to the **bold** limit, while values beyond the band do not. As the *number of* individuals falling within a marginal band increases, so does the likelihood of heard or flock benefit from Cu supplementation.
[b]Alternative criteria such caesruloplasmin and erythrocyte CuZnSOD activities are not included because they introduce additional problems of interpretation or standardization without adding significantly to the precision of diagnosis.
[c]Some data for cervines from Wilson and Grace (2001).
[d]Divide by 3.0 to obtain values on fresh weight basis.
[e]Multiply by 0.064 to obtain values in mg.

is exceedingly uncommon (Suttle 2010). Most cases of copper deficiency are indirect, as a result of excessive levels of molybdenum, iron, or sulphur (and, possibly, calcium or zinc) in the diet, which result in the conversion of copper into an insoluble, indigestible form within the rumen (Phillippo 1983, McClure 1994, Underwood & Suttle 1999). Hypocuprosis is most likely when there is high soil molybdenum, high soil pH (e.g., after liming; Phillippo 1983), immature plants, excess rainfall/irrigation, and/or contamination of forage with soil (Suttle 2004). Decreased use of sulphur-containing fertilisers and avoidance of excess levels of iron inclusion in mineral feed supplements appears to be associated with a decrease in the prevalence of indirect copper deficiency in the UK over recent years (Suttle 2010). It has been suggested that excess dietary molybdenum may have direct effects that mimic many of the features of hypocuprosis (Phillippo et al. 1982), although Suttle (2010) discounts this possibility. The main consequence of copper deficiency is upon the efficiency of food utilisation because of effects upon the integrity of the small intestine and of loss of activity of energy–metabolism (McClure 1994). Copper also has a role as an antioxidant, which may be of importance to reproductive performance (Lean et al. 1998).

Copper deficiency has long been associated with impaired fertility. This has been manifested as a reduction in first-service conception rates, impaired embryonic survival, a reduction in overall pregnancy rates, and poor display of oestrus. Impaired LH secretion has been implicated as the main means by which these effects may be mediated (Phillippo et al. 1982, 1987). Effects can range from negligible to pronounced (Corah 1996). All of the effects of hypocuprosis on fertility appear to depend on a concurrent excess of dietary molybdenum (Phillippo et al. 1982, 1987). Some studies have suggested that fertility may be responsive to copper supplementation (e.g., Pickering 1975), but other studies have suggested that fertility is not related to blood copper concentrations (e.g., Larson et al. 1980) nor does copper supplementation necessarily have a positive effect on fertility (Whittaker 1980). Moreover, in a number of studies in which copper deficiency has clearly been documented, there often is no effect on fertility or reproductive performance (e.g., Corah 1996). Indeed, Hawkins (2014) found an adverse effect of injecting CaCu EDTA 10 days before the start of mating upon subsequent reproductive performance.

One of the problems with determining whether copper deficiency is affecting fertility is finding an accurate measurement of copper status (Laven & Livesey 2005) because neither blood nor liver copper concentrations nor blood ceruloplasmin concentrations provide a full representation of animals' copper status. Suttle (2010) suggested the use of multiple criteria and, if there are a number of these that are below the lower limit of the 'marginal' band, a diagnosis of hypocuprosis is likely (Table 22.11). Values above the cutoff indicate that there is little likelihood of copper supplementation being beneficial.

Iodine and Goitrogens

Simple iodine deficiency occurs when intakes are less than 0.8 mg/kg DM (Alderman 1970) to 2.0 mg/kg DM (McClure 1994). Lean et al. (1998) considered that percutaneous absorption of iodine-based teat dips is adequate to prevent deficiency in milking cows. Iodine deficiency is largely manifested through the effects of a lack of thyroxine. As thyroxine is a general metabolic regulator (McDonald & Pineda 1989), its deficiency is associated with non-specific signs of ill thrift and poor growth. The main effects of iodine deficiency upon reproduction are also related to impaired thyroid function in the dam, embryo, or fetus. The most common abnormalities associated with iodine deficiency are embryonic death, abortion, and stillborn or weak, goitrous calves. Loss of libido and inhibition of oestrus behaviour (although not necessarily of ovarian cycles) have also been reported (Spielman et al. 1945, Williams & Stott 1966, McDonald 1980). However, the results of iodine supplementation trials (e.g., with injection of iodised oil; Logan et al. 1991, Mee 1991) upon fertility traits other than stillbirths are equivocal (Anderson et al. 2007).

VetBooks.ir

Disturbance of thyroid function can also be due to goitrogenic substance present in kale, lentils, soya bean, linseed, and certain strains of white clover (Boyd & Reid 1961, Tassell 1967). High levels of such goitrogenic substances can produce anoestrus in heifers (David 1965).

Manganese

Manganese is a cofactor in a number of enzymes that are responsible for gluconeogenesis (McClure 1994) and has a significant role as an antioxidant (Lean et al. 1998). Manganese is also involved in cholesterol synthesis and hence steroidogenesis. Both the pituitary gland and ovaries are relatively rich in this trace element. A variety of reproductive disorders that depress fertility in cows have been blamed on manganese deficiency, including delayed puberty, anoestrus, poor follicular development, delayed ovulation, silent oestrus, and reduced conception rates (Lean 1987, Hurley & Doane 1989, Kendall & Bone 2006). It also causes joint and limb deformities in calves. Under normal circumstances it is likely that normal pasture will provide the necessary requirement of 80 mg/kg DM (Alderman & Stranks 1967), although some foods (e.g., maize silage) are low in manganese. In addition, there is an interaction with the calcium to phosphorus ratio in the diet, with some evidence that high liming of pasture can cause manganese deficiency.

Phosphorus

The evidence for the importance of hypophosphataemia as a cause of infertility is conflicting. The provision of supplementary phosphorus has been shown to improve the breeding performance of grazing cattle (Sheehy 1946, Hart & Mitchell 1965, Tassell 1967). A number of authors have described infertility that was characterised by anoestrus, suboestrus, irregular cycles, and low conception rates (Hignett & Hignett 1951, Morrow 1969, Morris 1976), in the absence of other clinical signs of phosphorus deficiency. Others (Littlejohn & Lewis 1960, Cohen 1975, Carstairs et al. 1980) found no evidence of reduced fertility associated with phosphorus deficiency.

Daily phosphorus intakes should be about 13 g/day for maintenance, with about 7 g extra for each 4.5 litres of milk (Deas et al. 1979). Most forages contain adequate levels to meet these demands but deficiencies may occur on phosphate-deficient soils (McClure 1975). Morris (1976) suggested that deficiency can occur when the phosphorus content of the feed is under approximately 0.25%. High yielding cows need phosphorus in excess of that available in pasture, but because cereal grains contain large amounts, deficiencies are unlikely to occur. Blood phosphorus concentrations of less than 4 mg/dL in animals at peak production are indicative of deficiency. If hypophosphataemia is suspected, a rapid response can follow the feeding of dicalcium phosphate (150–200 g/day) or bone meal.

Selenium and Vitamin E

One of the key roles of selenium is as a component of the cytosolic enzyme glutathione peroxidase (GPX). Cytosolic GPX acts in concert with other antioxidants to prevent damage to cellular membranes induced by free radicals that arise from cellular metabolism of oxygen (Wichtel 1998a). However, many other selenium-containing enzymes exist, including iodothyronine deiodases and other glutathione peroxidases, some of which have functions that are quite distinct from the antioxidant role of cytosolic GPX. The roles of selenium are therefore widespread throughout the body:

- Lipid peroxidation: Selenium, in concert with the active derivative of vitamin E, α-tocopherol, prevents lipid peroxidation of membranes, particularly of the skeletal and cardiac muscles.
- Arachidonic rachidonic acid metabolism: Glutathione peroxidases are involved in the metabolism of arachidonic acid into the intermediate prostaglandins PGG and PGH (Hong et al. 1989).
- Phagocyte activity: Selenium deficiency, mediated through glutathione peroxidases, is associated with reduced bacteriocidal activity of neutrophils, reduced proliferation of lymphocytes and increased release of peroxides and macrophages (Wichtel 1998a).
- Iodothyronine 5-deiodinase: The enzyme, which converts thyroxine into the active thyroid hormone, triiodothyronine, is selenium-containing (Berry et al. 1991). Hence the growth retardation that is associated with selenium deficiency appears to be due, at least in part, to impaired thyroid function.

A wide range of effects of selenium deficiency on reproductive performance have been reported, including retained fetal membranes, poor uterine involution, metritis, cystic ovaries, and impaired fertilisation (Trinder et al. 1973, Harrison et al. 1986). Wichtel (1998a) noted that the effects of selenium deficiency on uterine involution and postpartum ovarian activity could be mediated through its effects on immune function, uterine contractility, thyroid hormone activity, or prostaglandin synthesis (Segerson et al. 1980, Hong et al. 1989, Spallholz et al. 1990, Wichtel et al. 1996).

Selenium deficiency can occur when soils contain <0.5 mg/kg or the diet contains <0.05 mg/kg selenium. Vitamin E deficiency occurs when animals graze postmature pasture, receive other dietary components that contain <0.7 mg/kg of the vitamin, or are fed diets that are high in polyunsaturated or rancid fats (McClure 1994). Diagnosis of selenium deficiency can be made by measuring circulating concentrations of selenium or, better, by measuring selenium stores in the liver (Table 22.12; Wichtel 1998b). Measurement of levels in feed, pasture, or soil is also often indicated. Supplementation is widely practised, especially in areas in which soils are known to be marginal or deficient. However, it should be remembered that excessive selenium is toxic, especially when it has been given by injection.

TABLE 22.12 Selenium reference ranges related to the growth of young cattle

	Whole Blood Se (nmol/l)	Serum Se (nmol/l)	Glutathione Peroxidase (kU/l)	Liver Se (nmol/kg)
Responsive	< 130	< 52	< 0.5	< 380
Marginal	130–250	52–100	0.5–2.0	380–650
Adequate	> 250	> 100	> 2.0	> 650

From Wichtel (1998b).

VetBooks.ir

Studies involving selenium-deficient Friesian–Holstein heifers have shown improved pregnancy rates after treatment (MacPherson et al. 1987). Taylor et al. (1979) found a lower abortion rate after selenium supplementation, whilst McClure et al. (1986) reported a higher first-service conception rate after selenium supplementation. Vitamin E deficiency is directly associated with embryonic loss in cows and, through its role in the immune system, may also affect the rate of uterine involution after calving (Lean et al. 1998).

Vitamin A and β-carotene

Diets that are deficient in β-carotene can result in impairment through direct effects of β-carotene and through vitamin A deficiency. McClure (1994) suggested that deficiency only occurs when animals have been on diets that contain less than 45 mg/kg β-carotene for a considerable period of time.

Early studies (Kuhlman & Gallup 1942, Madsen & Davis 1949, Byers et al. 1956) showed that vitamin A deficiency is associated with delayed puberty, low pregnancy rates, and poor conception rates. Subsequently, Lotthammer (1979) identified a direct effect of β-carotene though studies on feeds that contained adequate levels of vitamin A but were deficient in β-carotene. Diets that are deficient in β-carotene, but are adequate in vitamin A, have been reported to result in extended follicular phases, delayed ovulation, silent oestrus, follicular cysts (Lotthammer et al. 1978), low conception rates, low pregnancy rates (Cooke 1978), and impaired luteal progesterone synthesis (Jackson 1981).

However, not all studies have agreed with these results. Bindas et al. (1983), Ducker et al. (1984), Marcek et al. (1985), and Gossen and Hoedemaker (2005) all found that reproductive performance was unresponsive to β-carotene. The reasons for the different responses are difficult to explain. The current view of β-carotene is that, if it has a role in reproduction, it is probably related to its activity as an antioxidant, perhaps protecting the maturation of the oocyte (Ikeda et al. 2005) or development of the early embryo.

Zinc

Zinc is actively involved in a range of enzyme functions. The necessity for zinc appears to be greater in males (Hurley & Doane 1989) than in females (Pitts et al. 1966). Zinc deficiency in the bull may cause impaired fertility associated with an alteration in the latter stages of spermatogenesis (Corah 1996). This impairment of male infertility appears to be associated with the role of zinc as an activator of enzymes involved in testosterone synthesis. Zinc deficiency in the female may cause a decrease in fertility and abnormal oestrus behaviour (Corah & Ives 1991).

The uptake of zinc is impaired by copper, calcium, iron, molybdenum, and cadmium. However, Suttle (1994) suggested that the presence of zinc in soil and in galvanised pipeware means that deficiency is unlikely to occur. Whether there is any benefit from chelated zinc supplements is therefore open to question (Underwood & Suttle 1999). Zinc toxicity is rare, but excessive zinc supplementation may lead to perturbation of essential fatty acid metabolism and hence affect prostaglandin synthesis.

Antioxidant Function

A number of micronutrients are believed to act upon reproductive performance primarily through their role as antioxidants. Many metabolic processes produce superoxides that, through the Fenton reaction, produce highly destructive free radicals (Fettman 1991). Normally, the tissue-damaging effects of these free radicals are prevented by the presence of antioxidants. Many of these are essential micronutrients; so, when these micronutrients become deficient, free radical tissue damage occurs (Lean et al. 1998). Free radical damage includes the creation of toxic lipids, reactive proteins, free radical cascades, and nucleic acid damage. Transition metals, by virtue of their ability to change oxidation states, are the key component of many antioxidant systems.

McClure (1994) listed selenium, α-tocopherol, β-carotene, and copper as the key antioxidants. To this list, Lean et al. (1998) added manganese, zinc, iron, cobalt, and vitamin A. Glucose, sulphur-containing amino acids, and various proteins probably also exert some antioxidant role. Dietary sources, active forms, sites of action, and mechanism of action of the major antioxidants are listed in Table 22.13.

Phyto-oestrogens

When cows ingest large quantities of these substances they become anoestrous, with large ovarian cysts, vulval and cervical enlargement, and poor conception rates (Morris 1976). Such substances are found in subterranean clover, certain strains of red and white clover, and lucerne.

Investigation of Nutritional Factors as a Cause of Infertility

It is frequently impossible to accurately determine a specific nutritional cause of infertility because the clinical signs appear sometime after the deficiency has occurred. Methods such as the use of cumulative frequency graphs of conception rate or monitoring daily bulk milk protein concentrations can help to pinpoint the times when management changes took place that have adversely affected nutrition (see Chapter 25). Effects of improving nutrition are more difficult to determine because changes in the season of the year and management can also have an effect that can obfuscate the effects of changes in diet.

In most cases, the most important factor responsible for poor fertility is underfeeding. This is most commonly due to:

- Overestimation of the feeding value of forages. For conserved forage, it is important to obtain accurate analysis of the major food components from truly representative samples. For pasture, it is important to accurately estimate both the amount and the digestibility of the material that is present;
- Overestimation of feed intake under self-feed conditions. Self-fed silage is especially susceptible to overestimation. However, it should be noted that, in most situations in which self-feeding is practised, especially when there is inadequate feeding space for all cows to feed simultaneously, vulnerable cows (i.e., first calvers, smaller cows, etc.) will be at a significant disadvantage, in terms of feed intake, than their herd mates;
- Failure to appreciate the reduction of forage intake caused by high concentrate intake (Alderman 1970); and
- Underfeeding of concentrates due to automatic dispensers giving short measure. Parker and Blowey (1976) found errors of more than 50% in some cases. Manual dispensers in the milking shed are more commonly inaccurate than accurate.

It is necessary to calculate the requirements of the cows for maintenance and production and then obtain accurate information about the precise quantities fed. Contributions from mineral licks and other free access sources are difficult to quantify. Weighing, the use of a girth band measure, or condition scoring of a representative number of animals are also useful.

TABLE 22.13 Dietary sources, active forms, sites of action and mechanism of action of the major antioxidants

Dietary Input	Biologically Active Antioxidant	Site of Action	Mechanism of Action
Selenium	Glutathione peroxidase	IC, membrane	Reduces peroxides
Copper	Cu/Zn superoxide dismutase	IC	Scavenges O_2^-
	Ceruloplasmin	EC	Binds Cu, oxidises Fe
	Superoxide dismutase	EC	Scavenges O_2^-
Zinc	Cu/Zn superoxide dismutase	IC	Scavenges O_2^-
	Superoxide dismutase	EC	Scavenges O_2^-
	Metallothionein	EC	Binds metal ions
Manganese	Mn superoxide dismutase	IC	Scavenges O_2^-
Iron	Catalase	IC	Reduces peroxides
	Transferrin	ED	Binds iron
Cobalt	Vitamin B12		
Vitamin E	α–tocopherol	Membrane	Blocks peroxidation
Vitamin A	Retinol	EC	Maintains cell integrity
β-carotene	β-carotene	Membrane	Singlet oxygen
	Retinol	EC	Maintains cell integrity
Glucose	Ascorbate	EC	Radical scavenger
Sulphur-containing amino acids	Glutathione	IC	Replenishes glutathione peroxidase
Protein	Various	EC	Binds metal ions, scavenges OH

IC, intracellular; *EC,* extracellular.

Metabolic Profiles

Metabolic profiles were introduced in 1970 (Payne et al. 1970). Since then, they have frequently been used to help in the evaluation of the nutritional status of a herd, particularly in relation to fertility. Metabolic profiles are best used in conjunction with other direct assessments of nutrient quality (such as ME, digestibility, RDP, and UDP estimates of forages) and supply, together with milk volume and fat/protein content (Whittaker 2004). Samples that are commonly collected for interpretation of energy status are glucose, NEFA, and βOHB; for protein, samples include urea, albumin, and globulin (Table 22.14).

Other samples that are sometimes incorporated into metabolic profiles include the following:

- **Bile acids:** Although included as a means of assessing lipid infiltration of the liver, this is not reliable; liver biopsy is preferable.
- **Calcium:** As homoeostatic control is strong, calcium measurements are of little value except in clinical cases.
- **Magnesium:** Values below the normal range (0.8–1.3 mmol/L) may be indicative of incipient grass staggers if very low or of impairment of production due to subclinical hypomagnesaemia if marginal.
- **Inorganic phosphate:** Phosphorus deficiency is not common, so phosphate status should be checked before adding supplementary phosphate to the diet.
- **Copper:** Blood copper concentrations are not a reliable indicator of copper status (require liver samples), although concentrations decline when liver copper stores are depleted.
- **Glutathione peroxidase:** Because GPX concentrations are a long-term rather than short-term measure of selenium status, care is needed in interpreting results.
- **Liver enzymes** were initially commonly incorporated into metabolic profiles to provide an indicator of liver health. It is probably not cost effective to do so unless there is a specific indication for assessment of the liver.

Details of the tests and their evaluation are available in standard texts of cattle medicine.

Other Factors Affecting Reproductive Performance

Heat Stress

The temperature zone of comfort for dairy cows is between 5°C and 25°C (McDowell et al. 1979) and, when the environmental temperature rises above 25°C, reproductive performance is impaired. The effects of high temperature are exacerbated under conditions of high humidity (Gwazdauskas et al. 1973); calculation of a temperature–humidity index (THI) is a useful predictor of the degree of thermal stress to which cows are subject. The consequence of a high THI is that there is a significant reduction in conception rate in the hot season compared with the winter season; literature reviewed by De Rensis and Scaramuzzi (2003) showed a reduction of conception rate of 20% to 30% in

VetBooks.ir

TABLE 22.14 Normal ranges and interpretation of samples collected for metabolic profiles

Sample	Optimal Range (Lactating Cows)	Interpretation	Advantages	Disadvantages
Energy				
β-hydroxybutyrate	< 1.0 mmol/L	0.6–1.0 mmol/L: acceptable level of fat mobilisation > 2.0 mmol/L: ketosis	Stable in transit	Butyrate may be absorbed from butyric silage
Non-esterified fatty acids	< 0.7 mmol/L	> 1.5 mmol/L: ketosis	More direct measure of fat mobilisation than βOHB	Less stable in samples than βOHB May be raised in stressed animals
Glucose	> 3.0 mmol/L (plasma)	Variation within optimum range according to weight change Very high values in stressed animals	Sensitive to short-term changes in fermentable ME	Close homoeostatic regulation Must use oxalate-fluoride anticoagulant Measure in plasma rather than serum or whole blood
Protein				
Urea	Urea N: > 1.7 mmol/L Urea N: > 3.3 mmol/L Urea: > 3.6 mmol/L	Low: inadequate RDP:FME ratio Inadequate FME in diet High: excess RDP:FME		
Albumin	> 30 g/L	Low: poor liver health long-term underfeeding of protein		Serum samples have lower values than plasma
Globulin	< 50 g/L	High: indicates presence of infection		Not related to how acute or severe a disease process is

Derived from Whittaker (1997, 2004).

the hot season. Adverse effects upon reproductive performance can be particularly significant for high producing dairy cows in tropical/subtropical environments, even to the point of making dairying unsustainable under some conditions. Moreover, the effects of heat stress do not end as soon as the temperature cools to below the upper threshold, because there is good evidence of the effects of heat stress persisting into the autumn (De Rensis et al. 2017).

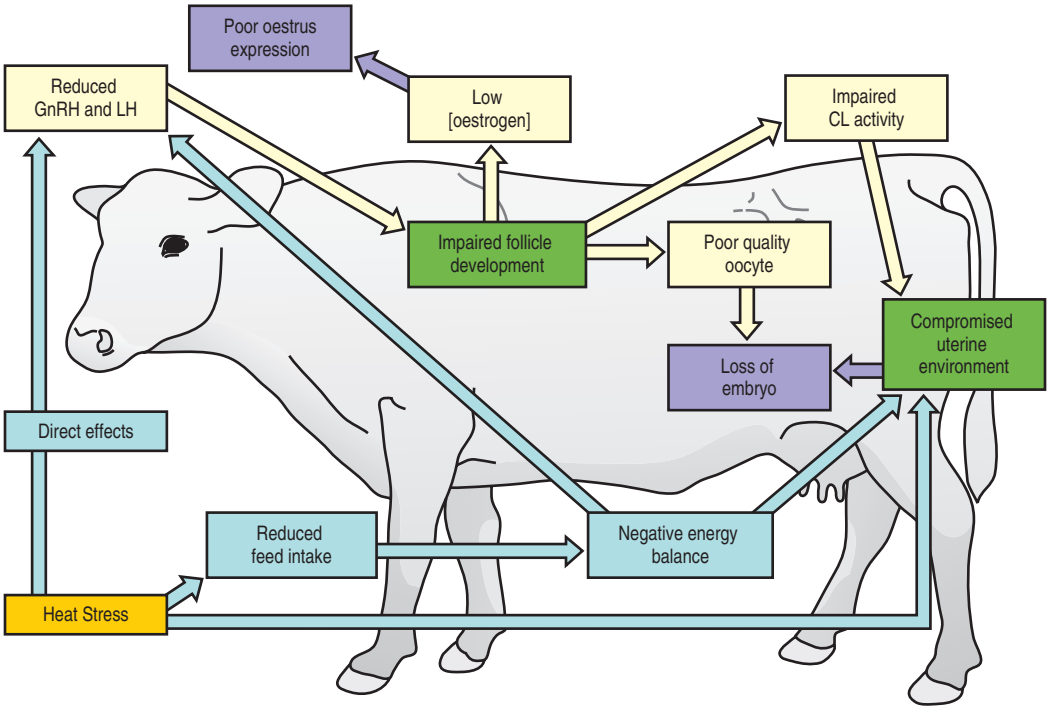
The main effects of heat stress upon reproduction in female cattle are upon follicular growth, ovulation, the expression of oestrus (Schuller et al. 2017), and upon the establishment of pregnancy (Fig. 22.37). Oestrus expression is reduced in heat stressed cows, in terms of the duration of oestrus and the ability of herd managers to detect oestrus (Hansen 2007). This is partly due to decreased locomotor activity (De Rensis et al. 2015). Up to 80% of oestrus periods may be undetected (Thatcher & Collier 1986) during periods of heat stress. It is also partly due to impaired development of preovulatory follicles. Heat stressed cows have abnormalities of dominant follicle hierarchy (Roth et al. 2000), resulting in lower oestradiol concentrations (Thatcher & Collier 1986, Lu et al. 1992) than in unstressed animals. Impaired follicle development, in turn, occurs due to impaired GnRH secretion and, thence, impaired LH and FSH secretion. The cause of the reduced activity of the reproductive endocrine axis is not fully understood but has been explained in terms of the effects of elevated prolactin or cortisol concentrations, inappetence, and impaired acid–base balance in heat stressed animals (De Rensis et al. 2017). In consequence, there is an increased prevalence of ovulation failure (López-Gatius et al. 2005), twin, and other abnormal ovulations, and there is impairment of oocyte development (Zeron et al. 2001) and maturation (Pavani et al. 2017). There is also an increased risk of either failure of luteal formation or the formation of CLs whose progesterone secretion is inadequate.

Many studies have shown that the establishment of pregnancy is also impaired when ambient temperatures are high (e.g., Barker et al. 1994). The effects of heat stress are primarily upon the early embryo. Most studies have shown that fertilisation rates are normal (Thatcher & Collier 1986, Wise et al. 1988), but embryonic death occurs between fertilisation and maternal recognition of pregnancy. Most deaths occur during the early cleavage divisions (Roman-Ponce et al. 1981, Putney et al. 1989, Ealy et al. 1993), although a lower rate of deaths also occurs between Days 8 and 16 (Biggers et al. 1986). Hansen (2007) suggested that the effects of heat stress are mediated through damage to the oocyte, impaired protein synthesis during the morula and blastocyst phases and, possibly, through impaired endometrial activity.

Effects of heat stress are also seen in later gestation. Significant pregnancy loss continues up to Day 50 of gestation (López-Gatius et al. 2004). Furthermore, placenta weight and calf birth weight are reduced in cows that calved in hot months versus those calving in cooler months or versus cows provided with cooling during the hot months (Thatcher & Collier 1986, Wolfenson et al. 1988). Thus heat stress may not only affect pregnancy rates if it occurs at the time of fertilisation but also impair pregnancy throughout its course.

The effects of heat stress can be overcome to a greater or lesser extent by cooling cows by providing shade (Vermeulen 1988), water sprays (Omar et al. 1996), or sprays used in combination with forced ventilation (Flamenbaum et al. 1988, Lu et al. 1992). Alternatively, or additionally, hormone treatments and fixed time AI can be used to circumvent the effects of heat stress. De Rensis et al. (2015) noted that hormone treatments to manage the effects

VetBooks.ir



• **Fig. 22.37** Possible mechanisms for the effect of heat stress on reproduction in the lactating dairy cow. Heat stress can act directly through the **reproductive endocrine system**, through **feed intake,** and directly upon the uterus. In consequence, **follicle development** is impaired and early embryo losses increase, resulting in infertility. The poor follicle development also causes a reduction in **oestrus expression**. (Based upon De Rensis & Scaramuzzi 2003.)

of heat stress should be suitable for fixe time AI, resolve anoestrus and abnormalities of ovulation, and be of short duration. GnRH given at the time of insemination increases conception rate (Ullah et al. 1996), but the response to Ovsynch (GnRH–$PGF_{2\alpha}$–GnRH) is variable and not particularly beneficial. However, replacement of GnRH with hCG or eCG appears to be beneficial in cows that are heat stressed, and administration of hCG after AI may also improve pregnancy rates (De Rensis et al. 2008, Shabankareh et al. 2010). Similarly, inclusion of progesterone in the synchronisation protocol may improve conception rates (Garcia-Ispierto et al. 2013). On the other hand, administration of progesterone after insemination does not appear to have any significant effect upon pregnancy outcomes (e.g., Correa-Calderon et al. 2016).

Hence, although heat stress causes a significant impairment of many parameters of reproductive performance (anoestrus, lowered conception rates, reduced calf birth weight, and, possibly, impaired postpartum uterine involution), simple management procedures are generally sufficient to mitigate or alleviate the problem. Simply providing shade and adequate access to water helps considerably, and cooling with water and/or forced ventilation is highly effective. In the longer term, selection for heat tolerance may be feasible; there are clear differences between breeds in terms of heat tolerance, and there are a number of candidate genes that have significant genetic variability within breeds (e.g., Macciotta et al. 2017).

The 'Repeat Breeder' Syndrome

The term 'repeat breeder' was coined to describe cows that failed to conceive after a number of services and regularly return to oestrus at a normal inter-oestrus interval. By mathematical chance, if cows have a 60% conception rate, about 6.4% of the animals in a herd will not have conceived after the third mating. It was originally considered that chance was the only factor in determining whether these animals failed to conceive. However, when the cows that repeatedly fail to conceive have been examined in more detail, it has been clear that they are not the random group of animals that mathematical probability would suggest, but rather contain a subset of cattle that are actually subfertile. Moreover, Barrett et al. (2004) showed that, rather than approximately 6% of animals being non-pregnant after the third service, the figure is closer to 12%, the difference between the theoretical and actual figures also being composed of a group of subfertile animals.

Early work on repeat breeders was responsible for the identification and subsequent elimination of some of the major venereal pathogens of cattle; yet, even when this had been achieved, there remained an irreducible proportion of cows that experienced repeated pregnancy failure. Some repeat breeders are cows that simply have gross pathology of the reproductive system, some functional form of infertility, or experience some managemental predisposition to infertility. A number of reviews have enumerated the causes of reproductive failure in such animals (Roberts 1986, Lafi & Kaneene 1988, Eddy 1994, Levine 1999). Many of these causes have been considered earlier in the chapter and can be diagnosed by careful clinical examination and history taking. The repeat breeder cow that presents the greatest clinical and managemental challenge, however, is the animal that continually returns to service in the absence of any obvious pathological disease.

Impaired Embryonic Development

Ayalon and co-workers undertook a number of pivotal studies of the repeat breeder cow. They found a slightly reduced fertilisation rate in repeat breeders compared with normal cows and that, after fertilisation, the two groups of cows exhibited very different patterns of embryonic survival. Repeat breeders suffered a significant level

VetBooks.ir

TABLE 22.15 Embryonic death in normal and repeat-breeder cows

Day After Fertilisation	PERCENTAGE OF ANIMALS WITH EMBRYOS	
	Normal	Repeat Breeder
2–3	85	71
11–13	74	50
14–16	73	50
17–19	60	43
35–42	67	35

Compiled from Sreenan & Diskin (1986; normal cows) and Ayalon (1978; repeat breeders).

of embryonic death (Ayalon 1972, 1978, Maurer & Echternkamp 1985) at around Day 6 pregnancy, with further losses at around Days 17 to 19 (Table 22.15). These timings are associated, first, with hatching from the zona pellucida and, second, with failure of the maternal recognition of pregnancy on Day 16. Embryos derived from normal cows failed to survive in the uteri of repeat breeders, whereas embryos derived from repeat breeders had normal survival rates in normal cows (Almedia et al. 1984, Ayalon 1984). Furthermore, the fertilisation and cleavage rates of oocytes collected by ovum pick-up and fertilised *in vitro* are similar in repeat breeder and normal cows (Bage 2003). Hence the problem of the repeat breeder is primarily in the uterine environment rather than representing a deficiency of the embryo itself, although by the seventh day of gestation, the *in vitro* developmental capacity of embryos derived from repeat breeders is compromised (Tanabe et al. 1985), as is their morphological development (Gustafsson 1985).

Thus provided one has excluded obvious pathological lesions, mismanagement of mating, and infectious diseases that impair reproductive performance, the three main causes of repeat breeding remain namely, abnormalities of the periovulatory period, chronic endometrial damage, and luteal deficiency.

Periovulatory Abnormalities

A number of studies of repeat breeder cows have shown endocrine abnormalities of the periovulatory period. Repeat breeders are likely to have delayed ovulation, an extended follicular phase and reduced signs of oestrus (Sood et al. 2015). These abnormalities appear to be associated with the presence of suprabasal progesterone concentrations during the follicular phase (Bage 2003, Bhupender et al. 2005), which Vos (1999) suggested allows follicle development but postpones the LH surge. Hence there is a longer interval between luteolysis and ovulation and a delayed LH surge, resulting in follicles and oocytes that are relatively aged by the time of ovulation. Repeat breeder cows are more likely to have two- than three-wave cycles (Perez et al. 2003), further increasing the probability of the presence of aged follicles. Repeat breeders are also more likely to have a delayed postovulatory rise in progesterone concentrations (Bage et al. 2002), possibly as a result of the impairment of the events around ovulation.

Luteal Deficiency

Progesterone is necessary for the maintenance of pregnancy. Until Day 150 to 200 of pregnancy the main source of the hormone is the CL, so if it is not completely formed or it is not functioning adequately, then insufficient progesterone is produced, and the pregnancy is at risk of failure. Luteal deficiency has been suspected of causing infertility for many years, and, although proof is difficult, treatment of repeat breeders is frequently based on this assumption.

The relationship between progesterone concentrations and pregnancy rate has been investigated on many occasions. Most of these studies agree that blood or milk progesterone concentrations in pregnant animals diverge from those that fail to conceive at some point between Days 6 and 14 postinsemination (e.g., Bulman & Lamming 1978, Lamming et al. 1989) and that this divergence is likely to be of importance for the success of embryo development. Kendall et al. (2009) also found that low milk progesterone concentrations on Day 5 (<3 ng/mL) was more common in repeat breeders (34%) than in normal cows (11%). Hence Starbuck et al. (1999) considered that pregnancy is unlikely if milk progesterone concentrations are less than 3 ng/mL on Day 5 post-insemination. One of the key effects of progesterone is upon trophoblast expansion: low progesterone concentrations are associated with suboptimal growth of the blastocyst and hence insufficient secretion of IFN-τ to prevent luteolysis (Demmers et al. 2001).

Damage to the Endometrium

Although chronic endometritis has been associated with the repeat breeding syndrome at an epidemiological level (e.g., Moss et al. 2002), some doubt has been cast on the importance of uterine infection. For example, Levine (1999) did not place great importance upon chronic uterine infection as a cause of repeat breeding, citing studies by Hartigan et al. (1972), DeKruif (1976), Hartigan (1978), and Roberts (1986) as evidence of a generally low infection rate and moderate bacterial recovery rates. More recently, this view was confirmed by Pothmann et al. (2015), who found evidence of subclinical endometritis in only 12.7% of repeat breeders; and by Jaureguiberry et al. (2017) who diagnosed subclinical endometritis (≥ 5% neutrophils in cervical cytobrush samples: see Chapter 23) in 24% of repeat breeders. The latter study also found that the presence of fluid in the uterine lumen was of better diagnostic value for repeat breeders than were cytobrush samples. Interestingly, studies from the Indian subcontinent do not support this view because, for example, Ramakrishna (1996) found 46 out of 60 repeat breeder cows to have significant bacterial isolates from cervical discharges, and Malik et al. (1987) found 370 out of 396 mucus samples from infertile cows to be infected. Similarly, Ahmadi et al. (2017) reported bacterial biofilms in the uterus of 12 out of 20 repeat breeder cows.

Moreover, infection does not have to be active at the time of sampling for infection-related uterine damage to have occurred. The effects of infection on endometrial scarring in the mare are well known (see Chapter 31), but even in the cow, there is increasingly clear evidence that chronic uterine damage results from infection (see Chapter 23). Gonzalez (1984) associated infertility with the degree of endometrial damage that was present in uterine biopsies, whilst DeBois and Manspeaker (1986), in their review of endometrial biopsies in cattle, noted that mild chronic endometritis is one of the most common causes of repeat breeding. Hence, it was their opinion that endometrial biopsy is an essential part of the examination of the valuable cow with unexplained infertility.

Uterine secretions of repeat breeder cows have been characterised as differing from those of normal cows (Zavy & Giesert 1994). Almedia et al. (1984) showed qualitative and quantitative differences in the ionic composition of uterine flushings of normal and repeat breeder cows. No clear-cut associations between biopsy lesions and uterine secretion characteristics are evident in the literature, and it might be argued that differences in uterine secretory

VetBooks.ir

profiles are as likely to reflect differences in luteal activity (or, at least, progesterone status) as the degree of histological change to endometrial structure. On the other hand, more recent genetic studies of repeat breeders have associated increases in interleukins and chemokine ligand in the lymphocytes in those with chronic endometritis, dysregulating of mucin genes in animals with and without chronic endometritis (Wagener et al. 2017), as well as abnormalities of TNF-α (Kalyaan et al. 2015).

Treatment

Given the relationship between low progesterone and pregnancy failure, attempts have been made to find cost-effective ways to augment circulating progesterone concentrations in the hope of improving the pregnancy rate in an entire herd, especially among the repeat breeders.

The main luteotrophic hormone of the cow is LH. Thus, if LH activity is enhanced (e.g., by injection of hCG or GnRH) after ovulation, stimulation of the development and function of the CL may result. Despite the long-standing use of hCG as a 'holding injection' in infertile cows, there is no statistically significant effect in improving pregnancy rates in either normal cows (Greve & Lehn-Jensen 1982, Sreenan & Diskin 1983) or repeat breeders (Hansel et al. 1976, Leidl et al. 1979).

Results for the use of GnRH at the time of insemination have generally been positive (Schels and Mostafawi 1978, Lee et al. 1981, Nakao et al. 1983, Morgan & Lean 1993). Hence the use of GnRH in this way is quite common (Malmo & Beggs 2000). Lean et al. (2003) undertook a meta-analysis of 40 trials on the administration of GnRH at insemination, with the result that the overall risk of pregnancy was increased by 12.5% in all cows but was increased by 22.5% when used in repeat breeders.

An alternative approach has been to give hCG or GnRH 11 to 13 days after breeding. The rationale for this approach is to induce accessory corpora lutea or luteinised follicles, or to augment the progesterone secretion from existing structures. Macmillan et al. (1986) and Sheldon and Dobson (1993) recorded benefits from such a regimen, but not all studies agree with this (e.g., Jubb et al. 1990). Meta-analysis of the effects of 8 to 10 μg buserelin or 250 μg GnRH on Days 11 to 14 after insemination (Lean et al. 2003) found that the risk of pregnancy to first service was increased by 7% to 10% at the first service but not at subsequent services. Nonetheless, they concluded that treatment with GnRH is likely to be cost effective.

Progesterone implants have been used to try to augment progesterone concentrations during the period when luteolysis is expected. However, Diskin and Sreenan (1986) concluded from meta-analysis of many early trials of the effects of progesterone administration upon pregnancy rate that it was ineffectual. However, interest in progesterone administration as a means of augmenting pregnancy rate has been rekindled, and a method that is increasingly widely practised is the reinsertion of previously used progesterone-releasing intravaginal devices (i.e., PRIDs or CIDRs). This practice may increase pregnancy rates (Macmillan et al. 1986) by augmenting circulating progesterone concentrations, but it has an additional advantage that returns to oestrus in non-pregnant cows are either synchronised or occur at a predictable time (Cavalieri et al. 2000a, b).

The Metritis Complex in Cattle

I. MARTIN SHELDON

Introduction

Microbial infections of the female genital tract often cause disease in cattle after calving. Postpartum microbial disease of the female genital tract is particularly common in *Bos taurus* dairy cattle, whereas disease is less common in beef breeds of *Bos taurus* and in *Bos indicus* cattle. Uterine disease is typified by the accumulation of pus in the genital tract, which often discharges from the vulva (Fig. 23.1).

Uterine disease is important in cattle because the consequences are subfertility and, in some cases, infertility. For example, bacterial infections of the uterus causing metritis lead to delayed insemination, reduced conception rates, and increased culling for failure to conceive. The cost to the dairy industry for treating metritis, reduced milk production, and replacing animals that fail to conceive at the farmer's desired time is estimated to be €1.4 billion every year in the EU (Sheldon et al. 2009). This chapter sets out the definitions, causes, diagnosis, treatment, and management of postpartum, non-specific uterine infectious diseases in cattle.

Defining the Diseases of the Postpartum Uterus

The definitions and brief details of non-specific, postpartum infectious diseases are presented first to provide a framework for understanding the aetiology, pathogenesis, diagnosis, and treatment of uterine disease. The typical incidence and duration of uterine disease is shown in Fig. 23.2.

Retained Fetal Membranes

Retained fetal membranes (RFM, see also Chapter 20) are defined as the failure of an animal to expel the fetal membranes within 24 hours of the end of parturition. Retained placenta is an alternative name used for RFM. There is some variation in the literature about the duration of retention that defines the clinical disorder. Some prefer to define retention as being for 12 hours; however, the timing is arbitrary, and most normal cows expel the fetal membranes within a few hours of parturition. The incidence of RFM varies among herds, but is typically 5% to 10% of animals. The importance of RFM is that they are associated with reduced milk yield and an increased risk of metritis.

Metritis

Metritis is most common within 10 days of parturition. Metritis is characterised by an enlarged uterus and a watery red-brown fluid to viscous off-white purulent, uterine discharge, which often has a fetid odour (Sheldon et al. 2006). The incidence of metritis varies between breed, country, and herd, but in a study of the records from 97,318 cows in the US, the lactation incidence of metritis, including RFM, was 21% (Zwald et al. 2004). However, in some studies the incidence is as high as 40% of the herd. The associated clinical signs are used to classify the severity of disease, which varies from unapparent disease to fatal toxaemic metritis.

Clinical Endometritis

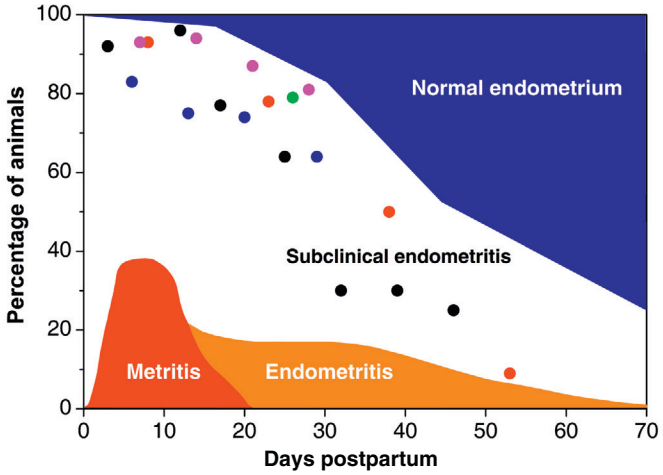
Clinical endometritis is defined as the presence of a purulent uterine discharge detectable in the vagina of cattle 21 days or more postpartum or a mucopurulent discharge detectable in the vagina after 26 days postpartum, (Sheldon et al. 2006). The incidence of clinical endometritis is around 10% to 20%, with variation between breed, country, and herd; a typical study reported that 16.9% of 1865 dairy cows were affected in Canada (LeBlanc et al. 2002a). A simple grading system based on the character of the vaginal mucus is readily used to evaluate cows with clinical endometritis and is prognostic for the likely outcome of treatment (Sheldon et al. 2006).

Subclinical Endometritis

Subclinical endometritis is characterised by inflammation of the endometrium in the absence of clinical signs of endometritis, which results in a significant reduction in reproductive performance. The inflammation is presumably associated with recovery of the tissues after metritis and clinical endometritis, trauma, or other non-microbial disease. Definition of subclinical disease is currently dependent on cytological analysis of samples that are collected from the surface of the endometrium by flushing the uterine lumen or by the use of an endometrial cytobrush. The proportion of animals affected varies widely among studies, ranging from about 11% to more than 40% of animals (Wagener et al. 2017). Diagnosis relies on the proportion of endometrial cells that contain more than a defined proportion of neutrophils at specific times after parturition.

VetBooks.ir

• **Fig. 23.1** A typical case of postpartum metritis in a dairy cow with accumulation of pus in the uterus, which is discharging from the vulva.



• **Fig. 23.2** The incidence of uterine bacterial infection and disease in postpartum dairy cattle (From Sheldon et al. 2009). Bacteria can be isolated from the uterus of most cows during the postpartum period; each marker (*circle*) indicates the percentage of animals with bacteria isolated from the uterine lumen in four studies (Elliott et al. 1968, Griffin et al. 1974b, Bonnett et al. 1991a, Sheldon et al. 2002b). The shaded areas represent estimates of the proportion of animals with metritis (*red*), clinical endometritis (*orange*), or a normal uterus (*blue*); the remainder of animals have subclinical endometritis (Gilbert et al. 2005).

Pyometra

Pyometra is characterised by the accumulation of purulent or mucopurulent material within the uterine lumen, causing distension of the uterus, in the presence of a closed cervix and a functional corpus luteum. Postpartum pyometra is uncommon and is thought to be caused by the growth of bacteria within the uterine lumen after the formation of the first corpus luteum (Noakes et al. 1990).

Inflammation in Other Parts of the Reproductive System

Oophoritis, cervicitis, and vaginitis are defined as inflammation of the oviduct, cervix, and vagina, respectively. The signs are typical of the cardinal signs of inflammation: redness, heat, swelling, pain, and loss of function. Although the incidence of oophoritis is often unclear, cervicitis and vaginitis are relatively common.

The Postpartum Period

The main reproductive events that are required after parturition to foster optimal future fertility are: prompt expulsion of the fetal membranes, followed by uterine involution; timely return of ovarian cyclical activity; regeneration of the endometrium; and efficient control of bacteria in the uterus.

Expulsion of the Fetal Membranes

The primary mechanism by which the caruncle and cotyledon of the placentome anchor to each other is the interdigitating fetal and maternal villi, and the presence of adhesive proteins at the fetomaternal interface. The surrounding and engulfing of the caruncle by the cotyledon provides physical anchoring (Eiler & Fecteau 2007). Detachment of the membranes requires release of the cotyledon from the caruncle by disruption of the physical and cellular arrangements that are present during pregnancy. There appear to be three main factors involved in the separation and expulsion of the fetal membranes:

- Maturation of the placenta, including biochemical and immunological changes at the fetal–maternal junction;
- Exsanguination of the fetal side of the placenta when the umbilicus ruptures, which causes collapse and shrinkage of the trophectodermal villi and their physical separation from the maternal crypts; and
- Uterine contractions, which aid in the exsanguination of the fetal side of the placenta and aid in the physical separation of the placenta by distorting the shape of the placentomes, thereby causing 'unbuttoning' of the cotyledon from the caruncle, and attempting to expel the dependent and detached parts of the fetal membranes.

Preparatory changes for the release of the fetal membranes are not confined to the peripartum period but begin during the late stage of gestation (Grunert 1986). These changes appear to be largely dependent on a critical sequence of changes in the concentrations of progesterone and oestrogen and the abundance of their cognate steroid receptors (Agthe & Kolm 1975, Chew et al. 1977, Boos et al. 2000). For example, the presence of subnormal oestrogen and oestrogen receptor concentrations may lead to RFM.

Physical changes that occur in association with the release of the fetal membranes include flattening of the maternal crypt epithelium and, in the last week of gestation, a reduction in the number of binucleate cells in the trophectoderm (Bjorkman 1969, Gross & Williams 1988). Relaxation of the superficial layers of the cotyledon is induced by proteases and collagenase, which break down the type I and III collagen that provides the tensile strength to the caruncular crypts (Boos et al. 2003, Eiler & Fecteau 2007). Likewise, collagenases also disrupt the anchoring attachments between the fetal and maternal villi. Failure of proteolysis is considered to be a key factor in failure of membrane detachment, although, curiously, there is no difference in the distribution of types I, III, or IV collagen in cows that do or do not retain their membranes (Sarges et al. 1998, Boos et al. 2003). Inhibition of collagenase activity by exogenous glucocorticoids appears to be a major contributing factor to the retention of the membranes associated with the premature induction of parturition with glucocorticoids.

Changes in the composition of the glue line adhesive proteins, which are present between the cotyledonary and caruncular epithelium, are of importance in the process of placental detachment.

VetBooks.ir

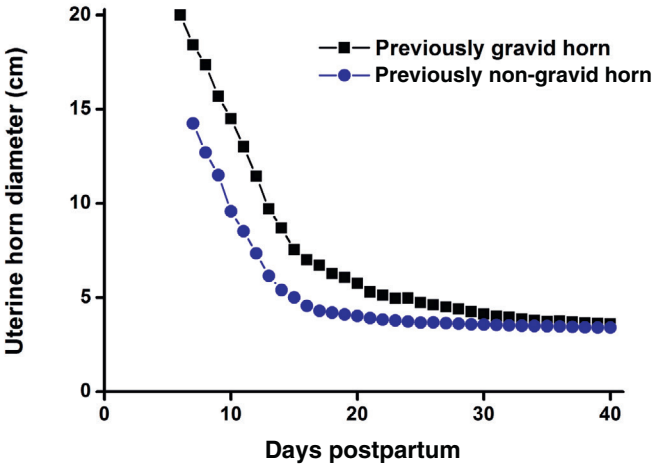
Proteoglycans are intercellular adhesion proteins that are present at the fetomaternal interface: there is evidence that the activity of the enzyme beta-*N*-acetyl-glucosaminidase, which is responsible for the metabolism of proteoglycans, is reduced in cows with RFM (Kankofer et al. 2000).

Changes in synthesis and metabolism of prostaglandins E and F are also associated with the process of detachment. Circulating concentrations of PGFM (13, 14-dihydro, 15-keto $PGF_{2\alpha}$, a stable metabolite of $PGF_{2\alpha}$) are higher and those of PGEM (a metabolite of PGE2) are lower in normal cows than in those with RFM (Wischral et al. 2001b). Placentomes from cows with RFM produce less $PGF_{2\alpha}$ and more PGE2 *in vitro* than do those from normal cows (Gross et al. 1987), and there is also interconversion of PGF to PGE in cows with RFM (Kankofer et al. 1994). Moreover, PGE secretion continues after parturition, as the retained membranes retain a degree of viability for some days (Eiler & Fecteau 2007). The PGF secretion in placental tissue from normal cows is responsive to stimulation by oxytocin, whereas that from animals with RFM is not (Slama et al. 1994). Deficiency of PGF synthesis is likely to be the consequence of a lack of maternal oestrogen synthesis, resulting in a failure of accumulation of prostaglandin precursors and arachidonic and linoleic acids in placental tissues (Wischral et al. 2001a, Wischral et al. 2001b).

Failure of oestrogen synthesis in the placenta is associated with inadequate placental or fetal antioxidant activity, in terms of peroxide damage to lipids, protein, and nucleic acids (Wischral et al. 2001b, Kankofer & Guz 2003, Gupta et al. 2005). It is probably for this reason that dietary deficiencies of antioxidants such as selenium and vitamin E predispose to RFM (Bourne et al. 2007). Excess PGE synthesis may be a response to maternal stress and oxidative injury or a response to infection (Wischral et al. 2001b, Herath et al. 2009a). As PGE is a potent immunosuppressive agent, PGE secretion may adversely affect the immunological environment of the postpartum uterus.

There is increasing evidence that the immune system plays a pivotal role in detachment of the membranes (Heuwieser & Grunert 1987, Peters & Laven 1996). Neutrophil, macrophage, and T lymphocyte invasion of the placenta occurs around the time of detachment, and there is evidence that deficiencies in the activities of each of these cells occurs in cows with RFM (Gunnink 1984, Kimura et al. 2002, Miyoshi et al. 2002). Cows with RFM also produce reduced quantities of the neutrophil attractant interleukin-8 (IL-8, also known as CXCL8) and other inflammatory mediators (Slama et al. 1993, Miyoshi et al. 2002, Davies et al. 2004). Moreover, in cows with RFM the activity of the neutrophil antiendotoxin protein, acyloxyacyl hydrolase, is reduced (Dosogne et al. 1999). This may put cows at greater risks from the effects of the endotoxin from bacteria that proliferate in the uterus postpartum. Finally, as leucocytes contribute to the collagenase activity of the parturient uterus, reduced leucocyte activity in cows with RFM may be a contributor to the reduction in collagen proteolysis in these animals.

The role of the cells of the immune system may be due in part to the role of MHC class I antigens in the process of placental detachment. It has been postulated that maternal recognition of fetal MHC antigens provides an initial trigger for placental separation because MHC class I compatibility between a cow and her fetus has been associated with an increased incidence of placental retention (Davies et al. 2004, Eiler & Fecteau 2007). It has been suggested that this indicates that alloreactivity to the fetal membranes by the dam is a significant event in the detachment of the placenta (Joosten et al. 1991).



• **Fig. 23.3** Uterine involution monitored in 24 dairy cattle, using transrectal ultrasonography to measure the diameter of the previously gravid and non-gravid uterine horns at the level of the attachment of the intercornual ligament (From Sheldon et al. 2003).

Uterine Involution

Involution is the term used to describe the physical reduction in size of the uterus and cervix after parturition (also see Chapter 7). Involution is thought to be driven by uterine muscular contractions, turnover of the extracellular matrix, necrosis and sloughing of the uterine caruncles, and regeneration of the endometrium (Gier & Marion 1968). Inserting a hand through the cervix is usually difficult in normal animals by 24 hours after parturition, and the cervix often only admits two fingers by 96 hours postpartum. By about 3 weeks postpartum, the entire genital tract is usually palpable per rectum. The previously gravid horn can still be identified because it is wider and longer than the previously non-gravid uterine horn. In parallel with the changes in dimensions, there is a remarkable change in the tissues, with catabolism, repair, and regeneration. In the first 30 days postpartum, the weight of the uterus decreases from about 9 kg at parturition to about 1 kg (Gier & Marion 1968).

The progress of uterine involution can be monitored by repeated estimation of the size of the uterus after parturition (Fig. 23.3). The most practical techniques to evaluate the size of the uterus are transrectal palpation and transrectal ultrasonography (Okano & Tomizuka 1987, Sheldon et al. 2000, Sheldon et al. 2003). It should be noted that dimensions estimated by transrectal palpation are often about 1 to 2 cm greater than ultrasound measurements, presumably because operators include the thickness of the rectal wall when using the former to estimate the diameter of the uterus. The size discrepancy between the previously gravid and non-gravid uterine horns is present up to 4 weeks postpartum (Okano & Tomizuka 1987, Tian & Noakes 1991b, Risco et al. 1994). However, the changes in uterine horn diameter are almost imperceptible beyond 4 weeks postpartum and are probably complete by 6 weeks.

The time to completion of uterine involution is often reported in the literature, but this endpoint is rarely used in clinical practice. On the other hand, factors that delay uterine involution are important in clinical practise because delayed involution of the uterus is associated with subsequent impaired fertility (Fonseca et al. 1983). The factors that delay involution include dystocia, hypocalcaemia, RFM, metritis, and endometritis.

VetBooks.ir

Regeneration of the Endometrium

The epithelium of the endometrium is often damaged during parturition, and inflammation, remodelling, and regeneration of the endometrium is part of the physiology of the postpartum period (Gier & Marion 1968, Wagner & Hansel 1969, Tian & Noakes 1991a). The caruncular tissue undergoes necrosis of the stratum compactum, and by 12 to 14 days postpartum the tissue sloughs as part of the physiological process of the puerperium (see Fig. 7.3). After the caruncular tissue is sloughed, there is reepithelialisation of the caruncles, advancing centripetally from the edges of the caruncle (Wagner & Hansel 1969). Loss of the epithelium is thought to be more likely in animals in which there has been damage during parturition or by microbial infection. As reepithelialisation progresses, the initially flattened epithelial cells develop their columnar appearance, typical of normal endometrium.

Neutrophils and lymphoid aggregates are common in the tissue during the repair of the endometrium, and they are likely to be part of the immune response to tissue damage and infection. Tissue repair is obviously important to counter the negative effects of trauma and as part of the healing process. Genes involved in extracellular matrix homoeostasis, such as the matrix metallopeptidases MMP1, MMP3, MMP9, and MMP13, are differentially regulated in cows with severe negative energy balance compared with more normal animals (Wathes et al. 2009). In most cows reepithelialisation of the caruncles and repair of the endometrial tissue to its normal architecture occur by about 20 to 30 days postpartum (Wagner & Hansel 1969, Archbald et al. 1972).

Return of Ovarian Cyclic Activity

The return of ovarian cyclic activity after parturition requires a coordinated programme of physiological events, involving the hypothalamus, pituitary, ovary, and uterus. Genetic and environmental factors influence these events, and often lead to subfertility; for details of return of ovarian cyclic activity consult Chapters 1 and 7. Briefly, during pregnancy there are high concentrations of oestradiol and progesterone in the peripheral circulation. Within a few days of parturition, the circulating steroid hormone concentrations decrease to basal values. About 7 days postpartum there is an increase in plasma FSH concentration, with subsequent recurrent increases in FSH concentrations every 7 to 10 days (Crowe et al. 1998, Duffy et al. 2000). The first postpartum dominant follicle, characterised by an internal diameter greater than 8 mm, is usually selected about 10 days after parturition. This dominant follicle may ovulate to form the first postpartum corpus luteum, or the dominant follicle may undergo atresia, with subsequent emergence of a second dominant follicle, or the dominant follicle may abnormally persist as a follicular cyst (Savio et al. 1990, Stagg et al. 1995, Beam & Butler 1997). The fate of the first postpartum dominant follicle depends on LH pulse frequency, and failure to ovulate is usually a consequence of inadequate LH pulse frequency and reduced ovarian follicle oestradiol (Beam & Butler 1999, Duffy et al. 2000, Cheong et al. 2016). In dairy cattle, metabolic stress – most often negative energy balance – is the main cause of reduced LH pulse frequency, although a range of other factors can affect ovarian cyclic activity (Cheong et al. 2016).

Of note when examining animals in the postpartum period is that the first dominant follicle is about twice as likely to be in the ovary contralateral to the previously gravid uterine horn. This imbalance in dominant follicle selection is still evident for the second dominant follicle, but the effect of the uterus on the distribution of ovarian dominant follicles is no longer evident beyond the third dominant follicle (Sheldon et al. 2000).

Control of Microbes in the Uterus

Understanding of which microbes are found in the female genital tract has changed markedly over the last 20 years. Previously, it was thought that the uterus was sterile during pregnancy, and that non-specific bacteria from the animal and the environment contaminated the uterus, during and after parturition. However, the uterus has a microbiota and is not sterile. Furthermore, although non-specific microbes from the environment contaminate the uterine lumen during and after parturition, specific microbes that are adapted to the endometrium are key to developing postpartum uterine disease. Outside the puerperium, other specific pathogens, such as *Salmonella* and *Campylobacter* species of bacteria and Infectious Bovine Rhinotracheitis and Bovine Virus Diarrhoea viruses, cause abortion, endometritis, and vaginitis (see Chapter 24).

It is widely accepted that most organs of animals, such as the gut, skin, and vagina, have a community of commensal, symbiotic, and pathogenical microorganisms – often termed the microbiota. There is emerging evidence that the uterus also has a microbiota and is not sterile. Studies using fluorescent probes to image bacteria and 16S ribosomal RNA gene sequencing of endometrium provide evidence that there is a sparse microbiota in the uterus even during pregnancy (Karstrup et al. 2017, Moore et al. 2017). The bacteria identified in these studies include *Trueperella, Fusobacteria* and *Prevotella* species. Although the finding of a microbiota in the uterus is important, the abundance of microbes in the uterine microbiota is substantially less than for the gut, skin, or vaginal microbiota. Furthermore, the abundance of bacteria in the uterine microbiota, outside the puerperium, is also a small fraction of those present in animals with postpartum uterine disease. Whereas many of the bacteria found in the postpartum uterus likely derive from the vagina, skin, gut, and the environment, it is possible that after parturition there is a bloom in the growth of pathogenical bacteria present in the uterus before parturition, which also help establish disease.

Pathogens in the Postpartum Uterus

Multiple species of bacteria are found in the postpartum uterus of cattle. However, as with most infections, disease depends on the balance among the microbes, the environment, and host defences. Most beef breeds and *Bos indicus* cattle are exposed to the same microbes as dairy cattle, yet clinical disease of the uterus is more common in dairy cows.

Postpartum uterine disease is principally associated with the isolation of pathogenical bacteria from the uterus. It is important to note that, unlike many specific clinical diseases, the metritis complex is polymicrobial rather than that found in other tissues in which there is often one-microbe-one-disease. Furthermore, an important concept is that all normal healthy animals have a substantial load of bacteria in the uterus after normal partition. As with many infections, the development of disease depends on the pathogens overcoming host defences. The microbial community in the uterus during the healthy or diseased postpartum period often fluctuates, with cycles of infection, elimination, and reinfection with bacteria. The bacteria most commonly isolated from animals with uterine disease are *Escherichia coli, Trueperella pyogenes, Fusobacterium necrophorum,* and *Prevotella* and *Bacteroides* species (Elliott et al. 1968, Griffin et al. 1974a, Huszenicza et al. 1991, Noakes et al. 1991). However, many additional species of

TABLE 23.1 Categorisation of bacteria isolated from the postpartum uterus of cattle, according to their potential pathogenicity *The categories are: (1) pathogens known to cause endometrial lesions; (2) potential uterine pathogens; and (3) bacteria not recognised as uterine pathogens that are likely contaminants of the uterine lumen*

Pathogens	Potential Pathogens	Contaminants
Escherichia coli	Acinetobacter spp.	Aerococcus viridans
Trueperella pyogenes	Bacillus licheniformis	Clostridium butyricum
Prevotella spp.	Enterococcus fecalis Haemophilus somnus	Clostridium perfringens
Fusobacterium necrophorum	Mannhiemia haemolytica	Corynebacterium spp.
Fusobacterium nucleatum	Pasteurella multocida	Enterobacter aerogenes
	Peptostreptococcus spp.	Klebsiella pneumoniae
	Staphylococcus aureus (coagulase +)	Micrococcus spp.
	Streptococcus uberis	Providencia rettgeri
	Bacteroidetes species	Providencia stuartii
	Firmicutes species	Proteus spp.
	Fusobacteria species	Proprionobacterium granulosa
		Staphylococcus species
		α-haemolyic Streptococci
		Streptococcus acidominimus

From Sheldon et al. 2002b.
Categories from: Elliott et al. 1968; Griffin et al. 1974a; Ruder et al. 1981; Olson et al. 1984; Huszenicza et al. 1991; Noakes et al. 1991; Dohmen et al. 2000; Sheldon et al. 2002b; Westermann et al. 2010.

bacteria are considered as pathogens, or potential pathogens, of the bovine uterus (Table 23.1).

The importance of pathogens for the postpartum uterus is supported by the ability to develop animal models of endometritis. The role of *E. coli* and *T. pyogenes* is highlighted by infusing *E. coli* and *T. pyogenes* into the uterus of naïve cows to create animal models of endometritis (Ayliffe & Noakes 1982, Amos et al. 2014). Infusion of both pathogens more reliably generates an animal model when using naïve heifers, but infusion of either pathogen also generates disease in cows, with often the second pathogen appearing in the uterine discharge within a week of starting the infusion of the first pathogen. When generating the animal model for endometritis, two additional features will help establish the model. The first is the use of exogenous progesterone, which may suppress immune defences. The second is that disease is more likely if the endometrium is gently debrided immediately before infusion of the bacterial suspension. Presumably, debridement of the surface of the epithelium disrupts the protective epithelium, allowing the pathogens to adhere and invade the underlying stroma.

The importance of specific pathogens causing metritis is also supported by reports of vaccines containing components of *E. coli, F. necrophorum,* and/or *T. pyogenes* that protect animals against metritis (Nolte et al. 2001, Machado et al. 2014). Some of the pathogens appear to be adapted to the endometrium or are specific to the bovine endometrium. For example, novel strains of *E. coli* have been isolated from the uterus of animals with uterine disease (Sheldon et al. 2010). These endometrial pathogenical *E. coli* (EnPEC) are more adherent and invasive for endometrial epithelial and stromal cells than *E. coli* isolated from the uterus of clinically unaffected animals; they stimulate endometrial inflammation, and they establish disease in animal models.

Trueperella pyogenes is the pathogen most associated with the severity of endometrial pathology and clinical disease (Bonnett et al. 1991a, Westermann et al. 2010). The link between *T. pyogenes* and disease probably depends on the cholesterol-dependent cytolysin and pyolysin secreted by *T. pyogenes.* Pyolysin causes cytolysis of a wide range of cells, but endometrial stromal cells are particularly sensitive to pyolysin (Amos et al. 2014, Preta et al. 2015). Pyolysin binds cholesterol-rich domains in the plasma membrane of endometrial cells to form pores in the plasma membrane, which lead to osmotic cell death (Amos et al. 2014, Preta et al. 2015). Endometrial stromal cells are probably particularly sensitive to pyolysin because they have abundant cholesterol. The stromal sensitivity to pyolysin may also explain how *T. pyogenes* switches from being a commensal bacterium in the uterus when the epithelium is intact to causing uterine pathology once the epithelium is breached during and after parturition, thereby allowing bacteria to access the stroma (Amos et al. 2014). Although pyolysin does not stimulate inflammatory responses, *T. pyogenes* does stimulate inflammation, presumably via endometrial cells recognising bacterial lipopeptides (Borges et al. 2012, Turner et al. 2014).

There is evidence for coinfections that foster disease. *T. pyogenes, F. necrophorum,* and *Prevotella* act synergistically to increase the likelihood and the severity of endometritis (Ruder et al. 1981, Olson et al. 1984). More recent studies, using aerobic and anaerobic cultures, confirm the importance of *E. coli, T. pyogenes,* and anaerobic bacteria (Dohmen et al. 2000, Sheldon et al. 2002b, Westermann et al. 2010). Interestingly, there is evidence for an association between *E. coli* and then colonisation by *T. pyogenes* (Williams et al. 2007).

Metagenomics techniques have found associations between uterine disease and bacteria that are not readily cultured by standard techniques (Machado et al. 2012, Santos & Bicalho 2012, Peng et al. 2013, Knudsen et al. 2015, Wagener et al. 2015). Although some of the studies find *E. coli, T. pyogenes* and the expected anaerobic bacteria, others report finding *Bacteroidetes* and *Firmicutes.* There remains a gap in understanding about how the latter 'unculturable' bacteria contribute to the pathogenesis of uterine disease. However, a consistent finding among most microbiology studies

• **Fig. 23.4** (A) Schematic 'reaction norm' of health status against pathogen load for two equally resilient groups of animals. The blue group has *impaired immunity,* with reduced health status and more pathogens, compared with the red group (Data from Raberg et al. 2007). (B) Two groups with similar immunity, but the red group is *less resilient,* with reduced health at the same pathogen load as the blue group (Raberg et al. 2007). (C) The reaction norm of postpartum uterine clinical health score (Sheldon et al. 2002b), against uterine bacterial load for dairy cows, in which a group of metabolically stressed cows producing more than 35 litres/day (x,*red line*; n = 56) were less resilient to infection than a group of animals producing less than 35 L milk/day (o, *blue line*; n = 34).

is that anaerobic bacteria are more abundant in the diseased endometrium than in healthy uteri. Perhaps this is not surprising, as the endometrium is a microaerophilic environment, with tissue damage likely reducing the oxygen tension further. Taken together, the evidence is that *E. coli, T. pyogenes,* and anaerobic bacteria are probably the main pathogens causing the clinical signs of uterine disease but that other pathogens may contribute to postpartum uterine disease.

Viruses and other microbes are rarely associated with nonspecific metritis or endometritis in cattle after parturition. One exception is Bovine Herpesvirus 4, which has been linked to sporadic cases or outbreaks of metritis or endometritis in dairy herds in several countries (Frazier et al. 2001, Monge et al. 2006). The link between Bovine Herpesvirus 4 and uterine disease may be explained by tropism of the virus for endometrial stromal cells and endometrial inflammation associated with viral infection (Donofrio et al. 2007).

Resilience to Infections

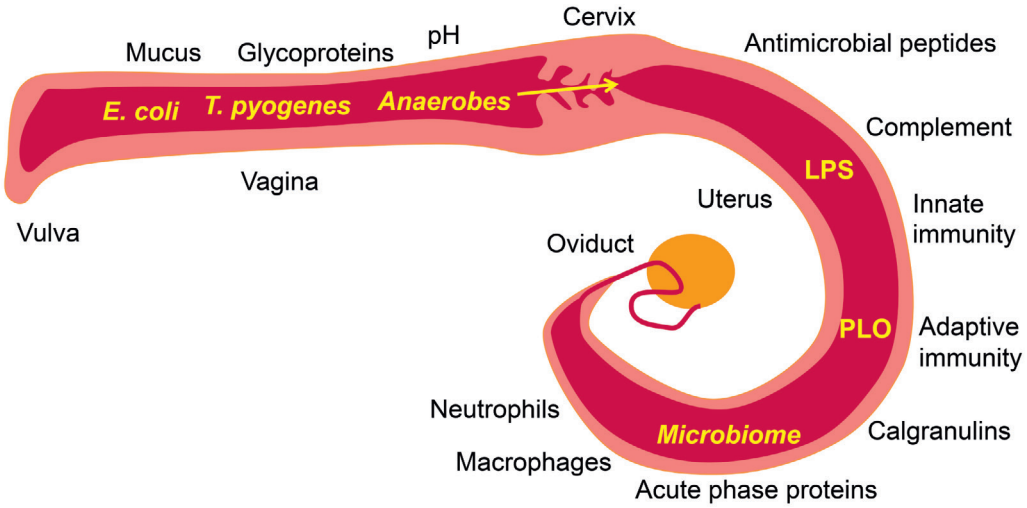
The ability to counter pathogenical microbes depends on an organism's *immunity* and *resilience* (Schneider & Ayres 2008, Medzhitov et al. 2012). *Immunity* is the ability to resist microbes and limit the pathogen burden by killing the microbes. *Resilience* is the ability to limit the effect of pathogens on health by tolerating a given microbial burden (Raberg et al. 2007). Failure of both immunity and resilience impair health. Much is known about immunity in the postpartum genital tract. However, resilience is increasingly thought to be important for maintaining animal health (Schneider & Ayres 2008, Medzhitov et al. 2012).

Fifty years ago, dairy cows tolerated the bloom of bacteria found in the uterus after parturition, and they did not develop disease. Now, 20% to 40% of cattle develop uterine disease each year (Sheldon et al. 2009) (see Fig. 23.2). This increased incidence of disease coincides with intensification of farming and breeding dairy cattle for increased milk yields over the last 50 years. Modern cows simply cannot consume enough food to meet the metabolic demand of producing more than 35 L milk/d. Typical metabolic energy requirements have risen from about 100 MJ/d to more than 240 MJ/d (Chagas et al. 2007, Kerestes et al. 2009). Consequently, these animals have reduced blood glucose, glutamine, and metabolic hormones (Doepel et al. 2006, Chagas et al. 2007). It is not clear if this increased postpartum uterine disease is a failure of immunity and/or resilience in cows. However, by comparing the health status of organisms with their pathogen load in populations, it is possible to disentangle the relative contributions of immunity (Fig. 23.4A) and resilience (see Fig. 23.4B) (Raberg et al. 2007). Data from a dairy herd of cows with similar genotype, in which milk production, uterine health, and bacterial load were recorded (Sheldon et al. 2002b), were used to determine whether the metabolic stress of high milk yields in early lactation perturbed uterine immunity or resilience. Postpartum cows under the metabolic stress of producing more than 35 litres milk/day had worse endometrial health with the same uterine bacterial load (see Fig. 23.4C), implying that metabolic stress perturbs uterine resilience. Thus factors that affect the resilience of the uterus are likely to be at least as important as immunity. However, it must be remembered that once pathogens overcome the mechanisms of resilience, then immunity and inflammation have a central role in the progression and the resolution of disease.

Physical barriers are an important feature allowing animals to tolerate pathogens (Fig. 23.5). The obvious anatomical barriers include the vulva, vagina, and cervix, which physically counter microbial infections ascending the reproductive tract to the uterus. However, during and after parturition, the vulva, vagina, and cervix are dilated, and so they are not effective barriers to ascending infections of the genital tract or iatrogenic contamination of the uterus with bacteria.

In humans, *Lactobacilli* species in the vaginal microbiota provide some protection against pathogens, probably by competing for nutrients and generating an acid environment (Ravel et al. 2011). However, the human is unusual in this respect, with cattle having a fraction of the lactobacilli of humans and a less acid vaginal environment (Miller et al. 2016). Whether manipulating the resident microflora of the vagina or the pH of the vagina to counter pathogens and limit uterine disease is in cattle is yet to be verified by clinical trials, but there is evidence

VetBooks.ir



• **Fig. 23.5** Outline of defence systems in the bovine female reproductive tract. (Modified from Sheldon IM. *Reproduction, Fertility, and Development.* 2015;27:72–81.)

that infusion of *Lactobacilli* into the vagina may have a beneficial effect (Deng et al. 2014).

Once pathogens enter the uterus, the ability to tolerate them is dependent on the resilience of the uterine tissues and cells. Most mucosal diseases develop after the epithelium is breached, allowing infection of the stroma. The endometrium is the mucosa of the uterus, and most of the pathology of uterine disease is in the stroma. The first line of defence is the physical barrier of the single columnar epithelium of the endometrium. The tight junctions between epithelial cells separate the apical and basolateral components of the endometrium, and this barrier counters microbial invasion from the uterine lumen. Epithelial cells are also more robust than stromal cells. For example, endometrial epithelial cells are more resistant than stromal cells to pore formation and cell death when exposed to *T. pyogenes* or the cholesterol-dependent cytolysin, pyolysin (Amos et al. 2014). This resilience of the epithelial cells may be because they contain less cholesterol in their plasma membrane than stromal cells. Indeed, reducing cellular cholesterol using methyl-beta-cyclodextrins protects stromal cells against pyolysin (Amos et al. 2014).

The mucus layer on the apical surface of epithelia provides an additional obstacle to microbes. The secretion and character of mucus in the genital tract is under the control of ovarian steroids, and during oestrus, mucus flow increases considerably. In contrast, the cervical mucus plug provides a physical barrier to ascending infections during gestation. The expression of MUC1 is induced when endometrial epithelial cells are treated with endotoxin from *E. coli* (Davies et al. 2008) and in cytobrush samples of the endometrial epithelium of cows with uterine disease (Kasimanickam et al. 2014). Lysozyme expression is also increased in the endometrium of cows with uterine inflammation, and lysozyme digests the peptidoglycans found in the cell walls of bacteria (Hoelker et al. 2012). Antimicrobial peptides and mucosal glycoproteins cover the mucosa of the vagina, cervix, and endometrium, where they also neutralise bacteria and prevent them reaching the plasma membrane of the epithelia. The principal cysteine-rich, cationic, antimicrobial peptides expressed in the bovine endometrium include β-defensins, lingual antimicrobial peptide (LAP), and tracheal antimicrobial peptide (TAP); several gene transcripts for antimicrobial peptides are more abundant in the face of microbial challenge (Davies et al. 2008, Chapwanya et al. 2009).

Although physical barriers and secreted proteins are important for resilience to microbes in the female genital tract, there are some caveats. First, microbes have evolved countermeasures and strategies to avoid many host defences. For example, some bacteria produce enzymes that lyse mucus to penetrate the protective layer, and many bacteria secrete proteases that can disrupt peptides and proteins produced by the host (Baxt et al. 2013). Second, immunity is principally responsible for initiating rapid inflammatory responses to resist microbial infections (Takeuchi & Akira 2010).

Resistance to Infections

Once pathogens overcome the resilience of the uterine tissue, innate immunity and adaptive immunity help resist infections by killing pathogens. Furthermore, much of the endometrial pathological change is a consequence of the inflammation associated with the immune response. Innate immunity is an immediate, non-specific defence system against pathogens, which does not depend on prior exposure to microbes. Adaptive immunity is dependent on antigen-specific receptors, and the response may take several days, depending on whether there has been prior exposure to the antigen. Several studies have examined the inflammatory response to infection in the endometrium. The expression of several cytokines and chemokines are increased in diseased endometrium, including IL1A, IL1B, IL6, CXCL8, CXCL5, TLR4, and PGES (Table 23.2) (Sheldon 2014). Animals with clinical endometritis also have higher concentrations of IL-1α, IL-1β, and IL-6 in uterine fluid than normal animals (Healy et al. 2014, Kim et al. 2014).

Innate Immunity

Innate immunity provides immediate non-specific defence responses against bacteria and tissue damage (Takeuchi & Akira 2010, Moresco et al. 2011). The result is uterine inflammation, influx of immune cells, changes in metabolism, induction of acute phase proteins, activation of the complement system, and other local defence

systems. The aim of these responses is to return the genital tract to a state of homoeostasis.

Acute phase proteins are synthesised in the liver, often in response to increased peripheral plasma concentrations of cytokines such as IL-6, and they have important functions in restoring homoeostasis after infection or tissue damage (Baumann & Gauldie 1994). These functions include haemostasis typified by the action of fibrinogen, antimicrobial effects, and the attraction and activation of phagocytes. The severity of bacterial contamination in the postpartum uterus is associated with the concentrations of acute phase proteins in peripheral plasma, including α_1-acid glycoprotein, haptoglobin, and ceruloplasmin, particularly in the presence of uterine infections with *E. coli* and *T. pyogenes* (Smith et al. 1998b, Sheldon et al. 2001). However, the acute phase response is not only initiated by infection but also by trauma (Baumann & Gauldie 1994). Indeed, parturition is a traumatic event, and as uterine involution progresses, there is a decrease in the concentrations of α_1-acid glycoprotein, haptoglobin, and ceruloplasmin (Sheldon et al. 2001). The local expression of genes encoding acute phase proteins has also been noted in the uterus and ovary, which may be of interest because they may provide further localised protection (Chapwanya et al. 2009, Fischer et al. 2010, Lecchi et al. 2012). However, it is possible that the more usual and more abundant hepatic production of acute phase proteins will be more relevant *in vivo.*

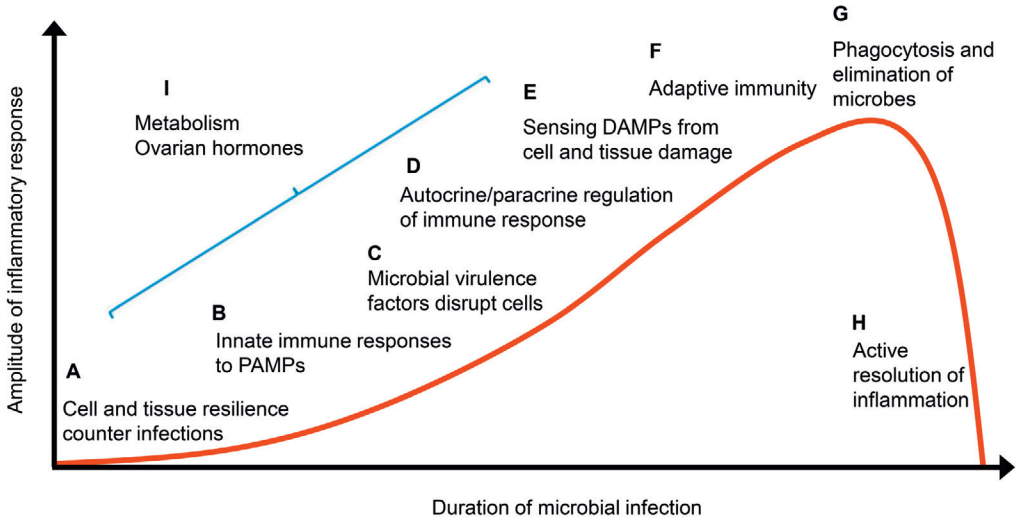
Antimicrobial S100 calgranulin proteins and cathelicidin are also more abundant in the endometrium of animals with uterine disease (Wathes et al. 2009, Swangchan-Uthai et al. 2013, Ledgard et al. 2015). The proteins are abundant in neutrophils and are associated with antimicrobial activity, attracting neutrophils to sites of inflammation and stimulating neutrophil activity.

Complement also provides defence against microbial infections. The complement system comprises about 20 proteins, which generate lytic complexes at the surface of pathogens and provide opsonins such as C1b and C3b, which interact with cell surface receptors to promote phagocytosis by neutrophils and macrophages. To avoid complement actions on tissue cells, the latter possess complement regulatory proteins such as CD46, CD55, and CD59 (Gasque 2004). Components of the complement system, such as the genes C1QA, C1QB, C1QC, C3, and C8, are differentially expressed in the endometrium of diseased postpartum cows with more severe negative energy balance (Wathes et al. 2009).

Although the proteins that counter microbes are important, much of the innate immune defence of the uterus depends on the detection of microbes by cellular–pattern recognition receptors. Host cells possess pattern recognition receptors that bind pathogen-associated molecular patterns (PAMPs). These PAMPs are usually highly conserved molecules found in prokaryotes, but not eukaryotes, and include lipopeptides, lipopolysaccharides, and microbial RNA and DNA molecules. The concept is that cellular receptors, such as Toll-like Receptors (TLRs) and NOD-like Receptors (NLRs), bind PAMPs (Takeuchi & Akira 2010, Moresco et al. 2011). For example, TLR2 on cells binds to bacterial lipopeptides, whereas TLR4 binds to endotoxin, which is the lipopolysaccharide cell-wall component of Gram-negative bacteria, such as *E. coli.* In general, the TLRs that sense bacteria are in the plasma membrane (TLR1, TLR2, TLR4, TLR5, and TLR6). Binding of PAMPs to TLRs activates intracellular signalling pathways that results in the production of inflammatory mediators IL-1β, IL-6, IL-8, and prostaglandin E_2. These inflammatory mediators attract and activate immune cells such as neutrophils and macrophages to clear the bacteria (Takeuchi & Akira 2010, Moresco et al. 2011). Other pattern recognition receptors are intracellular and principally detect microbes that invade cells. For example, the release of mature IL-1β is dependent on activation of the 'multiprotein inflammasome complex', often containing NLRP3 (nucleotide-binding domain and leucine rich repeat pyrin 3 domain), leading to caspase-1 activation to cleave pro-IL-1β to mature protein (Schroder & Tschopp 2010).

The receptors used by the innate immune system are principally expressed by hematopoietic cells such as macrophages, dendritic cells, and neutrophils (Takeuchi & Akira 2010, Moresco et al. 2011). However, bovine endometrial epithelial and stromal cells also express most TLR genes (Davies et al. 2008). Furthermore, these epithelial and stromal cells respond to bacteria, endotoxin, and lipopeptides, via TLR1, TLR2, TLR4, and TLR6, by secreting IL-1β, IL-6, IL-8, and prostaglandin E_2 (Herath et al. 2006, Cronin et al. 2012, Turner et al. 2014). Indeed, endotoxin switches endometrial epithelial cell prostaglandin secretion away from the

VetBooks.ir



• **Fig. 23.6** A schematic outline of the course of an infection (Sheldon et al. 2017). During an infection, microbes must first overcome the resilience of the endometrial tissue and cells (A). Sensing of PAMPs and vita-PAMPs leads to inflammation, with the secretion of cytokines such as IL-6 and chemokines such as IL-8 (B). The inflammatory response to PAMPs is further increased when host cells additionally sense microbial virulence factors (C), such as pore-forming toxins and bacterial secretion systems. The inflammation is scaled by autocrine and paracrine signalling (D), for example, via IL-6 receptor and STAT3 signalling to endometrial cells. Finally, cell damage and sensing of DAMPs also enhances the inflammatory response (E). Innate immunity also helps direct the adaptive immune response to infection (F). The consequences of inflammation include the immigration of phagocytes to help clear the microbes; phagocytes are attracted to the site of infection along a chemokine gradient and regulated by cytokines such as IL-6 (G). Once the microbes are controlled, there is active resolution of the inflammation and restoration of endometrial tissue homoeostasis (H). All these stages are modulated by hormones, particularly by the ovarian steroid hormones oestradiol and progesterone (I). (Modified from Sheldon, IM, Owens, SE, Turner, ML. *J Reprod Immuno* 2017;119:67–73.)

physiological F series to PGE, and this switch is not overcome by administering oxytocin to mimic the luteolytic signal (Herath et al. 2009a).

The inflammatory cytokines such as IL-6 bind their cognate receptors leading to increased permeability of vasculature and secretion of antimicrobial peptides, eicosanoids, and reactive oxygen species. Cytokines in the peripheral plasma drive systemic inflammatory responses distant to the site of infection; these include pyrexia, generalised vasodilation, and the release of acute phase proteins from hepatocytes. Chemokines such as IL-8 attract and activate neutrophils and monocytes to the site of infection. However, excessive inflammation leads to immunopathology or septic shock, and so innate immunity is carefully calibrated. A series of checks and balances are in place to scale inflammation to meet the level of microbial threat during the progression of an infection (Fig. 23.6) and to limit inflammation when infections are cleared (Blander & Sander 2012). One example in the bovine endometrium is the role of the intracellular signalling molecule STAT3 to regulate the secretion of IL-6 and IL-8 in stromal cells (Cronin et al. 2016). Another example is the apical secretion of IL-6 and IL-8 from bovine endometrial epithelial cells towards the invading pathogens in the uterine lumen and away from the underlying stromal cells (Healy et al. 2015).

Trauma to tissues associated with cell destruction by microbes or by physical damage during parturition may also contribute to inflammation of the endometrium. The ability of pattern recognition receptors to bind damage-associated molecular patterns (DAMPs) may provide an explanation linking tissue trauma to inflammation (Chen & Nunez 2010). Mammalian DAMPs include HMGB1, IL-1α, mitochondrial DNA, and ATP, which are released from dying or damaged cells (Chen & Nunez 2010). However, in the scaling of the inflammatory response, DAMPs are perceived as less of a threat than PAMPs (Blander & Sander 2012). Interestingly, innate immune responses may also be activated by cholesterol-dependent cytolysins or the ion fluxes that they induce (Gurcel et al. 2006, McNeela et al. 2010); this may be important for *T. pyogenes* infections because the bacteria secretes pyolysin, which forms pores in the plasma membrane of endometrial cells leading to leakage of potassium ions (Amos et al. 2014).

Innate immunity is an ancient evolutionary system, and so it is not surprising that it is integrated with other cellular homeostatic and metabolic pathways (Kotas & Medzhitov 2015). Dairy cattle are under metabolic stress after parturition, with reduced concentrations of nutrients and changes in metabolic hormones, including reduced abundance of glucose, glutamine, and insulin-like growth factor 1 (Chagas et al. 2007, Kerestes et al. 2009). Negative energy balance may impair the inflammatory response and clearance of bacteria from the endometrium, leading to chronic endometritis (Esposito et al. 2014). Certainly, the response to pathogen molecules is energetically expensive *in vivo* and *in vitro* (Turner et al. 2016, Kvidera et al. 2017). A striking example is that animals use more than 1 kg of glucose in the first 12 hours after challenge with endotoxin (Kvidera et al. 2017). Furthermore, the depletion of the key cellular nutrients, glucose or glutamine, reduces inflammatory responses by endometrial tissues *in vitro* (Turner et al. 2016, Noleto et al. 2017). If metabolic stress compromises the ability of animals to respond sufficiently to pathogens, the result may be persistence of infections and chronic inflammation.

VetBooks.ir

Neutrophils are the main innate immune cell-type found in the endometrium during the postpartum period. Uterine disease is associated with negative energy balance and reduced neutrophil function (Hammon et al. 2006, Galvao et al. 2010). Interestingly, the effects of metabolic stress and impaired neutrophil function are even evident before parturition (Hammon et al. 2006). Cows with a severe negative energy balance have persistent uterine inflammation, whereas animals with mild negative energy balance had recovered their energy balance and repaired their endometrium by 2 weeks after parturition (Wathes et al. 2009). Although uncommon, it is interesting to note that cows that are too fat at calving are also at risk of reduced neutrophil function and may develop endometritis (Zerbe et al. 2000). Metabolic status is often evaluated by monitoring body condition score during the postpartum period. An ideal body condition score profile has been proposed, with animals calving at score 3 to 3.5, using the 5-point body condition scoring scale (Chagas et al. 2007). It is important to minimise body condition score loss in the first 7 weeks postpartum to less than half a body condition score point.

Adaptive Immunity

Some microbes that infect the female genital tract, such as *Brucella abortus,* generate robust protective antibody responses, and effective vaccines are available. For postpartum uterine disease, the role of adaptive immunity in the endometrium is more implied than explicit. Areas rich in T cells and B cells are evident in the postpartum endometrium, often as lymphocytic foci within the stroma (Wagner & Hansel 1969, Bonnett et al. 1991b). Adaptive immune responses are also evident in postpartum animals, with increased abundance of antibodies (Dhaliwal et al. 2001). Furthermore, adaptive immunity may play a role in countering uterine infections as preliminary data on vaccines for metritis suggests they provide some protection against disease (Nolte et al. 2001, Machado et al. 2014). However, postpartum endometritis often occurs after successive calvings, and adaptive immunity does not appear to provide long-term protection.

Diseases of the Postpartum Uterus

Risk Factors for Uterine Disease

Uterine disease is most common in *Bos taurus* dairy breeds that have high milk yields, such as Holstein–Friesian cows. Genetic selection for milk yield is often associated with the increased incidence of uterine disease after parturition. However, genetic selection is increasingly focusing on health traits, and future genetic selection of dairy cattle is likely to reduce the risk of uterine disease. The heritability of metritis was reported to be 0.19 to 0.26 for primiparous and second lactation cows, respectively (Lin et al. 1989), although others have found lower heritability of 0.08 for metritis (Zwald et al. 2004).

The environment is an important determinant of susceptibility to several uterine diseases, and many risk factors have been associated with uterine disease. Indeed, environmental factors may be more important than genetic factors. For example, although some polymorphisms in genes associated with immunity have small effects on uterine health in dairy cows, environmental factors such as dystocia, parity, and ketosis are more predictive for uterine disease than the genetic markers evaluated so far (Pinedo et al. 2013). The environmental risk factors are associated with trauma to the female genital tract, disorders of metabolism, or problems with hygiene (Table 23.3).

Trauma

The environmental risk factors most likely to cause uterine disease are associated with tissue damage. Why trauma is important is not

TABLE 23.3 The environment and risk factors for uterine disease

VetBooks.ir

clear, but trauma may delay uterine involution, keep the cervix open, and allow bacteria to access the underlying stroma below the protective epithelium. Obvious causes of trauma include: dystocia, a large male calf, stillbirths, twins, first parity, and induction of parturition. However, RFM are the most important risk factor for uterine disease (Paisley et al. 1986, Kim & Kang 2003, Potter et al. 2010). The necrotic material associated with RFM provides a favourable environment for bacterial growth in the uterine lumen, and the retained membranes obstruct the physical barrier provided by the cervix, and delay uterine involution.

Hygiene

It is intuitive that the hygiene of the calving environment and the postpartum housing should be important for development of uterine disease. This might be reflected in the association between uterine disease and when or where cattle are housed, or the angle of the vulva that allows faecal contamination of the vagina. However, direct evidence for the importance of hygiene in the postpartum environment is limited, and some studies have found that the apparent level of hygiene is relatively unimportant (Noakes et al. 1991, Potter et al. 2010).

Metabolism

Uterine disease is associated with changes in metabolism after parturition or diseases that disrupt metabolism such as left displaced abomasum. Dairy cows are often under metabolic stress because they cannot consume enough food to meet the substantial extra demand for nutrients that are required for lactation. At the whole animal level the metabolisable energy required every day to produce 40 litres of milk is about 200 MJ, three times the 65 MJ needed for normal resting metabolism. Consequently, postpartum dairy cows lose weight as tissues are broken down to satisfy the dietary energy and protein deficits (Chagas et al. 2007). The animals also develop insulin resistance, resulting in reduced blood concentrations of insulin-like growth factor (IGF-1), glucose, and glutamine; in addition, the mobilisation of fat reserves increases the concentration of ketones such as acetoacetate and β-hydroxybutyrate (Doepel et al. 2006, Chagas et al. 2007, Wathes et al. 2011).

Metabolic stress in postpartum dairy cows may compromise their peripheral blood immune cell function (Cai et al. 1994, Hammon et al. 2006). Various defects in neutrophil function are reported in cows with diseases and disorders, including metritis, after parturition. For example, superoxide production and chemotaxis by neutrophils is lower before partition in cows that develop metritis than normal animals (Cai et al. 1994). Cows with metritis had lower neutrophil myeloperoxidase and cytochrome *c* reduction than cows with normal uterine health around the time of calving (Hammon et al. 2006). Cows that developed uterine disease also had a lower intracellular PMN glycogen level, which was associated with a greater degree of negative energy balance (Galvao et al. 2010).

Glucose and glutamine are the major carbon substrates used by most cells for metabolic energy. Cells demand even more metabolic energy and nutrient supply when immune responses are activated. Thus it is perhaps not surprising that deficits in glucose or glutamine blunt the inflammatory response in *ex vivo* experiments (Turner et al. 2016, Noleto et al. 2017). Limiting the availability of glucose to *ex vivo* organ cultures of endometrium reduces the secretion of IL-1β, IL-6, and IL-8 in response to endotoxin or lipopeptides (Turner et al. 2016). Similarly, depletion of glutamine, in the presence of abundant glucose, reduced the IL-1β, IL-6, and IL-8 response to endotoxin by at least 50% (Noleto et al. 2017). Effective innate immune responses in the endometrium depend on glucose availability, glycolysis, and glutamine abundance. As well as the dependence on the abundance of nutrients, hormones and intracellular regulatory pathways regulate cellular energy homoeostasis. The principal regulator of cellular energy is AMPK, which senses the ratio of AMP to ATP in the cytosol. A homeostatic level of AMPK activation fosters optimal inflammatory responses (Turner et al. 2016).

The effect of ovarian steroid hormones on postpartum uterine function is not clear. Progesterone is considered immunosuppressive, whereas oestradiol may enhance immunity and was used to treat uterine disease (Lewis 2003). However, there are conflicting data, and exogenous oestradiol infused into the bovine uterus during the postpartum period increased the abundance of bacteria in the uterus (Sheldon et al. 2004). Furthermore, the stage of the oestrous cycle, or exogenous progesterone or oestradiol, did not modulate innate immunity in *ex vivo* organ cultures of bovine endometrium (Saut et al. 2014). Similarly, treatment with oestradiol or progesterone, or inhibitors of oestradiol or progesterone nuclear receptors, did not affect gene or protein expression for IL-1β, IL-6, or IL-8 in endometrial cells or macrophages (Saut et al. 2014). Apart from ovarian steroid hormones, the metabolic hormones insulin and IGF-1 are obvious candidates that might link postpartum metabolic stress and immunity, as concentrations of IGF-1 are reduced, and animals are often insulin-resistant (Wathes et al. 2011, De Koster & Opsomer 2013).

When dairy cows mobilise adipose tissue to satisfy the negative energy balance of lactation, there is an increased peripheral plasma concentration of non-esterified fatty acids (Sordillo et al. 2009, Wathes et al. 2012). These fatty acids are metabolised in tissues to acetyl CoA to provide cellular energy, although excess fatty acid oxidation leads to increased production of ketones. During an immune response, tissue cells tend to further exploit fatty acid oxidation to supply nutrients, whereas immune cells exposed to pathogens often increase fatty acid synthesis as part of their inflammatory response (O'Neill et al. 2016). However, apart from cholesterol, there is limited information about the mechanistic dialogue between lipids and immunity in the bovine endometrium.

Most of the cholesterol in cells is contained within the plasma membrane, and the concentrations of this lipid are tightly regulated by cholesterol uptake, by cholesterol efflux transporters, and by cholesterol synthesis (Goldstein & Brown 1990). The first steps in cholesterol synthesis are encompassed by the mevalonate pathway, converting acetyl-CoA to isoprenoids, which are then converted to squalene and, ultimately, to cholesterol. Cholesterol is partially responsible for the fluidity of plasma membranes. Inhibition of squalene synthase can modulate innate immunity in the endometrium and reduce inflammatory responses to endotoxin (Healey et al. 2016). A discussion of the role of cholesterol in endometritis is incomplete without mentioning cellular resilience because many bacteria secrete pore-forming toxins that target cholesterol in plasma membranes. Reducing cellular cholesterol, using methyl-β-cyclodextrin or an endocytosis inhibitor, increases the resilience of stromal cells to PLO (Amos et al. 2014, Preta et al. 2015). Taking the observations together, reducing cellular cholesterol may limit inflammation but increase stromal cell resilience to pore-forming toxins.

Herd Size

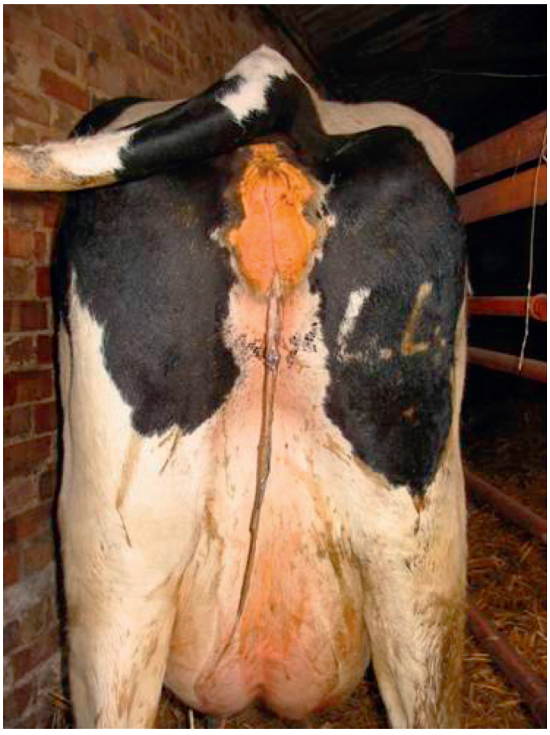
It is assumed that uterine disease is not a contagious disease. However, it is notable that larger herds tend to have more uterine disease, and disease is often more common in production systems

VetBooks.ir

in which animals are confined or managed as large groups. In addition, during experimental infections of naïve animals, disease often develops in the control animals that do not receive an intrauterine infusion of bacteria if they are not kept separate from the animals infused with bacteria.

Retained Fetal Membranes

Retained fetal membranes (RFM) are a common complication of bovine parturition. The predisposition to infections of the uterus means that RFM are an important contributor to bovine infertility. Occurrence of RFM (Fig. 23.7) is associated with the failure of the normal processes of dehiscence and expulsion. Hence the factors that cause RFM are those that interfere with the detachment of the fetal microvilli from the maternal cotyledons and those that interfere with the patterns of uterine contractility, particularly of third stage labour. The main aetiological factors associated with RFM are summarised in Table 23.4.



• **Fig. 23.7** Retained fetal membranes.

Anything that interferes with the process of maturation of the placentomes or causes birth to occur before maturation is complete can result in RFM. Premature birth is very commonly associated with retention. Cattle twins are usually slightly premature and so 30% to 50% of twin births are followed by retention. Premature removal of the calf by Caesarean section and induction of premature calving also cause retention (Gross et al. 1986). Likewise, heat stress can reduce gestation length and increase the incidence of retention of the afterbirth in dairy cattle. Cows that calved during the warm season in Georgia, US, where the mean daily temperature was 26°C, had a reduction of 2.8 days in gestation length and an incidence of retention of 24% compared with 12% for the remainder of the year (DuBois & Williams 1980). The gestation lengths for retaining cows were, on average, 5 days shorter than those of non-retaining cows.

Gross placentitis is also associated with retention of the membranes. Placentitis and RFM occur in cases of abortion due to *Brucella abortus, Salmonella dublin, Campylobacter fetus* and moulds such as *Aspergillus* or *Mucor* species, or genital infections around the time of parturition (Roberts 1986). Retention is also more likely to occur when many cows calve in the same accommodation in quick succession, leading to a buildup of more pathogenical contaminant organisms in the environment. Such outbreaks of retention have also been associated with metritis and calf scour (Roberts 1986). It has been suggested that *T. pyogenes* should only be considered causal of retention when there is evidence of a significant degree of placentitis (Laven & Peters 1996). When placentitis results in retention, it is due to inflammatory swelling of the caruncle and cotyledon, impaired endometrial secretory activity, and impaired myometrial contractility.

Retention also occurs when there is enlargement of the placentomes in the absence of placentitis. Such enlargement may occur in the presence of oedema of the chorionic villi, hyperaemia of the placentomes, advanced involution of the placentomes in postmature fetuses, and prepartum necrosis of the villous tips of the fetal placentome (Paisley et al. 1986, Laven & Peters 1996). These abnormalities may mechanically prevent the separation of fetal and maternal villi.

TABLE 23.4 Factors which predispose to retained fetal membranes

Abortion, especially when the cause is associated with placentitis	
Abnormal gestation length; either prolonged or shortened	
Dystocia, primary uterine inertia, delivery by Caesarean section	
Fatty liver, possibly because it predisposes to uterine atony	
Deficiencies of selenium/vitamin E or, possibly, vitamin A	
Failure of placental maturation	Twin births and induced-calvings are commonly associated with retention of fetal membranes, as the placenta had not completed the maturational changes that are required for normal separation. Heat stress, which often results in shortened gestations, can also result in increased incidences of retained fetal membranes.
Abnormalities of oestrogen; progesterone ratio in late gestation	
Secondary inertia caused by hypocalcaemia is weakly associated with RFM, which is probably because of the association of both with dystocia	

VetBooks.ir

Uterine inertia, particularly when it results in inadequate uterine contraction during the period of third stage labour, is variably associated with retention. Early studies associated impaired uterine contractility with retention, especially when secondary uterine inertia occurs as a result of dystocia (Jordan 1952, Venable & McDonald 1958). Not all studies agree with this view, however, although inertia may be associated with a retardation of delivery, the membranes have undergone normal maturation (Zerobin & Spörri 1972, Martin et al. 1981, Paisley et al. 1986). It is likely that few cases of retention are caused by uterine inertia and that, even when inertia occurs, detachment of the placenta is easily accomplished. On the other hand, dystocia and fetotomy are consistently associated with retention, to which inertia is likely to be a significant contributor (Wehrend et al. 2002, Eiler & Fecteau 2007). Uterine inertia caused by gross overstretching of the myometrium, such as in animals with hydrallantois, has been more definitely associated with retention (Arthur & Bee 1986), although the abnormalities of placenta and fetus in such animals suggest that other factors are likely to be involved. Uterine inertia due to hypocalcaemia has also been associated with retention (Arthur & Bee 1986, Gröhn et al. 1990, Wilde 2006). However, intervention studies, in which cows have been given calcium as a prophylactic or treatment for RFM, have generally not supported the view that hypocalcaemia has a critical role in the pathogenesis of the disease (Hernandez et al. 1999, Morton 2000, Melendez et al. 2003).

There is evidence of a higher incidence of RFM when cow diets are deficient in selenium and/or vitamin E (Trinder et al. 1973, Julien et al. 1976, Aréchiga et al. 1994, Allison & Laven 2000, Bourne et al. 2007). Correction of dietary deficiencies or supplementary feeding of selenium or vitamin E is commonly associated with a reduction of the incidence of retention (Wilde 2006). Nonetheless, some other studies found no reduction in RFM after prepartum supplementation with selenium (Gwazdauskas et al. 1979, Hidiroglou et al. 1987). Hence selenium deficiency may be a cause of a high incidence of RFM in certain deficient areas, but sporadic cases of retention are probably not associated with selenium deficiency.

Finally, a number of other factors have been associated with RFM. There is some evidence of a hereditary predisposition to RFM. Cows of the beef breeds are much less often affected than those of dairy breeds; in the latter the incidence is higher in Ayrshires than in Friesians. Old cows are more commonly affected than young ones. Springtime calving exerts a predisposing influence that might be connected with a vitamin A deficiency, which has been shown to produce retention under experimental conditions. Animals that have previously had RFM are more likely to do so again (Eiler & Fecteau 2007). The incidence of retention is higher in genetically high yielding dairy cows. In addition, cows on high nutritive planes at parturition are more prone to retention, as are cows with disorders of carbohydrate metabolism, such as fat cow syndrome, ketosis, or displaced abomasum, around the time of calving (Whitmore et al. 1974, Melendez et al. 2003).

Diagnosis and Incidence

Surveys of the incidence of RFM usually report an incidence of 4% to 8%, except in animals with dystocia, in which the incidence is higher. The effect of RFM depends largely upon the degree of uterine infection that takes place. Uncomplicated cases may be of little more consequence than the inconvenience of foul smelling membranes interfering with milking, although morbidity, as denoted by some temporary impairment of appetite and reduction of milk yield, has been estimated to occur in 55% to 65% of cases. In an important early investigation of the morbidity of RFM, it was observed that the pathogenicity of retention on appetite in 44 cattle (Palmer 1932) during the 14 days after calving resulted in appetite being good in 31.8%, fair in 54.5%, and poor in 13.6% of animals.

Mortality caused by RFM is usually associated with metritis and applies to 1% to 4% of cases (Roberts 1986). Cows with RFM that have calved spontaneously after a normal length of gestation generally depart little from normal health. On the other hand, when retention follows extensive obstetrical interference for dystocia, a severe metritis and toxaemia can supervene within 2 to 3 days, which can be fatal if untreated. Whether these cases can be directly attributed to the retention is, however, unclear because similar cases might have been equally ill if the fetal membranes had been expelled at the time of delivery. Clinical signs and treatment of metritis are discussed later in this chapter.

Duration of Retention

Cows that fail to expel the membranes within 24 hours or so are likely to retain them for 7 to 10 days. Myometrial contractions largely cease from 36 hours after the birth of the calf, so if the membranes have not been expelled by this time, freeing of the fetal villi from the maternal crypts eventually occurs as a result of bacterial putrefaction. This process starts within 24 hours of birth but takes several days to complete. Natural sloughing of the maternal caruncles also contributes to the subsequent dehiscence of the membranes, such that eventual expulsion of the membranes depends on uterine involution. The duration of retention seems to depend on several factors, such as the extent of the areas of attachment of the fetal membranes, the rate of uterine involution, the amount of uterine exudate, and the proportion of the afterbirth that had already passed through the cervix when retention began.

Effects on Fertility

RFM is not of itself associated with impaired subsequent fertility. This was first demonstrated by comparing the fertility of 44 cows with RFM, with 44 cows in the herd that had cleansed normally, finding that there was no significant difference in the subsequent breeding records of the two groups (Palmer 1932). A consensus has developed, which supports the idea that uncomplicated retention does not significantly affect the fertility of cows that are mated beyond 60 days from the last calving. The significance of retention is, therefore, dependent on the degree of metritis that occurs. This aspect of the condition was clarified by means of a retrospective analysis of 652 parturitions of 293 dairy cows in Canada, which revealed that RFM alone did not impair subsequent reproductive performance (Sandals et al. 1979). The animals that developed the metritis complex, with or without RFM, did, however, suffer significant increases in days open, services per conception, calving to first oestrus interval, and days from calving to first service. Various studies have confirmed these findings (Joosten et al. 1988, Borsberry & Dobson 1989, Esslemont & Peeler 1993, Kossaibati & Esslemont 1997, Morton 2000). The economic costs of a case of RFM have been estimated as GBP£300 to GBP£475 (Joosten et al. 1988, Kossaibati & Esslemont 1997).

Treatment and Prognosis

The treatment of animals with RFM has long been a contentious subject. A number of approaches have been taken to animals with this condition, including:

- No treatment;
- Manual removal;

VetBooks.ir

- Administration of ecbolic agents; and
- Treatment for metritis but no specific treatment of retention itself.

Manual Removal

The techniques used for manual removal of RFM range from externally applied gentle traction through to forced extraction, with manual separation of each cotyledon and caruncle. Manual removal is a superficially attractive method in that it immediately removes the stinking mass of putrefying afterbirth, thereby improving milking hygiene. However, manual removal may have little benefit or be detrimental for the animal. In a study that examined 501 cases of RFM, manual removal did not reduce the risk of metritis or endometritis and did not improve fertility compared with other treatments (Drillich et al. 2006b). The authors recommended that systemic treatment, based on elevated rectal temperature, was the optimal choice for treating RFM.

Forced extraction, once commonly practised, is now generally regarded as not advisable. An exception is when release of the membranes is simply impeded by constriction of the cervix or when there are only one or two remaining attachments to the maternal caruncles. Forced extractions of extensively attached fetal membranes can result in damage to the endometrium, and more distant parts of the membranes are often left behind (Grunert & Grunert 1990). If fetal cotyledons remain attached after forced traction, they may become detached later and could remain within the uterine lumen as foreign bodies (Roberts 1986). Similarly, the prevalence and severity of uterine infection are often worse after manual removal than after conservative treatment (Roberts 1986, Bolinder et al. 1988). Some suggest that the presence of pyrexia was an absolute contraindication to the forced removal of fetal membranes (Roberts 1986). Moreover, forced extraction is commonly associated with impaired subsequent reproductive performance (Bolinder et al. 1988).

The current recommendations for the manual removal of fetal membranes are that cows should not be examined until 96 hours after calving and that, if attempted, removal should be gentle, ideally limited to the withdrawal of the membranes from the genital tract after they have become spontaneously detached from the caruncles. Although in many animals, spontaneous detachment may have occurred within 96 hours, it is suggested that it is acceptable to leave membranes for 10 days before removal if this length of time was needed for their detachment (Roberts 1986). Even with minimal intervention, there appears to be no benefit from removal of the membranes (Laven & Peters 1996, Drillich et al. 2006b). In this context, farmers should also be discouraged from attempting to undertake forced removal of fetal membranes from their own cows because they are very likely to use too much force and to attempt removal too soon after calving.

Ecbolic Agents

Many attempts have been made to reduce the incidence of RFM or to hasten the release of the membranes once retention has occurred with ecbolic agents such as oxytocin or $PGF_{2\alpha}$. Oxytocin treatment has little or no beneficial effect (Miller & Lodge 1984, Garcia et al. 1992, Stevens & Dinsmore 1997) even when the uterus has been presensitised by the administration of oestrogenic substances (Arthur & Bee 1986). Similarly, a longer acting form of oxytocin, carbetocin, had no benefit for subsequent fertility when given to dairy cows immediately after parturition (Barrett et al. 2009). Prostaglandin $F_{2\alpha}$ and its analogues have also been used as ecbolic agents in postpartum cattle. Prostaglandins may assist in detachment of the membranes through direct actions upon the placentomes rather than just by an ecbolic action (Gross et al. 1986).

Treatment for Metritis Only

Uncomplicated cases of RFM require no immediate treatment. However, those cows with signs of metritis, such as pyrexia, inappetence, or reduced milk yield, need to be treated with antibiotic. A number of subsequent studies have confirmed that this is an appropriate treatment regimen (Drillich et al. 2006a, Drillich et al. 2006b). The use of parenteral antibiotic for the treatment of cows with metritis is discussed later.

Traditional practice has been that, after forced extraction of RFM or after unsuccessful attempts at extraction, antibiotics were placed into the uterus in an attempt to prevent endometritis. Intrauterine antibiotics reduce odour (Roberts 1986). However, antibiotics also reduce the rate of putrefaction of the membranes and the level of intrauterine phagocytosis, thereby prolonging retention (Paisley et al. 1986, Roberts 1986). Administration of intrauterine antibiotics to cows when they have retained membranes does not reduce the incidence of endometritis or improve fertility (Goshen & Shpigel 2006, Eiler & Fecteau 2007). Furthermore, some of the antibiotics that are present in intrauterine pessaries are inactivated in the presence of the debris that is contained within the uterus (Paisley et al. 1986), a problem that is often exacerbated by veterinarians failing to use the recommended dose. Hence there appears to be little to recommend the use of intrauterine antibiotics when retained membranes are present (Paisley et al. 1986, Goshen & Shpigel 2006, Beagley et al. 2010), although there are potential benefits for cows with metritis (Goshen & Shpigel 2006).

All cows that had RFM require examination and treatment for endometritis before breeding, ideally towards the end of the voluntary wait period (see Chapters 22 and 25). Diagnosis and treatment of endometritis is discussed later in the present chapter.

Collagenase

Infusion of collagenase solution into the stumps of the umbilical arteries of the retained membranes has proved an effective means of treatment (Eiler & Fecteau 2007, Beagley et al. 2010). Although not licensed for use in cattle, collagenase is used successfully to treat RFM in the mare (see Chapter 31).

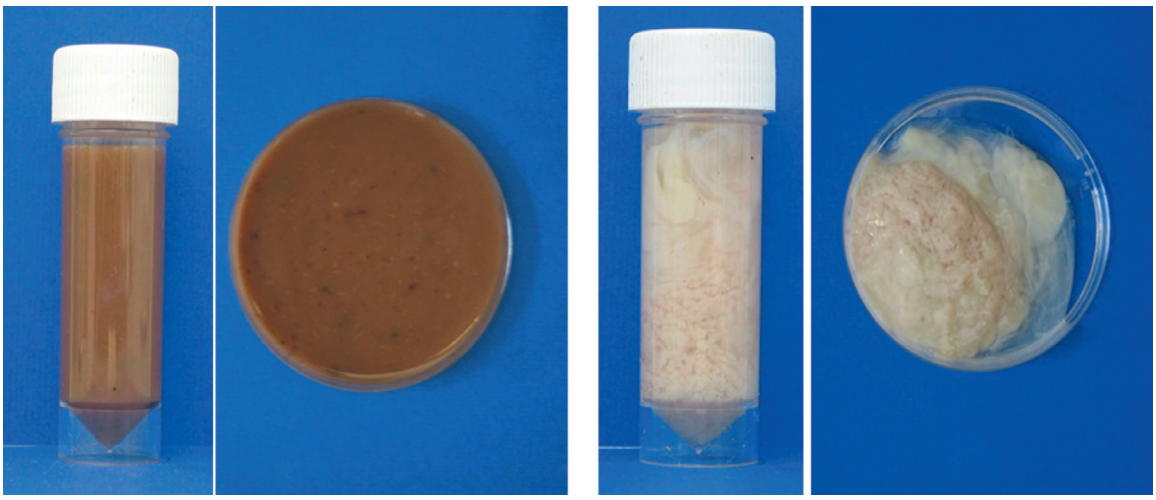
Metritis

Metritis usually follows an abnormal first or second stage of labour, especially when there has been a severe dystocia that has required prolonged traction or resulted in damage to the vulva and/or birth canal. The condition is also associated with uterine inertia, premature calving including abortion or induced calving, twin births, and RFM. Bacteria colonise and proliferate in the uterus and may cause pyaemia. Toxins produced by these bacteria are also absorbed from the uterus, resulting in toxaemia.

Diagnosis and Incidence

Metritis is more common in dairy and beef breeds of cattle and usually occurs within 10 days of parturition. Metritis is characterised by an enlarged uterus and a watery, red-brown fluid to viscous, off-white, purulent uterine discharge (Fig. 23.8), which often has a fetid odour. The severity of disease is categorised by the signs of health:

VetBooks.ir



• **Fig. 23.8** Animals with metritis have pus in the uterus that ranges from red-brown watery exudate that contains fragments of degenerating fetal membranes to off-white mucopurulent material.

- Grade 1 metritis: animals with an abnormally enlarged uterus and a purulent uterine discharge, but without any systemic signs of ill health;
- Grade 2 metritis: animals with an abnormally enlarged uterus and a purulent uterine discharge, with additional signs of systemic illness such as decreased milk yield, dullness, and fever; and
- Grade 3 metritis: sometimes called puerperal metritis or toxic metritis; animals with an abnormally enlarged uterus and a purulent uterine discharge, with signs of toxaemia such as inappetence, cold extremities, depression, and/or collapse.

Affected animals show both local and general symptoms, and the severity informs the metritis grade. The temperature of affected cows may be elevated to 40°C to 41°C initially but is often subnormal by the time veterinary attention is sought. Toxaemia or endotoxic shock result in clinical signs that may include: a fast pulse in the region of 100 beats per minute; rapid respiration; a sluggish capillary refill time; cold extremities; a moderate to severe level of dehydration; and a characteristic toxaemic diarrhoea. The vulva and vagina are typically swollen and deeply congested. The cotyledons are swollen and the fetal membranes often remain firmly attached. The uterus contains a large volume of pus; whereas off-white, mucopurulent material is often an encouraging sign, red-brown, watery, fetid, reddish, serous exudate that contains fragments of degenerating fetal membranes and other detritus warrants a more guarded prognosis (see Fig. 23.8). This fluid is discharged from the vagina accompanied by frequent expulsive straining efforts. Vaginal exploration of an affected case should be cautious, as it causes acute discomfort and is followed by severe and persistent expulsive efforts. Many animals with grade 3 metritis are recumbent by the time veterinary attention is sought, by which time they are usually anorexic. In these animals it is common for the infection to extend through the uterine wall into the peritoneum, causing a localised or generalised peritonitis. Many animals with grade 3 metritis also develop mastitis, particularly if they are recumbent, and many also have concurrent hypocalcaemia. The main differential diagnoses are: metabolic disorders; ruptured uterus; retained fetus; diffuse peritonitis; acute toxic mastitis; salmonellosis; and postcalving injuries (e.g., obturator paralysis).

The incidence of metritis varies between breed, country, and herd, but in a study of the records from 97,318 dairy cows in the US, the lactation incidence of metritis, including RFM, was 21% (Zwald et al. 2004). In a meta-analysis of records from more than 10,000 animals, there was evidence that postpartum metritis caused subfertility by increasing the time to first insemination by 7.2 days, reducing conception rate to first insemination by 20%, and increasing the calving to conception interval by 18.6 days (Fourichon et al. 2000). In some studies, metritis is also associated with reduced milk yields (Giuliodori et al. 2013).

Treatment and Prognosis

Grade 1 cases are often undiagnosed and untreated. Routine examination of postpartum cows is used in some herds to identify these animals. However, whether treatment is warranted is unclear. Parenteral antibiotic may help resolve the clinical signs but probably has little effect on health or subsequent fertility.

Grade 2 cases may require the parenteral administration of broad spectrum antibiotics, in combination with other supportive and symptomatic treatments, as appropriate to the severity of the condition. These grade 2 metritis cases warrant treatment, not least because metritis is painful (Stojkov et al. 2015). However, a review of 17 studies using ceftiofur to treat metritis found that although seven reported clinical improvement, there was no significant improvement in reproductive performance (Haimerl & Heuwieser 2014). Ampicillin trihydrate is also used to treat metritis. Ampicillin was at least as effective as ceftiofur in a study of 528 cows with metritis (Lima et al. 2014). If used, parenteral antibiotics should be continued for 3 to 5 days. Oestrogens are prohibited in many countries, and even when available, oestrogens are contraindicated as they increase the rate of absorption of endotoxin from the uterus. Oxytocin may be of some benefit, but only within 72 hours of calving. Prostaglandin $F_{2\alpha}$ is of little or no benefit despite a short-term ecbolic effect.

If the uterus contains an abundance of pus, uterine lavage and drainage can be attempted (Fig. 23.9). Physiological saline is flushed into the uterus using a wide-bore tube inserted through the cervix, with the end of the tube guarded by the operator's hand. Relatively small amounts of saline should be infused at a time as the uterus is too friable to cope with any buildup of pressure. The fluid is then syphoned from the uterus by lowering the tube and the process repeated several times. Although this procedure is commonly undertaken, it should be noted that it is associated with significant risks of uterine wall damage and toxin absorption as the uterine wall may be extremely friable. Intrauterine antibiotics are

VetBooks.ir

• **Fig. 23.9** Uterine lavage involves repeated cycles of infusing saline into the uterus (A), followed by syphoning the purulent suspension from the uterus (B).

inadequate as the sole route of antibiotic administration, although there may be some advantage to the infusion of soluble antibiotics, such as 5 g oxytetracycline in 100 to 500 mL normal saline, once uterine flushing is completed.

Even if animals are not treated, it is important to record the presence of disease because even grade 1 and 2 metritis cows should be examined for clinical endometritis 21 days or more after parturition.

Grade 3 cases of metritis are serious, and the prognosis should be guarded. Prognosis is poor if the animal is collapsed or if peritonitis is present. In this situation, before initiating treatment, a decision should be made whether the animal has a reasonable chance of recovery or whether it would be more cost effective, in some commercial production systems or from a welfare perspective, to slaughter the animal.

Treatment of grade 3 metritis requires both good nursing care and vigorous medication. As for most cases of sepsis, supporting the animal's physiology is probably more important than trying to kill the pathogens. The cow should be kept warm and made as comfortable as possible by, for example, transferring it to a well-bedded loose box. The animal should be fed and provided with water. The first step in treating these cases is to stabilise the circulatory system by giving fluids and non-steroidal antiinflammatory drugs (Smith 2005). Fluids can be given as 2.0 to 2.5 litres of 7% v/w saline intravenously followed by 25 litres of water administered by stomach tube, or 24 to 40 litres of isotonic electrolytes by stomach tube (Frazer 2005). Flunixin meglumine is probably the non-steroidal antiinflammatory drug of choice because of its antiendotoxic effects. Toxaemia is energetically expensive: animals use an extra kilogramme of glucose in the first 12 hours after an intravenous challenge with endotoxin (Kvidera et al. 2017). So, encouraging animals to eat and, perhaps, intravenous infusion of 500 mL of 50% glucose are beneficial for survival. Calcium should be given to treat or prevent secondary hypocalcaemia. Fetal membranes should not be removed, and vaginal examination should be very cautious. If the cow is continually straining, caudal epidural anaesthesia can be given, but this only gives transient relief for 1 to 2 hours. However, sometimes an epidural will break the cycle of pain and straining, which is often self-perpetuating and debilitating for the animal.

Parenteral antibiotic therapy should be initiated immediately, as for any cause of sepsis, and continued for 3 to 5 days. The choice of antibiotic remains contentious**,** and there are many arguments put forward in favour of one antibiotic over another, with little help from large scale clinical trials. Some favour bactericidal antibiotics to control systemic infection and pyaemia. Broad spectrum penicillins and cephalosporins are the most efficacious choices. Ceftiofur achieves concentrations in uterine tissue and fluid that exceed the minimum inhibitory concentration (MIC) for most of the common metritis pathogens (Drillich et al. 2006a) and appears to be effective in treating acute postpartum metritis (Chenault et al. 2004). In some studies there was also an improvement in subsequent fertility (Giuliodori et al. 2013). Some clinicians prefer bacteriostatic antibiotics as they limit the risk of further endotoxic damage during the killing of bacteria. Oxytetracycline has the advantage that it can be given at high dose intravenously, but the MIC of tetracycline for microbes causing intrauterine infections is often high**,** and sufficient concentrations of oxytetracycline are probably not attained in uterine tissue or the lumen (Smith et al. 1998a).

Recovery of animals with grade 3 metritis is marked by a return of appetite, cessation of diarrhoea, and a change in the contents of the uterus to a less fetid, thicker, more obviously purulent material. The major sequelae of this condition include localised or generalised peritonitis, ascending infection of the urinary tract

VetBooks.ir

(cystitis or pyelonephritis), pyosalpinx, and ovariobursal adhesions. Other complications of metritis include pneumonia, polyarthritis, and endocarditis. In pyaemic cases, abscesses may develop subsequently in the lungs, liver, kidney, or brain. The fertility of cows that recover from the condition is likely to be impaired, so animals should be monitored for subsequent endometritis and ovarian dysfunction.

Endometritis

Endometritis is a common condition of the cow. Unlike metritis, endometritis does not affect the general health of the cow, although it does impair fertility. Most of the specific pathogens causing infertility, such as *Campylobacter fetus* subsp. *venerealis* and *T. fetus,* do so because of the endometritis that they produce (see Chapter 24). However, the most common initiating cause of endometritis is a polymicrobial growth of bacteria in the uterus during the period around the time of calving, with subsequent overgrowth of pathogens such as *T. pyogenes,* usually in association with *F. necrophorum* and/or *Prevotella* species.

Clinical endometritis increases the interval to first insemination by 11 days and delays conception by 32 days, compared with animals that did not have endometritis (Borsberry & Dobson 1989). Cows with clinical endometritis between 20 and 33 days postpartum are 1.7 times more likely to be culled for reproductive failure than cows without endometritis (LeBlanc et al. 2002a).

Diagnosis and Incidence

Worldwide figures for the incidence of endometritis are varied, ranging from 35% to 45% in some studies, to other studies that report lower incidences of 6% to 10% (Fonseca et al. 1983, Andriamanga et al. 1984, Martinez & Thibier 1984, Borsberry & Dobson 1989). Typically**,** the incidence is 15% to 20% of animals. For example, a survey of 19,870 Holstein cows in Germany found a lactation incidence of 19.2% for endometritis (Gernand et al. 2012).

Clinical endometritis is characterised by the presence of a white or whitish yellow mucopurulent vaginal discharge in the postpartum cow; the condition is also known as leukorrhoea or whites. The volume of the discharge is variable but frequently increases at the time of oestrus, when the cervix dilates and there is copious vaginal mucus. Affected cows do not show signs of systemic illness. Subclinical endometritis is characterised by inflammation of the endometrium, typically associated with neutrophils in uterine luminal fluid, but without visible purulent material.

The presence of endometritis can be determined by transrectal palpation of the uterus, examination of the vagina and cervix for the presence of purulent discharge, and examination of cervical swabs for the presence of neutrophils. The risk of endometritis can also be inferred from a history of relevant aetiological factors in the peripartum period of individual cows.

Rectal palpation of animals with clinical endometritis frequently reveals delayed uterine involution, and a uterus that has a 'doughy' feel. There are correlations between the size and texture of uterus and cervix, the nature of the purulent exudates, and the degree of endometritis determined by biopsy, and the nature of the bacterial isolation (Studer & Morrow 1978). Nonetheless, rectal palpation is now regarded as being neither a sensitive nor a specific method for accurate diagnosis of endometritis as too many other factors interfere with the rate of change of size of the uterine horns over the postpartum period (de Boer et al. 2014). Hence reliance should not be placed upon this method as the primary means of diagnosis.

A simple grading system based on the character of the vaginal mucus is readily used to evaluate cows with clinical endometritis (Fig. 23.10A) (Sheldon & Noakes 1998, Sheldon et al. 2009). The endometritis grade correlates with the presence of pathogenical organisms associated with uterine disease (see Fig. 23.10B) and is prognostic for the likely outcome of treatment (see Fig. 23.10C).

The presence of purulent discharges can be diagnosed in a number of ways. Examination of the vagina with a clean gloved hand is simple, cheap, and effective, but some operators may cause discomfort to the cow. Although somewhat invasive, manual examination of the vagina carries little risk of further microbial contamination of the uterus in postpartum dairy cattle (Sheldon et al. 2002a). Manual examination of the vagina also facilitates collection of fluid from the vagina to evaluate the presence and odour of pus, which can be used to score the severity of disease and predict the likely success of treatment (Sheldon et al. 2006). Vaginal examination also allows the operator to detect damage to the wall of the vagina and cervix, indicative of obstetrical injuries, vaginitis, and cervicitis. However, as with any clinical examination, the evaluation of uterine disease is subjective, and there is interoperator and intraoperator variation (de Boer et al. 2014, Sannmann & Heuwieser 2015). Alternatively, a vaginoscope can be used to examine for the presence of discharge around the cervical os or in the cranial vagina. The most recently developed method is a rubber diaphragm on the end of a stainless steel rod (Metricheck), which is inserted into the vagina to collect a sample of discharges from the external cervical os/cranial vagina. This method is as effective as vaginoscopy but has the advantage of being quick and causing minimal discomfort to the cow. The Metricheck instrument and examples of purulent discharges collected during its use are shown in Fig. 23.11.

The absence of pus in the postpartum genital tract does not mean that the tract is normal and healthy. The importance of subclinical endometritis has emerged over the last 15 years, with the realisation that cytological evidence of inflammation of the endometrium is associated with reduced fertility (Kasimanickam et al. 2004, Gilbert et al. 2005). The cause of subclinical endometritis is not yet clear and may include resolving bacterial infections, immunopathology without pathogenical bacteria, or even aberrations of postpartum tissue regeneration and repair. Subclinical endometritis is characterised by inflammation of the endometrium that results in a significant reduction in reproductive performance in the absence of signs of clinical endometritis.

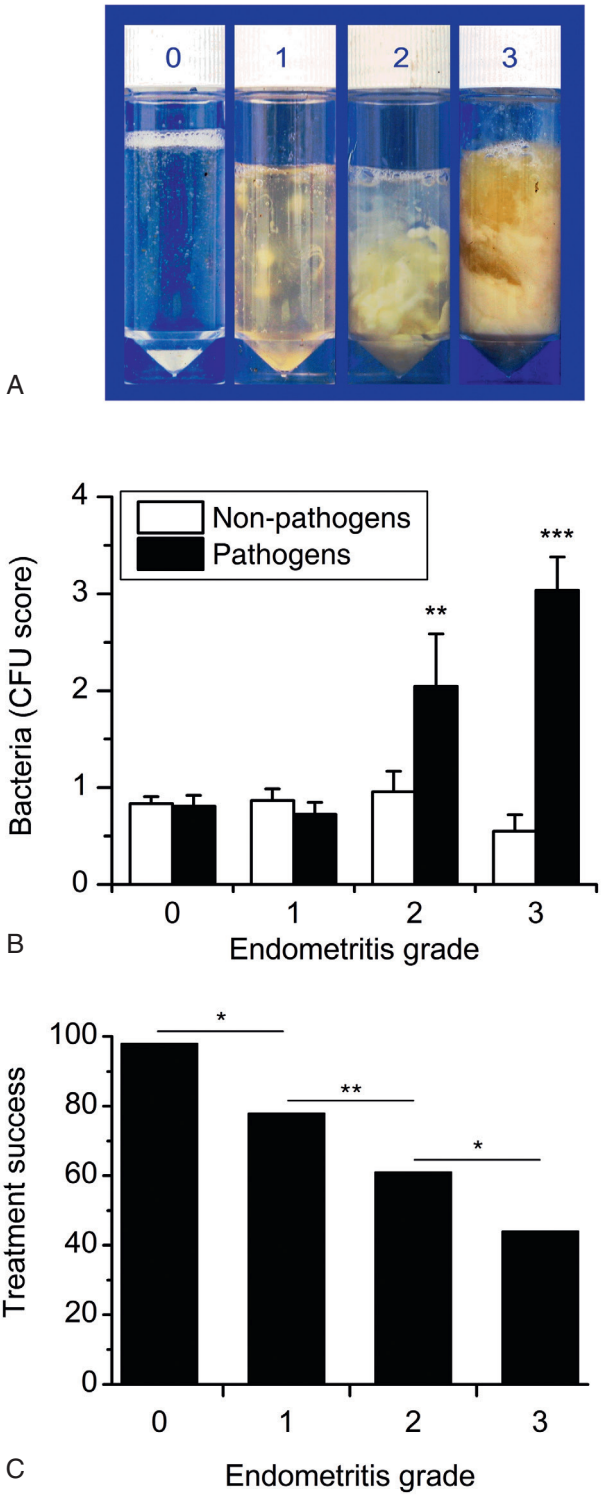
The Australian 'InCalf' survey of reproductive performance of dairy cattle (Morton 2000) identified a number of epidemiological factors that were associated with subfertility due to endometritis (Table 23.5). Identification of the cows in which these events occur allows them to be managed and/or treated appropriately before they are mated. The term 'at risk cows' has been proposed for these animals.

In the absence of a practical gold standard for the diagnosis of clinical endometritis, there is limited agreement among the diagnostic methods (de Boer et al. 2014). Beyond the clinical diagnosis, studies that use a reproductive outcome to determine the diagnostic criteria are most useful on farms.

Effects on Fertility

Endometritis reduces fertility by reducing the chances of conception. Consequently, there is an increase in the calving–conception interval, the number of services per pregnancy, and the proportion of cows that fail to conceive. Extension of the calving–conception

VetBooks.ir



• **Fig. 23.10** Grading scheme for clinical endometritis (Sheldon et al. 2009). (A) Vaginal mucus character is graded as 0 (clear or translucent mucus), 1 (mucus containing flecks of white or off-white pus), 2 (exudate containing < 50% white or off-white mucopurulent material), or 3 (exudate containing > 50% purulent material, usually white or yellow but occasionally sanguineous) (Sheldon et al. 2006). (B) Endometritis grades reflect the number of pathogenical (black bars) but not opportunist non-pathogenical (white bars) bacteria isolated from the uterus of cattle (Williams & Sheldon 2003); data are presented as semiquantitative scores of the number of colony-forming units (CFU) from uterine swabs, in which CFU is scored as 0 (no growth), 1 (< 10 CFUs), 2 (10–100 CFUs), 3 (101–500 CFUs), or 4 (> 500 CFUs). Values differ from endometritis grade 0 to **P < 0.01 to ***P < 0.001. (C) Endometritis grade is prognostic for treatment success (Sheldon & Noakes 1998); treatment success rates were determined as the percentage of animals (n = 300) with normal vaginal mucus 2 weeks after initial endometritis grading and treatment 21 to 28 days postpartum. Values differ between endometritis grades, *P < 0.05 and **P < 0.01. (From Sheldon IM, Cronin J, Goetze L, et al. *Biology of Reproduction.* 2009;81:1025–1032.)

interval has been shown to be an average of 12 days (Tennant & Peddicord 1968), 10 days (Bretzlaff et al. 1982), and 31 days (Borsberry & Dobson 1989). Endometritis also increased services per conception from 1.67 and 2.16 to 2.0 and 2.42, respectively (Tennant & Peddicord 1968, Bretzlaff et al. 1982). In two surveys, culling for failure to conceive was 14% and 21%, respectively, in cows with metritis compared with an average of 6% or 5% for unaffected animals (Tennant & Peddicord 1968, Bretzlaff et al. 1982).

The state of the uterus and its contents has been used as a prognostic indicator for cows with endometritis. For example, a significant correlation was found between the state of the uterus, as determined by rectal palpation, and the calving–conception interval, especially in relation to the amount of pus in the discharge (Studer & Morrow 1978). Similarly, observations of the nature of purulent vaginal discharges have also been used as a prognostic indicator. The presence of a purulent discharge and cervical diameter larger than 7.5 cm was also associated with impaired fertility (LeBlanc et al. 2002a). There tended to be an increasing impairment of fertility with increasingly purulent discharge. Mucopurulent discharge tended (P = 0.09) to increase time interval to pregnancy. In another study, purulent or foul discharge was consistently associated with a 20% reduction in pregnancy rate (Sheldon & Noakes 1998).

Endometritis therefore reduces the profitability of a dairy enterprise, and the cost can be calculated by relating it to the increase in the calving–conception interval. Losses are mainly due to an extended calving–conception interval, increased culling rates, reduced milk yield, and the cost of treatment (Kossaibati & Esslemont 1997). Most of these losses are preventable by instigating effective treatment of affected animals before the end of the voluntary wait period or start of the breeding season.

Treatment

Few aspects of theriogenology have attracted more debate than the treatment of endometritis. Two problems that impede the study of its treatment are: spontaneous 'self-cure', which has been estimated to be between 33% (Steffan et al. 1984) and 46% (Griffin et al. 1974a); and the variable criteria that have been used for its diagnosis before the setting out of agreed definitions (Sheldon et al. 2006).

There is, however, consensus on the following:

- There is little merit in performing routine swabbing and bacterial sensitivity tests before treatment.

TABLE 23.5 Factors associated with subfertility due to endometritis

Assisted calvings, especially when internal manipulation is required
Retained fetal membranes
Purulent vaginal discharges in the interval between calving and the start of mating
Premature calving (including twins, abortion); induction of calving before term has adverse effects on fertility in some, but not all studies
BUT NOT uncomplicated cases of hypocalcaemia

From Morton 2000.

- Intrauterine infusion of antiseptics is of limited value and, at worst, injurious to the uterus.
- Treatment should be delayed until at least 3 weeks postcalving (LeBlanc et al. 2002b).
- Rational therapy is based upon either hormonal stimulation of uterine defences or the use of antibiotics.

Stimulating Uterine Immunity

Three main methods have been used: (1) stimulation of oestrus with $PGF_{2\alpha}$ in animals that have an active corpus luteum (CL); (2) administration of low doses of oestradiol; and (3) stimulation of oestrus in animals that are anoestrous.

When there is a mature CL on the ovary, $PGF_{2\alpha}$ (or an analogue) is an effective means of treatment for clinical endometritis. Administration of $PGF_{2\alpha}$ causes luteolysis, thereby reducing progesterone concentrations and stimulating the return of oestrus. The cow will return to oestrus 3 to 5 days after treatment, often with a mild to moderate purulent vaginal discharge. It is preferable that animals should be treated before the end of the voluntary wait period, but if treatment has been delayed until after the start of the mating period, it is possible to serve or inseminate at the induced oestrus, unless the discharge is severe. Some cases of endometritis present with leukorrhoea when the cow is in oestrus; for these animals, $PGF_{2\alpha}$ may need to be given 7 to 10 days later when a responsive CL would be present. The response to $PGF_{2\alpha}$ treatment in terms of conception at the induced oestrus and final pregnancy rate is generally good (LeBlanc et al. 2002b) and markedly better than in untreated controls. Some have advocated intrauterine administration of $PGF_{2\alpha}$, but this appears to confer no particular advantages. Interestingly, pathogens switch prostaglandin secretion in the endometrium away from PGF towards PGE, which may also be why $PGF_{2\alpha}$ is a successful therapeutic (Herath et al. 2009a). Whether $PGF_{2\alpha}$ administration to cows without a CL is beneficial is not clear; in some cases there is a positive response but not in other cases (Steffan et al. 1984, LeBlanc et al. 2002b).

Historically, intramuscular injection of 3 to 5 mg of oestradiol benzoate to cows without a detectable CL has been used with some clinical success to treat endometritis (Sheldon & Noakes 1998), although fertility was not improved. The rationale for the use of oestrogens is that they increase uterine blood flow and stimulate the immune system, as occurs during oestrus. The withdrawal in the European Union of licensing for the use of oestrogens in food-producing animals means that this treatment is no longer legal in animals that are to supply milk or meat to those countries. High

VetBooks.ir

doses of oestrogens are contraindicated as they result in long-term down regulation of the hypothalamic–pituitary axis, resulting in anoestrus and ovarian cysts.

In animals without a CL, it is theoretically possible to induce oestrus with intravaginal progesterone-releasing inserts, but this practice is not recommended as many carry a contraindication for use in animals with vaginal or uterine infection. Induction of oestrus with gonadotrophin-releasing hormone (GnRH) has also been advocated as a means of treating endometritis in acyclic cows, although this is seldom undertaken now. With the use of ovsynch programmes for fixed time AI (see Chapters 8 and 27), many postpartum animals are inadvertently treated for endometritis as part of routine reproductive programmes in many dairy herds. However, studies suggest that ovsynch programmes have little benefit for the treatment of endometritis, and endometritis did not affect the outcome of ovsynch (Hendricks et al. 2006, Kasimanickam et al. 2006).

Antibiotics

A wide range of antimicrobial agents has been used in the treatment of endometritis. Although parenteral antibiotic treatment is needed for metritis, it is generally considered to be preferable to treat endometritis via the intrauterine route. Provided an adequate dose of antibiotic is used, this will result in effective MICs reaching the endometrium and being established in the intraluminal secretions. The latter point is important for the effective treatment of the disease because subtherapeutic dose rates are frequently used. In organic herds, antibiotics are not often permitted, and so mild antiseptics may be used, such as 2% povidone iodine or a hibitane solution (Mido et al. 2016). Some clear principles underlie the choice of antimicrobial and/or antiseptic agents:

- It must be effective against the wide range of aerobic and anaerobic, Gram-positive and Gram-negative bacteria that are present.
- It must be effective within the microaerophilic environment of the uterus.
- Whether an effective bactericidal or bacteriostatic concentration can be achieved at the site of infection by the intrauterine route of administration. When the intrauterine route is used, the substance must be evenly and rapidly distributed throughout the uterine lumen with good penetration into the deeper layers of the endometrium.
- It must not inhibit natural uterine defence mechanisms, particularly the cellular component.
- It must not traumatise the endometrium. Several of the vehicles used in the formulation of pharmaceutical preparations can damage the endometrium. Examples include propylene glycol, which can cause a necrotising endometritis; oils, which can cause granulomata; and chalky bases, which can cause irritation and blockage of endometrial glands.
- Treatment must not reduce fertility by producing irreversible changes in the reproductive system.
- Treatment must be cost effective by enhancing fertility.
- Details of its absorption from the uterus and excretion in the milk must be known, so that appropriate withdrawal times can be followed.

In consequence, several antibiotics are inappropriate. Nitrofurazone is irritant and has an adverse effect on fertility. Aminoglycosides are not effective in the predominantly anaerobic environment of the infected uterus. Field trials have also provided evidence for a lack of effectiveness of these drugs in the treatment of endometritis. Sulphonamides are ineffective because of the presence of paraaminobenzoic acid metabolites in the lumen of the infected uterus. Penicillins are susceptible to degradation by the large numbers of penicillinase-producing bacteria that are present in the diseased uterus.

Antibiotics that have been formulated for intrauterine use include oxytetracycline as an intrauterine infusion or in the form of pessaries and cephapirin as an infusion. Parenteral oxytetracycline penetrates the uterine wall and lumen (Ayliffe & Noakes 1978), but the MIC for many organisms is higher than can be achieved practically (Sheldon et al. 2010). Intrauterine oxytetracycline does not penetrate the wall of the uterus well, is not particularly effective against *T. pyogenes,* and can have a direct irritant effect upon the endometrium (Cohen et al. 1995). The main role for tetracycline is therefore as a prophylactic intrauterine antibiotic after assisted calvings. However, cephapirin has been widely studied as an intrauterine treatment for endometritis with positive results (LeBlanc et al. 2002b, Kasimanickam et al. 2005).

Prostaglandin $F_{2\alpha}$ Versus Intrauterine Antibiotics

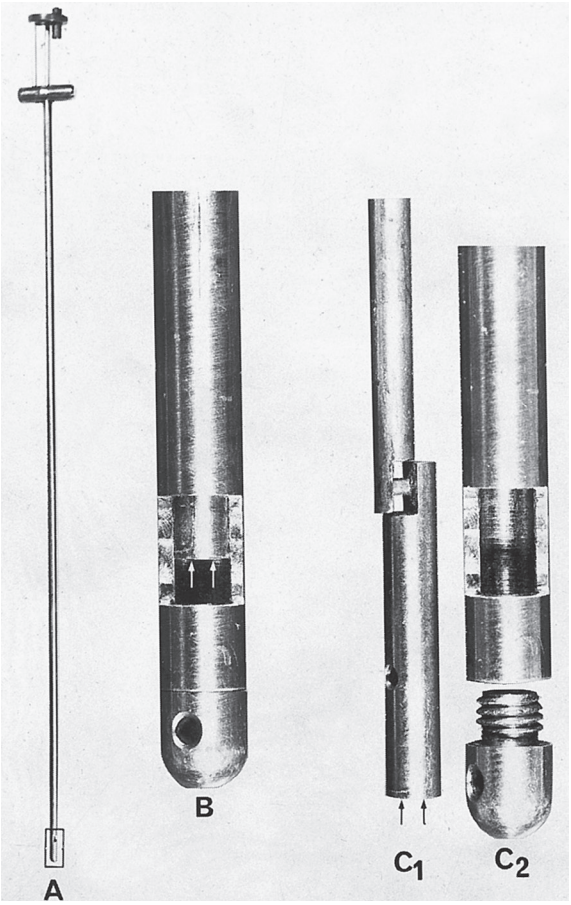
A comparison was made of the effectiveness of intrauterine infusion of 1500 mg oxytetracycline hydrochloride with intramuscular injection of the $PGF_{2\alpha}$ analogue cloprostenol or 3 mg estradiol benzoate as treatments for endometritis (Sheldon & Noakes 1998). It was concluded that, provided a CL was present, $PGF_{2\alpha}$ was the most successful treatment, both in terms of cure rate and calving to conception interval (Sheldon & Noakes 1998). Oxytetracycline was more effective than oestradiol but marginally less so than $PGF_{2\alpha}$. Similar results were found comparing a commercial antibiotic preparation with $PGF_{2\alpha}$ and oestradiol (Pepper & Dobson 1987). In another study the effect of intrauterine cephapirin on fertility of cows with endometritis was better than for a prostaglandin analogue if animals were unselected for the presence of a CL; but when cows with a CL were treated with PGF, the results of the cephapirin and prostaglandin treatments were similar (LeBlanc et al. 2002b). In the majority of the foregoing treatments the severity of the case adversely affected the cure rate. Thus the severity of endometritis should be recorded at the time of treatment and should be used for selecting animals for reexamination, and for prognosis (see Fig. 23.10C).

Subclinical Endometritis

Uterine biopsy has been used to study both the incidence of clinical and subclinical endometritis. Biopsies can be collected using a range of specialised instruments for endometrial biopsy, such as that shown in Fig. 23.12, or by using balloon biopsy forceps. Uterine biopsies collected from infertile cows reveals that many have subclinical endometritis. For example, a study in 1971 reported that 77% of infertile cows had endometritis: bacterial infection was found in 64% of these cows and 80% had lesions of endometritis evident in biopsies (Sagartz & Hardenbrook 1971). Likewise, another study showed that 50% of the genital tracts obtained from an abattoir showed histological evidence of endometritis, yet only 12.5% showed gross lesions (Hartigan et al. 1972). Hence the evidence from such biopsy studies is that many cases of endometritis are subclinical with no purulent discharge evident.

Although histological analysis of endometrial biopsies had previously shown endometrial inflammation in the absence of clinical signs, the importance of subclinical endometritis was first demonstrated in field studies by collecting samples from the surface of the endometrium using a cytobrush or uterine lavage (Kasimanickam et al. 2004, Gilbert et al. 2005). These studies found that the presence of polymorphonuclear neutrophils (PMNs) in smears

VetBooks.ir



• **Fig. 23.12** Uterine biopsy instrument (Hartigan et al. 1974). (A) Whole instrument showing window with cutting edge. (B) Close-up with edge partially withdrawn (*arrow*). Close-up views (C1, C2) show the cutting edge (*arrow*) and interchangeable tip (C2).

made from the endometrial samples was associated with reduced pregnancy rates. Consequently, subclinical disease is defined by the proportion of PMNs exceeding operator-defined thresholds, usually about 5% of cells in samples collected by flushing the uterine lumen or by endometrial cytobrush, in the absence of clinical endometritis, about 35 to 40 days postpartum (Sheldon et al. 2006, de Boer et al. 2014). In addition, if the cytology samples are analysed for gene expression, there is typically increased expression of inflammatory mediators (Gabler et al. 2009, Fischer et al. 2010, Gabler et al. 2010, Ghasemi et al. 2012).

Diagnosis

The cytobrush technique typically uses a cytobrush used for human cervical cytology that is screwed into a metal rod (Fig. 23.13), which is then protected by a plastic sheath, and inserted through the cervix using a method similar to artificial insemination. The brush is extruded and rolled along the endometrium in the body or horns of the uterus (Bogado Pascottini et al. 2016). After removing the instrument from the animal, a cytology smear is prepared on a glass slide. Alternatively, the uterine flush technique uses approximately 20 mL of sterile saline infused into the uterus through a catheter; the uterus is massaged, and the fluid aspirated via the same catheter (Gilbert et al. 2005). The suspension is then used to prepare a cytology smear on a glass slide, usually using a specialised centrifuge instrument designed to deposit cells evenly onto a glass slide, such as a cytospin machine. The slides are stained, and using a light microscope, the glass slides are examined, with 100 to 400 cells counted and the proportion of PMNs recorded. It is now suggested that counting 300 cells provides optimal reproducibility among observers (Melcher et al. 2014).

There is much debate about the proportion of PMNs that indicate the presence of subclinical endometritis, and the criteria differ with the time after parturition and vary among farms and operators (Sheldon et al. 2006, Melcher et al. 2014, Wagener et al. 2017). Criteria for the diagnosis of subclinical endometritis were proposed for different stages postpartum based upon the proportion of neutrophils present in cytology samples from cervical swabs (Table 23.6). For large herds it is possible to generate a farm-specific cut-off point for diagnosis of subclinical endometritis that compromises fertility. However, beyond 50 days postpartum the presence of any PMNs in cytology samples is now often regarded as abnormal. Interestingly, cytology does not always correlate well with endometrial biopsy (Westermann et al. 2010, Bogado Pascottini et al. 2016). However, both techniques are not practical for commercial dairy farms, and so alternatives are being sought to provide a cow-side test.

There remain many open questions about subclinical endometritis. This may partly be because inflammation is part of the normal repair process of the tissues during the puerperium, as well as infection also stimulating the accumulation of neutrophils in the uterus. The inflammation may also be associated with recovery of the tissues after metritis and clinical endometritis, trauma, or other non-microbial disease. In one study of 528 animals, more animals with metritis subsequently showed evidence of subclinical endometritis than animals without metritis (Lima et al. 2014). However, it is not clear whether subclinical endometritis is absolutely dependent on the presence of pathogens or may reflect dysregulation of the innate immune response even in the absence of pathogens.

Treatment

Current ideas for treating subclinical endometritis were reviewed recently (Wagener et al. 2017). Unfortunately, there is little agreement about whether or how animals with subclinical endometritis should be treated. On the basis that physiological mechanisms usually aim to restore homoeostasis, the most rational treatment for subclinical endometritis is to administer $PGF_{2\alpha}$ (or analogue) to animals with a CL. Other suggestions are the intrauterine infusion of antimicrobials or antiseptics or to flush the uterus as if performing an embryo collection.

Pyometra

Pyometra is defined as a progressive accumulation of purulent material within the uterus in the presence of an active CL (Sheldon et al. 2006). The condition occurs most commonly when uterine infection is not eliminated during the first follicular phase, and the resulting inflammation means that the uterus ceases to produce PGF. Consequently, the life span of the CL is prolonged. In most cases, pyometra occurs as a sequel to endometritis during the postpartum period. Venereal infections that cause embryonic death (notably *T. fetus*) can predispose to a high incidence of pyometra in an infected herd after mating, although occasional cases also occur after fetal death, maceration, and superinfection with *T. pyogenes.*

Diagnosis

Cows that suffer from pyometra show few or no signs of ill health. Hence the disease is generally discovered**:** (1) when affected cows

VetBooks.ir

are examined for the absence of cyclical activity; or (2) at the time of pregnancy diagnosis in a cow that was thought, on the basis of non-return to oestrus, to be pregnant. Because the cervix remains closed, the purulent exudate accumulates within the uterine lumen, although occasionally there is a slight or intermittent purulent discharge. The uterine horns are enlarged and distended (Fig. 23.14), quite often to an unequal degree, owing to incomplete involution of the previously gravid horn or to recent conceptus death. Differentiation of pyometra from a normal pregnancy can sometimes be difficult, but there are a number of distinguishing points:

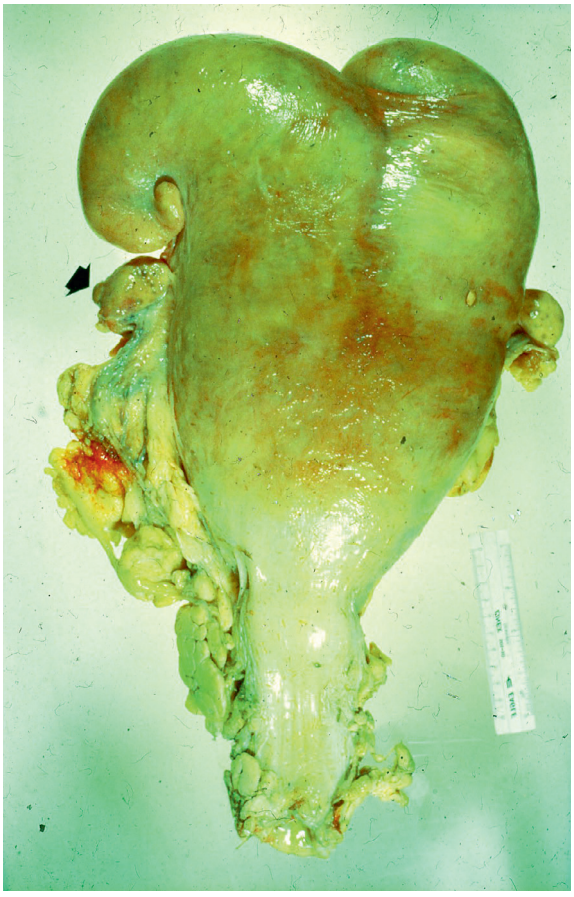
- The uterine wall is thicker than at pregnancy.
- The uterus has a more 'doughy' and less vibrant feel.
- It is not possible to slip the allantochorion (see Chapter 5).
- In some cases of pyometra, no uterine caruncles can be palpated. However, when the infection occurred in a non-involuted uterus, involution of the caruncles is delayed, and they may remain palpable for quite a long time.
- Transrectal ultrasonography will demonstrate the absence of a fetus and the presence of a speckled echotexture of the uterine contents compared with the black anechoic appearance of normal fetal fluids.

If there is any doubt about the differentiation between pyometra and pregnancy, the cow should be left untreated and reexamined later for evidence of change. Pyometra associated with *T. fetus* infection presents features that are different from those previously described. Uterine pus is, as a rule, much more copious and may attain a volume of many litres, and the uterus undergoes much greater distension than postpartum pyometra; the uterine pus is often fluid and is greyish-white or white. The mucus occupying the cervix is moist and slippery rather than sticky and tenacious, and motile trichomonads can generally be found in it.

Treatment

When the presence of pyometra is discovered at the time of pregnancy diagnosis, the decision is often made to cull the cow at the end of the current lactation. Treatment, if undertaken, is with $PGF_{2\alpha}$, which results in regression of the CL, dilation of the cervix, expulsion of the purulent fluid, and oestrus 3 to 5 days later. Provided that the condition is not too long standing and therapy is instituted quickly, there is a reasonable possibility that the cow will eventually conceive again. However, long-standing cases are associated with more severe degeneration of the endometrium, reducing the chances of subsequent conception. There may be advantages to the use of intrauterine cephapirin in conjunction with $PGF_{2\alpha}$ (or analogue), and multiple treatments at 11 to 14 day intervals may salvage animals for future breeding.

VetBooks.ir



• **Fig. 23.14** Uterus with pyometra, with evidence of a CL (*arrow*) with distended uterine horns.

Cervicitis and Vaginitis

Cervicitis and vaginitis may be caused by trauma during parturition or during obstetrical manipulation. Tearing of the cervix, vagina, and vulva are often self-evident during and after parturition. If these tears become infected, they can cause considerable swelling and pain, and animals often strain frequently. Treatment for vaginitis is usually symptomatic with emollient creams applied to the injured tissues and parenteral and/or local antibiotics.

Purulent vaginal discharge 21 days or more postpartum may indicate cervicitis or vaginitis rather than clinical endometritis. In some cases, purulent vaginal discharge may be associated with both vaginitis and endometritis; in other cases purulent vaginal discharge may represent vaginitis or cervicitis rather than endometritis (Denis-Robichaud & Dubuc 2015). It is thought that cervicitis, 21 days or more postpartum, is associated most often with prior obstetrical trauma and/or RFM. Cervicitis was diagnosed in 61% of animals in a study of 416 cows examined at 42 to 50 days postpartum (Hartmann et al. 2016). Cervicitis can affect fertility, with fewer animals pregnant by 300 days in milk (Deguillaume et al. 2012). Treatment of purulent vaginal discharge that is caused by cervicitis alone is often symptomatic, and so most of these animals are treated as if they had clinical endometritis.

Effect of Uterine Disease on Ovarian Function

Pathological changes in the endometrium during uterine disease are likely to be detrimental to fertilisation and conception. However, postpartum uterine infections also impair fertility after resolution of the clinical disease (Borsberry & Dobson 1989). Thus one must consider if uterine infections impair the oviduct, ovary, or the hypothalamic–pituitary axis.

The uterine tubes (oviducts) impede bacteria reaching the ovary; consequently, ovarian infections or abscesses are rare. However, extension of infection or inflammation into the oviduct likely disrupts the delicate balance of the immune systems that are required for fertilisation (Marey et al. 2016).

Beyond the tubular genital tract, uterine infection may impair ovarian function (Sheldon et al. 2014a, Bromfield et al. 2015). At a practical level, veterinarians should be aware that individual dairy cows with postpartum uterine infections have a slower growth of the dominant follicle, lower peripheral plasma oestradiol concentrations, and are less likely to ovulate (Sheldon et al. 2002b). At the herd level a history of uterine infection or dystocia are associated with a delayed return to ovarian cyclic activity, more cystic ovarian disease, and with prolonged luteal phases (Opsomer et al. 2000).

One possible mechanism linking uterine disease to ovarian dysfunction is that cytokines and PAMPs perturb the endocrine function of the hypothalamus and the pituitary, reducing the release of GnRH and LH, which effects ovarian function (Peter et al. 1989, Karsch et al. 2002). In postpartum cows, endotoxin in the uterus suppresses the luteinising hormone (LH) surge and prevents ovulation (Peter et al. 1989). In addition, during the follicular phase, endotoxin decreases LH pulse frequency, decreases oestradiol, and interrupts the LH surge and ovulation in cattle (Suzuki et al. 2001, Lavon et al. 2008). Similar observations have been made in sheep, which is the species most often used to study the effect of endotoxin in the ruminant brain (Karsch et al. 2002). Neuroendocrine activity at the hypothalamic level is inhibited by endotoxin suppressing both the frequency and amplitude of GnRH/LH pulses. However, there are also effects within the pituitary gland, as endotoxin lowers LH responses to exogenous GnRH (Karsch et al. 2002). Indeed, treatment of ewes with endotoxin suppresses the expression of genes encoding GnRH receptor (GnRHR) and LHβ (Herman et al. 2013). However, the peripheral plasma concentrations of FSH are unaffected by uterine disease in cattle, so that recurrent waves of follicles develop in the ovary, even during uterine disease (Sheldon et al. 2002b).

A second mechanism is that the cytokines, associated with the host defence response to bacteria in the uterus, may reach the ovary via the localised countercurrent mechanism, as used by prostaglandin $F_{2\alpha}$ during luteolysis (see Chapter 1). For example, cytokines such as IL-6 and TNFα perturb bovine ovarian follicular cell steroidogenesis (Alpizar & Spicer 1994, Spicer 1998).

A third mechanism linking infection of the endometrium with ovarian function is that PAMPs might also reach the ovary from the uterus. The concentrations of endotoxin in follicular fluid aspirated from dominant follicles is correlated with the severity of uterine disease (Herath et al. 2007). Notably, healthy ovarian follicles do not contain hematopoietic immune cells, so ovarian follicle responses to cytokines or PAMPs must rely on the granulosa cells and oocyte (Herath et al. 2007, Bromfield & Sheldon 2011). Indeed, endotoxin limits granulosa cell oestradiol production by reducing *CYP19A1* gene expression and aromatase protein levels (Herath et al. 2007, Price et al. 2013). Interestingly, granulosa cells isolated from growing or dominant ovarian follicles express most of the TLRs (Bromfield & Sheldon 2011, Price et al. 2013). Furthermore, PAMPs, such as bacterial endotoxin or bacterial lipopeptides, stimulate an inflammatory response by granulosa cells, with the secretion of IL-1β, IL-6, CXCL1, CXCL2, CXCL3,

VetBooks.ir

and IL-8 protein (Bromfield & Sheldon 2011, Price et al. 2013). Inhibiting *TLR4* or *TLR2* gene expression in bovine granulosa cells using siRNA reduced the secretion of IL-6 in response to their cognate PAMPs (Bromfield & Sheldon 2011, Price et al. 2013). So, granulosa cells in antral follicles clearly have roles in innate immunity. Endotoxin also reduces the primordial ovarian follicle pool with an associated increase in primordial follicle activation and loss of primordial follicle regulatory proteins (Bromfield & Sheldon 2013). However, not all stages of follicle development are sensitive to PAMPs, and endotoxin did not affect the growth and viability of individually cultured secondary follicles (Bromfield & Sheldon 2013).

During the later stages of ovarian follicle development, endotoxin stimulates IL-6 secretion from cumulus-oocyte complexes and activates cumulus expansion *in vitro* (Bromfield & Sheldon 2011). Inappropriate timing of cumulus expansion may contribute to infertility because expansion is normally closely coordinated with ovulation. Furthermore, endotoxin or IL-6 might reach the oocyte via the cytoplasmic transzonal projections from granulosa cells that synapse on the oolema. Indeed, endotoxin increases the incidence of meiotic arrest and germinal vesicle breakdown failure in bovine oocytes (Bromfield & Sheldon 2011). Furthermore, treatment of cumulus-oocyte complexes with endotoxin or PAM perturbed expression of genes such as *GDF9* and *NLRP5,* which are involved in oocyte maturation (Sheldon et al. 2014b). Oocyte development takes about 120 days between the primordial follicle stage to ovulation of a cumulus-oocyte complex. Thus it has been suggested that in cows inseminated 60 to 120 days postpartum, the oocytes that are ovulated may have been perturbed and be less fertile after exposure to metabolic stress (Britt 1992). Therefore limiting uterine disease is not only important for the affected animals but also for their offspring.

Conclusions and Outlook

Although there is a clear understanding of the clinical aspects and implication of postpartum uterine disease and some of the mechanisms of pathology, there are important outstanding questions. The most obvious question is: why are modern high-milk-yield cows so susceptible to metritis and endometritis? Allied to this, is what can be done to prevent uterine disease? Answering these questions is vital for sustainable intensification of the dairy industry over the next 50 years. Genetic selection for more resilient animals that are less susceptible to uterine disease is a priority for the dairy industry. In the meantime, veterinarians should consider that prevention is better than cure, and advise clients about animal nutrition and management to increase the resilience of parturient and postpartum animals so that they are better able to tolerate the presence of uterine pathogens without developing uterine disease.

Specific Infectious Diseases Causing Infertility and Subfertility in Cattle

TIMOTHY J. PARKINSON

Many of the infectious diseases of cattle adversely affect reproductive performance, either by direct effects upon the reproductive system or via indirect effects upon the general state of health of affected animals. In this chapter the effects of enzootic infectious diseases upon reproductive performance are considered; the effects of non-specific infections of the reproductive tract, such as the metritis complex, were considered in Chapter 23.

Infectious diseases can affect the reproductive system through:

- Impaired sperm survival or transport in the female tract, leading to reduced fertilisation rate;
- Direct effects upon the embryo, including infections that result in early embryonic death and those that infect the more advanced fetus or its placenta, resulting in abortion, stillbirths, or the birth of weak calves; and
- Indirect effects upon embryo survival, including infections that have adverse effects upon uterine function and those that infect the maternal component of the placenta. Again, these result in embryonic death, fetal death with abortion, mummification, or stillbirth.

The patterns of enzootic infectious diseases that affect reproduction have changed considerably in most developed countries over the past 40 to 50 years. The classic venereal diseases, campylobacteriosis and trichomonosis, have been largely eradicated in dairy cattle by the use of artificial insemination (AI) with semen from disease-free bulls. In beef cattle, in which natural service remains the predominant method of breeding, the control has been less complete. Most Western countries have successfully eradicated brucellosis through programmes based upon vaccination, blood testing, and slaughter. Conversely, other diseases, such as infectious bovine rhinotracheitis/infectious pustular vulvovaginitis (IBR-IPV), bovine viral diarrhoea (BVD), and leptospirosis, have assumed much greater importance, either because of a genuine increase in prevalence or the development of better diagnostic methods. Other diseases, whose effects upon reproduction were hitherto unrecognised, are now ascribed significance as reproductive diseases. Examples include ureaplasmosis, *Histophilus somni* infections, and abortions due to *Neospora caninum.* Yet, even though there has been a change in the importance of different specific infectious agents in causing infertility, none should be forgotten when investigating subfertility in a herd. Diseases that have been considered as being eliminated can still reemerge and can cause catastrophic effects if they gain entry to a herd with a low immune status to that disease.

Estimates of the prevalence of infectious diseases of reproduction largely depend on the successful diagnosis of causes of abortion. The data provided from this source provide only an approximate guide to the prevalence of diseases, however, because the percentage of fetopathies from which a specific infectious agent is identified is relatively small. In the results from the Veterinary Laboratories Agency of the Department for Environment, Food and Rural Affairs (UK), positive results were obtained in approximately 10% to 14% of submissions. When statutory submissions for brucellosis screening are omitted, the diagnostic rate is approximately 20% to 30%. Nonetheless, such data do show that the prevalence of many infectious causes of abortion has been relatively static or declining in the UK (Table 24.1) since first publication of the Veterinary Investigation Diagnosis Analysis (VIDA II) in 1977 (Veterinary Laboratories Agency 2016).

Bacterial Agents

Bovine Venereal Campylobacteriosis

Campylobacteriosis was spread around the major livestock-producing regions of the world with the early importations of cattle. Today, venereal campylobacteriosis is still one of the most important infectious causes of infertility in cattle throughout the world, despite prolonged efforts to eradicate it. Wherever the main method of breeding is by natural service (notably in beef herds), its venereal route of transmission has ensured that the organism remains a threat to cattle fertility. Most beef-producing countries are affected, including the US, Canada, Australia, Argentina and other countries in South America, and several countries in Africa (Michi et al. 2016). The disease occurs either with a continuous epizootic presence or with reemergence of the condition after a long period of supposed absence (e.g., the UK; MacLaren & White 1977). Where AI is the main method of cattle breeding (notably in dairy cattle), the incidence of campylobacteriosis has declined significantly.

Aetiology

Campylobacter fetus (originally named *Vibrio foetus*) is divided into two main subspecies. The most important of these in terms of causing bovine infertility is the subspecies *venerealis* (CFV), which, as its name suggests, is spread through coitus. The subspecies *fetus* (CFF, of which there are two main serotypes) is not spread venereally and is not normally considered to be a major cause of infertility

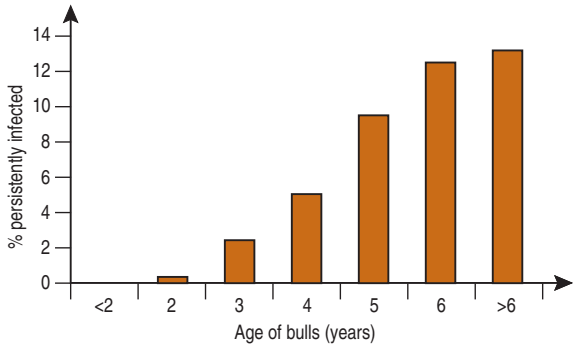
in cattle, although it can cause sporadic abortions (Thompson & Blaser 2000). In addition, 'intermediate' strains of CFF have occasionally been reported as a cause of infertility akin to that produced by CFV (MacLaren & Agumbah 1988). There have been many changes to the names given to the subspecies of *C. fetus* over the years, which make it difficult to follow the early literature.

Other species of *Campylobacter (C. coli, C. hyointestinalis, C. jejuni,* and *C. sputorum*) have been implicated in bovine abortions (Newell et al. 2000). In addition, there are a number of saprophytic species of *Campylobacter*, which may be present in the alimentary tract of cattle or in the prepuce of the bull. The main significance of these latter organisms (in terms of venereal campylobacteriosis) is that they can interfere with the diagnosis of pathogenical species.

Infection in the Bull

Infection of the bull does not cause any visible lesions of the genital tract nor does it cause interference to its reproductive behaviour or its semen quality. The bull simply acts as a carrier and transmits the infection at service to the female. The primary route of infection is venereal transmission. There are, however, also reports that bull-to-bull transmission may occur through mounting when bulls are confined together (Wagner et al. 1965). Infection through contaminated semen collection equipment is a well–recognised variant of the venereal route of transmission.

The organism is confined to the penile integument, glans penis, prepuce, and distal urethra (Thompson & Blaser 2000). Because the organism lives in the crypts of the penile integument, the likelihood of bulls becoming persistently infected increases with



• **Fig. 24.1** Relative risk of bulls of different ages becoming persistently infected with *Campylobacter fetus* subsp. *venerealis*.

age as the crypts become deeper and more extensive (Kennedy & Miller 1993). It is relatively unusual for bulls less than 4 years old to become persistently infected (Philpott 1968). Early work showed that only 5% of bulls under 4 years old persistently carry the infection (Adler 1956). When exposed to natural or artificial infection, few bulls less than 4 years old remained infected for no more than a few days, whereas bulls more than 4 years old generally became persistently infected (Dufty et al. 1975). Among older bulls there is less change in susceptibility with age: a study of bulls between 41 and 74 months of age (Bier et al. 1977) showed no increase in susceptibility over that period. Once infection is established, it does not usually undergo spontaneous remission: the bull remains infected for life. Typical patterns of persistent infection are shown in Fig. 24.1.

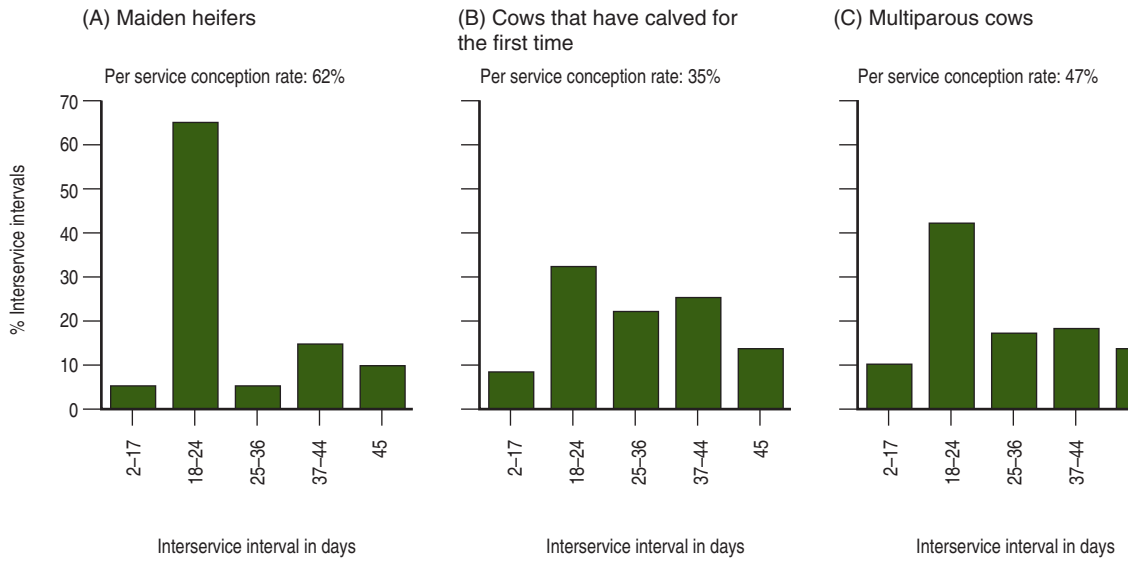
Infection in the Cow

Between 40% and 75% of non-immune female cattle become infected after a single service by an infected bull (Clarke 1971). The organism initially colonises the vagina, occasionally producing visible mild, mucopurulent vulval discharge. The organism multiplies in the vagina and, within a week, spreads to the uterus (Dekeyser 1984). Infection remains confined to the vagina in 10% to 20% of infected animals (Clarke 1971).

The organism causes a mild, subacute, mucopurulent endometritis, in which there is a substantial periglandular accumulation of lymphocytes (Dekeyser 1984). The severity of the endometritis is maximal somewhere between the 8th and 13th week after the initial infection (Estes et al. 1966, Dekeyser 1984). There is also infection of the uterine tubes in about 25% of animals, sometimes causing salpingitis (Roberts 1986). Inflammation of the cervix may also occur, causing an increased secretion of mucus. This mucus can be mixed with the uterine exudate to form a mucoflocculent vulval discharge. Infection is eliminated from the uterus and uterine tubes in a period of weeks or months, as an immune response is stimulated (Corbeil et al. 1974). Infection with CFV does not interfere with the process of fertilisation, but the low grade endometritis results in a uterine environment that is incompatible with embryonic survival (Dekeyser 1986). Thus, fertilisation occurs in the majority of susceptible females that are served by an infected bull but, because the uterine environment is unable to sustain a pregnancy as a consequence of the inflammation, the embryo dies at a variable time after conception.

Immunity (immunoglobulin (Ig)G-based) develops relatively slowly within the uterus, but when it has done so and the infection is eliminated from the uterus, cows conceive and remain pregnant (Thompson & Blaser 2000). Hence, after an average of about five

VetBooks.ir



• **Fig. 24.2** Distribution of interservice intervals in a dairy herd in which there is enzootic infection with *Campylobacter fetus* subsp *venerealis.* (A) Interservice intervals were normal in maiden heifers that were served by a newly acquired (virgin) bull. (B) In first-calving cows, interservice intervals showed evidence of embryonic death, which was accompanied by poor conception rates. (C) In the older cows, interservice intervals and conception rates were improved, although chronic campylobacteriosis remains evident.

services, the majority of cows become pregnant and carry their calves to term – although a proportion of susceptible cows and heifers conceive to first service by an infected bull and carry their calves to full term. About 5% of cows appear to be resistant to infection, remaining uninfected despite repeated introduction of the organism to the reproductive tract (Dufty & Vaughan 1993).

Infection can persist in the vagina for a considerable period of time as vaginal immunity is less effective than that within the uterus. The development of the persistent vaginal carrier is partly due result of the limited ability of the IgA that is produced in vaginal secretions to promote opsonization and phagocytosis. It is also due to the ability of CFV to alter its expression of surface antigens (surface layer proteins) in response to the presence of host antibodies (Garcia et al. 1995). It appears that this antigenic shift may be the primary means by which the organism escapes the hosts' immune system (de Vargas et al. 2002) in field infections. Vaginal infection persists in most cows for up to 6 months, and in approximately 50% of cows up to 10 months after the initial challenge (Vandeplassche et al. 1963, Plastridge et al. 1964). Although most (> 95%) cows manage to eliminate the infection from the vagina by the end of a normal gestation, some remain infected after calving and occasional animals (1%–2%) remain permanent vaginal carriers (Clarke 1971, Dekeyser 1984).

Clinical Presentation

The presence of venereal disease (although not specifically campylobacteriosis) should be suspected when there are high empty rates and/or a high proportion of late conceptions in natural-service herds that cannot be explained in terms of failures of other aspects of management.

When CFV infection is introduced into a naïve herd, a dramatic decrease in conception rate occurs. Per-service conception rates can be as low as approximately 20%. Infected cows return to oestrus, typically at an interval that is greater than the normal 18 to 24 day interval, depending on the time at which the embryo dies. Embryonic deaths occurring after recognition of pregnancy result in later returns to oestrus, which occur irregularly at more than 25 days after service (Fig. 24.2). The number of animals that eventually conceive depends on the length of the breeding season; usually there are several returns to service before sufficient immunity develops for the maintenance of a pregnancy. Most animals eventually become pregnant if the breeding season is long enough. A small number of animals abort, typically at 2 to 4 months of gestation (Frank et al. 1964), although neither a large number of abortions nor abortion storms are characteristic of venereal campylobacteriosis.

In a herd in which the disease is established, there are different patterns of reproductive performance in naïve and previously infected animals. In previously infected, recovered cows, vaginal infection is readily reestablished in 30% to 70% of animals that are served by an infected bull (Clarke 1971). Such infection does not establish well within the uterus, so the cows' fertility is much less impaired than during the initial episode of disease. Nevertheless, fertility never returns to normal: overall conception rates are lower than in uninfected cows, some animals abort (Roberts 1986), and occasional animals are rendered sterile through salpingitis (Clarke 1971). Hum (1996) estimated that pregnancy rates in a newly infected, seasonally calving, beef herd fall to about 40%, recovering to between 60% and 75% in a chronically infected herd. These figures compare with a 90% pregnancy rate in an uninfected herd. Naïve animals (typically either maiden heifers or first-calf heifers, depending on the herds' breeding policy) will continue to exhibit grossly impaired reproductive performance each year when they are first exposed to infected bulls.

The first sign of genital campylobacteriosis is a marked increase in the number of females returning to oestrus, some regularly and some irregularly, after service by a newly introduced bull. Although returns are not observed in many beef herds, the first sign seen by a herd manager is that often there is a disastrously low proportion of cows pregnant at the end of the breeding season. After experiencing serious infertility for about 6 months, a herd gradually becomes immune, and most of the cows that manage to conceive will be free of infection after they have calved. If infected bulls remain with the herd, reinfection of some cows when they are rebred results

VetBooks.ir

• **Fig. 24.3** Device for collecting preputial scrapings from bulls for the diagnosis of venereal campylobacteriosis or trichomonosis.

in a similar, but much less severe, infertility problem. Eventually, after 2 to 3 years, the fertility of such cows becomes acceptable, with only moderate infertility occurring (Roberts 1986). Among incoming heifers and in any newly acquired cows (i.e., in those animals that are not immune to the disease), campylobacteriosis will be perpetuated. When maiden heifers are bred to an infected bull, they will exhibit the low conception rates and irregular returns to oestrus that are characteristic of campylobacteriosis. If, however, they are bred to a virgin bull, they will not contract the disease until after their first calving, so will have normal fertility in their first season and very poor fertility in their second. Purchased animals, likewise, show the most significant effects of the disease during their first season in the herd.

Bulls are asymptomatic carriers of the infection.

Diagnosis

Methods that have been used to diagnose CFV infection include:

- Culture;
- Serology, including immunofluorescence, vaginal mucus agglutination, or vaginal mucus enzyme-linked immunosorbent assay (ELISA) tests; and
- Polymerase chain reaction (PCR).

Culture

Campylobacter fetus is a difficult organism to grow in culture. It is microaerophilic, fragile, fastidious in its media requirements, and generally obtained from an environment that is heavily contaminated with other bacteria. Consequently, although positive culture results are diagnostic of the infection, negative results must be interpreted with considerable caution. Samples that can be collected for culture include the following:

Vaginal wash: This method is a possibility, but isolation rates from females are extremely disappointing unless the animal is very recently infected. Pregnant animals are exceedingly unlikely to yield positive results; non-pregnant animals are only a little more hopeful.

Preputial scraping or the preputial wash: Swabs are much less effective than either of these methods. Bulls are much more likely to yield positive results than cows. A device for collecting preputial scrapings is illustrated in Fig. 24.3.

Samples from abortus material: Many of the isolations of CFV have been made from aborted material from cows, mainly from stomach contents of aborted fetuses. Despite the problems implicit with mustering of animals in hill country, specific effort needs to be devoted to the search for such aborted fetuses in the paddocks given the diagnostic value of aborted fetuses.

Because the organism is so fragile, it does not survive for long in flushing media. Hence immediate inoculation into transport medium, such as Lander's medium (Lander 1990) is recommended. If this is not feasible, the sample must be at the laboratory within 6 hours. After incubation of the Lander's medium under microaerophilic conditions, it can be subcultured onto blood agar and further incubated under microaerophilic conditions. Differentiating between CFV and CFF is done on the basis of biochemical tests (OIE 2017a).

Serology

Genital campylobacteriosis does not result in a measurable serum antibody response in either males or females. Hence, serological tests based on humoral antibodies are of little or no value.

Serological methods based upon the vaginal IgA response have been widely used as, even though that antibody is not particularly effective at eliminating CFV infection, it is a rapid and persistent response. However, serological methods do not accurately differentiate between CFV and CFF, so in situations in which cattle may have been exposed to CFF (e.g., where cattle and sheep are managed together), the reliability of tests based on vaginal mucous IgA decreases.

Tests based on vaginal IgA include the following:

Vaginal mucous agglutination test: Many authors agree that this test can be very useful at herd level (50% of infected animals will be detected), although results at individual animal level can be very misleading (MacLaren & Agumbah 1988). The test has, however, largely fallen into disuse as it cannot differentiate between CFF and CFV.

Immunofluorescence: Immunofluorescence, alone or in combination with culture, was considered to be a valuable adjunct to the diagnosis of campylobacteriosis. Indeed, Dekeyser (1984) considered it to be 'a quick, convenient and accurate method of diagnosing carrier bulls'. In the past, immunofluorescence was widely used in the diagnosis of campylobacteriosis, but, more recently, its inability to differentiate between CFF and CFV has led to a decline in its use.

IgA ELISA: An indirect ELISA test for the identification of immunoglobulin A (IgA ELISA) in vaginal mucous samples was developed in Australia (Hum et al. 1991). Field evaluation of the test suggested a specificity of 98.5% for the identification of CFV-infected herds (Hum et al. 1994). Where CFF infection of cattle may occur, the cross reactivity between CFF and CFV limits the usefulness of the test (McFadden et al. 2004, Benquet et al. 2005).

Monoclonal antibody ELISA: The limitations of polyclonal antibody ELISAs have led to the development of a monoclonal antibody assay (Devenish et al. 2005). In this assay, samples are exposed to a series of monoclonal antibodies that recognise either components that are present in all *Campylobacter fetus* strains or which are differentially present in CFF and CFV. The assay sensitivity is quoted as being 100% and its specificity of 99.5% relative to the results of culture. This method has been

VetBooks.ir

adopted by the OIE (2017a) as one of its suggested methods of diagnosing CFV.

Polymerase Chain Reaction

Many of the difficulties of culture and of crossreactivity between CFF and CFV can potentially be circumvented by the use of PCR methods. Over the past decade, PCR tests that have been developed (Hum et al. 1997, Schulze et al. 2006) can differentiate between CFF and CFV in culture. More recently, a sensitive PCR has been developed for use in the field that appears to be able not only to differentiate between CFF and CFV but also to identify the presence of CFV in grossly contaminated samples (i.e., preputial scrapings) or in samples from which culture has not been possible (McMillen et al. 2006). Despite the advances offered by PCR, van der Graaf-van Bloois et al. (2013) were of the opinion that, although PCR methods are able to accurately identify *Campylobacter fetus* to a species level, their specificity and sensitivity was insufficient to accurately separate CFF and CFV.

Prevention, Control, and Eradication

Prevention

Because CFV is only spread through the venereal route (or by contact with contaminated objects), preventative management aims to ensure that infected animals are not introduced into a susceptible herd. Breeding by AI is probably the most effective preventative measure of all, although this is not always feasible, especially in beef herds. For beef herds, preventative measures include (Peter 1997):

- Bulls should not be shared or rented, unless it is absolutely certain that they are disease-free;
- Culled bulls should be replaced with virgin bulls;
- Culled cows should preferably be replaced with virgin heifers, although the risk posed by heavily pregnant or freshly calved cows is small;
- Keeping the breeding season short (2–3 months);
- Avoiding common grazing with animals from other herds and ensuring that fences in and around the farm are stockproof; and
- Where CFV vaccine is available, all incoming bulls should be vaccinated at the time of breeding soundness examination, and all other animals should be vaccinated before the start of the breeding season.

Eradication

Eradication of CFV from infected herds is based on three features of its epidemiology: its transmission is exclusively venereal; bulls remain permanently infected; and that most (but not all) infected cows overcome the infection in a period of 3 to 6 months after the initial infective service.

In situations in which cattle can be bred by AI, this is probably the most effective means of control because incoming uninfected animals do not contract the disease and infected animals eventually become immune and removal of bulls from the herd prevents further venereal transmission of the disease. Although CFV does not survive through a normal gestation in most cows, there are occasional persistently infected animals. It has therefore been recommended that all cows in the herd are bred by AI until every exposed cow has completed two normal pregnancies. Other means of eradication include the following:

Split herd management: Rigid segregation of 'clean' animals (i.e., virgin animals or cattle that have never been mated by an infected bull) and 'infected' animals (i.e., all others), with progressive replacement of the latter by the former, has been recommended, although the effort required to maintain segregation is enormous.

Bull management: Peter (1997) has recommended the culling of older bulls (as these are more likely to be persistently infected), sexual rest, and testing of young bulls before the start of mating.

Antibiotic treatment: Infected bulls can be effectively treated with systemic or topical administrations of dihydrostreptomycin or topical administration of neomycin and erythromycin (Dekeyser 1986). However bulls that have been treated with antibiotics will be susceptible to reinfection if they mate with infected cows. Antibiotics have little beneficial effect in the cow whether administered locally or parenterally.

Vaccination

Vaccination programmes prevent the development of campylobacteriosis in susceptible cows and eliminate infection from affected cows (Schurig et al. 1978, Eaglesome et al. 1986). Vaccination should preferably be carried out 30 to 90 days before breeding commences and, because the immunity is relatively short-term, yearly revaccination before the start of the breeding season should be undertaken (Hoerlein 1980). Dekeyser (1986) reported that vaccinated females conceive normally, although many acquire a vaginal infection if they are served by an infected bull.

Vaccination can be used for prevention and treatment of campylobacteriosis in bulls (Clarke et al. 1974). Some studies (Bispig et al. 1981, Vasques et al. 1983, Hum et al. 1993) have suggested that vaccination alone is not effective at eliminating infection and so have recommended concurrent treatment with topical or systemic antibiotics. Protection of the male can also be achieved by the use of double doses of vaccine given on two occasions (Cortese 1999).

Vaccine failure, when it occurs, may be due to antigenic differences between local and vaccinal strains of CFV (Cobo & Favetto 2014) or to the ability of CFV to evade an IgA response.

Infection With *Campylobacter fetus* subsp. *fetus*

Campylobacter fetus subsp. *fetus* is commonly present in the gastrointestinal tract of cattle and sheep. It is transmitted through contaminated feed and water, and the venereal route is not generally regarded as being a significant means of transmission. It is generally associated with sporadic abortions and is not usually a cause of conception failure. Infection with CFF results in a transient bacteraemia, after which the organism localises in the placenta, sometimes resulting in abortion. The majority of such abortions occur between the fourth and seventh months of gestation (Thompson & Blaser 2000).

The placenta is usually autolysed, indicating that death preceded expulsion by a significant interval. Placental lesions are very similar to, although less severe than, those caused by *Brucella abortus*. Typically, there is necrosis, with yellowish-brown discoloration of the fetal cotyledons and leather-like thickening or oedema of the intercotyledonary allantochorion. Lesions in the bovine fetus are not specific (Kennedy & Miller 1993), a situation that is markedly different from the pathognomonic liver lesions in aborted ovine fetuses (see Chapter 29).

Although the venereal route of transmission is not regarded as of importance for CFF, it has been reported that some strains can be transmitted by that route, resulting in a syndrome that is more like classical venereal campylobacteriosis than the syndrome more

VetBooks.ir

normally associated with the organism (MacLaren & Agumbah 1988).

Brucellosis

Bovine brucellosis is usually caused by *Brucella abortus. Brucella melitensis,* transmitted from sheep and goats, can also cause disease in cattle. Although *B. suis* has been isolated from cattle in contact with infected pigs, it does not appear to cause disease in cattle (Robinson 2003). *Brucella abortus* affects Bovidae other than *Bos taurus,* including *Bos indicus,* yaks, domestic buffaloes and bison, and wild Bovidae, Cervidae, and Camelidae, with the result that infection can be maintained in wildlife populations. Brucellosis results in abortion, usually in the second half of pregnancy, together with metritis and retained fetal membranes (RFM). In bulls, it can cause orchitis, epididymitis, and infections of the accessory sex glands (Nicoletti 1986).

Brucella abortus occurs in most countries of the world in which cattle are kept in any significant numbers. Because of the enormous losses that the disease causes to dairy and beef cattle industries, it has been the subject of eradication schemes in many countries. Currently, *B. abortus* is found worldwide in cattle-raising regions, except for Japan, Canada, Scandinavia, Luxembourg, the Netherlands, some central European countries, Australia, New Zealand, and Israel, where it has been eradicated (OIE 2017b). The UK is considered to be free of the disease, and most of the states of the mainland US are also free (Yaeger & Holler 2007). The highest incidence is observed in the Middle East, the Mediterranean region, sub-Saharan Africa, China, India, Peru, and Mexico. Currently, countries in central and southwest Asia are seeing a substantial increase in cases (OIE 2017b). The OIE requires that brucellosis is a notifiable disease in each of its member countries.

Brucella infection is a serious zoonosis, as it is readily transmissible to humans, causing an acute febrile illness that may progress to a more chronic form. Human infection is mainly acquired by the oral, respiratory, or conjunctival routes, but ingestion of raw milk products constitutes the main risk to the general public in countries in which the disease is endemic. There is an occupational risk to veterinarians, abattoir workers, and farmers who handle infected animals/carcasses and aborted fetuses or placenta (OIE 2017c).

Aetiology and Pathogenesis

Most herd outbreaks have been caused by the introduction of carrier animals. Infection occurs primarily by ingestion but can also occur via mucous membranes. The principal source of infection is aborting cows in which the fetus, placenta, fetal fluids, and milk are all heavily contaminated. Ingestion of contaminated pasture, bedding, food, or water, or licking an aborted fetus, infected afterbirth, or genital exudate from a recently aborted cow are common means by which transmission occurs. Infection may even occur through the teat by infected milk of another cow or through the vagina by infected semen. Calves can become infected through contaminated milk or at the time of parturition.

The organism colonises the udder and supramammary lymph nodes of non-pregnant animals. In pregnant animals, production of erythritol within the placenta allows rapid multiplication of the bacteria, leading to endometritis, infection of cotyledons, and placentitis. The fetus is aborted 48 to 72 hours after death, by which time a degree of autolysis has occurred. The fetal membranes are very frequently retained. For a day or two before, during, and for about a fortnight after abortion the genital discharge of the infected female is highly infected. When the fetal membranes are retained, the uterus may not free itself of infection until about a month after delivery. After the completion of uterine involution, the organisms colonise the udder and supramammary lymph nodes in which, in the next gestation, infection of the placenta may again occur. The organism may live for months outside the animal body in aborted fetuses or fetal membranes but, when exposed to drying and sunshine, it is soon killed. The infantile uterus becomes infected in a very small proportion of calves that are born alive and survive rearing (Wilesmith 1978).

Clinical Signs

The main sign of brucellosis is abortion, which occurs mainly in the second half of gestation. Earlier abortions may occur at the beginning of an outbreak. Occasionally, fetal death is followed by mummification or maceration rather than abortion. Late aborted fetuses may be born alive but either die shortly after birth or are weak, unthrifty, and at risk of succumbing to calf diarrhoea.

Most cows that abort have RFM. The placenta appears dry, thickened, cracked, and covered by a yellowish exudate in the intercotyledonary areas. Cotyledons appear necrotic and may also be covered with an exudate. RFM is more common in cows that abort in later gestation and those that carry to term. Such animals show delayed involution of the uterus and are prone to secondary bacterial invasion with resultant puerperal metritis.

Diagnosis

Diagnosis is based upon the isolation of *B. abortus* from abortion material, milk, or necropsy material. In addition or as an alternative, specific cell-mediated or serological responses to *Brucella* antigens can be demonstrated (Robinson 2003).

The organism can be identified in stained smears prepared from suspected contaminated material, either using a modified Koster and Ziehl-Neelsen method or a fluorescent antibody technique (Brinley Morgan & MacKinnon 1979). Demonstration of acid-fast organisms provides a presumptive diagnosis, but *Chalmydia* or *Coxiella* can be mistaken for *B. abortus* in stained smears, and the sensitivity is low in milk (OIE 2017c). The organism can be isolated by microbial culture from the fetal stomach of an abortus, from fresh afterbirth, or from uterine exudate.

Diagnosis at the herd level as part of eradication schemes has largely relied upon serological tests upon biological materials such as milk, serum, vaginal mucus, and semen. Serology has also been used to confirm presumptive diagnoses based upon Ziehl-Neelsen staining and/or immunofluorescence. Serological tests that are currently in use for screening or diagnosis include:

- The rose Bengal plate test, which was introduced into the UK in 1970 as the main initial screening test of serum samples in the brucellosis eradication scheme (Brinley Morgan & Richards 1974); and
- The plate agglutination test, which was rated highest, in terms of sensitivity and specificity, of the conventional tests and is better than either rose Bengal or complement fixation tests (Gall & Nielsen 2004).

These two tests are known to have significant false-positive rates (i.e., they identify some non-infected animals as positive), so positive samples are reexamined using a more specific serological method.

- The milk ring test, which detects *Brucella* antibodies in milk, is very useful in screening the presence of brucellosis in herds by collecting bulk milk samples or in individual animals (Robinson 2003).
- Indirect ELISAs can be used for screening or diagnosis. They have the advantage of being cheaper and easier to use than

VetBooks.ir

many other methods (Gall & Nielsen 2004), and their diagnostic accuracy is at least as good as that of the complement fixation. Some ELISAs allow differentiation between vaccinated and infected animals test (Wright et al. 1993, Nielsen et al. 1996).

- Complement fixation test (CFT) and serum agglutination test (SAT) can be used. The SAT is no longer regarded as suitable for the diagnosis of brucellosis (Robinson 2003), as its specificity and sensitivity are poorer than those of the other tests (Brinley Morgan & MacKinnon 1979). The CFT identifies infected adults sooner after infection the SAT and, as the disease becomes chronic, the titres detected by the SAT tend to fall below diagnostic levels, whereas titres detected by the CFT persist at diagnostically significant levels. The CFT is also more effective than the SAT in differentiating titres arising from infection from vaccination. In calves vaccinated with Strain 19, titres detected by the CFT become negative in most cases by 6 months after vaccination, whereas an 18-month period is required for the SAT.

Molecular methods, including PCR, have also been developed for identification of *Brucella* strains. Differentiation is complicated by a high degree of DNA sequence homology within the genus, but tests are now available which allow identification of different strains (Ocampo-Sosa et al. 2005) and between pathogenical stains and vaccine strains (e.g., S19 or RB51 strains; Garcia-Yoldi et al. 2006, Lopez-Goni et al. 2011). PCR and other molecular methods for the diagnosis of *Brucella* species now appear to be sufficiently rapid, simple, and robust to provide species–specific information and to be useful for the epidemiological study of brucellosis (OIE 2017c).

It should be noted that, during an active infection of a herd, the results of tests should be interpreted with some caution. Negative reactions will occur during the incubation period; furthermore, it is quite common to get a negative reaction at the time of, and for a few days after, a brucellosis abortion. Infected bulls sometimes fail to react to the blood test, and it is considered that, if the agglutination test is performed on seminal plasma rather than blood, a better indication of infection will be obtained.

Control

Eradication

The Food and Agriculture Organization recommends the following sequence of action for eradication of brucellosis from a nation or region (Robinson 2003):

Phase 1: High or unknown prevalence, with no control programme. The first step is to identify the prevalence and distribution of the infection through programmes such as investigation of abortions and surveys of cattle on farm and in markets or at slaughter.

Phase 2: Mass vaccination. In the UK the first mass vaccination was undertaken with vaccines prepared from killed cultures of McEwan's *B. abortus* S45/20. This was later replaced with strain S19, a smooth variant of a strain of *B. abortus* of reduced virulence but of high antigenic quality. Strain RB51 (a rough strain) is also being used for vaccination; its advantage over S19 is that it is less likely to cross-react with serological tests for virulent strains. Vaccination should be supported by checks on and off farm that animals are seropositive.

Phase 3: Test and removal, segregation, or slaughter. Herds are tested for animals that are seropositive to virulent strains; these animals are segregated or slaughtered. Radostits et al. (2007) suggested that the incidence of infection has to be reduced to about 4% of the bovine population before a slaughter-based eradication programme is likely to be feasible. As eradication progresses, the proportion of false positives from the cross-reaction between S19 and virulent strains reaches a point at which it is more cost effective to desist with vaccination. Later in the eradication process, monitoring at a herd level (e.g., using bulk milk) or in markets or at slaughter is more cost effective than individual animal testing. The scheme that was used in the UK during this phase of the process is shown in Fig. 24.4.

Phase 4: Freedom. Criteria that have to be met to allow a region to be officially brucellosis free include that the condition is notifiable, that reactors are slaughtered, that vaccination is not used, and that the national/regional brucellosis infection rate has not exceeded 0.2% for at least 2 years. These criteria are reflected in current European Union regulations.

In the UK, the brucellosis eradication scheme also requires:

- Positive identification of cows and their calves;
- Traceable movements of cattle, so that potential carriers and in-contact animals can be found;
- Secure boundaries to individual farms or to eradication areas in order that uncontrolled movements of animals are prevented;
- Regular testing of all cows, followed by immediate slaughter of reactors, with compensation payment for slaughtered animals to ensure farmers' full participation in the scheme; and
- Isolation and testing of any cows that abort or have premature calvings; in the UK any animal calving at less than 271 days of gestation has to be sampled for brucellosis.

Local Control of an Outbreak

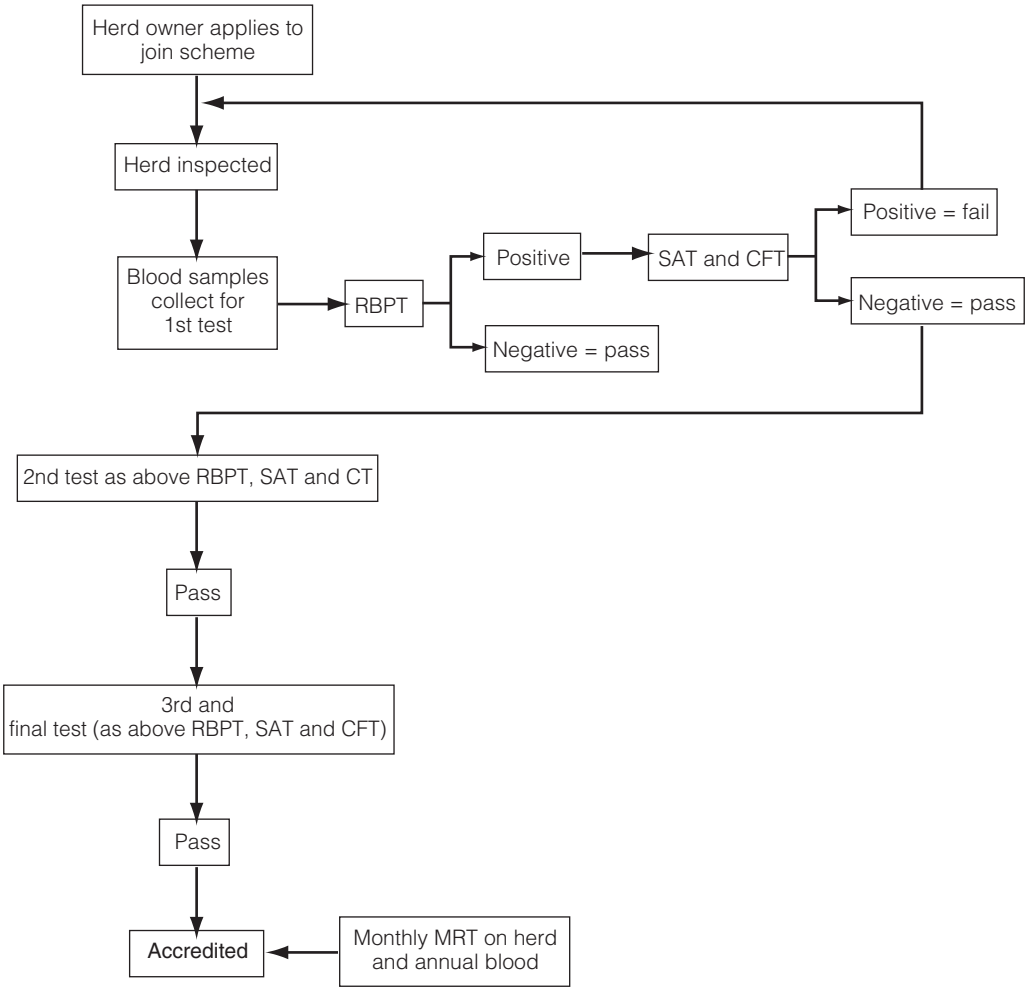
Should an outbreak of brucellosis occur, the disease is controlled on farm as far as possible by strictly isolating any animals that abort. Rigorous cleaning, disinfection, and disposal of infective material are practised. The complete isolation of the reactor from 4 days before calving or abortion to 14 days afterwards is the key to successful reduction in incidence of the disease on the farm. Calfhood vaccination should be performed in these infected herds. When the incidence of infection is sufficiently reduced, the reactors may be slaughtered.

Lastly, in heavily infected herds with current abortion, the spread of infection must be controlled in every possible way. It is best to isolate all parturient or aborting animals from 4 days before to 14 days after parturition. Disposal of infected material, thorough cleansing and disinfection after an abortion, and segregation of reactors are practised. There will be a shortage of young stock on such a farm, and this can be made good by buying in calves from disease-free herds; these calves and all other young stock are vaccinated. When the disease becomes quiescent - as shown by further blood tests - disposal of reactors may begin.

Tuberculosis of the Genitalia

Bovine tuberculosis has been eradicated in many countries of the world. However, before eradication schemes were implemented, it was an important cause of infertility, and thus where bovine tuberculosis still exists, it should always be considered as a possible cause. Infection may reach the tract either by spread from the peritoneum via the uterine tubes, or by penetration of the serosa, or by bloodstream invasion, in which case the endometrium may be involved in the absence of serous or tubal lesions. Occasionally,

VetBooks.ir



• **Fig. 24.4** Brucellosis testing scheme used in the UK, as part of Phase 3 of the OIE recommendations for the eradication of the disease. (MRT: milk ring test; RBPT: rose Bengal plate test.) (After Brinley Morgan and MacKinnon 1979.)

primary uterine infections may arise from contaminated instruments or hands during gynaecological or obstetrical interferences.

Tuberculosis of the uterus is not an inevitable barrier to reproduction, for it is possible for a calf to be born from a grossly infected uterus (the calf itself being affected by the congenital form of the disease), but it is probable in such cases that the uterine infection was acquired or, at least, developed rapidly, during pregnancy. The disease is also liable to develop in the reproductive organs after parturition.

Leptospirosis

Leptospirosis is an important zoonotic disease of cattle and other mammals that is caused by pathogenical spirochaetes of the genus Leptospira. Leptospires are currently classified into 10 pathogenical species, of which the most important to domestic species are *L. interrogans* and *L. borgpetersenii,* 5 intermediate species, and 6 saprophytic species (Caimi et al. 2017).

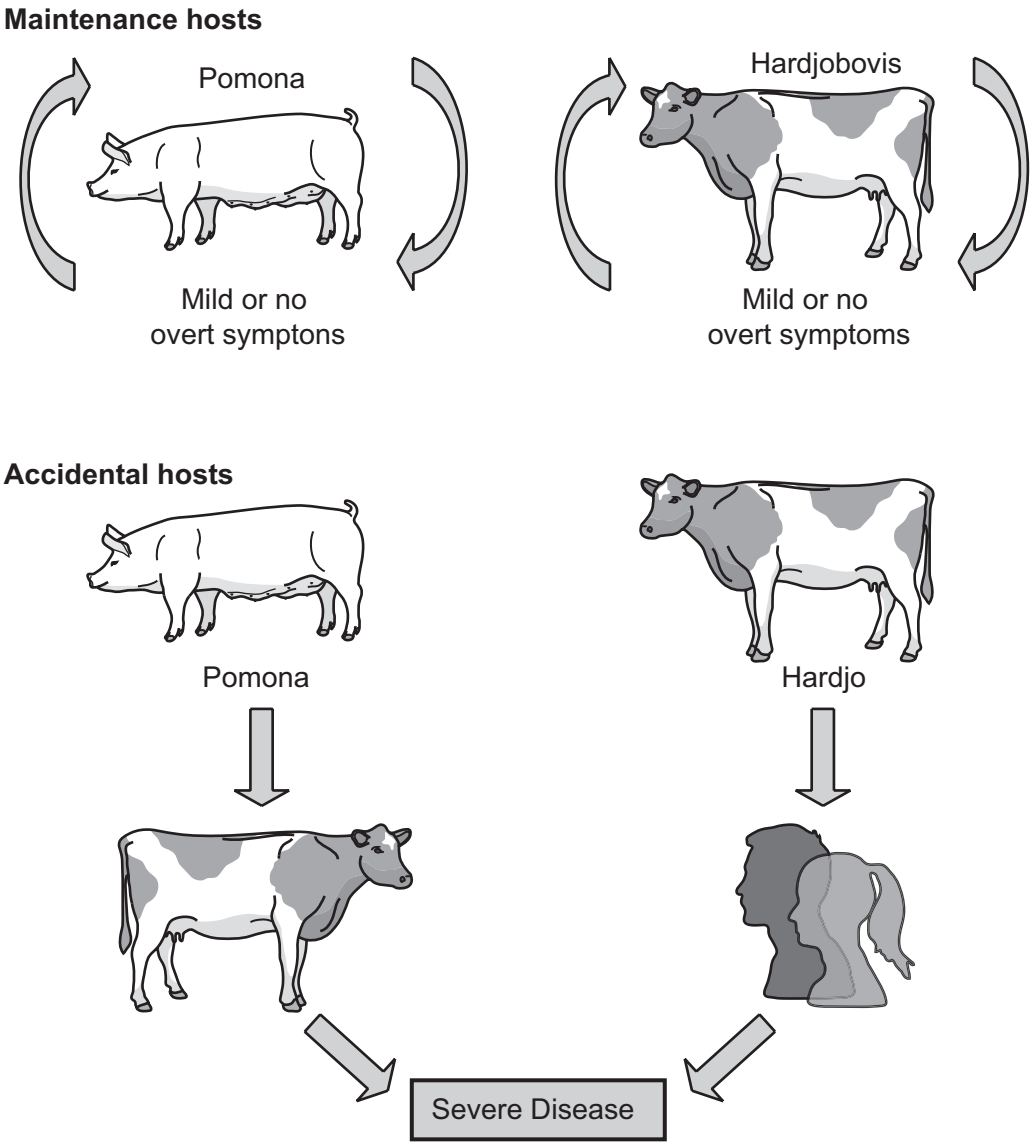
Leptospirosis has a worldwide distribution. Large numbers of cattle are affected. In the UK, Ellis et al. (1986) estimated its prevalence at approximately 60% based on microbiology and 27% based on serology. In New South Wales, King (1991) estimated that 27% of cattle were positive to *L. pomona,* 16% positive to *L. hardjo,* and 31% positive to both. In the studies of Hellstrom (1978) and Blackmore (1979) in New Zealand, 81% of herds had active or previous infection with *L. hardjo* and 36% had evidence of *L. pomona* infection.

Each serovar tends to be adapted to a particular mammalian species, known as a maintenance host. Levett (2001) defined a maintenance host as a species in which infection is endemic and in which it is usually transferred from animal to animal by direct contact. In the maintenance host the serovar causes relatively minor symptoms, but more severe disease occurs when infection of an incidental (i.e., non-maintenance) host occurs (Fig. 24.5). The main host-adapted strains of cattle are *L. interrogans* serovar Hardjo type hardjo-prajitno in the UK and *L. borgpetersenii* serovar Hardjo type hardjobovis in the US and Australasia. These serovars will be referred to subsequently in this chapter as *L. hardjo.* Serovars that commonly cause disease in cattle are the pig-adapted strain, *L. interrogans* serovar Pomona (*L. pomona*) and the rodent-adapted strains such as *L. interrogans* serovar Copenhageni. Accidental infection of humans with animal-adapted strains of *Leptospira* results in a severe, flu-like, sometimes fatal, zoonotic disease. Hence leptospirosis is of considerable public heath importance.

Aetiology and Pathogenesis

Infection can enter via skin abrasions or through the mucous membranes of the eye, mouth, or nose. It can also be transmitted

VetBooks.ir



• **Fig. 24.5** Leptospirosis in maintenance and accidental hosts (including humans).

in semen after natural service (Ellis et al. 1986), whereas its presence in vaginal fluids may suggest the possibility of direct venereal transmission (Loureiro et al. 2017). After infection a short latent period (5–14 days) is followed by a bacteraemia that, if caused by a host-adapted serovar (e.g., *L. hardjo*), causes relatively mild symptoms; however, if caused by a non-adapted strain (e.g., *L. pomona*), it results in an acute, severe, sometimes fatal disease. The bacteraemia lasts for some 4 to 5 days, after which the animal mounts an immune response against the leptospires. Thereafter, the organisms localise in tissues that are inaccessible to antibodies, particularly kidney tubules, cotyledons, and fetus (Higgins et al. 1980). Colonisation of the kidney results in excretion of leptospires in the urine for a period of time that lasts between several weeks and the entire lifetime of the animal (Thiermann 1982, Ellis 1984). Renal damage can be severe, which is more serious in non-maintenance hosts than in maintenance hosts. Excretion in the urine provides the major source of environmental contamination and of direct infection both of other cows and of humans. Other pathological changes, such as haemolysis, nephritis, and hepatitis, can also be serious in non-maintenance hosts.

Fetal infection, as a result of placentitis and leptospires crossing the placenta, varies in outcome depending on the stage of gestation. Abortion may result, or the fetus may produce antibodies and survive, or it may be stillborn or be born weak and latently infected. Leptospires can be present in postpartum discharges for up to 8 days (Ellis 1984) and can persist in the pregnant and non-pregnant uterus for up to approximately 150 and approximately 100 days after infection, respectively.

Transmission of leptospirosis depends on conditions favouring the survival of the organism in the environment, on the number of carrier animals in a population, and on the length of time for which carrier animals shed leptospires. The risk of infection increases when there is a high density of carrier and susceptible animals. Survival of leptospires in the environment depends on variations in temperature and humidity. Drying and pH values outside the range of 6–8 are detrimental to their survival in the environment, whereas warm, moist conditions favour its survival. The organism can survive for long periods in wet soil or stagnant water, and the risk of infection with *Leptospira* organisms increases during periods of high rainfall

VetBooks.ir

or flooding. Effluent is an important source of leptospires for feedlot cattle.

Clinical Presentation

Infection of naïve cattle with *L. hardjo* generally results in a mild disease. Most animals show no clinical signs but become carriers and excrete the organism in the urine. In other animals, clinical signs include the following:

- A transient rise in temperature and/or the appearance of being unwell or inappetent for a few days;
- Mastitis ('flabby bag') or a sudden drop in milk production (Ellis & Michna 1976); and
- Abortion or stillbirth occurring up to 6 or even 12 weeks after the acute phase of an infection. It can occur at any time from the fourth month to term; it is most common after 6 months. Abortion can occur in the absence of any clinical signs of disease (Thiermann 1982).

Infection with non-adapted serovars (notably Pomona, Canicola, Copenhageni, Icterohaemorrhagiae, and Grippotyphosa) results in an acute febrile disease, characterised by temperatures of 40°C or more, together with haemoglobinuria, icterus, and anorexia. Leptospiral mastitis may also be present. Deaths may occur, especially in calves, and there may be sporadic abortions or an abortion storm.

Diagnosis

There are no lesions that are specific for leptospirosis. The placenta of animals that have aborted may exhibit oedema of the intercotyledonary tissue, and the cotyledons may be fawn-coloured and flaccid. Aborted fetuses are usually severely autolysed, although some are quite fresh and oedematous. If fetal interstitial nephritis is present, it is pathognomonic. Antibodies in fetal serum are also diagnostic, but titres are low (~1:10), which requires specialised methods for identification (OIE 2017d).

It is possible to identify *Leptospira* organisms by direct isolation, dark-field microscopy, or fluorescent antibody staining of fetal fluids, kidney, or lung or cow urine. Although definitive, these methods are time consuming and demanding. Diagnosis therefore relies primarily upon serology upon maternal or fetal blood, for which the most widely used test is the microscopical agglutination test (MAT) or, more recently, ELISA. The MAT is the most widely used serological test and is the reference test against which all other serological tests are evaluated. ELISAs have been developed against whole cells and membrane proteins, with moderate success, although validation of the tests remains a constraint to their use (OIE 2017d). Additionally, PCR methods are being developed for the identification of serovars and for the rapid identification of leptospires in tissue/fluid samples. PCR methods are most fully validated for human samples (e.g., Thaipadunpanit et al. 2011) but are being increasingly evaluated for use in field isolates (e.g., Hamond et al. 2014, Martin et al. 2015). Balakrishnan et al. (2015), however, noted that despite recent advances in PCR technology, it remained less accurate than MAT in field samples.

Even using the 'gold standard' MAT, diagnosis is not straightforward. High titres against non-host adapted serovars, together with clinical signs of disease, can be diagnostic, although abortion can occur in the absence of high titres. Adapted serovars are more difficult. Even though active infection with *Leptospira* causes rising titres in paired sera, high MAT titres usually persist only for up to about 3 months after infection. Hence, titres are generally in decline by the time abortion occurs because there is usually an interval of 6 to 12 weeks between infection of the dam and fetal expulsion (Ellis 1984–1985). By that time the antibody titre of the dam is either falling, static, or not detectable. As a result, examination of paired sera (taken at abortion and 2–3 weeks later) from individual animals is of minimal diagnostic value.

TABLE 24.2 Number of cows to be sampled for the diagnosis of leptospirosis

Total herd size	20	40	90	120	300	≥ 450
Number of cows to be sampled	16	21	25	26	28	29

It is therefore preferable to use serology to identify the presence of active infection by using the MAT as screening test in herds in which the disease may be endemic. Numbers of animals from which samples should be collected are suggested in Table 24.2. Interpretation requires differentiation of active infection from vaccine titres:

- Titres of <1:400 probably reflect historical infection or vaccination titres. Most animals have titres <1:100 from approximately 3 months after vaccination.
- Titres of 1:100 are present in 40% to 70% of cattle naturally infected with *L. hardjo* regardless of their vaccination status.
- Titres of >1:1600 are indicative of active infection, but animals can have active infection with titres of <1:100 (Ellis et al. 1982).
- When more than 20% of the herd are seropositive or if titres are >1:1600, active infection is present and further spread of the disease is possible (Anon 1992).
- Titres after acute infection can be >1:25,000, and a significant increase in titres occurs if the samples are collected during an acute episode of leptospirosis.

Treatment and Control

General control measures related to good hygiene, thus minimising the risk of infection with leptospires from other host species, should be implemented. The spread of infection via the environment should also be controlled. There should be strict segregation of cattle from pigs, rodent control, and pig effluent should not be spread on grazing pastures for cattle. Fencing off or draining contaminated water sources are recommended to reduce the environmental load of organisms to which cattle are exposed. Sheep also excrete *L. hardjo* in their urine (Fang et al. 2015). Their role in the epidemiology of the disease in cattle is still not clear because sheep flocks in which cattle and sheep are grazed together show infection with *L. hardjo,* but sheep-only flocks do not (Hashimoto et al. 2010).

There are two methods of specific treatment and control: the use of a vaccine, or parenteral streptomycin/dihydrostreptomycin; or a combination of both. The antibiotic should be used at a dose rate of 25 mg/kg by intramuscular injection. Repeated doses may be necessary. Streptomycin is effective in clearing *L. pomona* from the urine of infected cattle, and treatment with antibiotic plus vaccination has been effective in arresting the progress of an abortion storm. In countries in which streptomycin is not registered for used in food-producing animals, other antibiotics (e.g., tetracyclines, ampicillin, or amoxicillin) can be used. Furthermore, *L. hardjo* may also be less susceptible to streptomycin than to alternative antibiotics (Prescott & Nicholson 1988, Radostits et al. 2007).

In closed herds, vaccination of all members of the herd should be done annually. In open herds, the frequency should be increased to 6-month intervals; this is particularly important for heifers between 6 months and 3 years of age (Ellis 1984). Vaccines are

VetBooks.ir

based upon bacterins, which produce relatively low antibody titres, but which confer protection for about 12 months. There is little or no crossprotection between the main serovars that affect cattle, so the use of bivalent vaccines (*L. hardjo* and *L. pomona*) or trivalent vaccines (*L. hardjo, L. pomona* and *L. copenhageni*) is common (Radostits et al. 2007). In situations in which the losses due to leptospirosis are low, vaccination may not be cost effective. However, the zoonotic risk of the disease is such that, even when losses are not great, public health authorities may exert considerable pressure to ensure that susceptible cattle are vaccinated. In New Zealand, a very high incidence of human leptospirosis occurred during the 1950s due to the high prevalence of the infection among dairy cows and the high proportion of the New Zealand labour-force who worked in livestock industries (Kirschner & McGuire 1957). The risk of human leptospirosis was considered of such significance that various programmes were introduced to limit the spread of the disease to humans, culminating in a vaccination programme for dairy cows (Oertley 1999). In excess of 90% of New Zealand dairy cows are now vaccinated against serovars Hardjo and Pomona and, when human leptospirosis does occur among farm workers, up to 90% of cases are associated with herds that are unvaccinated (Marshall & Chereshsky 1996).

Salmonellosis

Abortion due to salmonellae has been reported from many countries. Salmonellae may cause abortion as a result of prolonged pyrexia or as a result of infection of the fetoplacental unit.

Aetiology and Pathogenesis

Salmonellae are an important cause of losses in cattle, primarily through enteritis, septicaemia, and abortion. Nomenclature of salmonellae has undergone many changes over the years; most of the 'species' that were once recognised are now considered as serovars of a single species. Thus '*Salmonella typhimurium*' is correctly named '*Salmonella enterica* subsp. *enterica* serovar Typhimurium' (Grimont et al. 2000). In this chapter, salmonellae will be named according to species and serovar, e.g., *Salmonella* Typhimurium.

In Britain, salmonella-induced abortion has persisted as a continuing, although not a major problem, for some time (Table 24.1). The main organism involved is *Salmonella* Dublin, which is responsible for 80% of salmonella abortions (Carrique-Mas et al. 2010). *Salmonella* Dublin is not evenly distributed throughout the world. It is common in the UK (notably Dorset, Somerset, and southwest Wales) and Europe, South Africa, and parts of South America. In the US, it was confined to California and other regions west of the Rockies until recently, but has spread eastwards through the movement of infected cattle (Bulgin 1983, Radostits et al. 2007). Likewise, in Australia, it was confined to the southern states but has now also spread to Queensland (Trueman et al. 1996). *Salmonella* Typhimurium is endemic in cattle throughout the world but is not the major cause of reproductive failure; *S.* Newport is probably the most common of the exotic salmonellae to infect cattle, but a wide variety of other species are isolated during individual outbreaks. In New Zealand, *S.* Dublin is not present, but *S.* Brandenburg is a significant cause of abortion in cattle (Clark et al. 2004).

The disease is contracted after the consuming of feedstuffs or grazing of pasture that has been contaminated with faeces from infected animals, slurry from animal units, human sewage, or infected river water. After infection, there is an initial bacteraemia during which the organism spreads to the liver, spleen, lungs, and lymph nodes of the dam. Infection localises into placentomes 6 to 8 days later, causing a recrudescence of pyrexia. Death of the fetus and subsequent abortion occur as a consequence of the resulting placentitis. The proportion of the herd that is affected depends on the stage of gestation of animals at the time of infection. Commonly, only a small number of animals abort, although significant abortion storms can also occur.

Clinical Signs and Diagnosis

The classical signs of salmonellosis in adult cattle include a marked pyrexia (>40°C), severe diarrhoea, and dysentery, which may be associated with abortion. More frequently, salmonella abortions occur in late pregnancy in the absence of any other clinical signs, although malaise, pyrexia, and inappetence have also been recorded in some animals aborting because of *S.* Dublin infection.

A definite diagnosis depends on the isolation of the organism from fetal tissues and membranes, uterine discharges, or vaginal mucus. Culture of fetal stomach contents and/or fetal brain should routinely be carried out on aborted calves, as this is often the first indication of *S.* Dublin in a herd (Henderson & Mason 2017). Direct culture allows definitive identification of the causal serotype. Faecal culture from dams with clinical signs has only a modest sensitivity (38%), largely because of the very small numbers of organisms that are in the sample.

Serological tests can be used for *S.* Dublin although agglutinins fall to low titres fairly soon after the event (Hinton 1973). However, serology, either of individual animals or of from herd (in bulk milk) have higher sensitivities than faecal culture (80% and 55%–95% respectively; Warnick et al. 2006) and can be used to diagnose the presence of *S.* Dublin in a herd. Carriers are difficult to identify; however, shedding increases during periods of stress, and so there is a better chance of identifying such animals in postcalving cultures. O'Leary (2014) considered that, if the fetus is not available for culture, serology on maternal blood is the next best option for diagnosis.

Control

Cows that have aborted only excrete the organism for a very short period of time, unlike the continuous or intermittent excretion that occurs after enteric infection. Potential excreters need to be isolated until vaginal discharge ceases. Fetuses and fetal membranes, together with contaminated bedding, should be disposed of safely. Adequate cleansing and disinfection of premises should be performed. In the face of an abortion storm, reducing stock density (e.g., by dispersing or set stocking animals around the farm) may help to reduce spread between animals.

Vaccination can be used to control salmonellosis. A killed vaccine that contains *S.* Dublin and *S.* Typhimurium in many countries in which *S.* Dublin is present, and, in New Zealand, a vaccine that contains *S.* Bovismorbificans, *S.* Hindmarsh, *S.* Typhimurium, and *S.* Brandenburg is available. These vaccines can be used to either as a prophylactic measure (in conjunction with other hygiene and biosecurity measures) or to reduce the number of abortions in the face of an outbreak.

Listeriosis

Listeria monocytogenes is primarily a pathogen of the central nervous system in sheep and cattle, in which it causes encephalitis. It is consistently, although not frequently, isolated from bovine abortuses and is also a cause of abortion in sheep and goats (Chapter 29).

VetBooks.ir

Other species of *Listeria* (*L. ivanovii* and *L. seeligeri*) are also rare causes of abortion in cattle.

Aetiology and Pathogenesis

Listeria monocytogenes is ubiquitous in the environment, being present in the soil, sewage effluent, bedding, and foodstuffs. It persists, as it is particularly resistant to the effects of drying, sunlight, and extreme temperature. The source of infection in cases of abortion is almost always grass silage that is either grossly contaminated with soil, has a low dry matter content, or has undergone inadequate fermentation, resulting in a high-pH, butyric silage. Crossinfection between sheep and cattle is possible, and there is evidence that some individuals become symptomless carriers, excreting the organism in faeces and milk.

The organism gains entry by ingestion or by penetration of mucous membranes of the respiratory system or conjunctiva, as well as the central nervous system. The organism has a predilection for the placenta, causing a placentitis, death of the fetus, and abortion.

Clinical Signs

Abortions are usually sporadic, occurring towards the end of gestation. However, there are rare reports of serious outbreaks and very rare reports of abortion storms in some herds. In some individuals, there may be pyrexia before, at the time of, or after abortions have occurred. It is very uncommon for cows that show neurological signs of listeriosis to abort, and vice versa. The aborted fetus is usually autolysed but generally lacks specific lesions. However, the presence of multiple yellow or grey pinpoint necrotic foci in the liver and cotyledons, similar to those described for sheep, is characteristic of the disease.

Diagnosis

This is dependent on the identification of the organism in the abomasum and liver of the fetus and in the placenta and vaginal discharges, by a direct smear or by immunofluorescence. Culture of the organism is not easy, although a series of subcultures after refrigeration has proved to be successful. Serological tests are not used in its diagnosis.

Treatment and Control

Cows that show clinical signs of malaise and pyrexia may warrant prophylactic treatment with antibiotics to prevent abortion. Prophylactic treatment of the whole herd is contra-indicated due to the sporadic nature of the disease. If the source of poor quality silage can be identified, this should be withheld from cows in the second half of pregnancy.

Histophilus somni

Histophilus somni (formerly *Haemophilus somnus*) is a common inhabitant of the genital tracts of male and female cattle. The organism can be routinely isolated from the mucosal surfaces of the urogenital tract of normal healthy cattle in the absence of any macroscopic lesions (Eaglesome & Garcia 1992). There are reports of the organism being isolated from 28% of normal cows (Slee & Stephens 1985) and 90% of normal bulls (Janzen et al. 1981). *Histophilus somni* also infects sheep, but the strains differ between cattle and sheep so that crossinfection between species does not occur (Ward et al. 1995). *Histophilus somni* causes a number of syndromes in cattle (Radostits et al. 2007):

- Septicaemia
- Polyarthritis
- Pneumonia/pleurisy
- Thrombotic meningoencephalitis
- Reproductive disorders (strains *of H. somni* affecting the reproductive tract differ from those that cause systemic disease) (Szalay et al. 1994)
- Endometritis
- Vulvovaginitis and cervicitis (Patterson et al. 1984, Stephens et al. 1986)
- Granular vulvovaginitis (a differential diagnosis of ureaplasmosis) (Roberts 1986)
- Infertility associated with early embryonic death (Kaneene et al. 1987, Ruegg et al. 1988) and abortion (Stuart et al. 1990)
- Testicular degeneration, orchitis, epididymitis in the bull (Corbel et al. 1986, Jubb et al. 1993, Barber et al. 1994)

Histophilus somni is a relatively uncommon cause of abortion in cattle, having been recorded in 0.4% of diagnosed abortions in New Zealand (Thornton 1992) and 1.7% to 3% of abortions in Germany (Kiupel & Prehn 1986). Lesions of the aborted fetus and placenta are non-specific: typically an acute, non-suppurative placentitis mainly within the cotyledons (Jubb et al. 1993). Diagnosis can be made by culture of the organism, which can be difficult because of overgrowth by contaminants. Recognition of the organism may not always be straightforward, as it is pleomorphic. In addition, *H. somni* may be present alongside other potential abortive organisms, making it difficult to be certain whether it was the causal organism (Headley et al. 2015). Serological tests are currently unreliable.

There are few reports on the treatment of infected cows. Penicillin and streptomycin have been reported to be successful in treating cows in which *H. somni* was frequently isolated from cervicovaginal mucus and in which fertility was depressed (Eaglesome & Garcia 1992). Because the organism colonises the genital tract of the bull and can be isolated from semen, this may well be a source of infection of cows and heifers. Good hygiene and the use of combinations of antibiotics should control infection after AI. There is a recent report of *H. somni* being transmitted via embryo transfer and causing the death of transferred embryos (Scarcelli et al. 2004).

Bacillus licheniformis

Abortion due to *Bacillus licheniformis,* which was first identified in the UK in northern Scotland, Cumbria, and Northern Ireland (Counter 1984–1985), has been reported from many countries of the world. Although B. *licheniformis* is ubiquitous, the main source of infection is silage, or water, other foodstuffs, and bedding that become contaminated with silage effluent. Wet, spoilt hay can also be a source. The method of infection is not known, but it is probably haematogenous after entry via the gastrointestinal tract.

Sporadic cases occur in the third trimester of gestation and most commonly in the winter months (Agerholm et al. 1995). There are also reports of small outbreaks in two consecutive years (Counter 1984–1985). Sometimes live calves can be born with some evidence of placental lesions. *Bacillus licheniformis* causes a necrosuppurative placentitis, in which the allantochorion is dry, leathery, and yellow or yellowish-brown in colour, is sometimes oedematous, and has necrotic foci 2 to 3 mm in diameter. When the fetus has been infected, there will usually be evidence of a bronchopneumonia, fibrinous pleurisy, pericarditis, and peritonitis. Purulent exudate is often present in the airways. There are no systemic signs of disease in the cow (Counter 1984–1985). Diagnosis is by culture from

VetBooks.ir

the fetus (especially the abomasum), placenta, and vaginal swab. Isolation of *B. licheniformis* in the absence of tissue lesions in the fetus may be the result of sample contamination.

The only means of control is to avoid feeding infected silage or hay.

Other Bacterial Causes of Infertility

Many other species of bacteria (notably *Trueperella pyogenes, Aeromonas* spp., *Fusobacterium necrophorum, Escherichia coli,* and *Streptococcus* spp.; Table 24.1) are periodically isolated from bovine fetopathies (Rowe & Smithies 1978, Moorthy 1985, Smith 1990). These organisms are not regarded as primary pathogens but may be accidental contaminants of the uterus, probably after haematogenous spread in the dam.

Abortions may occur at any stage of gestation, although most commonly in the last trimester. Diagnosis is usually made by the isolation of the organism from the placenta, abomasal contents, or fetal tissues from which the organism is isolated in pure growth of bacteria from fetal viscera (particularly liver and lung) or stomach contents. It is very probably that it was the cause of the abortion, especially if lesions consistent with a bacterial infection are present and other causes for abortion have been ruled out. Because the abortions are sporadic, there are no suitable methods of treatment or control.

Mycoplasma, Ureaplasma, Acholeplasma, and *Chlamydia* Infections

There are many species of *Mycoplasma, Ureaplasma, Acholeplasma,* and *Chlamydia,* which are found as commensals of many species of animals. They have been implicated in disease in as much as they are commonly isolated from diseased tissue. However, they are also found in healthy tissues, and experimental studies to demonstrate pathogenicity are relatively limited (Eaglesome & Garcia 1992), so it is more likely that in most situations they are opportunistic, rather than primary, pathogens. For example, Ball et al. (1978) recovered mycoplasmas from 23.7% of aborted placental material and none from normal controls, and from 4.4% of aborted fetuses and 1.3% from non-aborted controls. On the other hand, infections with various *Mycoplasma* species and with *Ureaplasma diversum* have been associated with female infertility, abortion, and male infertility, and for some species (notably *M. bovigenitalium* and *M. bovis*) there is conclusive evidence of a role as a pathogen.

Spread of mycoplasmas and ureaplasmas is largely through infected semen or via the respiratory route. It is therefore better to use AI rather than natural service until bulls are known to be free of infection. However, because AI may also play a role in the spread of infection, it is suggested that the standard Cassou pipette should be protected by a disposable polythene sheath to prevent vulval or vaginal contamination before it is introduced through the cervix. The uterus can be infused with a solution containing 1 g of tetracycline or spectinomycin (where these are licenced for use in cattle) one day after insemination, a treatment that has been shown to improve pregnancy rates. A number of antibiotics have been incorporated in semen for the control of these organisms. A combination of lincomycin, spectinomycin, tylosin, and gentamicin added to raw semen, and non-glycerolised whole-milk- or egg-yolk-based extenders have been shown to control *M. bovis, M. bovigenitalium,* and *Ureaplasma* spp. (Shin et al. 1988).

Mycoplasma bovigenitalium

Mycoplasma bovigenitalium is commonly found in the vaginal mucus of normal cows (Trichard & Jacobsz 1985), repeat breeders, and subfertile cows in which no other cause of infertility could be determined (Langford 1975, Nakamura et al. 1977, Kirkbride 1987). The organism may also cause granular vulvovaginitis (Afshar et al. 1966, Irons et al. 2004), although the evidence for its role in natural occurrences of the disease is not unequivocal, and it has been suggested that a considerable degree of strain-to-strain variability in pathogenicity exists (Saed & Al-Aubaidi 1983).

Mycoplasma bovigenitalium is also a common isolate from semen and preputial washes of bulls (Fish et al. 1985, Kirkbride 1987), and spread of the organism from affected bulls to cows has been demonstrated. It has been implicated as a cause of seminal vesiculitis, as it is both isolated frequently from clinical cases and can infect the vesicular glands after experimental inoculation. When it infects the testes or epididymides, it may cause detrimental changes to semen quality, especially after cryopreservation.

Mycoplasma bovis

Mycoplasma bovis is widespread, but not ubiquitous in cattle populations; it is commonly isolated from cattle in the UK and US and is present in Australasia (Nicholas & Ayling 2003, Ayling et al. 2004). It causes respiratory disease, otitis media, and polyarthritis in calves (Henderson & Ball 1999), mastitis in adults (Kirk et al. 1997), and infects the female genital tract (Irons et al. 2004). It is a successful colonist of the vagina and uterus, causing persistent infections (for 1 and 8 months respectively), extensive endometritis, salpingitis, and even peritonitis. Infection occurs through the respiratory, mammary, or male and female genital tracts. It can be spread through AI with infected semen: Stipkovits et al. (1983) recorded seroconversion of cows that had been inseminated with contaminated semen that subsequently aborted. Infection of the male can cause orchitis and seminal vesiculitis and affects semen quality (Nicholas & Ayling 2003). Natural and experimental infections cause abortions (Stalheim et al. 1974, Bocklisch et al. 1986) and the birth of premature calves.

Diagnosis of *M. bovis* can be made by serology, PCR, or culture from individual animals, or by bulk milk serology or PCR for the identification of infected herds. ELISA can be used for serology on individual animals but is better used to identify seroconversion or high titres in groups of animals. It can also be used in bulk milk. Alternatively, the organism can be demonstrated in bulk milk or pathological specimens using PCR. Culture is the definitive means of identification, but is technically demanding and has a risk of providing false negative results. Samples for culture require careful handling, including transport in specialised media (Maunsell et al. 2011). Lesions in abortions can include mild through to severe placentitis, although not every case from which *M. bovis* is isolated presents with placental lesions. Likewise, fetal lesions can range from placentitis, suppurative fetal bronchopneumonia, fibrinous peritonitis, myocarditis, and epicarditis through to no gross lesions (Yaeger & Holler 2007, Watson et al. 2012). Although it is seldom found in the reproductive tract of normal cows, isolation of the organism from the placenta or aborted fetus can be considered significant (Kirkbride 1990).

Control of *M. bovis* abortion is difficult as (i) it is sporadic, (ii) there is a very limited range of antimicrobial agents that are both efficacious against mycoplasmas and are licenced for use in food-producing animals, and (iii) there is a dearth of vaccines that have demonstrated efficacy against *M. bovis* abortion. Maintenance of a closed herd is considered the best way of preventing its infection

VetBooks.ir

with *M. bovis* (Gonzalez et al. 1992), although its potential for transmission through AI semen can nullify even this method.

Other *Mycoplasma* Spp.

Other *Mycoplasma* species (e.g., *M. alkalescens, M. arginini, M. bovirhinis, M. californicum, M. canadense, M. mycoides* subsp. *mycoides* (LC), and Group 7 *Mycoplasma*) have been isolated from abortuses, the genital tracts of cows and bulls, and semen (Boughton et al. 1983, Kapoor et al. 1989, Gilbert & Oettle 1990, Hum et al. 2000), usually with no evidence of consequential pathology. Hassan and Dokhan (2004) therefore suggested that interpretation of a causal role for these organisms in an abortion should rest upon demonstrating the presence of lesions in the fetus that are compatible with the known pathological effects of mycoplasmas.

Mycoplasmas are fragile organisms that require careful handling for successful microbiological culture. Specialised transport media are therefore recommended (Yaeger & Holler 2007). Provided samples are appropriately collected; most bovine mycoplasmas can be recovered using conventional *Mycoplasma* media, although some may require special supplements or conditions for optimum growth (Eaglesome & Garcia 1992).

Ureaplasma diversum

Ureaplasma diversum is a common inhabitant of the genital tract of the cow. It is most commonly found in the vagina and vestibule, but it persists only briefly in the uterus and uterine tubes. It also affects male animals, resulting in seminal vesiculitis, granular balanoposthitis, and impaired semen morphology (Marques et al. 2009). In cows *Ureaplasma diversum* infection has been associated with granular vulvovaginitis (Schweighardt et al. 1985, Rae et al. 1993, Farstad et al. 1996). Acute infection produces granules around the clitoral region and on the lateral walls of the vagina, which are accompanied by hyperaemia of the vulva and a profuse, mucopurulent vaginal discharge. Large, purulent lesions may also be present, which resemble those of infectious pustular vulvovaginitis (IPV, bovine herpesvirus–1, BoHV-1: see later in this chapter). These may give way to less obviously inflamed, chronic lesions. Gaeti et al. (2014) identified *U. diversum* in cattle with pustular vulvovaginitis that were negative for BoHV-1, although other cattle that had no lesions also had the organism within the vestibule.

Samples should be collected from areas of active inflammation for diagnosis of granulomatous vaginitis. For the diagnosis of abortion, samples should include lung, placentome, stomach contents, and amniotic fluid (Yaeger & Holler 2007). If *Ureaplasma* has caused the abortion, the placenta is likely to be thickened and opaque, accompanied by a mononuclear inflammatory infiltrate, fibrosis, and interstitial necrosis with the lungs displaying a non-suppurative alveolitis with mononuclear inflammation of the tissues surrounding the airways (Jubb et al. 1993).

Ureaplasma diversum can also produce endometritis and salpingitis (Kirkbride 1987). These lesions have been associated with high levels of embryonic death and returns to oestrus, which are accompanied by a mucopurulent vaginal discharge. Abortions may also occur as may the birth of weak calves. Abortions usually occur in the last trimester of pregnancy. Macroscopic lesions of the placenta include thickening of large areas of the amnion and intercotyledonary zones of the allantochorion. The thickened regions are opaque white/yellow, with foci of fibrin exudation and haemorrhage. Usually, no gross lesions are seen in the fetus, but lesions can occur in fetal conjunctivae and lung. These lesions, together with microscopical lesions in the placenta, are quite characteristic, but not pathognomonic, for *U. diversum* abortions. On the other hand, *Ureaplasma* may often be isolated as an incidental finding from calves that have been aborted for other reasons, although differences in virulence of strains probably account for the presence of the organisms in normal reproductive tracts. Hence unless there are histological lesions in the abortus that are characteristic of ureaplasmosis (Murray 1992) or the presence of a virulent strain is demonstrated, *Ureaplasma* isolations should be interpreted with a degree of caution. *Ureaplasma diversum* can be isolated by culture, although it is a difficult organism to grow. It can also be demonstrated by PCR, which may also be of value in discriminating between the more and less virulent strains (Marques et al. 2011). Multiplex PCR may also be of value in isolating *U. diversum* from samples containing mixed infective agents (Tramuta et al. 2011).

The main means of transmission of the infection is by the venereal route. Infected semen used in AI seems to be of particular importance, since its deposition into the uterus allows the development of chronic endometritis rather than of acute vulvovaginitis. However, infection of virgin females and males has been described and it has been suggested that direct transmission between females, or even transmission by dogs sniffing the vulvas of cows (Doig et al. 1979), may occur. Whether it is transmitted between bulls is uncertain.

Acholeplasma spp.

Three species of Acholeplasma have been isolated from cattle: *A. modicum, A. laidlawii,* and *A. axanthum* (Kirkbride 1987). Of these, *A. laidlawii* has been isolated most often, largely from the bull. The current consensus is that *Acholeplasma* is a non-pathogenical commensal.

Chlamydia

Chlamydiae are Gram negative, obligate intracellular parasites. Mammalian strains of *Chlamydia psittaci* have long been associated with abortion and infertility, but until recently, the literature has been fragmentary and complicated. Recent reclassification of the Chlamydiaceae into species that are more closely aligned with host species and disease syndromes has increased the complexity of nomenclature in the literature, but has also clarified understanding of their role in bovine infertility. There has also been confusion with the condition of foothill abortion (see Chapter 28) because at one time, this was believed to be caused by *C. psittaci.* Because both abortion due to *C. abortus* and foothill abortion are sometimes called epizootic bovine abortion, there remains a degree of confusion in the literature.

Chlamydiae were classified into two genera, *Chlamydia* and *Chlamydophila,* in 1999. After some years, these genera were reunited into the genus *Chalmydia* (Pillonel et al. 2015), partly as a result of disagreements over the 1999 classification (e.g., Stephens et al. 2009). In consequence, there is much confusion in the literature over the nomenclature of the chalmydiae that affect domestic animals. In this section the convention will be adopted to refer to all species by their current genus title, *Chlamydia,* regardless of the nomenclature used in the original papers. The genus contains three species that are commonly associated with reproductive disorders in cattle – *C. pecorum, C. abortus,* and *C. psittaci* – and other species (e.g., *C. pneumoniae, C. gallinacea, C. suis*) that are commonly found in cattle (Li et al. 2016) but are not characteristically associated

VetBooks.ir

with reproductive disease. The order Chlamydiales also contains the recently discovered organism *Waddlia chondrophila* (Livingston & Longbottom 2006), which may also affect reproduction in cattle.

Chalmydiae are probably ubiquitous in cattle (Reinhold et al. 2011), although the role of chlamydial agents in bovine fertility has not been considered as a major threat to cattle industries (Livingston & Longbottom 2006). Many animals appear to be carriers of the infection (DeGraves et al. 2003), but the incidence of abortion due to the organisms appears to be low. Development of more sensitive diagnostic tests may lead to greater significance being attributed to *Chlamydia* (Borel et al. 2006) but the question of the presence of the organism versus its role as a pathogen is often obscure.

Chlamydiae are shed in many secretions and excretions, including vaginal, ocular, and nasal fluids, semen, and urine and so forth, with faecal shedding being the most important route. Organisms are also present in aborted material, including the fetus and placenta (Kaufold et al. 2014a). Infection usually occurs through inhalation or ingestion, including from abortus material, and venereal infection may possibly occur.

Control of chlamydial infections is difficult. In theory, tetracyclines or macrolides could be used to treat pregnant cows that have been exposed to infection, but this is not really practicable because it requires knowing that the secondary chlamydaemia has not occurred, and animals must be treated until normal calving. Moreover, it is likely that antibiotic treatment may promote persistent/latent infection (see Reinhold et al. 2011), which would mitigate the use of such treatments. An increased risk of chlamydial disease is associated with poor herd management and hygiene, but causal links have not been established (Reinhold et al. 2008). Pregnant animals should be segregated from potential sources of infection, particularly abortus material. Vaccines are available for use in sheep but none has yet been developed for use in cattle.

Chlamydia abortus

Chlamydia abortus occurs in cattle, sheep, and other domestic ruminants throughout most of the world, particularly Europe, the US, and the Indian subcontinent. In sheep the organism is responsible for ovine enzootic abortion (see Chapter 29). Infection is probably by ingestion of infected material, but venereal spread via the semen of infected bulls also seems probable (Storz et al. 1976). After infection of the cow, there is colonisation and replication in the endometrium, resulting in endometritis (Bowen et al. 1978) and embryonic death (Yaeger & Holler 2007). The incubation period for the disease is variable, ranging from 5 to 125 days in experimental infections (Storz & McKercher 1962). Moreover, some animals become infected and abort in the same season, whereas others become infected in one season, remain infected, and abort in the subsequent season (Aitken 1983). Reinfection of cattle previously exposed to the organism also results in reduced fertility. On the other hand, carrier states appear to be common, even in virgin animals (DeGraves et al. 2003, 2004).

Abortions usually occur after the seventh month of gestation but have been reported from the fifth month. Abortions are more likely to be sporadic in cattle than in sheep, although abortion storms of up to 20% of pregnancies have been reported. Infection in the last trimester of pregnancy may also result in the birth of live, weak calves. Most cows show no signs before abortion, but experimental infection has resulted in an intermittent, mucoid, vulvar discharge, together with transient diarrhoea, pyrexia, and lymphopenia. Retention of the fetal membranes after abortion is common. Infertility that is not associated with abortion can also occur: Kaltenboeck et al. (2005) demonstrated that subclinical, non-venereally transmitted infection with *C. abortus* has an influence on fertility and suggests that infertility can be caused by reinfection with the organism.

In bulls, *C. abortus* infection can cause epididymitis, seminal vesiculitis, and testicular degeneration (Storz et al. 1968), which may progress to atrophy. It can also be found in clinically normal bulls (Teankum et al. 2007).

Humans who work with aborting ewes can become infected with *C. abortus,* and abortions have occurred in pregnant women (Aitken & Longbottom 2004). Presumably the same could also occur by contact with aborting cattle.

Chlamydia pecorum

Chlamydia pecorum is an endemic intestinal species in cattle (Li et al. 2016), which can also cause systemic illness or affect fertility. Infection can result in severe diseases, including polyarthritis, enteritis, keratoconjunctivitis, pneumonia, and sporadic bovine encephalomyelitis (Livingston & Longbottom 2006). Infection is also associated with uterine infection, infertility, and abortion. Infection may result in endometritis, although more severe disease, including metritis and salpingitis, has resulted from experimental infection (Wittenbrink et al. 1993a, b, Jones et al. 1998). Pyrexia, malaise, and/or a purulent vaginal discharge (Livingston & Longbottom 2006) and low grade/subclinical vaginitis (DeGraves et al. 2003) have also been reported.

Waddlia chondrophila

Waddlia chondrophila is a member of the order Chlamydiales, which has been implicated in bovine abortions. It has been isolated from a number of aborted fetuses (Barkallah et al. 2014), and serological responses to the organism has been associated with pregnancy failure (Dilbeck-Robertson et al. 2003). Moreover, *W. chondrophila* has been identified in the placentas of miscarried human pregnancies (Wheelhouse et al. 2016). Crawford et al. (1989) described the effects of *W. chondrophila* on a bovine fetus after direct administration of the pathogen caused death of the fetus within 2 weeks. Wheelhouse et al. (2016) also administered the organism to pregnant heifers: they failed to cause abortion, but placentitis was identified in one heifer and the organism was isolated from the affected placenta. It is therefore feasible, but unproven, that *W. chondrophila* could be a source of sporadic abortions in cattle.

Diagnosis

The gross pathology of abortions due to chlamydiae in cattle is similar to that occurring in ovine enzootic abortion. The intercotyledonary areas of the placenta are more frequently affected, being thickened and leathery in appearance with a reddish-white, opaque discoloration oedema is quite common. In the aborted fetus, the liver is enlarged with a coarsely nodular surface, a firm consistency and a mottled reddish-yellow colour (Shewen 1986). The fetus may have a pot-bellied appearance due to ascites, and there may be subcutaneous oedema.

The organisms can be cultured from aborted fetuses and discharges after the use of transport media. Tissue can be used to prepare Giemsa-stained smears for the identification of elementary bodies or inclusions. Most infections are now diagnosed by antigen detection ELISA or immunostaining (Aitken & Longbottom 2004) or by PCR (Borel et al. 2006, Menard et al. 2006), which can be used for identification of chlamydiae in the field or after culture.

VetBooks.ir

Serological tests include the complement fixation test and ELISA, but such methods lack specificity.

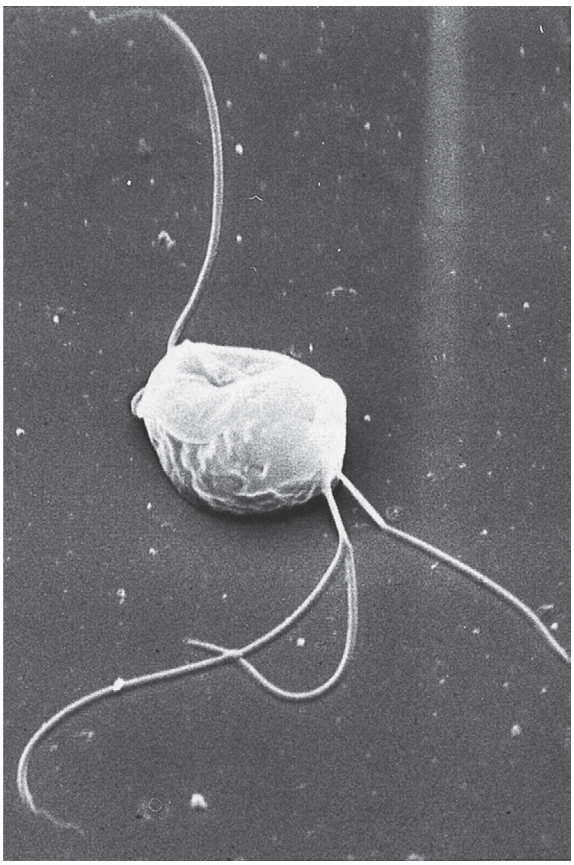
Protozoal Agents

Trichomonosis

The recognition of *Tritrichomonas* (formerly *Trichomonas) foetus* infection as a cause of infertility was an important advance in our understanding of the role of specific venereal pathogens in cattle (Riedmuller 1928). Enzootic trichomonosis was brought under control in the dairy herds of many countries by the widespread introduction of AI during the 1950s and 1960s. However, worldwide, trichomonosis remains a major cause of reproductive failure that is present at a high prevalence in geographical regions in which natural service is the predominant means of cattle breeding. Characteristically, this more commonly involves beef than dairy herds, but the prevalence of infection can be high where dairy herds are bred by natural service. A high prevalence has been reported from many countries, including some states (e.g., California and Florida; Skirrow & BonDurant 1988, BonDurant et al. 1990, Rae et al. 2004), but not all (Grotelueschen et al. 1994, Fox et al. 1995) states of the US, Canada (Copeland et al. 1994), South Africa (Eaglesome & Garcia 1992), Brazil (Jesus et al. 2003), and Australia (Dennett et al. 1974). Geographical isolation has permitted the virtual eradication of trichomonosis in the UK and New Zealand, yet even in these countries, occasional reemergence of the disease can occur from time to time (Taylor et al. 1994, Oosthuizen 1999). Hence whenever natural service is used, trichomonosis must not be overlooked as a cause of infertility.

Aetiology and Pathogenesis

Tritrichomonas foetus is an obligate venereal pathogen. The parasite can be identified by the presence of three anterior flagellae and a characteristic undulating membrane that is visible because of its wave-like motion on one side of the organism when viewed under phase contrast or dark field microscopy (Fig. 24.6). In wet preparations its characteristic jerky, rolling motion can be seen at 100x or 250x magnification.



• **Fig. 24.6** Scanning electron micrograph of *Tritrichomonas foetus* (16,500x).

TABLE 24.3 Relationship between age and *Tritrichomonas foetus* infection in Californian beef bulls

<2	259	1	<0.4
>2	465	29	6.2

From: BonDurant et al. (1990).

The Bull

Tritrichomonas foetus causes an asymptomatic infection of the bull, residing in the crypts of the penile integument and preputial mucosa. Once infected, bulls can remain lifelong carriers. Younger bulls are less liable to become persistent carriers than older bulls because the crypts of the penile integument and preputial mucosa are less developed in younger than older animals (Peter 1997). Hence, bulls that are less than 3 years old are likely to have short-term infections or to be transient carriers, whereas older animals are more likely to become persistently infected and to perpetuate the infection from season to season (Table 24.3). Infection of bulls usually occurs as a result of coitus with an infected cow; however, it can also be transmitted though infected semen collection equipment. It has been suggested that bull-to-bull transmission could occur through bulls riding each other, but there is no conclusive evidence for the spread of infection in this way.

The Cow

Persistently infected bulls are the primary source of infection, although there can be passive transfer from a previously uninfected bull that has recently served an infected cow (Rae & Crews 2006). Infection can also be disseminated by AI with infected semen, as *T. foetus* survives routine processing of semen for AI. Very rarely, cows can be infected via fomites, such as a contaminated vaginal speculum. Although the number of trichomonads needed to establish an infection in the cow is large (probably several thousand; Clarke et al. 1974), transmission rates are high. Under conditions of heavy work, the number of trichomonads present in the preputial area of

VetBooks.ir

the bull is reduced, so transmission may be less than 100%; but under normal conditions, it is common for virtually every cow that is mated by an infected bull to become infected.

Tritrichomonas foetus colonises the uterus, cervix, and vagina but survives poorly on the vulva. It causes a mild catarrhal endometritis and vaginitis, with oedema of vulva, perivaginal tissue, and uterine wall. It does not generally invade through the epithelial surface. The disease does not prevent fertilisation but causes embryonic death, resulting in an irregularly extended return to oestrus. Many pregnancies fail at between 30 and 50 days of gestation (Parsonson et al. 1976), although some may occur at a sufficiently advanced stage of gestation to be recognised as an early abortion. It has been suggested (BonDurant 1997) that embryonic death occurs as a result of damage to the developing placentomes. A few animals exhibit normal or even short returns to oestrus. Embryonic death is not infrequently (up to 10% of cases) accompanied by the development of pyometra, in which the uterus is filled with enormous quantities of trichomonad-filled, thinnish pus. Vaginal discharge of this pus is common.

Antibody-mediated (IgG and IgA) immunity develops over several months (Skirrow & BonDurant 1990), so after a series of returns to oestrus, cows develop sufficient immunity to maintain a pregnancy to term. Many cows experience a series of embryonic deaths before they become pregnant and carry the calf to term. Epizootics of the disease in the 1940s were characterised by an average of five returns to oestrus before conception occurred (Bartlett 1948). The time taken for clearance of infection from affected cows is very variable, ranging from 95 days in heifers to 22 months (Parsonson et al. 1976, Skirrow & Bon Durant 1990). Most cows that calve have successfully eliminated the infection and do not pose a risk as long-term carriers, but some animals become persistently infected (i.e., through a gestation and into the next breeding season; Rae & Crews 2006) and act as a reservoir of infection to the herd (Skirrow 1987). Immunity is short term, probably lasting a maximum of 15 months (Clarke et al. 1983a), so that cows are fully susceptible to infection in successive seasons.

Clinical Signs

Introduction of trichomonosis into a herd is associated with a disastrous decline in fertility, with extended returns to oestrus, long inter-calving intervals, and an increased proportion of animals culled for failing to conceive. The presence of pyometra and early gestation abortions is also suggestive of the presence of the disease. Animals that fail to conceive often exhibit mucopurulent vaginal discharge at the time of return to oestrus, and manipulation of the uterus often provokes a discharge from the vulva in which motile trichomonads can be demonstrated. Likewise, the uterine contents in pyometra after *T. foetus* infection are usually voluminous, fluid, odourless, and greyish-white and contain trichomonads in great numbers. Infected cattle therefore have the following clinical presentations:

- Become pregnant and carry to term without clinical signs of infection developing;
- Return to multiple services but show no obvious signs of infection and oestrous cycles may be regular or irregular;
- Fail to become pregnant and develop an oedematous condition of the endometrium with a mucoflocculent discharge;
- Become pregnant but abort at 2 to 4 months of gestation; and
- Develop pyometra and become acyclic.

Some abortions occur between the second and fourth months of gestation, but very few occur after the fourth month. In later term abortions, trichomonads can be found in the chorion, fetal lung, and fetal gut. The fetus is smaller than is appropriate to the period of gestation because of growth retardation. In such abortion cases, the fetus, which is grey in colour, is generally expelled complete in its membranes. There are no signs of putrefaction and *T. foetus* can readily be demonstrated in fetal fluids. Parasites quickly disappear from the vaginal discharges after abortion (usually within 7 days).

Diagnosis

Diagnosis of trichomoniasis is much easier than that of campylobacteriosis. A positive diagnosis of trichomoniasis depends on a demonstration of live *T. foetus* organisms from specimens obtained from the genital tract of female cattle, preputial material of bulls, or aborted fetal and placental tissues.

Diagnosis in the cow is best achieved by demonstrating the presence of trichomonads in uterine pus, vaginal discharges, cervical mucus, or abortus material. The best source of material is the fetal membranes or the organs of an aborted fetus (especially the abomasum). Elimination rates of infection are highly variable after an infected mating, so failure to demonstrate the presence of the organism does not necessarily imply its earlier absence. Material contaminated with faeces should be discarded because non-pathogenic trichomonad-like organisms (Taylor et al. 1994) may be present. In the bull, diagnosis is made by the collection of preputial scrapes or preputial washes. Vigorous scraping of the preputial mucosa to obtain as much smegma as possible (Eaglesome & Garcia 1992) is the traditional method of collection. Stoessel and Haberkorn (1978) suggested that thorough scraping of the prepuce was needed to diagnose the presence of trichomonads, but Oosthuizen (1999) reported a very high reliability of preputial washings (using about 50 mL of phosphate-buffered saline or lactate Ringer's solution) collected from heavily sedated bulls. The bull should be allowed a period of 5 to 10 days of sexual rest before sampling so that the number of trichomonads can increase. The most reliable material for diagnosis in infected herds is preputial or vaginal washings or scrapings (OIE 2017e).

Whatever the source of the material that might contain trichomonads, it should be handled with care as the organism is fragile and degenerates very rapidly after death. Hence unless samples are handled properly, the organism may be absent by the time the samples are examined. Various media can be used for culture, including:

- Clausen's medium (Eaglesome & Garcia 1992);
- Diamond's medium (Diamond 1983); and
- InPouch TF system (Biomed Diagnostics Ltd) (Borchardt et al. 1992).

Organisms are visualised after culture. It is recommended that samples are transported to the laboratory in a Diamond's or InPouch medium rather than in a simple buffer. Temperature should be maintained between 22°C and 37°C. Culture systems using modified Diamond's medium and the InPouch TF have been considered as a 'gold standard' for the diagnosis of trichomonosis (Rae & Crews 2006).

The InPouch TF system for field culture consists of a clear flexible plastic pouch with two compartments. The upper compartment contains special medium into which the sample is introduced. Field samples for direct inoculation into the culture pouch would normally be collected by the preputial scraping technique. After mixing, the medium is forced into the lower compartment, and the pouch is then sealed and incubated at 37°C. Microscopic examination for trichomonads can be done directly through the plastic pouch. A preliminary diagnosis of trichomoniasis is made

VetBooks.ir

by observing motile trichomonads at 200x to 400x magnification. When present, the trichomonads are usually found in the corners and near the bottom of the lower or incubation compartment of the pouch. They are identifiable by their size, the presence of flagellae, and the 'undulating membrane'. For samples collected from bulls, the sensitivity of the InPouch system has been estimated at between 84% and 96%, and that of Diamond's medium as 78% to 99% (OIE 2017e). Specificity approaches 100%. Hence a proportion of infected bulls will not be detected at the first examination (Schonmann et al. 1994), so a second or third examination may be required to ensure that a bull really is negative.

PCR methods have recently been developed for the diagnosis of trichomonosis, which can differentiate between *T. foetus* and faecal trichomonads that contaminate the bovine preputial cavity (Campero et al. 2003, Dufernez et al. 2007), can be used to confirm the identification of *T. foetus* after initial culture (Parker et al. 2001, Grahn et al. 2005). PCR can be used for direct diagnosis of trichomonosis in field samples (Felleisen et al. 1998) with much higher sensitivity than using culture alone (McMillen & Lew 2006). However, samples must be assessed soon after collection: sensitivity declines rapidly with storage (Mukhufhi et al. 2003). It is considered that specificity and sensitivity of PCR are similar to those of the InPouch method (OIE 2017e).

Treatment and Control

Control can be attempted by:

- Eliminating bulls and replacing natural service by AI;
- Active management of groups of cows and use of bulls; or
- Treatment and/or vaccination of cows and bulls.

Artificial Insemination

Control through AI is based upon the assumption that recovery in the female is spontaneous and that infection of healthy animals cannot occur if natural service is replaced by AI using semen from non-infected bulls. Of all of the available methods, the elimination of bulls from the herd and the use of AI with uncontaminated semen is by far the most effective and efficient means of control. The method does require that cows should be bred exclusively by AI throughout at least one, and preferably, two seasons. Pregnancy rates to AI are likely to be poor during the initial period of its introduction because many of the cows may still be infected.

Group Management

Many different ideas have been suggested as ways of managing trichomonad-infected herds without resorting to the total use of AI. Most of these are similar to the control methods for bovine venereal campylobacteriosis (see earlier in this chapter).

An alternative strategy relies upon the limitation of effects of the disease by only using young bulls for breeding. It is argued that, because 2-year-old bulls are relatively resistant to infection, their use in breeding will result in less spread of the disease than occurs with older bulls. However, reliance upon the resistance of young bulls is unlikely to result in elimination of infection (Christensen et al. 1977), although their use may well help to reduce the level of infection that is present.

Treatment

As a general principle, carrier bulls should be culled because infection persists indefinitely. Bulls can potentially be treated with topical substances (e.g., iodine-based compounds, acriflavine, and imidazoles), but success rates are variable, elimination of infection is not reliable, and the application of such substances is anything but straightforward. Alternatively, dimetridazole or metronidazole can be potentially be given orally or intravenously. They have unpleasant side effects but are relatively effective. Ipronidazole can be used but has to be preceded by the use of broad spectrum antibiotics to kill non-specific bacteria in the prepuce that break down the imidazole (Skirrow et al. 1985). Resistance to the entire group of imidazoles is easily induced by the use of subtherapeutic doses. Unfortunately, none of these therapeutic substances is licensed for use in cattle in the UK or US. A newer antibiotic, trichostatin, has been found to be effective against *T. foetus in vitro* and *in vivo* (Otoguro et al. 1988). Even when treatment of individual animals is effective, it has no effect upon the presence of disease in the herd unless other steps are taken to ensure its eradication.

Vaccination

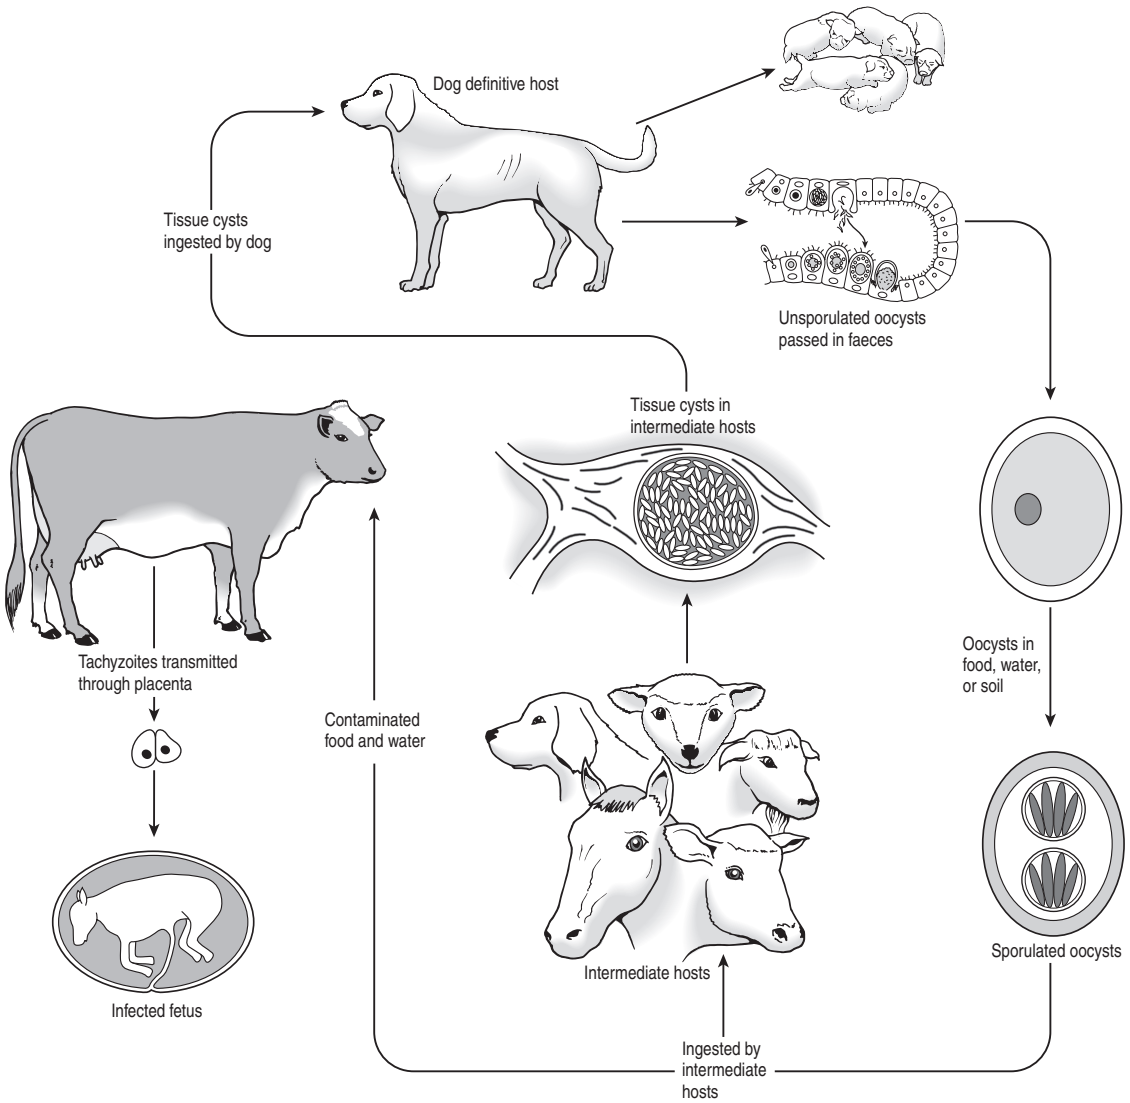
Many attempts have been made to develop a vaccine against *T. foetus.* Initial work used killed trichomonads in a mineral oil adjuvant (Clarke et al. 1983b), which helped eliminate infection from bulls. However, most development has been based upon fragmented cells or isolated membrane fractions, which stimulate a significant antibody response (Schnackel et al. 1990). These too have helped prevent and/or eliminate infection in cows and bulls (Kvasnicka et al. 1989, Hall et al. 1993, Hudson et al. 1993a, b).

In the US, a vaccine against *T. foetus* is available (TrichGuard; Fort Dodge). It requires two subcutaneous injections 2 to 4 weeks apart with the last injection given 4 weeks before the beginning of the breeding season (Rae & Crews 2006). Each subsequent year, all cows should receive a booster injection 4 weeks before the beginning of the breeding season. The vaccine does not prevent infection or disease but reduces the incidence and duration of infection of cows after service by an infected bull (BonDurant 1997). In experimentally infected heifers, TrichGuard increased the proportion of animals that conceived and that gave birth to a live calf (Edmondson et al. 2017) However, as the vaccine does not completely protect, it can only be used as an adjunct to other control or prevention methods (Cortese 1999). Curiously, although early studies in Australia suggested that vaccination conferred protection upon bulls, more recent American studies have found that vaccination has little effect upon either the incidence or the duration of infection in the male (Cortese 1999). However, despite these evidences for the effectiveness of killed whole-cell *T. foetus* vaccines, when Baltzell et al. (2013) undertook a meta-analysis of relevant literature, they found only moderate evidence for its efficacy: the relative risk for infection was 0.89, for failure to conceive was 0.8, for abortion risk was 0.57, and the data were too imprecise to calculate an effect upon duration of infection. It was not possible to calculate an effect upon infection of bulls.

Neosporosis

Neospora caninum was first discovered as a protozoan parasite that causes encephalomyelitis of dogs (Dubey et al. 1988). Neosporosis is now recognised as a significant cause of bovine abortion in most of the major cattle-producing regions of the world. It has been recorded in the UK, the US (Dubey & Lindsay 1996), Canada (Alves et al. 1996), Argentina (Campero et al. 1998), South Africa (Jardine & Last 1995), Zimbabwe (Wells 1996), Australia (Obendorf et al. 1995), New Zealand (Thornton et al. 1991), and many other countries. In 1999 Tenter and Shirley suggested that *N. caninum* was responsible for 6000 abortions per annum in the UK. Reichel

VetBooks.ir



• **Fig. 24.7** Life cycle of *Neospora caninum*.

et al. (2013) undertook a meta-analysis of published sources on the economic effect of the disease: they estimated a median cost to dairy farms in the UK of US$700 to $2100; in the US of US$3700 to $16,100; in Australia of US$2500 to $18,000; and in New Zealand of US$4500 to $68,000.

Aetiology and Pathogenesis

The dog is both the definitive host and an intermediate host for the parasite (McAllister et al. 1998). The life cycle consists of three infectious stages: tachyzoites, tissue cysts, and oocysts (Dubey 2005) (Fig. 24.7). After ingestion of tissue cysts, dogs may pass small numbers of unsporulated oocysts in their faeces, which may contaminate feed or water of grazing animals and which are reasonably resistant in the environment. It is likely that other canids (e.g., foxes, coyotes) and scavenger species may also be definitive hosts (Wapenaar et al. 2006). When sporulated oocysts are ingested by an intermediate host (dogs, grazing species, and birds), sporozoites are liberated into the intestinal tract, which then penetrate cells to become tachyzoites. These divide rapidly, causing tissue damage, and then spread to a variety of tissues including neural cells, macrophages, fibroblasts, vascular endothelial cells, hepatocytes, and placenta. Thereafter, the parasite forms bradyzoites (tissue cysts), predominantly in neural tissue (Antony & Williamson 2003, Weston 2008). These tissue cysts can subsequently be eaten by a definitive host, thereby perpetuating the cycle. Transmission to the definitive host occurs mainly after ingestion of fetal or placental tissues infected with tissue cysts.

Vertical transmission via the placenta to the fetus is considered to be the main route by which cattle became infected (Anderson et al. 2000). Marugan-Hernandez (2017) summarised the routes of vertical transmission as follows:

- Transplacental transmission result from an endogenous or exogenous source of infection.
- Endogenous transmission occurs when there is reactivation of tissue cysts in a previously/persistently infected animal and is associated with a pattern of sporadic abortions and reproductive failure in the herd.
- Exogenous infection occurs after a primary horizontal infection (i.e., oocysts are ingested by a pregnant animal) and is associated with an outbreak of abortions, usually in a naïve herd.

There is no direct evidence for horizontal transmission from cow to cow (Anderson et al. 1997). However, epidemiological evidence

VetBooks.ir

from abortion storms suggests a point source of infection (McAllister et al. 2000). Furthermore, de Magalhaes et al. (2014) concluded from studies of seroconversion rates in cattle that horizontal transmission could occur in approximately 3% of animals. Routes of horizontal infection could include colostrum, fetal membranes, and fluids from infected cows or oocyst-contaminated feed. The presence of *N. caninum* in semen also raised the possibility of this route of transmission (Piagentini et al. 2012). Likewise, horizontal transmission could occur if cattle ingest tachyzoite-contaminated pasture and have concurrent oral lesions (such as occur when permanent incisors are erupting) that would allow haematogenous spread. None of these routes of infection has been convincingly proven, although there is a clear association between the presence of *Neospora* infection in farm dogs and the risk of abortion in dairy cows (Bartels et al. 1999, Wouda et al. 1999). On the other hand, some farms have a high proportion of adult cattle that seroconvert without any increase in the occurrence of abortions.

Clinical Signs

Neospora caninum infection causes abortion at any time after 3 months of gestation, although abortions are most common in the fifth to seventh months. Infection of an immunologically competent fetus most commonly results in the birth of a live, congenitally infected calf, although stillbirths also occur. Thus fetuses may be resorbed, mummified, autolysed, stillborn, born alive with clinical signs, or born clinically normal but chronically infected (Dubey 2005). A congenitally infected heifer calf is capable of vertically transmitting the infection to the next generation when she becomes pregnant, thus maintaining infection within a herd. Repeat abortion may occur in some infected animals. Abortions may present as:

- An abortion 'storm', in which up to 40% of a herd may abort in one season (Anderson et al. 1995). There appears to be two circumstances in which this occurs:
  - simultaneous exposure cattle to infective oocysts from a definitive host, as described previously by Marugan-Hernandez (2017); and
  - exposure to another infectious agent (e.g., BVD virus) or factor that suppresses immunity (Antony & Williamson 2003)
- Sporadic abortions in endemically infected herds. Abortions can be an ongoing problem, with an abortion rate that is high but not catastrophic. Other herds experience clusters of abortions over a period of 2 to 3 months, presumably reflecting the timing of exposure to the parasite (Weston 2008).

Patterns of abortion also differ between congenitally infected animals and those that become infected after birth. Congenitally infected animals are permanently infected and are at a high risk of abortion, particularly in their first gestation. Thereafter, they are more likely to produce live calves, although there is a very high probability (75%–90%) of their offspring also being congenitally infected. Animals infected by horizontal transmission may abort or may produce uninfected or congenitally infected calves depending on their immune status and the stage of gestation at which they were infected.

Calves that are congenitally infected with *N. caninum* may be underweight and/or have neurological signs, including ataxia, impaired proprioception, or an inability to rise. Neurogenic flexion or hyperextension of the limbs may occur (Barr et al. 1993). Exophthalmia, asymmetry of the eyes, and hydrocephalus have also been reported (Dubey 2005). However, most calves that are congenitally infected are clinically normal (Thornton et al. 1991).

Diagnosis

Abortion due to *N. caninum* may need to be differentiated from other protozoal agents such as *Toxoplasma gondii* or *Sarcocystis.* Abortion diagnosis is made by a combination of serology, with immunohistochemistry and histopathology of aborted fetuses.

Fetuses aborted due to *N. caninum* infection are characteristically moderately to severely autolysed (Abbitt & Rae 2007). Diagnosis of *N. caninum* infection is relatively straightforward, using serology and/or demonstration of tissue cysts. The organism can cause lesions in several organs, of which fetal brain is the most consistently affected. Typically, there is a focal encephalitis characterised by necrosis and non-suppurative inflammation. Because most aborted fetuses undergo rapid autolysis, even semiliquid brain tissue should be fixed in 10% buffered neutral formalin for histological examination. In calves that are congenitally infected with *N caninum,* one of the specimens of choice for diagnosis is brain and spinal cord from dead calves. Non-suppurative lesions are also present in the myocardium, skeletal muscle, and, occasionally, the liver and lung (Weston 2008). Non-suppurative lesions are also present in the placenta, which often presents with multifocal necrotic foci within the cotyledons combined with intact intercotyledonary areas. Inflammatory infiltrates begin in the maternal caruncles and then extend to the fetal cotyledon, with the appearance of areas of haemorrhage and necrosis (Marugan-Hernandez 2017). Confirmation of a presumptive diagnosis on the basis of histology requires demonstration of the presence of tissue cysts by either immunocytochemistry or serology.

PCR methods are available for the diagnosis of the presence of *N. caninum* in both fetal tissues (Reitt et al. 2007) and colostrum (Moskwa et al. 2007). However, McInnes et al. (2006) noted that, although the presence of *N. caninum* can be demonstrated by PCR, neither the presence nor absence of antibodies or DNA could unequivocally support or exclude it as the cause of abortion. Hence they concluded that additional criteria are required for a positive diagnosis of neosporosis as the cause of an abortion or that it is best used to confirm a presumptive diagnosis made on clinical signs and pathological lesions.

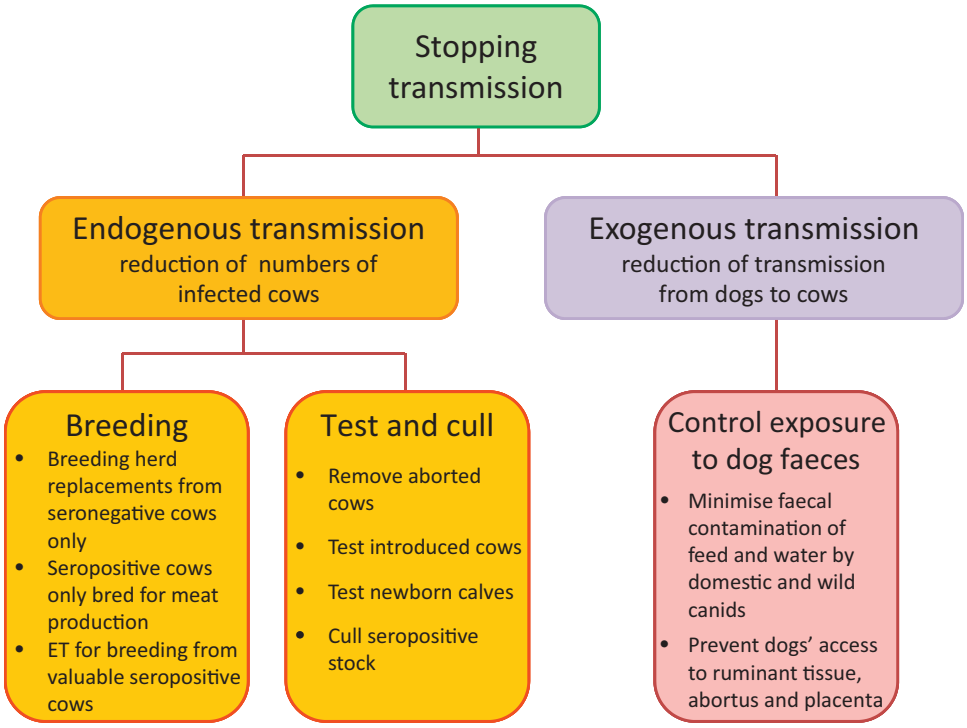
There are several serological tests that can be used to detect neosporosis in dairy herds, including immunofluorescent antibody (IFAT) and ELISA tests. IFAT titres of more than 1:200 are often regarded as being indicative of previous infection, whereas a titre of more than 1:2000 is indicative that a recent abortion was due to *N. caninum.* However, because of the widespread prevalence of seropositive cows, a positive result does not necessarily indicate infection at the time of testing, only that the cow had been exposed to the disease at some previous time. Moreover, non-aborting cows have been reported with titres of more than 1:4000, although titres can have dropped significantly in cows in the interval between infection and abortion.

Fetal serology can definitively demonstrate the presence of infection with *N. caninum,* although the absence of a positive response is not a definitive indication that infection did not occur, especially in early gestation fetuses that have not become immunologically competent. In live calves that are congenitally infected with *N. caninum,* precolostral serum is the specimen of choice for diagnosis.

Prevention and Control

The vertical transmission of *N. caninum* and limited understanding of the means whereby horizontal transmission occurs makes control difficult. There are three main strategies that are in use: management of breeding to reduce vertical transmission; testing and culling affected animals; and reduction of the canid-ruminant

VetBooks.ir



• **Fig. 24.8** Approaches to the control of *N. caninum* infections and abortions. Pathways showing ways for the reduction of the number of *N. caninum*-infected cows, for managing exposure to dogs and canids, and for preventing transmission of *N. caninum* to cattle. (Based on Reichel et al. 2014 and used with permission.)

life cycle (Fig. 24.8). None are fully effective, but depending on the circumstances of the herd, all may help to reduce the incidence of abortions. Vaccination, the potential fourth method of control, is not currently feasible. There is no effective means of treatment.

If vertical transmission (i.e., from one generation of cattle to the next) can be prevented, future generations of cattle will be uninfected and should have a reduced risk of abortion, provided that further exposure to oocysts can be prevented (Reichel et al. 2014). Thus cows that are seropositive, which are likely to be infected, will produce daughters that are also infected and are at risk for abortion at least in their first pregnancy. Not breeding herd replacement from such animals or breeding them only for production of slaughter-generation animals will preclude such vertical transmission. Avoiding bringing seropositive animals into the herd (whether home-bred seropositive calves or purchased animals) will also reduce the risk of vertical transmission. When the proportion of infected animals in a herd is relatively small, carriers can be identified by serology and culled (Reichel & Ellis 2002), thereby preventing vertical transmission. If calves are required from infected cows (e.g., when valuable genetics need to be conserved), these can be derived by embryo transfer, provided uninfected recipients are available.

Measures that can be taken to limit horizontal spread include:

- Ensuring that cattle do not have access to contaminated feed or water;
- Removal and disposal of abortus material and afterbirths immediately after birth; and
- Preventing dogs from having access to cattle feed, effective rodent control, and preventing wild carnivores from having access to abortus material.

A killed *N. caninum* vaccine, based on inactivated tachyzoites, has been developed, but does not appear to stimulate protective immunity. Use of the vaccine reduced the incidence of abortions but did not prevent them (Choromanski & Block 2000, Romero et al. 2004). One of the main problems with vaccination is that cows that are apparently immune to the disease (i.e., are seropositive) can still undergo repeat abortions. Vaccination appears to be more effective at preventing abortion due to new infection after the ingestion of *Neospora* oocysts than it is at preventing abortion in animals with congenital infection (Trees & Williams 2003, Dubey 2005). Based upon experience of toxoplasmosis in sheep, Marugan-Hernandez (2017) considered that live vaccination was likely to give the best results, so long as a low virulence isolate with low capacity to persist in the host can be identified.

Sarcocystis spp.

Sarcocystis is a very rare cause of bovine abortion (Abbitt & Rae 2007). Protozoa of the *Sarcocystis* genus have a two-host life cycle. The definitive host, which is a carnivore, sheds infectious sporocysts in its faeces. The intermediate host ingests the sporocysts, which develop into sarcocysts in the muscle of the host. Of the three species of *Sarcocystis* that occur in cattle (Markus et al. 2004), *S. cruzi* appears to be able to cause abortion. Clinically, abortions are indistinguishable from those caused by *Neospora;* differentiation depends on immunohistochemistry or PCR.

Viral Agents

Bovine Viral Diarrhoea

Bovine viral diarrhoea (BVD) virus was initially recognised as a cause of diarrhoea during the 1940s. Although it was originally considered to be a simple virus-induced diarrhoea, more recent

VetBooks.ir

understanding of the infection has shown that it also causes infertility and abortion. Worldwide, BVD virus is a major cause of abortions, resulting in both sporadic abortions and abortion storms.

Aetiology and Pathogenesis

Bovine viral diarrhoea virus is a pestivirus of the Flaviviridae family, which also contains classical swine fever and border disease of sheep. There are two genotypes of BVD virus: BVDV-1, which has a worldwide distribution, and BVDV-2, which is largely restricted to the US. Disease associated with BVDV-2 is generally much more severe than that resulting from BVDV-1. BVDV is also divided into non-cytopathic strains and cytopathic strains, based upon their effects upon cells in tissue culture. Both the non-cytopathic and cytopathic isolate exist within each of the two BVDV genotypes. There is strong evidence that the non-cytopathic biotype mutates to the cytopathic biotype in persistently infected (PI) animals.

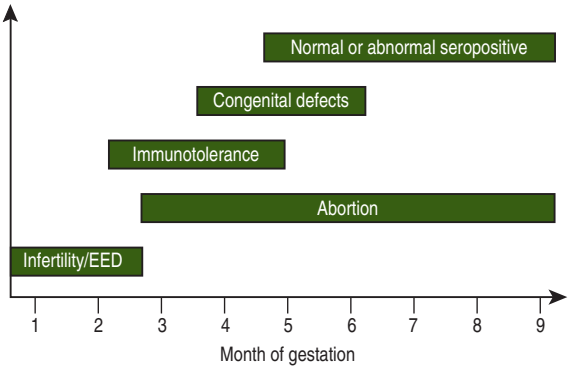
The main route of infection of naïve animals is via respiratory secretions, but it can also spread in uterine secretions and abortuses, urine, milk, semen, faeces, and saliva. BVDV can also be transmitted through virus-contaminated embryos (Avery et al. 1993). It appears that relatively close contact, including nose-to-nose and sexual contact, is required for infection to occur. Acutely infected animals, flies, aerosolised virus, and contaminated pens or veterinary equipment have also been implicated in transmission (Lanyon et al. 2014). Infection of naïve animals results in a transient viraemia, which may be accompanied by pyrexia, mild inappetence and diarrhoea, depression, and a period of immunosuppression, from which animals recover in a few days. Some affected animals may develop oculonasal discharges, salvation, and oral erosions, and, occasionally, there may be more severe disease. Most animals, however, show little or no clinical evidence of infection (Barr & Anderson 1993, Radostits et al. 2007). In pregnant females, transplacental infection of the fetus occurs during the period of viraemia.

Depending on the time of its occurrence, infection of the fetus can result in early embryonic death, abortion, birth of live or stillborn calves with congenital defects, birth of live calves with a persistent BVDV infection, or birth of seropositive calves that are immune to the virus. Such persistently infected (PI) animals are the main means of spread of the virus and are considered to be the main means by which BVDV infection is maintained in populations of cattle (Bolin 1990a).

Mutation of the non-cytopathic biotype in PI animals results in the development of mucosal disease. Mucosal disease is generally considered to be a sporadic condition, affecting single animals or small numbers of animals in a sequential manner. However, if there are a large number of PI animals in a herd (as might occur if infection was introduced to a herd at the susceptible stage of pregnancy), an outbreak of disease can occur when animals with mucosal disease excrete cytopathic biotype virus that infects the other PI animals. In this circumstance, mucosal disease appears to behave as a simple infectious disease. It is generally considered that cytopathic biotype cannot cause transplacental infection, nor can it cause PI animals.

Clinical Signs

Infection with BVDV causes reproductive failure in naïve and PI females but rarely in seropositive animals. The introduction of BVDV to susceptible breeding females around the time of insemination and during the embryonic and early- to midfetal period can result in a range of reproductive disorders and neonatal diseases (Fig. 24.9). In addition, acute infection with BVDV can allow other infections (notable *Neospora caninum*) to undergo recrudescence.



• **Fig. 24.9** Potential clinical effects upon reproduction in cattle after infection with bovine viral diarrhoea virus at different stages of gestation (EED, early embryonic death). (Redrawn from Grooms and Bolin 2005.)

Infection From Before Mating to Day 30 of Gestation

Infection can occur at mating if cows are bred by a PI bull or an animal that is transiently infected with BVDV (Kirkland et al. 1991), or if inseminated with semen that is contaminated with the virus (Virakula et al. 1993). Infection with BVDV at or around the time of breeding can have a significant effect on reproductive performance: affected animals are less likely to become pregnant (Houe et al. 1993, Grooms 2004) due to conception failure and impaired early embryonic development (McGowan et al. 1993). This in turn is due to effects upon follicle and oocyte function, the magnitude of the LH surge (Ssentongo et al. 1980, Grooms et al. 1998), and the uterine environment. Oocytes can be infected with BVDV, which may explain why calves born to PI cows are always PI themselves (Lanyon et al. 2014). Pregnancy failure may be manifest as a low non-return rate or as irregular, prolonged returns to oestrus. The birth of PI calves after insemination of cows with semen infected with BVD virus has also been reported (Meyling & Jensen 1988).

Infection Between Days 30 and 150 of Gestation

Infection of the fetus in this period of gestation can lead to:

- Fetal resorption (Days 30–40), mummification, or abortion;
- Immunotolerance and the birth of PI calves (Days 30–150); and
- Congenital defects, mainly of the central nervous and ocular systems (Days 80–150).

Fetal deaths after BVDV infection of susceptible dams can occur at any point of gestation, although they are most common during the first trimester. Depending on the time of infection, fetal resorption, mummification, or expulsion can occur. Expulsion of the fetus may occur from days up to several months after fetal infection (Bolin 1990a).

Fetuses that survive infection with non-cytopathic BVDV between Days 18 and 125 of gestation (McClurkin et al. 1984) are immunotolerant to the virus and subsequently become persistently infected with BVD virus. Most infections that result in the development of PI calves occur before Day 75 (Roeder et al. 1986) but, although immunotolerance is uncommon after Day 100, it can occur until Day 125 (Grooms 2004).

Infection between Days 80 and 150 of gestation can result in the birth of calves with congenital abnormalities, predominantly of the central nervous system and eyes (Table 24.4). Typically, there is a time interval of between several days and 2 months between infection with BVD virus and abortion (Bolin 1990a).

VetBooks.ir

TABLE 24.4 Congenital abnormalities associated with bovine viral diarrhoea virus infection during midgestation

Nervous System	Eye	Other Systems
Cerebellar hypoplasia	Cataracts	Long bone deformities
Hypomyelinogenesis	Microphthalmia	Stunted growth
Hydrocephalus	Retinal atrophy	Brachygnathias
Microcephalus	Optic neuritis	Hair abnormalities, alopecia

Infection in Late Gestation

Irrespective of the biotype, infections of the fetus in the later stages of pregnancy that do not cause abortion will lead to the birth of an immune calf, because the fetus can develop a measurable antibody response to the organism by 5 to 6 months of gestation (Bolin 1990b).

The Trojan Cow

A non-PI cow that is carrying a PI fetus can be considered a 'Trojan cow' (Lanyon et al. 2014). The cow appears immune to BVDV and is healthy, but the PI calf that she is carrying will shed large quantities of BVD virus once it is born. Previous observations have shown that Trojan cows have antibody titres during mid to late pregnancy that are significantly higher than those of seropositive cows carrying normal calves (Brownlie et al. 1989, Lindberg & Alenius 1999). This high antibody titre is very probably a result of the continual antigenic challenge of the cow.

Abortion

Abortions can occur at any stage of gestation. Most losses occur before the third trimester, as the fetus is increasingly able to mount an effective immune response against the virus as gestation advances, but some abortions in the third trimester of pregnancy have also been attributed to BVD virus (Moennig & Leiss 1995, Grooms & Bolin 2005).

Fetuses aborting from BVDV infection may be expelled autolysed, mummified, or in fresh condition at various stages of pregnancy. However, because of the relatively long interval between infection and abortion, the fetus is often severely autolysed. There are no pathognomonic fetal lesions associated with BVDV infection but, if the fetus is reasonably fresh, there may be histological evidence of dermatitis, meningitis, destruction of the cerebellar cortex, and bronchiolitis.

Diagnosis

Aborted or Congenitally Malformed Fetus

Demonstration of BVDV in any tissues of affected fetuses or calves by virus isolation, immunohistochemistry, demonstration of BVDV antigen in fetal fluid or skin by ELISA, or PCR testing of fetal fluid would confirm the presence of BVDV infection (Lanyon et al. 2014). When infection is acquired after Day 150 to 180 of gestation, the fetus is able to mount an immune response, will eliminate the virus, and will be born BVDV antibody-positive, antigen-negative (Hansen et al. 2010). Neonatal serology must be undertaken in precolostral animals to avoid confusion with maternal antibodies. Virus can be recovered from fetal lymphoid tissues (spleen, thymus, and ileum), lung, or liver by virus isolation, PCR, or immunohistochemistry. It is preferable to submit multiple fetuses until the virus is isolated (Grooms & Bolin 2005).

Herd Infection

The presence of active BVDV infection in a herd can be inferred from clinical signs, the presence of PI animals and monitoring programmes. Bulk milk monitoring is an effective means of detecting the presence of a PI animal among the lactating cows, owing to the very large amount of virus that such animals produce. Bulk milk testing can be undertaken by ELISA (Pritchard 2001, Thobokwe et al. 2004) or, more usually now, by PCR (Renshaw et al. 2000, Pritchard 2006).

Serology is relatively difficult to interpret, as the virus is widespread and antibody titres are long lasting, with the result that high titres can be indicative of historical, rather than current, infection. It is also difficult to differentiate between natural infection and vaccination titres (Grooms & Bolin 2005). However, serology of young (~9 months old), unvaccinated animals that are used as 'sentinel animals' is a useful means of monitoring the presence of active infection. The presence of antibody titres in these unvaccinated cattle indicates recent virus exposure and is a strong indicator that BVDV is present on the farm (Houe 1992, Pillars & Grooms 2002). Likewise, antibodies in the serum of precolostral calves are also indicative that active infection occurred during their gestation. Booth and Brownlie (2016) noted that bulk milk antibody tests provide an initial, rapid, and cost effective assessment of the BVDV status of dairy cattle. It is generally accepted that high antibody levels correlate with a high probability of the presence of a PI animal. They also considered that antibody tests on young animals are valuable because such cattle will be seronegative if unexposed; the presence of antibodies demonstrating an active immune response (in contrast to maternal colostral antibodies) means that they have been infected within the 9 months of their life. That, in turn, would indicate the presence of active infection on the farm.

Demonstrating the presence of PI animals can be used to confirm that active infection with bovine viral diarrhoea is occurring. Samples for the diagnosis of PI animals include (Kelling 2007):

- Virus isolation (blood; buffy coat). Samples should not be collected from calves that have maternal antibody. It may be necessary to differentiate PI animals from those with acute, transient, infections. High sensitivity and specificity;
- Immunocytochemistry (ear notch biopsies). Can be used on any animals. High sensitivity and specificity;
- PCR (blood, serum, skin biopsies, ear notch). High sensitivity, but specificity can be affected by non-specific reactions; and
- ELISA for viral antigen (blood). High specificity and sensitivity (Hill et al. 2007) also used to differentiate between persistent and transient infections.

Control

Control should be aimed at preventing entry of BVD virus to naïve herds and preventing the spread of the virus in infected herds.

Biosecurity measures to prevent the entry of infection include maintaining a closed herd, testing all incoming animals for the presence of BVD virus/viral antigen (i.e., identifying persistently or transiently infected animals), and ensuring no pregnant animal that might be carrying a PI calf is brought on to the farm. Bulls that are purchased and brought on to the farm from outside sources pose a significant risk of infection to herds that are otherwise closed. It is possible that the disease may be transmitted from other ruminants, so maintaining separation between such animals and susceptible cattle is recommended. It is possible that semen could be infected with BVD virus, but disease control at bull studs should preclude this.

VetBooks.ir

TABLE 24.5 Bulk milk BVDV antibodies: likely significance and suggested actions

Antibody Level	Indicative Proportion of Seropositive Cows (%)	Herd Status		Possible Further Action
Low	< 5	Naïve		Test young stock to ensure continued lack of exposure
Intermediate	5–25	Low exposure	May indicate historical or acute infection	Test 'sentinel' animals and/or first lactation heifers. If antibody – ve, continue monitoring. If + ve, consider implementing control measures
	25–65	Moderate exposure		
High	> 65	High level of exposure; recent exposure to infection, with a high probability of persistently infected (PI) animals		Implement eradication policies to remove PI animals. Vaccination should be considered

Based on Brownlie (2005).

Various strategies exist for controlling infection in affected herds, depending on the level of disease that is present in the herd (Table 24.5). The use of a PI animal as an 'endogenous vaccinator' has been recommended in the past, but this is now very strongly discouraged (Brownlie 2005). It is now considered preferable to identify and remove PI animals because these are the main source of infection. This will not prevent spread by continued transient infections, so vaccination may also be required.

Modified live and killed vaccines have been developed for control of BVD. Advantages of modified live vaccines are a long duration of action and interstrain crossreactivity. Conversely, they may cause immunosuppression and have been associated with fetal abnormalities (Kelling 2007). Killed vaccines neither have immunosuppressive effect nor have they been associated with fetal abnormalities, but they may not protect against abortion when animals are exposed to high levels of infection (Laven et al. 2003, Packianathan et al. 2017). The whole herd may be vaccinated or just the heifers (maiden and primiparous animals), depending on circumstances (Brownlie 2005). It has been suggested that, if live vaccine is available, cattle should be vaccinated with killed vaccine before being given the live vaccine. Eradication regimes are being implemented in many countries in which bovine viral diarrhoea is endemic. These schemes are beyond the scope of the present text.

Bovine Herpesvirus 1

Bovine herpesvirus 1 (BoHV-1) has a worldwide distribution and is associated with infectious bovine rhinotracheitis, infectious pustular vulvovaginitis (IPV), balanoposthitis, abortion and infertility. There are three subtypes of BoHV-1 (Babuik et al. 2004), which are associated with different diseases (Table 24.6). Within subtypes, there are strains that cause different levels of severity of disease.

Aetiology and Pathogenesis

Infection occurs by the respiratory route and, in the case of IPV, by the venereal route. It may also be transmitted through infected bedding, sniffing of the vulva and perineum of infected animals, and via contaminated semen. Abortus material is also a significant source of infection.

Infection can result in clinical presentations of disease of varying degrees of severity. Animals may become asymptomatic latent carriers directly after infection or after recovery from clinical illness. Latent infections are maintained in the trigeminal and sacral ganglia.

Acute signs of respiratory or genital disease appear after a latent period of 10 to 20 days, with respiratory symptoms generally being of short duration. Lesions associated with IPV may be present for a longer period – sometimes up to several weeks. Excretion of virus in respiratory or genital secretions continues for approximately 14 days. However, animals that become latent carriers may resume shedding of the virus periodically during times of stress (e.g., calving, transport) or after corticosteroid administration, at any time for the remainder of the animal's life.

TABLE 24.6 Disease syndromes associated with different subtypes of Bovine Herpes Virus (BoHV)-1

	SYNDROME		
Type	Infectious Rhinotracheitis	Infectious Pustular Vulvovaginitis/ Balanoposthitis	Abortion
BHV-1.1	+	-	+
BHV-1.2a	+	+	+
BHV-1.2b	+	+	-

The interval between infection with an abortifacient strain and expulsion of the fetus is much more variable, ranging from a few days to full-term delivery of a stillborn or affected calf (Miller et al. 1991). It has been suggested that the duration and variability of the interval between infection of the dam and abortion of the fetus represents a period in which the virus resides in the placenta without infecting the fetus itself (Kendrick 1971).

Clinical Signs

The genital form of the disease may present without other symptoms or be accompanied by respiratory disease. It is unusual for IPV and abortions to present together.

Infectious Pustular Vulvovaginitis

The onset of vulvovaginitis is sudden and acute. Signs appear 24 to 48 hours after venereal transmission. Heifers tend to be more severely affected than cows. The vulvar labia become swollen and tender and, in light-skinned animals, deeply congested. This is quickly followed by the development of numerous red vesicles on the mucosa. These may rapidly rupture or develop into pustules which give rise to haemorrhagic ulcers.

The quantity of vulvar discharge is variable, ranging from small quantities of exudate that adheres to the vulval and tail hairs, to a

VetBooks.ir

copious mucopurulent discharge. A speculum is useful to examine the vaginal mucosa, but because of the pain and discomfort, caudal epidural anaesthesia is worthwhile. The lesions are obviously painful because affected animals are restless, with swishing of the tail, and dysuric, with frequent urination and straining. There may be transient pyrexia and reduced milk yield, but the systemic effects are variable depending on the presence of respiratory problems. The acute phase of the disease will subside in about 10 to 14 days, but a few animals will display a persistent vulval discharge for several weeks.

When females show signs of IPV, the bull must be examined for the presence of lesions because, unlike the situation with most venereal diseases of cattle, the signs in the bull are dramatic (see Chapter 36).

Infertility

Infection with BoHV-1 around or after the time of breeding is associated with poor fertility. Insemination with infected semen results in poor pregnancy rates (Kendrick & McEntee 1967, Parsonson & Snowdon 1975). There are various contributors to this. First, Miller and van der Maaten (1984) showed that there is a localised endometritis that follows intrauterine inoculation of BoHV-1. Second, there are necroses and lymphoid proliferation in the parenchyma of the corpus luteum, as well as in non-luteal ovarian parenchyma, and there are necrotic follicles in the ovaries (Miller & van der Maaten 1986). Additionally, the presence of BoHV-1 in semen impedes binding of sperm to the zona pellucida, thereby reducing fertilisation rate (Tanghe et al. 2005). Intrauterine inoculation with BoHV-1 on Days 7 and 14 after breeding is associated with embryonic necrosis or the absence of a conceptus and a delayed return to oestrus, signifying that embryonic death had occurred. It appears that embryonic death is the result of a direct invasion of BoHV-1 into embryonic cells (Bowen et al. 1985, Miller & van der Maaten 1986, 1987). Progesterone production is reduced in response to BoHV-1 challenge, not only in the cycle in which the challenge occurs but also, in a significant proportion of animals, in at least one subsequent cycle. From these data, Chase et al. (2017) concluded that the corpus luteum is a major site of BoHV-1 pathology in situations in which infection occurred within 4 to 9 days after oestrus and that progesterone concentrations were decreased regardless of whether the animal had luteal lesions.

Abortion

Worldwide, BoHV-1 is a significant cause of bovine abortion. Kirkbride (1992) reported that, among nearly 9000 abortions that occurred between 1980 and 1990, BoHV-1 was responsible for 5.4% of incidents. Murray (1990) found IBR to be the causative agent in 13% of 149 calves that were aborted over 2 years in northwest England. Most abortions are sporadic, but abortion storms can occur (e.g., Tanyi et al. 1983). However, abortion is considered to be a less significant consequence of BoHV-1 infection in the UK and Europe than it is in North America (Caldow & Gray 2004). Only Subtype 1.2b, which does not cause abortion, is present in Australia and New Zealand. Respiratory disease is not always evident before abortions occur, although the length of time between infection and expulsion of the fetus can mean that earlier respiratory disease may be overlooked (Barr & Anderson 1993).

Abortions occur from 4 months of gestation to term, most commonly between the fourth and eighth months of gestation. Some calves are stillborn, and a few may be born alive but succumb subsequently. The effects of virus infection may be due to the strain of the virus: Miller et al. (1991) reported that infection of heifers at 25 to 27 weeks of gestation with Subtype 1.1 resulted in abortions 17 to 85 days later, but those given Subtype 1.2a delivered full-term calves, some of which had BoHV-1 neutralising antibodies in precolostral serum. On the other hand, the interval between the time when the fetus itself becomes infected (i.e., rather than the dam) and its expulsion is relatively short: Kelling (2007) suggested that it is no more than 7 days. Regardless, the interval between fetal infection and expulsion is sufficient for the fetus to become highly autolysed or, less commonly, mummified. Retention of the fetal membranes is a common sequel to abortion.

Diagnosis

The genital tract lesions of IPV are fairly characteristic of the disease but must be differentiated from granular vulvovaginitis due to *Ureaplasma* spp. and catarrhal vaginocervicitis. After the presence of genital lesions, vaginal swabs, preputial washings, and semen should be placed in virus transport medium. Paired serum samples should be taken from the affected cows.

A severely autolysed aborted fetus is highly suggestive of BoHV-1 infection. There is frequently a liquefactive necrosis of the whole of the kidney cortex with perirenal haemorrhagic oedema. Histologically, there is always focal necrosis of the liver, and in many cases there are necrotic lesions in the brain, lungs, spleen, adrenal cortex, and lymph nodes. There are characteristic virus inclusion bodies at the periphery of these necrotic lesions in fresh experimental cases, but, because of autolysis, they are not always demonstrable in field cases of abortion. Virus may be present in any fetal tissues and in the cotyledons (Kirkbride 1992). The best means of identifying BoHV-1 in an aborted fetus is though PCR of the fetal liver. Crook et al. (2012) compared IHC and PCR-based methods of diagnosis with routine diagnostic measures; the former identified 10 of 400 abortions as being due to BoHV-1, but routine methods only identified 2 of 400 cases.

Serology is of little value in establishing a diagnosis of BoHV-1 abortion in endemic regions, as maternal infection may precede abortion for up to 2 months. Hence paired serum samples are unlikely to demonstrate a postinfection rise in titres because, by the time abortion occurs, maternal antibody levels may have already peaked, and demonstrating a rise in specific antibody levels may no longer be possible (Borel et al. 2014). Serological examination at a herd level may be of some value. Kirkbride (1990) recommended collecting paired serum samples from at least 10 cows, which should reveal seroconversion or a fourfold increase in titres if BoHV-1 infection is active in the herd.

Control

Spontaneous recovery of the genital lesions will occur, and therefore treatment is not really necessary. However, the administration of emollient creams to the vulva, vagina, and penis may be useful. Vulval stenosis and penile/preputial adhesions and phimosis can occur during the healing phase (see Chapter 36). Infected animals should be isolated and natural service suspended. Vaccination, together with sound biosecurity measures, is the most effective way of controlling the disease. A number of vaccines are available, including modified live and killed vaccines. Heifers should be vaccinated after 6 months of age and before their first service; thereafter, annual vaccination is preferable.

Pregnant animals should only be vaccinated with a killed vaccine, as modified live vaccines can potentially produce all of the effects of natural BoHV-1 infections upon the reproductive system (Miller 1991). Abortions have also been reported after vaccination with

VetBooks.ir

a modified live vaccine (Kelling et al. 1973), but there is disagreement regarding whether this is a consequence of the vaccine per se or to other strains of the virus. Ostertag-Hill et al. (2015) examined BoHV-1 isolated from animals that had aborted after vaccination, with the finding that many disease isolates had genetic differences from the vaccine strain and that some animals had a number of different genotypes present. On the other hand, Fulton et al. (2015) and Chase et al. (2017) considered that a significant proportion of fetal losses originated from vaccine use. In contradiction to both of these studies, the meta-analysis of Newcomer et al. (2017) of the effects of vaccination against BoHV-1 upon abortions showed that the relative risk of abortion in animals that had had a modified live vaccine was 0.42, whereas it was 0.37 in those that had had an inactivated vaccine. When only field challenges were included, vaccination reduced the relative risk of abortion to 0.64. Interestingly, in view of the potential immunosuppressive effects of BVDV, Walz et al. (2017) showed that prebreeding vaccination and annual revaccination with modified live BoHV-1 and BVDV vaccine conferred significant protection against this potentiating effect of one virus upon the other, although when vaccinated heifers were inoculated with high doses of BoHV-1 virus and exposed to an animal persistently infected with BVDV, it did not entirely preclude abortions.

Taken together, these data support the earlier recommendation of Kelling (2007):

- Beef heifers should be vaccinated before the start of the breeding season.
- Dairy heifers should be vaccinated at 4 to 6 months and 8 to 12 months.
- Thereafter, cattle should be vaccinated at routine postcalving examinations.

Vaccination of bulls is of questionable value because they will be seropositive on blood testing and may be rejected for sale as being infected. Routine examination of semen for the presence of the virus is preferable as a method of control.

Bovine Herpesvirus 4

Bovine herpesvirus 4 (BoHV-4) is present worldwide and can affect cattle and other domestic and wild ruminants. The virus usually results in a subclinical infection, but it can cause reproductive disease such as endometritis, vulvovaginitis, and abortion. The virus was first isolated from a case of endometritis by Park and Kendrick (1973) and has subsequently been found in cases of endometritis and metritis in several countries. It has a specific trophism for endometrial stromal and epithelial cells (Donofrio et al. 2007), which suggests that its role may be as a primary pathogen rather than merely a coincidental isolate. Likewise, Czaplicki and Thiry (1998) have associated seropositivity to BoHV-4 with abortion, and infection of the fetus by the virus has also been demonstrated (Kendrick et al. 1976).

The BoHV-4 virus can be detected by PCR, but because of the carrier status that occurs with herpesviruses, the presence of the virus does not necessarily equate with its causal role in disease. Serology, using an ELISA, is also possible (Anon 2017).

Bluetongue

Bluetongue is an infectious, non-contagious, vector-borne disease that affects domestic and wild ruminants. It is mainly a disease of sheep and deer, but cattle and wild ruminants are important reservoir hosts for the virus. Cattle are particularly significant in the epidemiology of the disease due to the prolonged viraemia in the absence of clinical disease (OIE 2017f). Bluetongue is found mainly in countries between 40°N and 35°S (Radostits et al. 2007) and is endemic in the western states of the US. Since 1999, there have been significant outbreaks of the disease in Europe. Initially, they were in southern European countries (Greece, Italy, Corsica, and the Balkans), but since 2007, there have also been outbreaks in Germany, France, the Low Countries, and the UK (European Union Reference Laboratory, 2017). Bluetongue is not present in Canada and New Zealand. In Australia there is evidence of its presence, but there is no clinical evidence of disease (Kirkland 2004). There are at least 26 serotypes of bluetongue (Maan et al. 2012) that are classified antigenically and taxonomically as bluetongue virus, but each serotype is unique and may not cause clinical bluetongue disease (Walton 2004). Different serotypes have different geographical distributions.

The virus requires insect vectors for its transmission and is not normally transmissible from animal to animal. *Culicoides* midges are the main vectors in the US, where the main agent is *ulicoides sonorensis*. In Africa and southern Europe, the main aent is *C. imicola*. The recent spread into areas of central and northern Europe that are beyond the northern limit of occurrence of *C. imicola* suggests that new insect vectors are involved: namely, *C. obsoletus* and/or *C. pulicaris,* which are widely distributed throughout northern Europe, appear to be the most likely candidates (Mertens & Mellor 2003). Different serotypes are associated with different primary vectors (Walton 2004). Competent vectors for bluetongue are present in Australia, but the geographical separation between vector-prone regions, and cattle- and sheep-raising areas would mitigate the risk of an incursion of bluetongue virus obtaining access to the national sheep flock (Tay et al. 2016).

Outbreaks of bluetongue have generally been described as being worse in the summer than in the winter, according to the number of vectors in the environment. Brand and Keeling (2017) have suggested that periods of warmth, in which insect biting is maximal, followed by cooler weather to prolong the life of the insect, may be associated with high intensity of bluetongue transmission, and that epizootics (at least in more marginal ranges for the vectors such as the UK) are associated with the prevalence of such weather patterns. It appears that the outbreak in northern Europe has also been accompanied by a change in the infectivity of the virus, such that it can persistently infect ovine T cells, thereby having a more effective mechanism for 'overwintering' between one vector season and the next (Mertens & Mellor 2003). There may also be some possibility of transmission by ticks, keds, and mosquitoes (Radostits et al. 2007). Bulls that are infected by bluetongue virus can transmit the virus in their semen (Bowen & Howard 1984), and it is possible for the virus to be transmitted by direct transfer of blood from an infected animal.

In cattle, clinical disease is rarely caused by bluetongue virus (Radostits et al. 2007), but it does have a number of effects upon bovine reproduction. Several serotypes have been identified as causing fetal infection (Savini et al. 2012) and, during the European epizootic outbreak in 2007 to 2008, serotype 8 (BTV-8) was recognised to have the ability to cross the placenta and result in fetal loss and the birth of viraemic offspring. Infection before Day 100 of gestation can lead to abortion, mummification of the fetus, or stillbirths. Nusinovici et al. (2012) found that exposure of naïve herds to BTV-8 virus was associated with an increase in the occurrence of abortions, regardless of the stage of pregnancy. Overall, there was a 7% increase in late returns to service, but exposure in the first 3 months of pregnancy was associated with

VetBooks.ir

a 15% increase of late return-to-service. Calves may be born alive that are weak and ataxic or are persistent carriers of the infection (Roberts 1986). However, teratogenic effects are more likely than abortion (Kelling 2007). The neuropathogenicity of the virus produces hydranencephaly (Howard 1986) and cerebral cysts, sometimes with consequential abnormal contractures of extremities. Live-born calves can show clinical signs of abnormal behaviour ('dummy calves') such as circling, head pressing, incoordination, and blindness (Wouda et al. 2009); the later in gestation the infection occurs, the more mild the effect upon the fetus is likely to be.

In the aborted fetus, diagnosis of bluetongue can be made by demonstration of central nervous lesions (Barr & Anderson 1993) or by virus isolation from fetal blood, spleen, lung, or brain. PCR is now the preferred method of identifying the virus, with serogroup-specific tests or gene-sequencing used to identify the virus serotype (OIE 2017f). Serology (serum neutralising assay or ELISA) can be used to diagnose maternal infection, although the presence of antibody–negative, viraemic animals during an epizootic outbreak can confuse diagnosis (Osburn et al. 1981).

Live attenuated vaccines are available for bluetongue, which generally confer good protection against infection and abortion. There is evidence that serotypes 2 and 9 in attenuated live vaccines have caused abortions in their own right (Savini et al. 2012), but the proportion of abortions (i.e., compared with total vaccinated animals) was very low, and the recovery of vaccinal strains from abortuses lower still. There is also a risk of attenuated vaccine strains reverting sufficiently to 'wild type' that they can be transmitted through vectors (Savini et al. 2008). Hence Osburn (1994) recommended that, if vaccination is used, it should be confined to the vector season. Vaccines are currently under development that utilise purified viral proteins rather than attenuated live strains.

Schmallenberg Virus

Schmallenberg virus is a member of the family Bunyaviridae and a member of the Simbu serogroup, together with Akabane virus (Wernike et al. 2015). Schmallenberg virus was first reported in 2011 as an unknown disease of dairy cows associated with non-specific signs of fever, diarrhoea, and decreased milk production. Subsequently, calves were born that showed different degrees of malformations. After ruling out other known pathogens, the virus was isolated and named the Schmallenberg virus. The virus affects wild and domestic ruminants and has also been detected by serology in wild boar and alpacas. It is spread by biting *Cullicoides* midges (C. *obsoletus, C. dewulfi, C. chiopterus, C. scoticus, C. punctatus,* and *C nubeculosus*) (Kauffold et al. 2014b). It spread rapidly through Europe in the years after 2011, is also present in Turkey, and may be present in Jordan. It has not yet been reported from elsewhere in the world (OIE 2017g). However, Sohier et al. (2017) noted an increase in cases in Belgium in 2016 and suspect that the virus may develop a 4- to 6-year cycle of activity. The prevalence of the virus in herds (> 95%) and of animals within a herd (> 85%) is high (Veldhuis et al. 2013).

In adult cows, the signs include fever, reduced milk production, and diarrhoea. In naturally infected pregnant cattle, vertical transmission of the virus to the fetus can occur between Days 80 and 150 of pregnancy (Kirkland et al. 1988), resulting in embryonic mortality, fetal malformations, abortions, and stillbirths in approximately 3% of calves (Dominguez et al. 2014). Birth defects include arthrogryposis, scoliosis, sunken eyes, cataracts, maxillary retraction dental irregularities, hydranencephaly, and cerebellar hypoplasia. Limb contractures or deformities can occur, which can also result in dystocia. Most affected calves are born dead (Kauffold et al. 2014b).

The presence of Schmallenberg virus can be demonstrated by PCR or by virus isolation from cows during the period of viremia. In stillborn or malformed newborns or abortuses, the virus can be similarly demonstrated in fetal brain, spleen, meconium, and amniotic fluid (Bilk et al. 2012). Once cattle become infected with Schmallenberg virus, they develop long lasting immunity (Méroc et al. 2015), and virus specific antibodies in the dam can be detected by virus neutralisation, indirect immunofluorescence, or ELISA (Kauffold et al. 2014b). Bulk milk antibody ELISA can also be used as a means of monitoring the presence of the infection in a herd; it is generally highly correlated seroprevalence among cows (Collins et al. 2017), although there have been occasions when bulk milk has tested positive despite only a few seropositive animals in a herd (Daly et al. 2015).

There is no specific treatment against the Schmallenberg virus. There are two inactivated-virus vaccines available in the UK and France, which can be used in sheep and cattle. Cattle require two vaccinations are required at an age ≥2 months and again 3 weeks later. It is not yet known how long protection may last, but is assumed to be ≥12 months. Additional control may be through control of the vector or ensuring that animals are at the susceptible stage of pregnancy during the vector-free season (Kauffold et al. 2014b).

Akabane Virus

Akabane virus was first isolated in Japan in 1959. It is classified in the Simbu group of the Bunyaviridae family along with Schmallenberg virus, with which it shares many similarities. Akabane virus has been reported in a number of countries in the African continent, the Middle East, Southeast Asia, and Australia. It is also transmitted by *Culicoides* midges, and it is likely that the vectors of bluetongue are also effective as vectors for Akabane virus (Kirkland 2015). There is a seasonal pattern to the disease. In temperate countries, the vector in most abundant in the summer, so the disease follows suit. In warmer countries, the disease is less common in the dry season – again, in parallel to the abundance of the vector. Changing or unusual climatic conditions allow the vectors to spread beyond their usual range, where they encounter naïve cattle that are susceptible to infection (Tranter et al. 2010).

In a naïve animal a bite from an infected midge results in multiplication of the virus at the site, followed by viraemia within 1 to 6 days. In most cases, infection produces no overt clinical signs, although some strains of Akabane virus can cause encephalitis in adult cows or in newborn calves.

In naïve pregnant animals, the virus can spread to the placenta where it replicates and spreads to the fetus. The virus then multiplies in cells of the fetal brain and spinal cord, resulting in hydranencephaly and/or arthrogryposis (Parsonson & McPhee 1985). There is no evidence that the virus can affect the early embryo before the development of the placentome, so most of the damage is seen in calves whose dams were infected between 3 and 6 months of gestation. The first sign of the infection in a herd is abortions at 4 to 6 months of gestation; some limb deformities may be present, but severe hydrancephaly will be revealed at post mortem examination (Kirkland 2015). Calves that are infected at up to Day 120 of gestation are likely to show hydrancephaly, and those infected between Days 105 and 150 of gestation are likely to show arthogryposis of multiple joints and limbs. Calves infected later in gestation may show signs of acute encephalitis, such as flaccid paralysis of the legs, hyperextension of joints, and difficulty

VetBooks.ir

in standing. Once the fetus has become immunocompetent, damage is less apparent or does not occur (Tranter et al. 2010). Thus the incidence of defects in calves may be as high as 50% if cows are infected in the third or fourth month of gestation, declining to approximately 25% in the fifth month and approximately 5% in the seventh month (Kirkland et al. 1988).

Serology (ELISA or virus neutralisation) of the fetus or neonate is the most useful diagnostic test. The presence of antibodies to Akabane virus in precolostral serum or fetal fluids is strong evidence that the calf was infected in utero. However, the absence of specific antibodies does not exclude the diagnosis if infection precedes the development of immunological competence. Maternal serology is only of value if the affected cattle are from a region where the virus is not endemic (Tranter et al. 2010). PCR may be considered to detect virus in tissue of an aborted fetus or in cotyledons of the placenta; various refinements of the basic method have been published to improve the sensitivity of the diagnosis (Shirafuji et al. 2015) or to rapidly differentiate between Akabane and Schmallenberg virus (Lee et al. 2015).

The effects of Akabane can be controlled by vaccination of susceptible animals before exposure to vectors. Various live and inactivated vaccines are currently licenced for use in Japan and South Korea (Iowa State University 2017). Inactivated vaccines have the advantage of being suitable for the emergency vaccination of pregnant animals. Vector control may be considered as may the feasibility of avoiding having animals at the susceptible stages of pregnancy during the vector season.

Epivag

Epivag is a specific bovine venereal disease causing epididymitis and vaginitis in cattle in east, south, and central Africa (Hudson 1949, Roberts 1986). In cows, it causes diffuse infection of the vagina, characterised by a reddened mucosa, but without ulcers, erosions, or vesicular lesions. A severe mucopurulent vaginal discharge may be present during the earlier stages of the disease. Most infected cows fail to conceive to service. Many eventually recover, but about 15% to 25% of animals become sterile because of the presence of lesions of the uterine tubes such as adhesions, hydrosalpinx, and ovarian and bursal adhesions. Likewise, some cows develop parametritis as a result of epivag infection (McEntee 1990), and adhesions may be widespread throughout the pelvis and even extend into the abdomen.

Most bulls have a mild balanoposthitis after infection, although, because this is far less severe than IPV infection, it may not be observed. Subsequently, most bulls develop an induration of the epididymis, particularly of the tail. Testicular degeneration, atrophy, and fibrosis are a common sequent of the infection, and orchitis may also occur (Rocha et al. 1986).

The causal organism has not been definitively characterised. Theodoridis (1978) partially characterised a series of viruses from cattle with the epivag syndrome, including some that were related to bovine herpesviruses. However, although the vaginitis component of the syndrome could be induced by various strains of these herpesviruses, the epididymitis could not. Hence it remains unclear whether the syndrome is caused by a bovine herpesvirus and, indeed, whether herpesviruses are the sole causal agent.

Catarrhal Bovine Vaginitis

This contagious, mainly venereally-transmitted, disease was first described in South Africa (Van Rensburg 1953); since then it has been reported in many countries. It is believed to be caused by an enterovirus from the enteric cytopathic bovine orphan (ECBO) group (Straub & Böhm 1964), although this remains to be proven. Transmission of the disease is primarily by the venereal route, but it can also be spread by faecal contamination of the vulva or by animals licking the perineum of infected and non-infected individuals. Therefore the disease occurs in virgin heifers.

Affected cows have a profuse, postcoital, non-odourous, yellow, mucoid vulval discharge. The cervix and vagina are inflamed, but there are no pustules such as occur in IPV infection and no fever. The typical yellow gelatinous exudate frequently accumulates in the vagina, varying in quantity from a few to several hundred millilitres. The disease persists for a few days to a few weeks. Only a few animals show clinical signs of the disease at any one time. As a consequence, pregnancy rates are reduced, and there are prolonged, irregular returns to oestrus, presumably due to late embryonic death. In some herds, fetal mummification, abortion, and stillbirth have been reported as being a problem. Bulls may or may not become clinically infected, but ECBO serotypes have been associated with seminal vesiculitis and infertility lasting up to 90 days (Bouters et al. 1964).

Diagnosis can be made on serological examination of paired blood samples collected at least 15 days apart for evidence of rising antibody titres; the first sample should be collected as soon as possible after the disease is suspected. The virus can be isolated from vaginal mucus, but the recovery rate is frequently low (Huck & Lamont 1979).

There is no specific treatment or vaccine. Infected bulls should not be used for service for several months even after clinical signs of disease have disappeared. Potentially infected animals should be isolated after purchase, and in closed herds serological examination of potential additions to the herd might be contemplated.

Transmissible Genital Fibropapillomas

Wart-like tumours commonly occur on the penis of young bulls (see Chapter 36), and occasionally, similar growths occur on the vulva, perineum, and vestibulovaginal epithelium of heifers. They are caused by a virus of the papovavirus group and are transmitted by contact with infected animals.

These fibropapillomata typically regress spontaneously in 2 to 6 months; the speed of regression may be expedited by the use of a wart vaccine (formalised tissue). Except insofar as the larger tumours (which may be removed surgically) might interfere mechanically with coitus, they do not cause infertility in female animals.

Fungal Agents (Mycotic Abortion)

Fungal invasion of the placenta and fetus is a frequent and consistent cause of abortion in cattle (Table 24.1). Abortions are normally sporadic, although in some herds the incidence may be as high as 5% to 10%. The frequency of diagnosis is high in the northeastern states of the US, in which mycotic abortions accounted for 22% of all infectious abortions and 5.1% of all abortions investigated (Hubbert et al. 1973). Similarly, in South Dakota, US, a survey over a 5-year period found that 14.6% of all infectious abortions were due to fungi; this was 4.8% of the total number of abortions (Kirkbride et al. 1973).

Aetiology and Pathogenesis

The fungi that are most frequently isolated after abortion are *Absidia* spp., *Rhizopus* spp., *Mucor* spp., and *Aspergillus* spp. Other fungi

VetBooks.ir

such as *Mortierella wolfii* and *Petriellidium boydii,* together with yeasts such as *Candida* spp., have also been implicated. Worldwide, *Aspergillus fumigatus* is the most common cause of abortion (Pepin 1983), being the cause of 60% to 80% of mycotic abortions (Knudtson & Kirkbride 1992), but other species can be locally important. In the North Island of New Zealand, for example, *M. wolfii* is the most important causal organism.

In the UK, mycotic abortion is much more prevalent during the months of December to March than during the rest of the year. Abortions are associated with the feeding of poor quality hay and silage, particularly when cows are also in confined housing (Williams et al. 1977). It is assumed that infection of the placenta and fetus occurs as a result of haematogenous spread of the organism from the alimentary or respiratory tract. Infection progressively spreads through the placentomes, causing abortion once too much of the placenta has been affected for the fetus to remain viable. Evidence of infection in the fetus is frequently also present, particularly the skin and lungs (Walker 2007). Mycotic infection does not invariably cause fetal death and abortion; sometimes, infected calves are born alive.

Clinical Signs

Abortions usually occur between the fourth and ninth months of gestation, with most occurring between the seventh and eighth months. When present, the appearance of lesions on the fetus and placenta are characteristic of mycotic infections. The whole or part of the placenta appears discoloured grey, yellow, or reddish-brown, with the intercotyledonary areas of the allantochorion appearing thickened, wrinkled, or leathery. Those cotyledons that have attached portions of the corresponding caruncle after the placenta has been shed appear thickened and have a cup-like or coffee bean appearance (Pepin 1983). Between 25% and 33% of fetuses have characteristic skin lesions (Austwick 1968, Kendrick 1975), which are circumscribed, greyish-white thickened patches similar in appearance to skin ringworm in calves and young cattle. These appear dry when *A. fumigatus* has caused the abortion and moist when it is due to *Zygomycetes* (Walker 2007). Skin lesions are not normally present in *M. wolfii* abortions.

There are no other clinical signs of disease in the dam associated with abortion due to *A. fumigatus*. A significant proportion of cows that abort because of *M. wolfii* infection develop mycotic pneumonia that is invariably fatal a few days after abortion.

Diagnosis

The presence of typical lesions of the placenta and fetus is highly suggestive of mycotic abortion. The main differential diagnosis is *Bacillus licheniformis*.

Laboratory confirmation requires submission of placental tissue, preferably the whole organ (Pepin 1983). Culture from placental tissue is of no value because the placenta is usually contaminated after it has been expelled. Culture from fetal lungs and abomasum is more reliable, but contamination can occur.

Mycotic abortion can be diagnosed by demonstrating fungal hyphae in the placenta, either histologically or in scrapings after digestion in 10% KOH solution (Pepin 1983). Fixed placenta is the best sample to submit. A range of other tissues (including lung, liver, and brain) should be examined histologically if placenta is not available. Fetal bronchopneumonia is common with all types of mycotic abortion and, if present, is considered diagnostic.

Conclusive diagnosis of mycotic placentitis can be made if (Kirkbride 1990):

- Characteristic lesions of placentitis are present in association with the presence of mycotic elements.
- Characteristic lesions of fetal dermatomycosis are present in association with the presence of mycotic elements.
- There is a fetal bronchopneumonia associated with mycotic elements.

Serological tests are, at present, unreliable and cannot be used for routine diagnosis.

Control

There is no practical treatment for mycotic abortion. The feeding of mouldy forage or the use of mouldy bedding should be avoided. There is no point in examining the suspect feed because *Aspergillus* and other fungi are normal inhabitants of such forages and will almost invariably be present.

Diseases of Unknown Aetiology

Foothill Abortion (Syn. Bovine Epizootic Abortion)

This disease was first identified in the mid-1950s in California. It is characterised by a high, late term abortion rate (30%–40%) during the last trimester of gestation or by the birth of weak calves to cows and heifers newly introduced to beef herds in particular areas of the states of California, Oregon, and Nevada (Barr & Anderson 1993). Abortions are confined to the habitat of the argasid tick *Ornithodoros coriaceus,* which appears to be an essential vector for the disease.

Identification of the causal organism was difficult. Early studies suggested that the disease was due to *Chlamydia* spp. However, it progressively became evident that this is not the case, and that foothill abortion is a separate disease entity from bovine chlamydial abortion (Barr & Anderson 1993). The early literature remains confusing as a result. Recent studies using PCR on aborted fetuses and the tick vector (King et al. 2005, Chen et al. 2007) have identified a novel deltaproteobacterium, which is closely related to *Polyangium cellulosum,* a member of the order Myxococcales, as the aetiological agent (Stott et al. 2015).

Abortions are seasonal, occurring 3 to 4 months or more after exposure to ticks. The agent appears to infect the fetus by crossing the placenta from the infected dam. Infection of the fetus needs to occur at about 60 to 140 days of gestation for fetal disease to occur. Most abortions occur in the third trimester, usually as sporadic occurrences but occasionally as a 'storm'. Cattle that abort show no other clinical signs, either at the time of abortion or subsequently. Once abortions have occurred, animals are immune, so the cattle that are at greatest risk are those calving for the first time and animals that have been moved into a tick-infested region (BonDurant et al. 2007). Infection late in pregnancy can give rise to the birth of live, weak calves (Barr & Anderson 1993). It is not yet known whether infection early in pregnant can result in early embryonic death.

Lesions in aborted fetuses are characteristic and are used in its diagnosis. Abortuses are typically not autolysed but have enlarged lymph nodes, spleen, and liver and a reduction in the size of the thymus (Jubb et al. 1993). There may be petechial haemorrhages of the mouth, tongue, thymus, lymph nodes, and elsewhere (Storz 1971). Histology is required to confirm the diagnosis; there is initial lymphoid hyperplasia, which may be followed by acute necrosis of lymphoid organs (BonDurant et al. 2007). Although the causative organism has not been definitively identified, its

VetBooks.ir

presence in abortus material can be identified by a PCR against the 16S bacterial ribosomal gene (Stott et al. 2015).

Control is attempted by ensuring that susceptible animals are exposed to ticks before they become pregnant. Although simple in theory, it is difficult in practice to find a 'window' of time between the periods of risk from ticks and the cattle being in sufficiently advanced gestation to avoid abortions.

Veterinary Control of Herd Fertility in Intensively Managed Dairy Herds

CHRIS HUDSON, JOHN GEORGE COOK AND RICHARD LAVEN

Introduction

Background

Control of cow fertility is critical to running a profitable dairy enterprise because of the shape of the cow's lactation curve. Daily milk production increases after parturition up to a peak (usually at 40–80 days postcalving in mature cows), after which it declines with time. This effect is much less marked in first lactation heifers, which typically have much 'flatter' lactation curves, but it is still important. Therefore in order to produce milk efficiently, cows are required to calve at regular intervals throughout their productive lives so that they spend most of their time in the relatively productive part of the lactation curve.

Both artificial insemination and natural service are common in the main dairying nations, and many herds use a combination of both. Cows are commonly considered eligible for breeding after a set period of time after calving (the voluntary wait period, VWP) in herds calving year-round and during a specified window of time during the year in seasonal calving herds. The choice of VWP policy is determined by the herd manager and is usually influenced by lactation curve shape and herd replacement policy. Cows that fail to become pregnant sufficiently quickly after becoming eligible for breeding are commonly culled from the herd; the decision on the stage at which this happens typically varies between cows.

Evolution of Dairying and Fertility Management

Dramatic changes have occurred to the global dairy industry over recent decades, brought about through improvements to management, feeding, and breeding practices. Genetic advances have led to breeds that are heavier, leaner, and have a higher milk yield potential. Deregulation of supply in many markets has also exposed the dairy producer to the effects of widely fluctuating milk prices, as dairy commodity prices rise and fall in response to global influences as well as local circumstances.

Although the future is difficult to predict, it seems likely that there will be a continued general increase in herd size, alongside an increase in the number of farms producing milk aimed at small, but high value, markets. Large herd size offers the potential to reduce overhead costs per litre in exchange for a greater market share, whereas the niche market benefits from a potential higher product value. The dynamics of health and fertility management are fundamentally different in larger herds, and the challenge for herd owners and veterinary surgeons is to understand how their roles need to change. The obvious and clear incentive that should motivate dairy producers to improve health and fertility is the undoubted financial benefits that can be gained from such improvements, and in larger herds it is logical that these improvements should be carried out in an evidence-based and planned manner. However, in many cases, early 'health planning' initiatives simply led to the construction of documents solely designed to comply with the requirements of farm assurance schemes and large retailers. A clear distinction should be drawn between this approach and a more holistic approach to herd health and production monitoring, which should be a continuous, active, and ongoing process involving regular monitoring of key parameters and processes; this requires a detailed knowledge of the farm as well as excellent record keeping.

Arguably, there is no reason why a similar approach should not be undertaken for herds of all sizes. Nevertheless, although both large and small dairy herds face the same reproductive management issues, in larger herds the problems become magnified, and the potential economic consequences are larger and accrue faster. Larger herds are characterised by some fundamental differences that go beyond their size and structure, which necessitate a different approach to the problem of reproduction.

The provision of labour, both in terms of quantity and quality, is a key area as herds expand in size. Larger herds involve more cows and more staff, but generally fewer people per cow; many large herds operate at around 1 person per 120 cows. Historically, dairy herds have relied on skilled individual staff to retain a high level of individual cow knowledge, but as the herd gets bigger, this level of individual attention to detail becomes impossible to sustain. At a certain herd size, it becomes necessary to replace this day-to-day individual cow knowledge (what is essentially a data capture and storage function) with technology, usually in the form of computer software packages. Technology means that the skill levels of the average farm worker do not need to be as high as in smaller herds, but key skills areas remain that, as yet, cannot be successfully replaced by technology, such as evaluation of calving issues or the carrying out of artificial insemination (AI) procedures. When technology can have an effect, it should go without saying that there should be a cost benefit. For example, the use of pedometers to aid oestrous detection may improve submission rates but potentially could incur increased costs if logistic considerations, such as cow identification and handling and separation facilities,

VetBooks.ir

are suboptimal; as a consequence, greater labour costs may be incurred in physically finding the cows to serve.

Increased numbers of staff mean that senior staff must learn to interact and manage subordinate personnel, and there is no doubt that this represents a huge challenge on larger units. Personnel management (and sometimes language) skills are needed that are not necessary in a smaller herd employing maybe a single member of staff. Greater numbers of employees incur a greater staff turnover, and issues with sickness, holiday, and work rotas can be disheartening; although the overall skill level may be reduced, herd performance should not be limited by the least skilled worker. As herds expand, job roles, such as milking, may become more mundane and routine, whereas other roles become more specialised such as, for example, that of parlour manager. Systems will need to be in place to ensure that all staff are adequately trained to allow them to carry out their job role to a given standard and that performance is monitored. Motivation of staff, continuing education, and the opportunity for progression may be crucial for success in many larger herds. The importance of high quality data and data management cannot be overemphasised in larger units. However, as time spent at the computer keyboard increases, it becomes vital that methods of data capture are as automated and speedy as possible, so the time that key managers spend in the cow-centric actions resulting from that data increases, and less time is spent inputting it.

Cows in larger herds are often split into multiple management groups, but group sizes of over 200 are common, resulting in more cow-to-cow interactions. However, the effects of behaviour and group sizes on health, welfare, and production are not well understood and will vary depending on herd facilities. Larger herds can consider management strategies, such as milking heifer-only groups, to mitigate some of these effects. Larger groups theoretically may improve oestrous detection, as more cows will be simultaneously sexually active. In reality, differentiating and identifying cows with short duration and less intense oestrous expression can be very difficult in large groups.

For the herd owner, changing to an environment with more staff to manage, a reliance on data, and a magnification of cost structures requires considerable adaptation and learning. Senior managers in large herds often have high levels of formal education and an in-depth knowledge of both the biology of the dairy cow and business management; this drastically changes the level and quality of input required from their professional advisors.

Veterinary surgeons working with large herds should realise that there is a shift in emphasis towards the use of data and team approaches and a clear focus on profitability. Critical to the management of larger herds is to have systems in place that monitor critical indicators and provide an early warning system of health and production problems. Many of the traditional roles and technical tasks carried out by veterinary surgeons in smaller herds will often be undertaken by trained herd staff; the role of the veterinary surgeon is to provide an independent evaluation of those systems and any changes proposed.

As the dairy industry has evolved, the techniques used to manage reproduction have also evolved. Between 1956 and 1967, research took place that largely established the mechanism of luteolysis (see Chapter 1). In 1979 the first prostaglandin (PG) product (Lutalyse, dinoprost trimethamine) was licensed for use in cattle by the United States Department of Agriculture (USDA), becoming the first pharmacological agent used to manipulate reproduction in dairy cows. The first systematic and structured use of these products was termed 'targeted breeding', in which cows were injected on either a weekly or a fortnightly basis, and then either inseminated at observed oestrus or inseminated at a fixed time interval after the injections were administered. The procedure could be further refined by transrectal veterinary palpation or, later, ultrasound examination of cows to identify those animals likely to have a corpus luteum (CL) and therefore thought more likely to respond to treatment.

Conception rates from insemination to observed oestrus occurring after prostaglandin administration proved to be acceptable. In contrast, the results of inseminations conducted at a fixed time were disappointing because the timing of ovulation relative to prostaglandin injection was highly variable depending on the stage of follicular wave development at the time of the prostaglandin injection.

This led to the development of the 'Ovsynch' protocol, which has now become widely adopted globally within the dairy industry as a breeding tool to ensure timely insemination of cows (Pursley et al. 1995; see Chapter 8 for further details). This protocol offered dairy producers the first opportunity to adopt fixed time insemination as a viable management strategy. More recently, it has been shown that conception rates could be improved if the 'Ovsynch' protocol could be commenced during a particular part of the cycle (day 4–12); this led to the development of presynchronisation protocols (see Chapter 8 for further details).

In some large herds, especially in North America, it has become common practice to breed all cows by timed AI using synchronisation programmes. For example, Souza et al. (2013), based on a survey of over 1 million inseminations from 40 US states, reported that 30% of all inseminations were timed AI after a synchronisation programme. This is for a variety of reasons. First, large herds may find it more convenient and cost effective to organise labour and work routines in a consistent manner so that certain tasks always occur on a certain day of the week. This can allow skilled staff to focus more on certain other aspects of cow care at specific times and, by doing so, generate other health and welfare benefits. Second, in some herds, suboptimal oestrous detection prevents generation of sufficient pregnancies to sustain viable production, leading to adoption of 100% timed AI.

However, the routine use of synchronisation programmes, without any attempt being made to identify natural oestrus (which is particularly common when presynchronisation programs are used), combined with conception rates that are usually around 35% (Souza et al. 2013), means that on many farms a high proportion of cows are receiving 10 or more hormone injections or treatments before they become pregnant and some are receiving more than 20. This is undoubtedly an ethical and an animal welfare issue, especially when routine synchronisation is used without addressing the underlying issues causing the need for that synchronisation. This is consistent with the findings of Higgins et al. (2013), who reported that 65 of 93 UK dairy veterinarians judged the long-term routine use of synchronisation programmes as "unacceptable" if they were used at the start of the breeding period without addressing the underlying issues causing the fertility problem. This begs the question that if one of the key underlying causes of the poor fertility in the herd is its genetic make-up, does continuing to breed for production, without a focus on fertility, count as a failure to address the underlying causes?

The majority of respondents (> 70%) to Higgins et al. (2013) wanted to see a decrease in the use of hormones to control fertility in dairy cattle. Achieving such a decrease may be difficult. First, there was a considerable variation in attitude across the respondents in the study by Higgins et al. (2013), and it is highly likely that veterinary perspectives on the routine use of hormones may differ across different systems (for example, in North America it is likely that acceptance of routine treatment would be higher

VetBooks.ir

TABLE 25.1 Examples of published levels of reproductive performance worldwide

Nation	Year	Parameter	Reported Average	Trend Over Time	Reference
US	2006	CI CR	422d 30%	Deterioration in both measures 1996–2006 (CI more marked)	Norman et al. (2009)

CI, calving interval; *CR*, conception rate/risk; *21d PR*, 21-day pregnancy rate/risk; *SR*, submission/serve rate; *CFS*, calving to first service interval; *6 wk ICR*, 6-week in calf rate; *3 wk SR*, submission rate in first 3 weeks of breeding period.

than in the UK, where fixed time AI is used alongside oestrous detection). Second, hormone treatments are a significant source of income for veterinary practices, and it is likely that a focus on management rather than treatment will reduce veterinary incomes (Higgins et al. 2013). For these reasons, any decrease in the use of hormones for routine oestrous synchronisation is likely to come from pressure from outside the industry (as happened in New Zealand when the use of corticosteroids for inductions at the end of pregnancy was banned).

In the authors' opinion, there should be few situations in which the reasons driving the use of synchronisation programmes cannot be addressed and performance improved without necessarily using hormones. Combining good oestrous detection with appropriate synchronisation of target cows provides a comprehensive system of sequential 'pregnancy traps' as cows progress through lactation.

Using this reasoning, many large herds find that sufficiently high levels of reproductive performance can be achieved and sustained by applying protocols at the herd level and thus removing the need to individually examine each cow before deciding on an appropriate course of action. Substantial cost savings can also be made by abandoning individual cow level decisions. In these situations, it is vital that veterinary surgeons have a thorough understanding of herd level risk factors if their actions and decisions are to remain relevant and add value to a dairy business.

Levels of Reproductive Performance and Trends over Time

Typical levels of reproductive performance vary widely across the dairying nations of the world, with poorer overall performance usually encountered in systems involving high milk yields and better performance often associated with seasonal calving. Examples of publications describing reproductive performance measurements from samples of herds worldwide are summarised in Table 25.1.

Across most areas, there is a medium to long term declining trend in fertility (Brownlie et al. 2014, Hudson et al. 2010, Morton 2011). This is commonly associated with rapidly increasing milk production, which not only may compromise fertility by making cow energy balance more challenging to manage but also as a consequence of genetic selection focused heavily on production merit (Lucy 2001, Royal et al. 2000). However, during the last decade the trend has halted or even reversed in many countries; this may be associated with an increased understanding of the economic importance of fertility, adoption of new technology to assist breeding, and the more widespread use of fertility measurements as part of genetic selection indices.

Evaluation of Herd Fertility

Herd Recording Systems

Accurate recording of reproductive events is critical, both for individual cow management decisions and to allow effective monitoring of herd reproductive performance. Irrespective of how events are recorded, the approach should be consistent (e.g., between members of staff and over time) and comprehensive. The events that should be recorded are outlined in Table 25.2, including an indication of the minimum level of data recording required for useful analysis, as well as additional information that allows greater insight if collected.

In addition to these events, some metrics and monitoring approaches also require evaluation of 'metadata' for the herd – for example, the herd's VWP policy or the date of the planned

VetBooks.ir

TABLE 25.2 Reproductive events which should be recorded in a dairy herd to facilitate effective monitoring

Event	Minimum Information	Additional Information
Calving	Cow ID, date, parity	Level of intervention, calf outcome
Insemination	Cow ID, date	AI/natural, sire, operator (for AI), observed heat/FTAI
Pregnancy diagnosis	Cow ID, date, result	
Reproductive disease		Cow ID, date
Oestrus no serve		Cow ID, date
Other veterinary examination		Cow ID, date, result, treatment

start of mating. Depending on the computer software being used for analysis, the user can often add these additional parameters.

A wide variety of different dairy herd management software systems exist that can be used to record and store these data, and this varies widely in different areas of the world. In some cases the herd management system is linked with the milking plant, but specialised stand-alone software is also very common. For most medium to large dairy enterprises, efficient management is very difficult without the use of on-farm computerised records. A major challenge in analysing fertility performance of a herd is the variation in the degree to which the various software systems are able to calculate and present reproductive performance measurements. Commonly, different programmes calculate different metrics and often use different calculations or methods so that different values for the same metric can be derived from the same set of data, depending on which software is used. One approach to this problem is the development of analysis software, which can use data from varied sources and apply analysis in a consistent fashion.

Bureau recording systems (in which a third-party organisation collects and stores farm data) represent an alternative or supplement to on-farm software systems. Commonly, this service is provided by organisations also supplying milk quality testing, such as milk recording organisations or dairy herd improvement associations. These systems can usually accept data input either from on-farm paper records or by extracting data from an on-farm software system. Some bureau recording systems also provide an Internet-based portal where farmers can enter event data directly into the central database. Analysis of this collated data is then commonly available via a dedicated website; the degree of reproductive monitoring available through such systems varies greatly between providers and is often more limited than would be accomplished using specialised monitoring software. In addition, some bureau services allow downloading of their data for use by farmers and/or advisors; this can provide a way to obtain data in a consistent format for analysis, but sometimes data quality is reduced or event detail lost from the original source.

Irrespective of the source of the data, it is important to treat it critically and to recognise that poor data quality can influence the results of analysis. The most common problem is missing event records. For example, when not all inseminations are recorded (the final, successful insemination of the lactation being the most likely to be captured), the herd's performance in terms of submission rates for service will appear artificially poor, whereas the conception rate will be artificially inflated. There are algorithmic approaches to evaluating fertility data quality, and some software products offer data quality assessment.

There is a clear trend throughout the agricultural industry for increased amounts of data to be generated and recorded over time. Examples from the dairy sector would include the more widespread adoption of sensor technology such as activity monitoring as a heat detection aid. The ability to integrate these data with that from other sources and use it to generate additional insight is likely to become ever more important to the veterinary advisor in the future.

Aspects of Reproduction which Should Be Monitored

Herd-level reproductive performance can be monitored in a variety of ways, but whichever measures are used, it is important that they cover the relevant areas comprehensively. A hierarchical approach can be useful, in which a small number of measurements of overall reproductive performance are used as the main short-term metrics and a wider set of measurements covering the components of reproductive success used when the headline performance is suboptimal. The two key elements that should be covered are submission (the ability of cows to express oestrous behaviour and the ability of the farm's system to detect it) and conception (including successful maintenance of pregnancy). When overall performance does not meet targets, it is often useful to decide which of these two areas should be the focus of attention by assessing measures specific to each element. It is also important to monitor the level of reproductive disease a herd is experiencing so that specific problems can be identified and addressed.

Clear and transparent terminology should be used when defining reproductive performance; this is often hindered by the myriad of performance measurements available. Each has its own advantages and disadvantages, and it is the responsibility of the veterinarian to identify the best way of reporting reproductive performance for each farm. The measurements chosen should reflect the key issues on the farm and allow comparisons to be made with other similar farms. It is not helped when different names are used for the same measurements (see Boxes 25.1 and 25.2).

• BOX 25.1 Risk vs Rate

A rate is the frequency of an event per unit population per unit time. The numerator is the number of events, and the denominator is the animal-time units at risk. This is most widely understood in the context of disease incidence rate: for example, 4 cases of endometritis per month in a herd of 100 cows would equate to an incidence rate of 48 cases per 100-cow-years.

A risk is the frequency of an event, given a designated number of times when it could happen ('trials'). It has no units, as the numerator is the number of cases, and the denominator is the number of trials; e.g., in the herd described previously, assuming all cows calve once in 12 months the risk of endometritis is 48/100 or 0.48.

Reproductive performance metrics can be broadly categorised into interval- or rate/risk-based measures. Many of the risk/rate-based measures are more accurately described as risks, rather than rates (e.g., conception rate). However, across the industry and worldwide it is far more common to refer to rates rather than risks, so to avoid confusion we have used the term 'rate' in this chapter.

VetBooks.ir

• BOX 25.2 Pregnancy and Conception Rates

Conception rate has commonly been used to describe the risk of a cow becoming pregnant after a given insemination. This is technically inaccurate, as the proportion of cows that conceive (i.e., have a fertilised embryo) is much greater than the proportion that are pregnant by the time of pregnancy diagnosis. Pregnancy rate would perhaps be a more biologically accurate term but is commonly used in other measures (such as proportion of eligible cows becoming pregnant per unit time).

For clarity, in this chapter, we have used conception rate to signify the risk of pregnancy after insemination, and pregnancy rate for proportion of eligible cows becoming pregnant over a defined period of time.

• **Fig. 25.1** Example 21-day pregnancy rate report generated using the DairyComp 305 software package (using a 50 day VWP). Br Elig: number of cows eligible to be inseminated in this time window; Bred: number of cows inseminated; Pct: percentage of cows eligible to be served that are inseminated (submission rate); PgElig: number of cows eligible to become pregnant (differs from Br Elig as cows die, leave the farm or are declared barren); Preg: number of cows that actually become pregnant; Pct2: number of successful outcomes achieved expressed as a percentage of the maximum possible at the start of the window (21-day PR); Aborts:number of abortion cases subsequently reported. *Start of the 21-day period †Unknown pregnancy status, awaiting pregnancy diagnosis ‡Note that the totals exclude cows from the last two 3-week periods as the outcomes of these events remain unknown until pregnancy is diagnosed.

Pregnancies per Unit Population Time

'Herd pregnancy risk' is an estimate of the instantaneous probability that an open, eligible cow will become pregnant per unit time in the future. The magnitude of the hazard or risk of pregnancy occurring is determined by the management and environment to which the cow is exposed. In all-year-round calving herds, it is most usefully monitored using the 21-day pregnancy rate (21-d PR) (Ferguson & Galligan 1999, Fetrow et al. 2007). An example of a 21-d PR report generated from the DairyComp 305 software package is shown in Fig. 25.1. For a specific 21-day period, the 21-day PR is calculated as follows:

$$21d\ PR = \frac{Number\ of\ cows\ becoming\ pregnant}{Number\ of\ cows\ eligible\ to\ be\ become\ pregnant} * 100$$

It is important to clearly identify which cows are eligible to be included in the denominator. First, cows are included as eligible if, at the start of the 21-day period for which the PR is being calculated, they had passed their VWP and were not pregnant. Eligible cows also have to have been present in the herd throughout the entire 21-day period (i.e., they must not have been sold or died or otherwise exited the herd), and they must not have been identified as 'not to be inseminated' (and therefore not to be retained in the herd). Finally, ideally all eligible cows should have a pregnancy diagnosis or subsequent insemination that clearly identifies their pregnancy status (yes or no) at the end of the 21-day period. There is some variability between software programmes in how cows are handled which are eligible for only part of a 21-day period; this is important to understand in order to interpret results, especially when rates calculated in different packages are compared. Discrepancies between software packages are commonly accounted for by differences in the way programmes handle cows as they pass their VWP, exit the herd during a cycle, or are inseminated after pregnancy loss.

The related measurement, 21-day submission rate (or 21-day insemination rate), uses the same definition of an eligible cycle, but 'has been inseminated at least once during the cycle' as the outcome; a cow is either categorised as being inseminated (yes) or not (no) during an eligible cycle.

The use of 21-d PR has several advantages over other methods of monitoring reproduction, as the effects of lag, bias, momentum, and variation are minimised (Fetrow et al. 2007). A time lag occurs in all measurements of reproductive performance, as there is an inevitable delay between when a cow is inseminated and when she can be examined for pregnancy. However, by using 21-day PR, this is limited to as short a period as possible so that changes in management and environment that affect reproductive performance are reflected quickly. This means that 21-day PR can be easily used to evaluate and compare different groups and interventions. In reproductive calculations, bias occurs when selection of cows for inclusion or exclusion occurs. For some measurements, only cows currently present in the herd or cows diagnosed as pregnant are included, with cows failing to be inseminated or pregnant being ignored. In contrast, the calculation of 21-d PR includes all eligible cows, whether they were inseminated or not, and includes cows that have left the herd (provided it was after the 21-day period being measured).

A parameter shows momentum when historic data significantly contribute to its calculation. This means that the effect of recent changes (either positive or negative) can be hidden by historic events. As 21-day PR is based on a specific period of short duration, historical data (such as conception rates 60 days ago) have no influence. This does mean that 21-d PR can vary significantly over a short period of time, and that sampling variation can become a problem in smaller herds (see section later in this chapter on Key Epidemiological Concepts). In such circumstances, other measurements of reproductive performance or averaging 21-d PR over a longer time period may be appropriate, even if this increases lag and momentum. Importantly, the short focus of 21-day PR means

VetBooks.ir

that it is possible for two herds to have similar 21-day PR yet still have different proportions of pregnant cows with a differing pattern of when they became pregnant.

Efficiency of reproduction is influenced by four factors: submission rate (the proportion of eligible cows served per unit time, commonly 21 days); conception rate (the proportion of inseminations leading to a pregnancy); the VWP is and the length of time after calving when it is deemed acceptable to continue inseminating a cow. The latter two factors are both under the direct control of the herd manager. The aim of the VWP, is to provide sufficient time that the chance of pregnancy in an inseminated cow is not compromised by a genital tract that has not fully recovered from the previous calving or a cow in excessive negative energy balance. Typically, on non-seasonal calving farms, cows will not be inseminated (even if they are seen in oestrus) for 35 to 60 days after calving; the exact value depending on the farm situation. On seasonally calving farms the interval between calving and a cow becoming eligible for AI or natural mating is not usually a set period of time, as all non-pregnant cows become eligible for mating when the breeding season starts (usually 85 days after the start of calving).

The acceptable time postcalving when a decision is made to stop inseminating a non-pregnant cow (which will then be culled at the end of lactation) is often established for individual cows, with higher producing individuals**,** those of higher genetic merit, and those with high milk yield persistency being allowed a higher maximum time interval. However, in seasonal or block calving herds, the choice of a maximum interval between calving and insemination is determined at the herd, not the individual, level. In such herd**s**, it is the length of the breeding season that is the key influence on reproductive efficiency.

Once these two parameters are set by management, reproductive efficiency is determined by the proportion of eligible cows that are inseminated per unit time (submission rate) and the proportion of inseminated cows that become pregnant (conception rate). If these two figures are calculated over a 21-day period, the 21-d PR can be estimated by multiplying insemination rate by conception rate.

When calculating average 21-day PR over a longer time period, it is important that it is calculated as a weighted mean of the sum of the pregnancies divided by the sum of eligible cycles (rather than a simple mean of the 21-d PR in each 21-day period). This is particularly important if timed AI programmes are used, as an unweighted mean will tend to underestimate the value of such programmes as it ignores the relative numbers of cows eligible in each 21-day period.

Although the 21-day PR can be calculated from the insemination and conception rates, it can be calculated without any knowledge of either as the only data required are the number of cows which became pregnant during the 21-day period and the number of cows that were eligible to become pregnant during that period. The key advantage of this method of calculation is that it eliminates the need to ensure identical time frames to calculate insemination and conception rates. This metric can therefore also be used effectively in herds relying entirely on natural service by running a bull or bulls with eligible cows.

The 21-day PR approach also provides flexibility as it can be calculated by calendar date (the most common approach), days in milk, days since an event, or days with bull. It can therefore be applied to a variety of herd situations. Fig. 25.2 shows an example of a 21-day PR report calculated by days in milk, with the same data displayed graphically in Fig. 25.3. Comparisons of performance between all-year-round calving herds that operate different VWPs can be made by applying a standard VWP to the calculations for each herd. For example, a herd that operates a VWP of 68 days, because all first inseminations are carried out to a double 'Ovsynch' protocol, could have a 21-day PR of 30% when calculated using the 68-day VWP. This would be equivalent to a 24% 21-day PR for a herd breeding to observed oestrus from 50 days. This again illustrates the point that 21-day PR does not provide information on the pattern of when cows become pregnant, either within that 21-day period or relative to calving.

• **Fig. 25.2** Example 21-day pregnancy rate report by days in milk (explanations as for Fig. 25.1 generated using DairyComp 305).

When comparisons are made between herds, it is recommended that the 21-day PR should be evaluated in all cases using a 50-day voluntary waiting period and that in herds that choose to operate with a different VWP, herd managers should be constantly aware of the 21-day PR; this should be evaluated for both a 50-day waiting period (i.e., with cows becoming eligible for inclusion in the 21-day PR 50 days after calving) and for the actual VWP used on the farm. The former will allow valid comparisons with other similar herds, whereas the latter provides information on the technical success and performance of the programme.

Reproductive performance of a dairy herd is ultimately determined by how rapidly the herd management 'turns open cows in to pregnant cows', a process most accurately measured and monitored using 21-day PR. It is for this reason that 21-day PR has become the standard measure of reproductive performance in many herds.

Other Fertility Measurements

Measurements of Overall Performance

Traditionally, the focus of fertility has been ensuring the production of one calf per cow per year. This led to the adoption of the calving interval (the interval, usually in days, between successive calvings for an individual cow) as a standard measure of fertility. At the herd level, the average calving interval across a cohort of lactations (e.g., the most recent completed lactation for each cow in a herd at a specific point in time) is referred to as the calving index. The traditionally accepted optimum for calving interval is 365 days, although there is increasing evidence that extended intervals can be just as economically efficient (e.g., see Lehmann et al. 2016).

Irrespective of the optimum value, the usefulness of calving interval as a fertility measurement is limited by its historic nature, which results from the requirement for two successive calvings. This introduces a significant time lag in assessing fertility as there are typically 270 to 285 days between the successful conception and subsequent calving (and thus the calculation of the calving interval). Calving interval is thus a reflection of what happened over 9 months ago, not what is happening currently. In addition, it has two further deficiencies. First, it ignores heifers, which do not contribute to a calving interval until they reach their second lactation. Second, it ignores cows which fail to become pregnant and are culled for failure to conceive. Thus in a herd with a 25% culling rate and a 25% replacement rate, average calving interval will be based on only 50% of the cows in the milking herd.

The calving interval is the sum of two components: the interval from calving to conception and the interval from conception to subsequent calving. The latter component is not really a measure of reproductive efficiency as it is simply the length of gestation and therefore not directly under the control of the herd manager (although this may change with increased availability of quality bulls selected for short gestation length; Jenkins et al. 2016). In contrast, the interval from calving to conception is a reflection of reproductive efficiency as it is a measure of how quickly cattle become pregnant after calving.

The calving–conception interval (CCI) is calculated by counting the number of days from calving to the service that resulted in pregnancy (usually the last recorded service date). So, to calculate the CCI requires three data points per cow: calving date, date of the successful insemination, and a positive diagnosis of pregnancy. To achieve a calving interval of 365 days, the target CCI needs to be 85 days (assuming a gestation length of 280 days). In effect, CCI is simply a way to measure CI with a shorter time lag as the outcome is determined by pregnancy diagnosis rather than by waiting for the subsequent calving, although pregnancy loss can introduce variation between one and the other.

A cow's CCI is composed of two components: the length of the VWP and the number of days between a cow becoming eligible for insemination and becoming pregnant. The first factor is a management decision; the second reflects the reproductive performance given that management decision. In this, it is similar to the 21-day PR. However, a key disadvantage is that, in contrast to 21-day PR, it is an interval-based measurement that does not include data from cows which failed to become pregnant.

The failure of the CCI to include data from cows that failed to become pregnant led to the development of the related measurement: 'days open'. For cows that conceive, days open is equivalent to the CCI, whereas for cows not conceiving, the days open is defined as the time from calving to culling or death, or the maximum interval between calving and insemination.

This difference between CCI and days open highlights the inherent issue with using interval data to evaluate fertility at the herd level, which is identifying the point at which it is possible to collate data and create a meaningful figure. For days open, the definition requires that the measurement is calculated only when all the cows in the group under evaluation have either reached the time after calving when they will no longer be inseminated or have been culled/sold. Although the addition of data from cows that failed to conceive reduces the issue of bias, it increases lag time. In systems in which cows can be inseminated up to 300 days after calving, this can significantly delay fertility evaluation. In contrast, for CCI the definition is more flexible, so it can be calculated earlier; however, if it is calculated too early (i.e., at a timepoint when only a limited proportion of the cohort being measured have conceived), then it will be biased and of limited value. But defining 'too early' is inherently subjective – clearly if

VetBooks.ir

only 10% of the selected group are pregnant, then calculating CCI is of limited value, whereas if 90% are pregnant calculating CCI is likely to be useful; thus CCI may be useful depending on the farm situation.

The distribution of CI, CCI, and days open is very commonly right (or positively) skewed, i.e., there is a 'long' and/or 'fat' tail to the right of the peak. This can result in the mean interval being significantly influenced by a small proportion of the animals. Days open is typically even more right skewed because of the inclusion of cows culled for failure to conceive, which will all have high values. When evaluating these figures on a herd basis, the median (i.e., the 'middle' interval where the intervals are arranged in ascending order) is therefore generally a more accurate reflection of the performance of the herd (or a typical cow in the herd). It is useful to examine both the mean and the median value as this can give an impression of the degree of skewness of the distribution. Either figure should be used alongside a measure of dispersion, such as the interquartile range, to show how much variability there is in performance between individual cows. Evaluation of the distribution of individual intervals using graphical representations such as histograms and boxplots can provide additional insight. If this approach is being used as a key metric, it can be useful to evaluate days open and CCI at the same time, as this will provide an assessment of performance with and without the potential distorting effect of high values from cows which failed to conceive.

The difficulties in determining when to calculate intervals has resulted in the development of rate-based measurements designed to reflect overall reproductive performance. The most important of these is the 21-day PR, which was discussed earlier, but this is not the only rate-based measure. Morton (2003) described three ratios which are commonly used in Australia and elsewhere to summarise reproductive performance:

1) 100-day in-calf rate: the proportion of cows eligible for rebreeding that conceive within 100 days of calving;
2) 200-day not-in-calf rate: the proportion of cows eligible for rebreeding which do not conceive within 200 days of calving; and
3) 6-week in-calf rate: the proportion of cows eligible for rebreeding that conceive within 42 days of the start of the breeding season.

The first two are used in all-year-round calving farms, whereas the third is designed for seasonal or block calving. Compared with the 21-day PR, the 100-day in-calf rate and 200-day not-in-calf rate have greater lag but may be simpler to calculate and easier for the farm staff to understand. It is important to realise that both measurements, but particularly 100-day in-calf rate, are significantly affected by the choice of VWP. If the VWP is 60 days, then 100-day in-calf rate reflects the success rate during the first 40 days (around two oestrous cycles) after the end of the VWP. If the VWP is then decreased to 40 days, then each cow will have 60 days (around three oestrous cycles) to become pregnant. This is likely to result in an increased 100-day in-calf rate, even though reproductive efficiency has not changed.

Ideally, whichever measurement is used to define overall reproductive performance, it should be used alongside an assessment of the proportion of the herd that were culled due to failure to conceive. If the causes of culling are recorded correctly, then this figure is valuable for interpreting measurements (such as CCI) that exclude cattle that did not conceive as well as determining the economic effect of poor fertility. Unfortunately, in many circumstances such records are not available as the reason for culling is not recorded. Furthermore, especially if only one reason for culling is recorded, the interpretation of the reasons can be difficult; for example, was the cow with a high cell count culled because of the high cell count or because she failed to become pregnant? Ensuring that culls are properly recorded, so that both the timing of the cull and the key reasons for culling (which may be multiple) are known, can be useful for fertility investigations.

If good culling records are not available, then the proportion of the herd being culled after an insemination can be used to estimate the number of cows that have been culled for failing to conceive on the principle that most 'non-fertility' culls will not be inseminated during the lactation as they are already identified for culling. However, there are clearly other reasons why a cow might leave the herd after being inseminated, and the relative prevalence of this will vary from herd to herd and over time, making such proxy measurements difficult to interpret consistently.

Specific Measurements Underlying Overall Performance

For all of the measurements of overall performance, there are two key factors that underlie those figures: i) the interval between cows becoming eligible to be inseminated (either after the VWP or after an unsuccessful insemination) and being inseminated ('submission'); and ii) the risk of an inseminated cow becoming pregnant ('conception').

The most commonly used measurement interval reflecting the speed of submission for first service is the calving-to-first-service interval. This measurement, like CCI, is dependent on VWP as:

$$\text{Calving-to-first-service interval} = \text{VWP} + \text{interval from VWP end to first service}$$

The interval from VWP to first service is determined by when cows first show oestrous activity after the end of the VWP, and also the proportion of oestruses that are detected. The length of the VWP is crucial as, even if all cows are cycling normally and all oestruses are detected, then average calving-to-first-service interval will be, at best, 11 days longer than the VWP (based on an average oestrous cycle length of 22 days). So, if the VWP is 60 days, then calving-to-first-service interval will be at least 71 days. However, in reality the calving-to-first-service interval will be more than 11 days longer than the VWP, as not all cows will be cycling and not all oestruses will be detected.

As with CCI, the calving-to-first-service interval tends to be right skewed so that the median may better reflect herd performance than the mean. It is also important to calculate a measurement of the spread of the distribution (such as interquartile range), as well as the median. Evaluation of the distribution visually (e.g., using a histogram) is also often useful. As with other interval-based measurements, identifying when it can be calculated for a group of cows is not simple.

Alternative rate-based measurements have thus tended to replace the calving-to-first-service interval. The most important of these is the 21-day submission rate (as described in the previous section):

$$21d\ submission\ rate = \frac{Number\ of\ eligible\ cows\ inseminated\ in\ a\ 21d\ period}{Number\ of\ cows\ eligible\ for\ insemination\ in\ the\ same\ 21d\ period} * 100$$

This measurement has the same advantages as the 21-day PR and can be used in the same way to create an ongoing updated rolling average, particularly in herds in which reproduction data is kept on a computer database. The 21-day (or 24-day) submission

VetBooks.ir

rates can also be calculated for specific inseminations, particularly the first service. First service submission rate (usually defined as the proportion of cows inseminated within the first 24 days after the end of the cow's VWP), like calving-to-first-service interval, will identify how quickly cows are served once they are eligible for insemination. Unlike calving-to-first-service interval, it lacks bias as it includes all eligible cows not just those that have had a first service. It also has less momentum, so it is better at showing trends over time than the calving-to-first-service interval. However, all cows that fail to be served within 21 or 24 days of the end of the VWP are treated the same; in contrast, calculating calving-to-first-service interval and its distribution will provide information on how long these 'failures' take to be inseminated for the first time.

Achieving a high submission rate is dependent on good oestrous detection. Indeed, in some publications, submission rates are referred to as heat or oestrous detection rates. However, especially in the period immediately after the end of the VWP (or start of the breeding season in seasonally calving herds), submission rates are also dependent on the proportion of cows that are cycling normally. If there are high levels of anoestrus and/or endometritis, submission rates can be low even though heat detection is good.

It is therefore important, if submission rates are low to distinguish between poor oestrous detection and acyclicity. Unfortunately, without additional monitoring (such as frequent progesterone testing), establishing the actual heat detection rate is not possible.

From Table 25.3, the true oestrous detection rate equals a/a + b. However, the only data available on most farms are a + c and b + d. Without additional data, it is not possible to know how many of the oestruses detected were false positives (c), or the number of false negatives (b), the cows that have been in oestrus but have not been detected. However, on farms in which veterinary examination of cows not seen in oestrus is routine, the results of such examinations can provide a useful clue as to the role of acyclical cows in depressing submission rates.

This means that apparent oestrous detection rates (and submission rates) can be falsely inflated if farmers or farm staff regularly submit cows for insemination that are not in oestrus. This could easily happen on a farm that heavily focuses on fertility, and as a consequence, the staff are paid bonuses to improve submission rates. One approach to monitoring, which can provide insight into this, is the evaluation of the intervals between successive inseminations.

The commonly accepted range for the normal length of a bovine oestrous cycle is between 18 and 24 days (see Chapter 1), so ideally the majority of interservice intervals will fall within this range. Intervals between 36 to 48 days suggest that one oestrus has been missed, and intervals of 54 to 72 days suggest that two oestruses have been missed.

Evaluation of the distribution of interservice intervals (for a given time period) can provide useful insights into both the rate and accuracy of oestrous detection. Intervals are usually categorised in relation to the accepted normal cycle length (see Table 25.4).

Relatively high proportions of intervals at less than 18 and 25 to 35 days are indicative of inaccurate heat detection (i.e., a problem with cows being served when not in oestrus); more than 10% of intervals in the former category is sometimes used as a threshold for this. A high proportion of intervals in all categories more than 24 days suggest late embryonic or early fetal death; high proportions of intervals more than 35 days tend to suggest a high proportion of missed oestruses. These suggestions should be supported by evaluating the distribution of interservice intervals, alongside other fertility parameters.

A measurement of overall quality of oestrous detection (known as oestrous detection efficiency) is calculated from the percentage of all intervals within each category, as follows (using the categories defined in Table 25.4):

$$ODE = \frac{b+d}{a+b+c+2(d+e)} * 100$$

Recent evidence suggests that in at least some dairy cow populations, 18 to 24 days may not represent the most appropriate choice of the normal range for this type of analysis and that a high proportion of intervals are at 25 and 26 days (Blavy et al. 2016, Remnant et al. 2015). This should be recognised when interpreting interservice intervals and rates derived from them (such as the proportion of returns to service occurring at 18–24 days after a previous insemination, sometimes referred to as returns submission rate).

Measuring the risk of an inseminated cow becoming pregnant is much simpler as this can be calculated from the number of inseminations given (note this is not the same as the number of inseminated cattle) and the pregnancy test results for the inseminated cows. Conception rate can be defined as the proportion of inseminations leading to a pregnancy (see Box 25.2).

The inverse of conception rate is the average number of services per pregnant cow. Conception rate is a very flexible measurement; although it is commonly calculated and presented on a monthly basis, it can be used for any defined group of inseminations. However, similar to 21-day PR, care must be taken when comparing values between groups if the number of cows per group is small. Examples of groups for which conception rate can be measured include: those based on days in milk (which will identify if specific lactational stages are affecting underlying cow fertility); parity (particularly useful for identifying issues with heifers in their first lactation); fixed-time inseminations (FTAI) after synchronisation programmes (in which conception rate is the best measure of the success of such programmes); and number of inseminations a cow has received.

TABLE 25.3 Test characteristics of a farm's oestrous detection

c)	25–35 days	
d)	36–48 days	Double normal interval length
e)	> 48 days	

VetBooks.ir

When accurate pregnancy test data are not available, non-return to service at a specified timepoint (e.g., 24 days or 56 days post-insemination) may be used as a proxy outcome. Although better than nothing, the non-return rate is not a good measurement of the success of insemination because it is dependent on both the conception rate and the submission rate of non-pregnant, but inseminated, cows. Thus a low non-return rate can indicate either good reproductive performance (high conception rate), or poor reproductive performance (low return to service submission rate). The influence of submission on this measurement is dependent on the timepoint chosen – rates of non-return at later timepoints (e.g., 100-day non-return rate) are likely to be more reflective of true conception rates but introduce an increased lag into the metric.

Of the two factors influencing overall reproductive performance, oestrous detection and submission is generally more susceptible to human control than conception rate. On most farms, improving the submission rate so that more cows are inseminated (and thus have the chance to become pregnant) will be more effective than focusing on improving the chance of individual cows becoming pregnant to a single service. Improving the submission rate can result in improved reproductive performance, even if the conception rate is reduced, provided the reduction in conception rate is less than the increase in submission rate. This principle is the basis by which oestrous synchronisation works: more cows are inseminated (often 100% of a group), so more cows become pregnant, even though at the individual cow level the risk of conception may be lower than if the cow was inseminated to an observed normal oestrus.

In addition, it is important to recognise that poor understanding of oestrous detection is an important cause of low conception rates. This occurs when an inappropriately high proportion of cows are inseminated when not in oestrus. This problem commonly goes hand in hand with poor submission rates (i.e., herds that are incorrectly identified in oestrus are also more likely to miss true oestrus), although this is not always the case.

Monitoring Reproductive Disease

Minimising reproductive disease is essential for optimising fertility. In order to do this, it is essential that reproductive disease is clearly monitored and recorded. The reproductive diseases can be divided into those diagnosed by the farmer and those in which veterinary intervention is required for diagnosis.

The key diseases that need to be accurately identified by farm staff are dystocia and retained fetal membranes (RFM) because in most cases veterinary involvement is not necessary. In both cases a clear definition is needed so that, as much as possible, records are consistent within farms (and, if feasible, between them). Dystocia (see Chapters 11–18) can be recorded simply as an assisted calving but ideally should be categorised based on difficulty: (1) no assistance; (2) slight assistance (one person without calving aids); (3) considerable assistance (one person with aids or more than one person); (4) veterinary assistance, including Caesarean operation (Mee et al. 2011). Categorisation will limit the effect of different farmer approaches to dystocia (e.g., interventionist or not); the dystocia risk should be reported as incidence per calving. This is because using time-based measurements, such as cases per cow per year, means that long calving intervals can reduce the apparent rate of dystocia, as fewer cows will calve each year. Comparison between groups can be useful, particularly comparing heifers calving for the first time with older cows, and between animals bred to different bulls, especially when beef and dairy bulls are used on the same farm.

Even though, in the vast majority of cases, treatment of RFM is unnecessary; retention of the membranes is a key risk factor for uterine infection (both metritis and endometritis; see Chapter 25) and thus for future reproductive performance. Recording which cows have had RFM will identify those that need additional observation in the immediate postpartum period, and examination/treatment before being bred, even if there has been no apparent clinical effect. Using consistent definitions is important. The simplest definition of RFM is a cow that retains its membranes for more than 24 hours. This is not necessarily the most accurate definition, but it is easy for farmers to record accurately (Laven & Peters 1996); as with dystocia, RFM should be reported as incidence per calving cow.

Metritis and abortion (see Chapters 23 and 24) need to be identified by farm staff, but recording will be more valuable if there is veterinary involvement. For metritis, veterinary involvement in developing the strategies to identify sick cows in the early postpartum period is likely to make them significantly more effective. This is because there is no simple single clinical sign that will identify metritis, so skilled staff are required to identify sick cows in the immediate postpartum period (Burfeind et al. 2014). Again, metritis should be reported on the basis of incidence per calving cow.

Loss of the fetus after the diagnosis of pregnancy can be a significant problem. Abortion (loss of one or more calves between 152 and 270 days of gestation) can be diagnosed by the farmer if the aborted fetus is identified**.** However, abortion incidents appear to be underrecorded on many farms (Lemire et al. 1993). Fetal loss, from the time of pregnancy diagnosis to 152 days, is commonly not recorded as a discrete event by farmers, although measuring the proportion of cows being re-inseminated after a positive pregnancy diagnosis can be a useful guide (Forar et al. 1995). Thus the true level of fetal loss (and to a lesser extent abortion) can be challenging to estimate in the absence of diagnosis of the pregnancy status.

The simplest measure of abortion frequency is the incidence risk of abortion, expressed as a percentage of pregnancies. This is useful for quick calculations such as identifying abortion outbreaks. However, it is better to assess abortion risk, particularly over longer periods of time, using a days-at-risk model. This is because abortion data is both right and left censored. The data are right censored principally because, once cows have aborted, they stop contributing days-at-risk. Estimating a simple proportion ignores the effect of early abortions; in addition, pregnant cows can be sold, culled, or die. These animals need to be included in days-at-risk and, ideally, pregnancy tested before removal. The data are left censored as the cow is not 'at risk' of detectable abortion until after pregnancy diagnosis has occurred. Early pregnancy diagnosis increases the apparent rate of fetal loss – not only because it increases days at risk but also because most fetal loss occurs early in gestation, and there is a significant negative association between the risk of fetal loss and days pregnant (Forar et al. 1995). Abortion rate per 100 days-at-risk accounts for many of these issues but is more complex to calculate and interpret. Survival analysis, which plots abortion risk against gestational age, is the most useful method as this can take into account differences in the timing of pregnancy diagnosis. The key issue with days-at-risk is identifying when the abortion occurred; to obtain accurate information requires close observation and regular monitoring of pregnancy status. The latter is likely to be feasible only when a problem is suspected as a result of an increased number of apparently pregnant cows failing to calve.

Endometritis (see Chapter 23) is one of the most important reproductive diseases in terms of its effect on reproductive performance

VetBooks.ir

(Gilbert et al. 2005). Although some cows with endometritis will show a vulvar discharge, the majority will not; thus identifying endometritis needs an active rather than a passive approach (Gilbert et al. 2005). Various methods of diagnosing clinical endometritis have been used, but probably the simplest and quickest to use on a routine basis is the Metricheck device (see Chapters 23 and 24). In addition to being quicker, the Metricheck device causes less discomfort to the cow and has a greater sensitivity compared with vaginoscopy, although specificity is reduced (LeBlanc et al. 2002).

Whatever method is used, routine examination for endometritis should be undertaken before the breeding period, i.e., before the end of the VWP in all-year-round calving herds or the planned start of mating in seasonal ones. Ideally, it should be done at least 3 weeks before intended breeding as, if treatment is successful, the cow should have at least one oestrus before the start of breeding. The timing of the diagnosis relative to calving is important as early diagnosis and treatment improves reproductive outcomes; but cows should be at least 4 weeks postcalving before being treated (LeBlanc et al. 2002). Endometritis frequency is most usefully measured as an incidence risk per cow calved; if a cow has more than one diagnosis of endometritis during a lactation, it should only contribute once to the numerator.

Monitoring Fertility in Nulliparous Heifers

When monitoring reproductive performance, it is important that nulliparous heifers are not excluded. Several studies have demonstrated that replacement heifers calving for the first time at around 22 to 24 months of age are likely to be the most productive and profitable individuals in the herd (Bach 2011, Brickell & Wathes 2011, Sherwin et al. 2016). In order to achieve this, heifers must conceive promptly and maintain pregnancy once they have reached target breeding age or size; breeding from around 13 to 14 months is usually required to achieve the target age at first calving.

Monitoring heifer performance can be done using broadly similar approaches to those described for the milking herd. When record keeping for this group is good and herd policy sufficiently clear and consistent (such that every animal becomes eligible for breeding at a specified age and all insemination and pregnancy diagnosis events are recorded accurately), the 21-day pregnancy rate approach can work well. As with adult cows, the proportion of eligible heifers becoming pregnant per unit time can be evaluated over time or by heifer age. This approach can also be useful when only natural service is used, with service dates unrecorded, but periodic early pregnancy diagnosis performed.

Again, as in adult cows, interval-based measurements can also be useful. In heifers, age at first calving is the most commonly used, but the interval from target breeding age to first insemination can also be useful. In both cases, it is useful to evaluate the distribution of intervals or at least to calculate both the mean and median rather than relying on a single average value. Interservice intervals can also be used, although it is likely that oestrous cycle lengths tend to be shorter in nulliparous animals (Wolfenson et al. 2004). Conception rates can also be analysed in exactly the same way as in cows, although this is usually only practical in herds using AI.

Key Epidemiological Concepts

When analysing any aspect of herd performance data, it is important to keep some basic principles of epidemiology and statistics in mind. Perhaps the most useful is the effect of the size of the denominator population and the potential for sampling variation when the denominator is small. Herd size clearly plays an important role here; in very large herds, it is rare for small denominators to be a practical problem. However, even in herds with hundreds of animals, the denominator for a particular performance metric may still be small. For example, in a herd with good fertility performance, only 12% to 18% of cows are likely to be eligible for breeding at any one time. Thus a herd with 200 cows may only have around 25 eligible for service in a given 21-day period. If around 20% of these are expected to become pregnant, this would represent only five expected pregnancies. Clearly, there is potential for this outcome to be influenced by chance, and one or two more (or less) pregnancies will make a relatively large difference to the outcome being measured. If the analysis is restricted to cows eligible for first insemination or at a specified stage of lactation, then the denominator clearly becomes even smaller.

Some analysis software gives an indication of the uncertainty in an estimate of a particular performance measurement, for example, by providing p-values for contrasts or showing confidence intervals around estimates of proportions. It can also be useful for the size of the denominator to be displayed alongside the result so that the user has some ability to judge empirically the potential for sampling error to be important. There are no 'hard and fast' rules, but the approach outlined in the previous paragraph can be useful (i.e., considering the potential for a small number of fewer or more events to influence the measured outcome to the extent that decision making may be influenced). When this problem is encountered, commonly the most appropriate option is to increase the time frame of the analysis to increase the effective size of the denominator. For example, in the 21-day pregnancy rate example described previously, the 9-week or 12-week rolling average may reflect true performance more accurately than the rate in each individual 3-week period.

In this context, it is also interesting to consider the concepts of type I and type II error. These terms describe the potential errors in making an inference from a given result. A type I error refers to accepting or acting on an apparent trend or association, which is actually due to chance. A type II error is the reverse: failing to accept or act on a trend or association which is real. The probability of making either error is based on the level of evidence the decision maker requires before acting; when this is very strong, type I errors become less likely but type II errors more likely. There is an important contrast here between clinical epidemiology at an individual herd level and epidemiological research. In the latter situation, avoiding a type I error (for example, in promoting a research finding which is illusory) is often much more important, so relatively strong evidence is required in order to take action. When working with a single herd's data to drive herd level decision making, it is usually necessary to act based on weaker evidence, as the cost of failing to act in the face of a genuine trend is larger relative to the cost of acting on false evidence. For example, a p-value less than 0.05 or 0.01 is commonly used to signify statistical significance in a research context – at a herd level, use of this criterion would generally mean that change is rarely advocated.

The Economics of Reproduction

Components of Economic Loss

It is clear that a herd with very poor reproductive performance will suffer economic losses in a variety of areas, and fertility has commonly been cited as a key driver of efficient milk production (Evans et al. 2006, LeBlanc 2007). Decreased milk production is

VetBooks.ir

the most obvious source of this loss, with longer intervals between calvings leading to cows spending relatively more of their lives in later lactation, when daily production is lower and feed conversion less efficient. However, this needs to be balanced against the fact that cows with shorter calving intervals will spend an increasing proportion of their lives dry and that high culling rates to maintain a short calving interval can also reduce overall efficiency. Reproductive (or 'failure to conceive') culls are the other commonly recognised source of financial loss due to subfertility. Culling cows which fail to become pregnant incurs a cost as the slaughter value of a cull cow is generally substantially lower than the cost of producing or buying a replacement; this is highly variable. In areas where seasonal and year-round calving herds are both common, cows not becoming pregnant during the breeding season are often sold to year-round calving herds, which can decrease the net replacement cost. It is also important to consider the potential increase in herd asset value, when a cull cow is replaced with a heifer. In herds in which replacements are homebred, there is usually a finite pool of animals that can enter the herd per unit time and therefore a fixed maximum number of culls if herd size is to be maintained. In this situation, reproductive culling can utilise replacements that could otherwise be profitably employed replacing culls for poor production or health reasons.

However, there are a number of other mechanisms by which poor reproductive performance can have an economic cost. Although it can be considered that calves are a by-product of dairy production, they are also an income source, whether reared as herd replacements or sold for beef production. Clearly, the more frequently cows calve in a herd, the larger the number of calves produced per year. There are also direct costs associated with reproduction, such as labour, semen, medicines, and veterinary time. However, some costs are much less obvious, and are harder for herd managers to appreciate. For example, a substantial association has been demonstrated between the duration of the calving interval and the risk of a cow being culled from the herd in the subsequent lactation (Pinedo & De Vries 2010).

There are also some less obvious economic disadvantages associated with shorter calving intervals. Decreasing the number of calvings per unit time (either at cow or at herd level) decreases the risk of diseases associated with calving, including mastitis and lameness, as well as reproductive disease. Pregnancy is also associated with a decrease in milk yield, so cows that become pregnant in early lactation would be expected to have lower yields compared with a similar non-pregnant cow. However, this change is relatively small and has only been demonstrated in the later stages of pregnancy (Roche 2003).

Approaches to Estimating Economic Loss

Two main methods have been used to combine the costs described previously and generate estimates of the likely effect of reduced reproductive performance on profitability. The traditional approach has tended to involve estimating the cost per additional day added to a cow's calving interval, based on the principle that each additional day that the calving interval is extended postpones the subsequent lactation by 1 day, thus effectively substituting it with a day at the end of the current lactation (Esslemont & Kossaibati 2002). Cost in milk production is therefore estimated by subtracting the expected daily yield for the additional day at the end of lactation from the average expected daily yield in the subsequent lactation and multiplying this by margin over feed cost. Daily costs can also be allocated to other components of economic loss and added to this to provide an estimate. As with other approaches, estimates derived by this route are sensitive to a variety of inputs that can change markedly over time, perhaps most notably milk price. Therefore especially in areas in which milk price is mostly driven by the global commodity market and is highly volatile, it is of limited value to produce even 'typical' figures that are widely used across the industry. Estimates should be made at herd level and adjusted to reflect changing market situations. An example of such an estimate is given in Table 25.5.

TABLE 25.5 An example of a cost estimation using a 'cost per day' approach

Cost per Day (£)	365–395d	396–425d	> 425d
Lost milk (margin)	1.57	1.79	1.90
Lost calf value	0.25	0.25	0.25
Extra serves and vet treatment	0.70	0.70	0.70
Gain in yield when empty	–0.13	–0.13	–0.13
Reduced disease risk	–0.43	–0.43	–0.43
Total	£1.96	£2.18	£2.29

Estimation of the economic effect of reproductive performance also lends itself well to simulation-based approaches, which have also been used extensively in this field. This approach is much more flexible, can account more appropriately for a wider range of considerations, and is generally considered likely to produce more robust results. However, it is inevitably less transparent, so that the results are more difficult to explain and justify. It is also harder to customise or update estimates derived using this approach to reflect a specific farm situation, although tools (such as that described by Giordano et al. 2012) for this are available. It appears common for both approaches to generate broadly similar estimates under most circumstances, although this may change as simulation models become more complex and realistic. Simulation can also be used to evaluate the economic value of fertility in block-calving systems (Shalloo et al. 2014).

Veterinary Management of Reproduction

Change in the Role of the Clinician

The last 50 years have seen an evolution in the role of the veterinarian in herd reproduction. Initially, the focus tended to be on identification, diagnosis, and management of individual 'problem' cows, such as those observed to have vulvar discharge or abnormal oestrous cycles. Subsequently, the emphasis expanded to cover the examination of clinically normal cows, with a view to implementing management strategies solely to reduce the time to conception. This included routine examination of cows not seen in oestrus by a specific point in lactation or presentation of cows for pregnancy diagnosis to identify and treat non-pregnant animals. Routine fertility visits to carry out these examinations have been a mainstay of farm animal veterinary practice worldwide over the past 20 to 30 years. More recently, the focus has moved on, and it is now widely recognised that the veterinarian should also be able to add significant value to herds in monitoring data and giving appropriate management advice. This is now a core part

VetBooks.ir

TABLE 25.6 Example of groups of cows selected for examination at routine visits with major differential diagnoses and key features of suggested examination

Reason for Presentation	Example Criteria[a]	Main Focus of Examination	Major Differential Diagnoses
Postnatal examination	• Routine at around 21 DIM • Abnormal vaginal discharge < 21 DIM	• Vaginal examination • +/– uterine ultrasonography	• Normal • Endometritis • Postpartum anoestrus
Oestrus not observed	• No oestrus behaviour observed by 42 DIM • Not inseminated by VWP + 21 days • Not inseminated as expected after previous treatment	• Ovarian palpation/ ultrasonography	• Normal • Cystic ovarian disease • Postpartum anoestrus • Abnormally persistent corpus luteum • Endometritis
Pregnancy diagnosis	• > 30–50 days after last insemination	• Uterine palpation/ ultrasonography • +/- ovarian examination	• Pregnant • Non-pregnant
Repeat breeder	• > 3 unsuccessful inseminations	• Uterine palpation/ ultrasonography • Ovarian examination	• Apparently normal • Identifiable uterine/ ovarian pathology
Unexpected reproductive events	• Abnormal vulvar discharge > 20 DIM • Short or inconsistent cycle lengths • Oestrus behaviour after positive PD	• Determined by reason for presentation	• As appropriate to reason for presentation

[a]Criteria will depend on voluntary wait period, clinician, and farmer preference for pregnancy diagnosis timing and level of veterinary input and should be discussed on commencing visits.

of veterinary involvement in reproduction for many dairy cow clinicians.

Routine Fertility Visits

Routine fertility management visits are used by many dairy herds around the world as an essential element in the process of assisting cows to become pregnant, so that they are retained in the herd for a further lactation. However, in the larger more progressive dairy farms typically found in North America, the routine pregnancy diagnosis examination is not part of the process of optimising pregnancy rates but is seen as a key audit point measuring the outcomes of the processes and systems in place. In these circumstances the regular pregnancy diagnostic examination is used as a means to gather information, validating the current process, and evaluating any changes, either intentional or unintentional, which may have occurred. A regular assessment of the success of the reproductive programme in place is also essential to allow the veterinarian to review compliance with the programme and to prescribe the medicines necessary for the programme to be implemented by farm staff. In this context the regular routine visit is truly part of an integrated herd health system, of which reproduction is only one important aspect. In a successful situation the farmer should gain an improved income that exceeds the cost of implementation; the veterinarian profits from the sale of professional skills. In the North American situation, the veterinarian sits as the judge of the reproductive programme that is in place.

Generally at each visit, cows will have been selected for examination based on an 'action list', often generated by a computer software system using predetermined criteria agreed upon by the herd owner; the categories of animals presented for examination will vary from herd to herd. An example of the groups of cows presented is shown in Table 25.6. For each cow presented, an accurate up-to-date record of all her lactation events should be readily available, and, likewise, all findings and actions taken at the visit should be transferred back to the main records system in a timely manner. For herds using a high degree of planned synchronisation protocols, the only cows presented may be those for pregnancy diagnosis, as preplanned schedules may dictate the enrolment of cows to those protocols; for ease of allocating and planning labour, the work may occur at a different time of the week. In these situations the prescribing veterinarian should have been involved in the planning and setup of the programme and preferably have a clear knowledge of which cows will receive which treatments and on which day.

It is important to understand that a cow appears on an action list because she has fallen outside certain agreed reproduction targets set by the herd management team and therefore may be in a situation in which her profitability is falling to an unacceptably low level. The common practice of a herdsperson editing the 'action list' and removing cows before a visit is therefore to be discouraged as those cows removed from the list are only likely to become even less profitable and ultimately hasten their culling from the herd. A major objective of the reproductive programme should be to ensure that every cow has an equal opportunity to become pregnant and be retained in the herd. Similar thinking should apply to cows presented as 'not seen in oestrus' or that are overdue for insemination; failure to take action will almost always result in a greater delay in the cow becoming pregnant, with the consequent reduction in her profitability. The frequency of herd visits can also have an effect on the speed with which cows become pregnant as more frequent herd checks means that, on average, cows will be examined for pregnancy earlier and action on open cows is taken sooner.

For herds undertaking routine visits, the physical facilities should also allow for calm, quiet, stress-free handling of cows. In situations in which cows must be held in pens away from bedding and feed, it should be for a maximum of only 45 minutes to avoid a significant negative effect on the cow's daily time budget (Grant & Albright 2001). Handling facilities that are appropriate for

VetBooks.ir

smaller herds will be inappropriate for handling larger numbers of cows; for example, a holding pen and crush may be adequate for a 100-cow herd but not for a 1000-cow dairy. When cow handling operations are located away from cow housing and feeding areas, regular inspection of those areas should still be undertaken to assess any effect they may have on reproductive performance or, indeed, other aspects of herd health.

Cows presented for routine examinations should always be inspected for general attitude and appearance, body condition, cleanliness, and, when possible, locomotion scoring. It is good practice to keep written records of these observations at each visit for future review.

Although it is common practice to examine the reproductive tract and ovaries of cows presented at routine visits in order to formulate a course of treatment based on individual cow findings, there is growing evidence that many problems with oestrous cyclicity that manifest themselves as a number of gross ovarian changes are in fact due to disturbances in follicular growth; these have resulted from metabolic or infectious insults that the cow suffered during the transition phase. Attending veterinarians should also bear in mind that seasonal effects also influence ovarian cyclicity and that, for example, it is normal for the incidence of ovarian cysts to triple during the autumn in the northern hemisphere associated with shortening day length (Nelson et al. 2010).

Monitoring reproductive performance (as described in the previous sections) is also a core element of the routine fertility visit and can be included in a variety of ways. For example, a specific additional meeting or visit could be set up on a regular basis, ensuring that appropriate members of the farm management team are present (including those responsible for high level management decisions, day-to-day management of the herd, as well as any other relevant professionals such as the herd's nutritionist). Alternatively, or additionally, some time could be set aside at the end of routine fertility visits to assess and discuss performance (and, as a result, potential management changes) in a more informal way, with outcomes summarised in a short e-mail or note.

The frequency with which monitoring is carried out depends on herd size and seasonality. Larger herds will accumulate higher numbers for monitoring much more quickly, so they are generally more appropriately monitored on a more frequent basis (for example, fortnightly monitoring may be appropriate for a very large, year-round calving herd). This allows changes to be put in place rapidly in response to a perceived change in performance. In smaller herds, making decisions based on a small denominator population (e.g., measuring conception rate based on a small number of inseminations) risks identifying a false trend or association (see Key Epidemiological Concepts section). This means that monitoring in smaller herds is inevitably more retrospective, with decreased ability to react quickly to changes. In order to minimise the temptation to commit this error, it is often appropriate to evaluate data from smaller herds less frequently. For example, a chi-squared test of a change in conception rate from 40% to 30% (a change of highly clinically important magnitude for most herds) produces a p-value of almost 0.28, when there are 25 inseminations in each group (i.e., 25 at 40% and 25 at 30%). This is roughly the number of inseminations that might be expected in a 100-cow herd in each month; the p-value can loosely be interpreted as suggesting a 28% chance that the difference observed is due to chance rather than to a genuine change in performance. The degree of certainty required in order to justify implementing changes will vary between decision makers and different situations, but including two or three months' worth of inseminations (n = 50, p-value = 0.12; and n = 75, p-value = 0.06) would make this trend much more convincing. Monitoring conception rate should perhaps be justified in a herd of this size on a monthly basis, always using 2- or 3-month rolling averages as the key metric. In contrast, a 400-cow herd serving around 95 cows per month would be able to have a high degree of confidence that a change from 40% in one month to 30% in the next month would reflect a true change in performance; here, monitoring would be justified on a fortnightly or monthly basis.

Even when good quality herd records do not exist, some degree of useful monitoring may be accomplished based on the events that are observed at visits. In this situation the number of positive pregnancy diagnoses should be a key metric. This can be compared with the estimated number required at each visit to represent one pregnancy per cow in the herd per year and gives an impression of the level of overall performance. Again, this should be based on the total number aggregated over an appropriate number of previous visits, based on the size of the herd.

Herd Level Aspects

The first step in improving a herd's reproductive performance should be to employ the monitoring approaches described in previous sections in order to determine whether the focus should be on improving submission rates for insemination (in herds using AI), improving conception rates, or reducing the level of reproductive disease. It is frequently most appropriate to select one of these areas for initial improvement, even when performance is suboptimal in multiple areas; it can be challenging to attempt to improve several aspects at once. Reasons for poor performance in each area and potential management changes that can be implemented to address these are discussed in Chapter 24, but some common problems are highlighted in the following sections.

Improving Submission Rate

Rate of submission for service (in herds using AI) is predominantly determined by two elements: the rate or 'sensitivity' of the farm's oestrous-detection system and the ability of the cows to express oestrus. There are often limited clues from data analysis that can help to distinguish between these as potential reasons for a suboptimal submission rate, but strong seasonal patterns tend to suggest an environmental component. Generally, therefore, the approach to a poor submission rate involves assessing both elements to identify risks, and using judgment to determine which area is most likely to be limiting or whether elements of both should be improved.

Expression of oestrus is dependent on a number of factors. These broadly fall into those relating to the cow's environment and management and those directly relating to the individual cow. A number of environmental factors have been associated with oestrous expression, such as lack of appropriate space (especially lack of loafing space in cubicle housing; Pennington et al. 1985), poor quality or badly repaired floor surface, and high temperature and/or humidity. Management factors such as time budget (which can become limited, for example, when a group is milked three times daily with a long milking time) and group size are also common problems. Of the cow factors, lameness is perhaps the most important and frequently encountered. There is a substantial body of evidence associating lameness with decreased reproductive performance at cow level (Sogstad et al. 2006, Machado et al. 2010), although this effect may be relatively small at herd level (Hudson et al. 2014). High milk yield has also been reported to be associated with decreased intensity and duration of oestrus

VetBooks.ir

(Lopez et al. 2004), but there is little evidence that this association is mediated by negative energy balance.

The efficiency of the farm's system for detection of oestrus clearly depends on the method or methods of oestrous detection employed. When visual detection is used, frequency and timing of detection alongside training of observer are critical. A number of visual signs have been described, among which observing a cow standing to be mounted by another cow is usually considered the most reliable (sometimes described as the 'primary' sign). It is widely accepted that observation of this sign alone is sufficient to diagnose oestrus. Less reliable (or 'secondary') indicators include mounting other cows (either at head or hindquarters), chin-resting, and vulva sniffing. Van Vliet and Van Eerdenburg (1996) describe a scoring system for visual detection that assigns a number of points to each of the behaviours observed and suggests diagnosis of oestrus when a score threshold is reached. Even when this is not used systematically, this scoring system can be a very useful training aid to help observers rank the relative importance of the various signs. Evidence suggests that modern Holstein cows commonly demonstrate standing oestrus (i.e., standing to be mounted) for an average of around 7 to 8 hours (Sveberg et al. 2011, 2015, Yoshida & Nakao 2005), which means that fewer than three periods of detection spaced evenly through the day may reduce effectiveness substantially. Use of information can also be useful in aiding visual oestrous detection. A number of systems can be used to remind farm staff which cows are likely to be in oestrus on which days (i.e., those 19–26 days postinsemination); recording 'reference' heats (when a cow is observed in oestrus during the VWP, so not inseminated); allows anticipation of an 'expected' oestrus date for the cow's first eligible cycle.

A number of oestrous detection aids are available, and are widely adopted in most major dairying nations. The simplest of these involve simple physical approaches to detecting when a cow has been mounted by another cow (and is therefore assumed to be in standing oestrus). These devices include tail paint or chalk, self-adhesive scratch cards, and capsule-type systems (see Chapter 24). These have various strengths and weaknesses, and there is no compelling evidence to support use of one over the other. In practice, it appears that one or the other commonly works better in a particular farm situation. Reported sensitivities of these systems vary widely (probably because of differences in cow and environment factors between studies, which are very commonly based on a single herd); they range from around 35% (Holman et al. 2011) to over 90% (Xu et al. 1998).

A more sophisticated (and more expensive) approach is the use of sensor technology, either as a standalone system or integrated with milking parlour or voluntary milking systems. Activity monitoring is by far the most common sensing approach used for oestrous detection, and has been relatively widely adopted since the mid-2000s. These systems detect an increase in activity (usually via an accelerometer attached to a leg or neck collar), as cows move about more when demonstrating oestrus. An increase in activity beyond a specified threshold above that expected triggers an alert that the cow may be in oestrus. As with other methods, a range of test characteristics are reported in the literature. Reported sensitivity values are typically in the range 60% to 90%, with positive predictive value generally 70% to 95% (Firk et al. 2003, Holman et al. 2011, Roelofs et al. 2005). Both the algorithms for interpretation of activity data and the sensors themselves are continuously being improved, so it is likely that this method will become increasingly effective in future.

Implementing a combination of more than one method is often associated with the highest levels of submission rate, plausibly because different methods detect different oestrous behaviours. Milk progesterone testing can also be useful (greatly facilitated when tests can be done quickly at cow side). It is especially useful when used in parallel with a measurement that would be expected to increase sensitivity but decrease specificity of oestrous detection; for example, reducing the threshold required to trigger an alert on an activity monitor system. Alerts associated with activity levels above the previous (higher) threshold could still be used as a basis for insemination with no further evidence, and alerts between the new and old thresholds screened using milk progesterone, thus inseminating cows when the progesterone level is low. This often detects a higher proportion of oestruses without the drawback of inseminating more 'false positive' cows. Effective use of veterinary examinations and fixed-time artificial insemination protocols can also be extremely helpful in improving submission rates; these are discussed elsewhere in this chapter.

Improving Conception Rate

As with submission rate, there are a wide variety of possible causes of poor conception rate. Nutrition is one of the most commonly implicated areas; there are a number of possible nutritional factors that may influence conception rate. Perhaps the most common is excessive negative energy balance (NEB) during early lactation (see the review by Roche (2006)). Analysis of body condition score data and estimation of blood ketone and non-esterified fatty acid concentrations can be very helpful in quantifying postcalving energy balance and evaluating the potential importance of this aspect for a particular herd. Energy balance may also play a role in mediating the association between conception rate and temperature and humidity, a key environmental factor influencing conception rates. Micronutrient nutrition can also influence conception rates, although in most systems, this is uncommon compared with the effects of negative energy balance. When NEB is the key factor, data analysis can reveal lower conception rates in early lactation or in higher yielding cows; if micronutrients are involved, conception rates tend to be poor across all inseminations. The role of subacute ruminal acidosis in compromising conception rates remains controversial.

A number of diseases are also associated with reduced conception rates. Probably the most important (in this context) are the postcalving reproductive diseases, including retained fetal membranes, metritis, and endometritis. These are strongly associated with decreased fertility and should always be considered when a high rate of such diseases is observed in conjunction with poor conception rates (especially when conception rate is particularly low in early lactation). Herd level infectious diseases, such as bovine viral diarrhoea, infectious bovine rhinotracheitis, leptospirosis, and Johne's disease, have also been associated with decreased conception rates (see Chapter 24). The evidence for this is especially clear when disease enters a previously naïve herd; the size of association tends to be much smaller and the evidence more equivocal for the effect of such a disease in a herd with a moderate level of endemic infection. Non-infectious endemic diseases, such as mastitis and lameness, have also frequently been associated with reduced conception rates in individual cows but are probably a relatively rare cause of a poor conception rate at herd level (Hudson et al. 2014, 2015). Some venereally transmitted diseases (such as campylobacteriosis) are associated with decreased conception rate in herds using at least some natural service.

Finally, there are a number of factors associated with insemination that can result in disappointing conception rates. For artificial insemination, these include poor semen quality or storage, thawing

VetBooks.ir

and handling, as well as inappropriate timing of insemination relative to signs of oestrus, and inaccurate heat detection (i.e., insemination of cows outside of true oestrus). The latter problem can sometimes be identified by a high proportion of interservice intervals of 'unexpected' duration (i.e., not multiples of the expected normal oestrous cycle length), especially intervals less than 19 days. Cow-side milk progesterone testing may be a useful tool here; for example, measuring progesterone in the next 50 cows to be inseminated allows calculation of the positive predictive value of the herd's heat detection (i.e., proportion of apparent heats that represent a true oestrous event). When natural service is used, establishing the semen quality of the bull team is important, alongside factors such as the ratio of bulls to eligible cows and general bull health.

In herds using natural service alone (where a bull is running with the eligible cows at all times), it is rational to assume that conception rate is the main limiting factor for fertility in most situations, provided that the bull has been observed to have a normal level of libido and good physical mobility.

Minimising Reproductive Disease

A strong association exists in dairy cows between the incidence of inflammatory and metabolic diseases in the first 2 months postpartum and reduced fertility and pregnancy loss during the subsequent lactation (Santos et al. 2010). Calving-related disorders and those that affect the reproductive tract are major contributors to anoestrus or the occurrence of abnormalities of ovarian cyclicity diagnosed later in lactation such as ovarian cysts and anoestrus. It is estimated that approaching half of all cows experience one or more calving-related health disorders in the first 60 days postpartum. Almost all dairy cows are known to experience bacterial contamination of the uterus in the first 2 to 3 weeks postpartum, which, along with the necessary repair of the endometrium during involution (see Chapter 7), means that some degree of uterine inflammation is necessary and is indeed a normal and necessary component of involution (Sheldon et al. 2009). The innate immune system is the main protection for the uterus**,** which may be overcome by overgrowth of pathogenical bacteria**,** or the severity and duration may become excessive resulting in the impairment of future fertility. The high incidence of disease is attributable in part to the reduced innate immune function and regulation of inflammation that occurs in all cows from approximately 2 weeks prepartum to 3 weeks postpartum (Kehrli et al. 1999). However, the metabolic adaptations of insulin resistance (IR) and NEB also contribute to the reduced immune defence. Homeorrhetic adaptations to lactation require that every cow experiences a degree of NEB and IR to support lactation, but as with uterine inflammation, the concern is for cows that experience a severity of these states that goes beyond the merely adaptive to become a contributor to disease and impaired reproduction. The point at which reproductive tract inflammation and metabolic status shift from the physiologically normal to the undesirable is likely to involve a number of multifactorial interactions; these remain poorly quantified and understood. It is well known that during the transition period the dairy cow is at particular risk of the effects of NEB, and it is intriguing that it seems likely that the metabolic milieu that accompanies transition may be responsible for the initiation of inflammation without the presence of a pathogen.

Although relatively little is known about how reproductive tract disease may be influenced by management, it is known that cows that develop severe metritis will have eaten less than normal cows in the 2 to 3 weeks preceding the onset of the disease; reductions in feed intake are associated with increased circulating concentrations of NEFAs, which may indirectly or directly inhibit neutrophil function (Hammon et al. 2006, Huzzey et al. 2007, Ster et al. 2012). The high degree of oxidative stress also experienced by early lactation dairy cattle also contributes to a proinflammatory state that may not be helpful for immune defence mechanisms (Sordillo & Aitken 2009).

Based on current understanding, there are few management practices that can be recommended with certainty that will prevent inflammatory reproductive tract disease in the postpartum period. Current understanding suggests that the objective should be to support and maintain innate immune function to prevent the risk that the normal postpartum bacterial contamination and inflammation does not progress to infection and disease. Suggested management practices generally recommended for peripartum cows that may reduce the incidence of postpartum reproductive tract disease are shown in in Box 25.3.

The aetiologies of cystic ovarian disease and anovulatory anoestrus and associated risk factors are generally considered to be similar to those associated with uterine disease, although less well understood (see Chapter 22).

The causes of abortion are generally much better understood and can broadly be categorised as infectious (including neosporosis and brucellosis) and non-infectious (including stress and exposure to fetotoxic agents). These are covered in more detail in Chapter 24. From a herd perspective, it is important to remember that a certain level of abortion is expected; levels higher than 3% to 5% are commonly considered to merit investigation.

• BOX 25.3 Suggested Management Practices to Reduce the Risk of Reproductive Tract Disease

- Dry cows off to ensure a target dry period length of 35 to 60 days for at least 85% of the herd.
- Prevent overconsumption of energy above requirement during early part of the dry period.
- Provide unrestricted feed access at all times for all dry cow groups.
- Ensure feed is provided ad lib, and all cows can eat at the same time when fresh feed is delivered.
- Provide a minimum of 75 cm of utilisable trough space per cow.
- Provide at least 10 cm of water trough space per cow, sited at a least 2 points in the pen.
- Provide adequate cow comfort with cubicles or open yards to ensure at least 11 to 12 hours lying time per cow per day – at least 1 cubicle per cow and for open bedded areas at least 10 m^2 per cow plus an additional 1 m^2 per additional 1000 kg of milk production over 10,000 kg.
- Minimise group and social changes. Aim to restrict grouping changes to a weekly event at most; ideally use an 'all-in/all-out' system to maintain the same social group over the dry period.
- Ensure each cow spends a minimum of 10 days exposed to an appropriate precalving ration.
- Dry cow and fresh pens should have sufficient capacity to cope with variations in calving pattern. Facilities should provide 130% of average monthly capacity in year-round calving systems.
- Ensure excellent ventilation of dry and fresh cow buildings. If necessary, provide heat abatement, fans, and sprinklers for when the temperature humidity index (THI) exceeds 68.
- Manage overall nutrition for target body condition (BCS) at calving of 3 to 3.25 (on a 5-point scale) and maintain a minimum of 2.5 with no change from dry off to calving.

VetBooks.ir

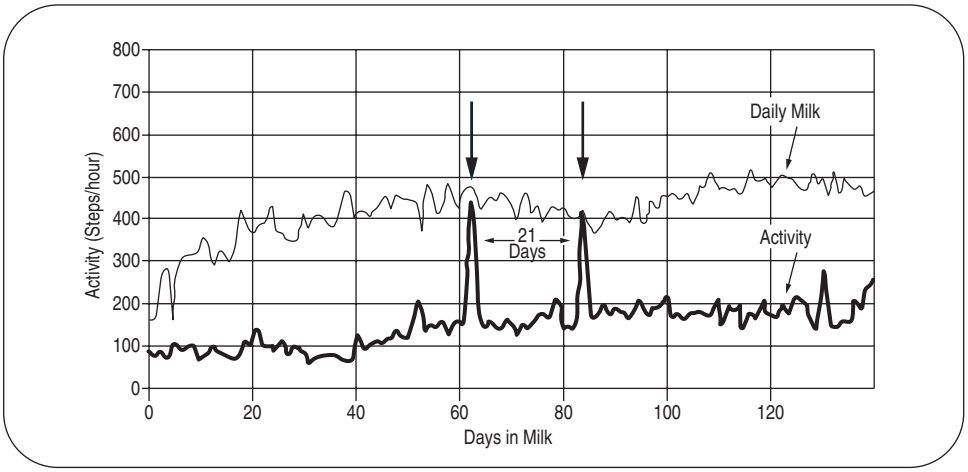
Reproductive Protocols

A number of reproductive management protocols, or controlled insemination programmes, have been developed over the years to meet the need of larger dairy herds. As discussed earlier, on many farms, especially in larger herds, hormone-based programmes such as Ovsynch are being increasingly used so that insemination of eligible cows becomes part of the weekly routine and does not interrupt the normal daily workflow of the dairy unit. However, it is the authors' opinion that an effective oestrous detection system should still be pivotal in an integrated approach to dairy herd reproductive management and should be part of a normal, fixed, daily routine and carried out in a manner specified in written protocols. For example, if a system of tail chalking or tail painting is used, it should be clearly understood by all personnel. Likewise, when telemetric systems of heat detection are in use, data gathered must be checked at least daily so that cows can be inseminated within an appropriate time window (Fig. 25.4).

The protocol chosen depends on the time and skills available on the farm to continue to detect oestrus. Programmes that rely on inducing CL-regression, such as those utilising double or multiple injections of prostaglandin, require an element of oestrous-detection to produce acceptable results and are best described as oestrous synchronisation programmes. Variations on programmes that utilise induced CL regression include systems in which a veterinary examination to identify the presence of a CL, either by manual palpation or ultrasound, is done before injection and that the reproductive tract is healthy; this is a system commonly used in smaller herds. A surprisingly large number of herds still simply administer $PGF_{2\alpha}$ every 2 weeks to non-pregnant cows and simply observe for oestrus. This system can work well if a CL is present and is an easily administered programme requiring minimal record keeping; it can be used for cows and heifers. Good oestrous detection is essential for success. Veterinary examination may be seen as an advantage or disadvantage in these programmes as there are unnecessary costs incurred in examining large numbers of cows that do not require examination. In contrast, protocols that rely on induction of ovulation (such as Ovsynch and related programmes) are much more likely to produce better results to TAI without oestrous detection. Such synchronisation protocols are most often used to ensure timely insemination of cows by a target 'days in milk' to ensure every cow receives a first insemination at a time in lactation that allows her the opportunity to become pregnant and retain her place in the herd. Cows found not pregnant can also be enrolled on to synchronisation protocols to ensure timely reinsemination. In some herds that operate very intensive reproductive programmes, the first GnRH of the Ovsynch protocol can be given to all cows 7 days before pregnancy examination without terminating the pregnancy and so shortening the time to reinsemination by 7 days, a practice commonly termed 'Resynch'. It is worth noting that outcomes from re-synchronisation protocols may be poorer when the interval from the preceding insemination is less than 30 days (Fricke et al. 2003). Perhaps it should also be noted that in herds in which oestrous detection is excellent, aggressive resynchronisation may actually lengthen days open as the initial GnRH treatment may interfere with normal folliculogenesis, thus delaying normal oestrus and ovulation.

The success of these programmes is heavily dependent on compliance with the injection schedule, which requires a high degree of staff skill and training. In a three-injection programme, if compliance is 90% (such that 90% of the cows get the correct treatment on the correct day), only 73% ($0.9 \times 0.9 \times 0.9 = 0.73$) of the cows will complete the programme correctly. Programme compliance can be checked based on audits of the amount of drug used versus cows injected and/or by periodically sampling some cows on either day 7 of a programme or on the day of insemination for milk progesterone measurement.

For herds that use a combination of oestrous detection and synchronisation to ensure that each cow receives a timely first insemination, the question arises as to the 'days in milk' when cows should be enrolled on the synchronisation programme, with most herds opting to ensure that every cow receives a first insemination by 75 to 80 'days in milk'. The rationale for this timing is based on the information that cows that show an early return to cyclicity and an early first ovulation postpartum are likely to be inseminated to a naturally occurring oestrus before this time and conceive earlier than those that show a delayed return to cyclicity and a delay in the first ovulation postpartum (Galvão et al. 2010). The major factors contributing to the absence of cyclicity observed in some cows are the calving-related disorders of the reproductive tract. The number of cows failing to resume cyclicity by 50 to 65 days in milk in many herds is in excess of 20% (Santos et al. 2010). Thus the percentages of cows requiring synchronisation to achieve a first insemination by this time can be used as a crude assessment of health at calving. In herds that combine oestrous detection with synchronisation to achieve their first insemination by 80 days in milk, it is suggested that a target of no more than 25% of first inseminations should be to synchronised inseminations.



• **Fig. 25.4** Example of the output from a simple on-farm pedometer activity monitoring system.

VetBooks.ir

Most synchronisation protocols used in cows (with the exception of periodic injections of $PGF_{2\alpha}$) are unsuitable for use in heifers due to the difference in follicular dynamics. Addition of an intravaginal, progesterone-releasing device will significantly improve conception rates for fixed-time insemination of heifers (see Chapter 8 for further details).

Routine synchronisation of heifers has the same ethical and welfare issues as routine synchronisation of lactating cattle, although the reasons for its use are generally different – namely difficulty in organising oestrous detection in the heifer group versus underlying poor oestrous behaviour in lactating cows. However, in contrast to lactating cows, synchronisation of heifers can have welfare benefits for the treated animals as the compact calving pattern produced allows the creation of heifer groups that, on larger farms, can be kept together after lactation or, even on smaller farms, carefully managed to minimise the effect of the transition from pregnancy to lactation (Boyle et al. 2013, Neave et al. 2017).

It should always be borne in mind that, despite the use and development of sophisticated controlled breeding programs, ultimately herd reproductive performance will remain dependent on and restricted by the overall standard of the management of health and nutrition of the herd. Pregnancies resulting from controlled breeding programmes will still be subject to the same level of embryo loss and abortion as those resulting from insemination to spontaneously occurring oestrus. Ultimately, success will depend on an integrated approach to fertility management, with the use of synchronisation protocols being just one aspect of a sound reproductive management programme.

Veterinary Control of Herd Fertility in Pastoral Dairy Herds

RICHARD LAVEN

The main features of the annual reproductive calendar are illustrated in Table 26.1 (Holmes et al. 2002).

For a spring calving herd the aim is to have cows calving over a relatively short period during late winter/early spring. They will then be rebred approximately 3 months after the start of calving. The planned start of mating is a set calendar date, designed to result in cows starting to calve at the correct time in the next year. So, in a Northern hemisphere system, where the aim is to have cows starting to calve in the beginning of February, the planned start of mating (PSM) needs to be set 282 days before then (i.e., a PSM date of 27 April for a calving period beginning 3 February).

As mating starts on a specific date, cows become eligible for breeding at a range of postpartum intervals; there is no set voluntary waiting period (VWP). The length of the mating period determines the length of the calving period, so for a compact calving the recommendation is to have a breeding season of 12 weeks or less. However, on farms with moderate to poor fertility, a 12-week breeding season would result in too high a proportion of cows that have failed to conceive ('empty' cows) and that will need to be culled at the end of the season. The length of the breeding season is thus a compromise between the duration of the calving period next spring and the 'empty rate' at the end of this year. This can have positive consequences – with good fertility, the breeding season can be reduced to less than 12 weeks as the target 'empty rate' can be obtained before the 12-week target. The tighter calving pattern that this facilitates brings benefits both in staffing and activity management and in production efficiency (by matching stage of lactation more closely to grass growth and quality).

For the standard 12-week breeding season, the most common practice is to have 6 weeks of AI, usually to bulls of dairy breeds, so that all cyclical cattle can have at least two opportunities to become pregnant. This is usually followed by 6 weeks of breeding with sweeper bulls, which can be extended if the proportion of cows that show heat when the bulls are introduced is higher than expected. On Australasian farms, pregnancy testing has traditionally been undertaken approximately 6 weeks after the bulls have been removed. However, this is now changing, with more herd pregnancy testing at approximately 6 weeks after the end of AI, followed by retesting of cattle not diagnosed as pregnant 6 weeks after the end of the breeding season. The additional early pregnancy diagnosis allows fetuses resulting from AI to be accurately aged, so that the success of the AI breeding period can be properly monitored. In contrast to all-year-round calving herds, cows that are identified at any stage as being non-pregnant are not treated or reinseminated. Once confirmed as non-pregnant, cows remain in the milking herd until they are culled, which, provided grass is available, is usually at the same time as the pregnant cows are dried off.

In New Zealand, drying off time is dictated by the availability of pasture (which is weather dependent) or cost effective supplementary feeds (such as forage crops and palm kernel extract). Most farms in New Zealand aim to dry off cattle as late in the autumn as possible, but this still results in an average lactation of 275 days with a dry period length of approximately 90 days (McDougall 2010). This is because cows tend to be dried off as a group or herd rather than individually, based on expected calving date. In addition, early dry off before the main date is often used as a management tool to preserve grass, reduce bulk somatic cell count, and aid the management of body condition, further reducing average lactation length.

In Australia, where the cost of supplementary feeding with grain is much less than in New Zealand, dry period lengths are shorter and tend to be based on calving date; even in Tasmania, which has the most New Zealand-like system, average lactation length is approximately 300 days (Anon 2015). In Ireland, where dry cows are commonly housed and fed grass silage, dry period length is shorter than in New Zealand but still not as short as would be recommended based on calving date; Cummins and associates (2016) reported that 79% of spring calving herds had an average dry period length between 8 to 12 weeks.

In Australia and New Zealand calving takes place at pasture, with the aim of calving approximately 90% of the herd within 6 weeks of the planned start of calving. In Irish-style systems, in which cows are housed to prevent the effect of winter grazing on spring grass growth, cows should calve before turnout, with a lower target of having 75% of cows calving within a period of 6 weeks from the commencement of calving.

Key Issues Affecting Reproductive Performance

Body Condition Score

In any dairy system, the balance between energy intake/output and fertility are closely linked. In a pasture-based system, there is not the option to alter the diet to increase energy intake. Energy

VetBooks.ir

TABLE 26.1 Annual calendar of suggested main managemental and reproductive events in a spring calving, pastoral dairy herd

Late Winter/Early Spring

- Cows calving
- Pregnant cows on restricted grazing; may be supplemented with forage crops (such as fodder beet) or grass/maize silage
- Calved cows on unrestricted grazing
- Yearling heifers starting to show significant oestrous activity

Late Spring

- All cows should have calved within 8–10 weeks.
- Oestrus observation starts at least 31 days before planned start of mating. All calved cows tail painted at this time.
- Normal cows should show oestrus within 40–50 days of calving. Anoestrous cows identified and treated before the start of the mating period.
- All cows examined and treated for endometritis before start of premating oestrus observation period.
- Planned start of mating is 83 days after planned start of calving. Aim to breed all cows to AI at least once in the first 6 weeks of the mating period.

Summer

- All cows and 15-month-old heifers should be mated by midsummer.
- Pregnancy test cows and 18-month-old heifers.

Autumn

- Dry off once pasture becomes scarce and/or milk production declines to uneconomic levels.
- Adjust feeding of dry cows to ensure cows calve at correct condition score. Separate thin animals and feed more generously.

Derived from Holmes et al., 2002.

intake is dependent on pasture availability and pasture quality, which are both dependent on pasture management. Furthermore, it is not just current pasture management (e.g., current rotation length, grazing heights, and residual dry matter) that influences pasture quality and availability; it is also past management, especially during the spring season. Poor pasture management during the dry period (i.e., winter) will significantly reduce pasture growth in the spring. The difficulty of feeding the dry cow in winter from grazed grass and maintaining optimal grass growth in the spring is the key driver for housing of the dry cow on Irish pasture-based farms and also the main reason why many dairy farms in New Zealand winter their cows away from the main farm.

Body condition score (BCS) is the best method of monitoring energy balance in adult dairy cattle. In grazing cattle, as in cows fed a total mixed ration, the expectation is that in early lactation there will be a dip after calving as the cow mobilises body tissue to produce milk (Fig. 26.1), with BCS reaching a nadir before the planned start of mating. If BCS is not managed effectively, then fertility will suffer. The key targets are BCS at calving and the loss of BCS between calving and mating. In order to meet the BCS targets for calving, BCS needs to be closely monitored in late lactation so cows can be fed during the early dry period to meet the BCS target.

There are strong links between BCS and reproductive performance, with BCS at calving and/or mating tending to be positively associated with performance and increased loss of BCS being negatively associated (Roche et al. 2007). In seasonally calving herds, the most important effect of low BCS and of excess BCS loss is probably their effect on the postpartum anoestrous interval. This is because the short breeding season means that any delay in returning to oestrus, particularly in late calving cows, reduces the chance of a cow becoming pregnant to AI and increases the chance of a cow failing to get pregnant at all. Interestingly, for BCS at mating, though not at calving or nadir when the relationship was a simple linear one, Roche et al. (2007) found a curvilinear relationship with the odds of oestrus being observed before the planned start of mating being greatest with a BCS of 5.5 (on a 1–9 scale).

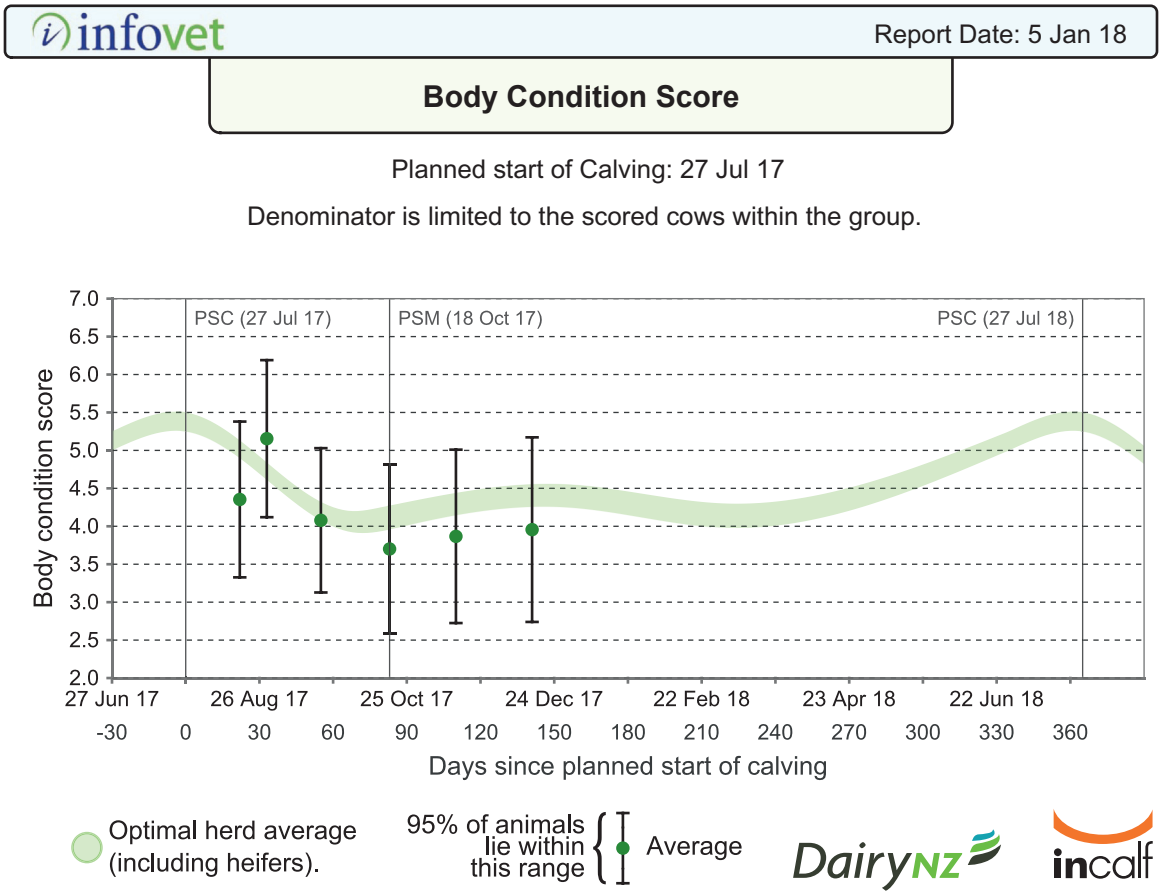
Calving Pattern

Attaining a compact calving pattern by inseminating and getting cows pregnant early in a short breeding season is essential for optimising profitability in a seasonally calving pasture-based system. However, the current year's calving pattern has a major effect on the likelihood of getting a compact calving next season. If the current year's pattern is compact (60% calving within the first 3 weeks, and 90% in the first 6 weeks), then it is relatively easy to maintain a compact calving pattern. In contrast, if calving is extended over a long period or large numbers of cows calve after the first 6 weeks, then it can be difficult to achieve a compact calving period in the next year without a high replacement rate.

The effect, like BCS, is principally mediated through return to cyclicity. Cows that calve later in the season will have shorter intervals from calving to planned start of mating than cows which calved earlier. This has two effects: first, there will have been less time to complete involution and restore normal uterine and ovarian function; second, they are more likely to be in negative energy balance. Both of these effects combine to result in later calving cows being more likely to show no heat before the planned start of mating; consequently, later calving cows are less likely to conceive to AI and less likely to become pregnant at all.

The calving pattern also affects the age at which nulliparous heifers are first bred. As with the milking herd, heifers become eligible for mating on a calendar date, not on an age or weight basis. This ensures that heifers calve at (or, more commonly, somewhat before) the same time as the main herd. If the herd has a compact calving pattern, then heifer replacements will be born over a short period of time (often not much more than a month); in contrast, if the calving pattern is extended, then the variability in age between heifers will be greater. In the latter case, if the heifers are all bred at the same time, some heifers will calve at 21 to 22 months of age and will be smaller and lighter and therefore more likely to have delayed return to cyclicity and an increased risk of failing to become pregnant during the breeding season. Delaying insemination until a heifer is 14 months of age will reduce the interval between her first parturition and the start of the subsequent breeding season, again increasing the risk of failing to become pregnant during the breeding season. In New Zealand, most heifers are bred to a small stature bull, usually a 2- to 3-year-old Jersey bull, reducing the need for management around calving. This reduces the rate of genetic gain as replacements are not produced from the animals with the best genetic merit. Furthermore, as well-grown heifers have high fertility and will get pregnant more quickly than well-managed lactating cows, producing at least some replacements from heifers will produce a better-matched age group than producing them from mature cows alone.

VetBooks.ir



• **Fig. 26.1** Recommended body condition score targets relative to planned start of calving (PSC) and planned start of mating (PSM) for pasture-based cattle in New Zealand. BCS scale is 1 to 9 scale; to convert to Irish 1 to 5 scale: IRE = 0.81 + 0.4 NZ.

As stated earlier, a poor calving pattern is the biggest barrier to improvement in reproductive performance on seasonally calving farms. Culling late calving cows is an essential part of improving calving pattern, but is not sufficient on its own; the culled cows need to be replaced by cows that calve early in the calving season. The best way of doing this is by increasing the number of heifers kept as replacements. In a herd in which the replacement rate is normally 25%, improving the calving pattern will need at least 30% of the herd needs to be replaced annually by early calving heifers.

Heifer Management

Rearing heifer replacements is one of the biggest costs on a dairy farm, so it is essential to produce quality heifers that will have long and productive lives, which necessitates good reproductive performance in their first and subsequent breeding seasons. Monitoring and meeting bodyweight targets is crucial if this goal is to be met. On many farms the targets (Table 26.2) are set based on the average mature live weight in the herd, but with good quality genetic data and computerised systems, the targets can be set at the individual cow level (Roche et al. 2015).

Regular monitoring, ideally monthly, is essential. First, simply meeting the final 22-month target does not prevent the effect of earlier poor growth. Heifers that fail to meet the breeding target but that are closer to achieving the precalving bodyweight target are often small and fat, increasing the risk of dystocia and of future reproductive problems. This can be identified by measuring stature and BCS alongside live weight. Second, regular monitoring allows early intervention either at the group or individual level. Consecutive weight measurements can be used to calculate the rate of weight gain, and plotting this against current weight will allow heifers to be categorised into (Fig. 26.2): i) On track: weight gain and current weight better than target; ii) Recovering: current weight less than target but weight gain better than target; iii) Monitor: current weight more than target but weight gain below target; and iv) Action: current weight and weight gain less than target.

TABLE 26.2 Recommended targets for live weight for pasture-fed heifers

Age	Target
3 months (weaning)	20% of mature live weight
11–12 months (puberty)	50% of mature live weight
14–15 months (breeding)	60% of mature live weight
22 months (precalving)	90% of mature live weight

Anovulatory Anoestrus

In seasonal systems all non-pregnant cows become eligible for mating once the breeding season has started. This means that cows that

calve more than 6 weeks after the start of calving, have less than 40 days to return to normal cyclicity. Furthermore, cows with any reproductive abnormality, such as dystocia or endometritis, may have only a short time to restore normal function before the start of the breeding season even if they calve in the first 6 weeks. It is thus unsurprising that a high proportion of cattle in such systems (around 20%; Rhodes et al. 2003) fail to show oestrus before the start of the breeding season. Although 10% to 30% of these cattle have ovulated but not shown oestrus, the principal problem is anovulatory anoestrus, i.e., follicular waves have restarted but the dominant follicles have undergone atresia rather than ovulation. Cows that do not show oestrus before the planned start of mating have significantly reduced fertility compared with normal cows, even if a CL is present, and it is recommended that they should be treated with a progesterone-based synchronisation programme that is timed so that synchronised cattle are inseminated on the first day of the breeding season (McDougall et al. 2005).

Monitoring Herd Fertility

In contrast to all-year-round calving herds, in which constant ongoing veterinary monitoring of fertility is a key part of the veterinarian's role, in seasonally calving farms, most fertility assessment occurs after the end of the breeding season and is aimed at identifying the issues that have occurred during that breeding season so that changes can be made in order to improve the performance in the next season.

The retrospective nature of much of the assessment lends itself to a standardised approach; a standard format for this (the fertility focus report; Fig. 26.3) has been successfully adopted in New Zealand and Australia. This report is centred on the 6-week in-calf rate (the proportion of the eligible cows that got pregnant during the first 6 weeks of mating). This is useful for benchmarking between years and between farms as it is standardised with clear criteria for numerators and denominators and with little influence of farm management choices (such as breeding season length). A cow is defined is eligible (i.e., it is included in the denominator) if she has calved on or between 130 days before and 59 days after mating start date. This calving needs to be on the farm in question, and she needs to be not culled or sold before the start of mating. To calculate the numerator only two additional pieces of information are required: the start of the mating season (which is based on the pattern of AI and is thus recorded by the insemination company) and aged pregnancy tests that confirm when during the 6-week period the cow became pregnant (recorded by the veterinarian or lay scanner). The latter requires pregnancy testing at the end of the breeding season, 11 to 14 weeks after the start of mating. Before the introduction of the fertility focus report, many herds just had a single pregnancy test approximately 6 weeks after the end of the breeding season that identified non-pregnant cows and divided pregnant ones into late (probably bull mating) and early (probably AI). So to get accurate 6-week in-calf rates has meant an additional pregnancy diagnosis. However, this has not proven a problem in most herds. In those herds that do not undertake early pregnancy diagnosis, the 6-week in-calf rate can be calculated from the percentage of the herd calved in the first 6 weeks of the calving period and the 3-week submission rate. In addition to accurate calving records (required for an accurate denominator), this calculation only requires accurate recording of insemination data rather than pregnancy diagnosis.

The requirement for accurate aged pregnancy tests (rather than just differentiating between cows pregnant in the first 6 weeks and those which became pregnant after that) is because the rates are calculated using survival analysis, with the survival curve being a key component of the fertility focus report (see Fig. 26.3). This allows the calculation of the 6-week in-calf rate to include eligible cows that have been culled or sold before the end of the period. The not-in-calf rate is calculated using the same process; this measure is very much secondary to the in-calf rate as it is strongly influenced by breeding season length, which is under management control.

The New Zealand dairy industry target of 78% was set by identifying the median in-calf rate of the top 25% of herds. A whole farm model was then used to calculate the economic effect of having a 6-week in-calf rate below that target. This showed that for a milk price of NZ$5.50 per kg milk solids (i.e., fat and protein) and a 3 cows/ha stocking density, a 1% increase in 6-week in-calf rate was equivalent to NZ$4 per cow (Brownlie et al. 2011). However, although this is a valuable calculation, particularly when identifying potential returns from improving fertility, it is only indicative. This is because two farms can have the same 6-week in-calf rate but very different reproductive performance. For example, a herd which has a 75% 6-week in-calf rate in which all the cows became pregnant on the first day of the breeding season has better performance than a herd with a 75% 6-week in-calf rate in which all the cows became pregnant on day 40. This is the same issue identified in Chapter 25 for 21-day pregnancy rate; measuring proportions over a fixed time period obscures how quickly cows get pregnant. This issue is more important for 6-week in-calf rate, than 21-day pregnancy rate as the data are accumulated over a longer period of time.

This is highlighted by the response to treatment of cows that do not show oestrus before the planned start of mating. Such treatment does not improve 6-week in-calf rate (McDougall et al. 2010); the economic benefit of synchronisation results from cows getting pregnant more quickly and calving earlier in the next season and thereby having a longer lactation (more 'days in milk'). More conventionally, synchronisation improves productivity by reducing calving-to-conception interval.

Having highlighted the 6-week in-calf rate the fertility focus report then identifies the factors underlying that performance – submission rate and conception rate. The targets for these rates are set at 90% and 60% respectively, based on obtaining a 78% 6-week in-calf rate, assuming submission rate and conception rate remain consistent over the 6-week period (this produces the dotted curve on the survival graph).

However, it is common to find changes in submission rate and, particularly, conception rate between the first 3 weeks of the breeding season and the second. For example, in Fig. 26.3 the 3-week submission rate is 93% and conception rate (based on the entire 6-week period) is 52%. Using the same calculations as in Table 26.3 would produce a 3-week in-calf rate and a 6-week in-calf rate of 48% and 73%, respectively, whereas the actual figures were 60% and 75%, respectively, consistent with a large reduction in conception rate in the second 3-week period.

The next row identifies the factors that may be underlying reproductive performance. The first column has data specifically relating to heifers – first, their calving pattern and, second, their submission rate in the first breeding season after calving. The fertility focus report excludes data from pubertal heifers as cows are only included in the denominator once they have entered the milking herd. So the calving pattern data for heifers is the first time their data is included in the fertility focus report. However, it is an extremely retrospective measure of heifer fertility as it is an assessment of a breeding season that started over 14 months

Behind Your Detailed Fertility Focus Report

Report period: Cows calved between 07/06/14 and 13/12/14.
This was the most recent period with sufficient herd records that enabled an analysis to be completed.

Calving system: Seasonal
Your herd has been classified as seasonal calving because most calvings occurred in a single batch lasting less than 21 weeks.

Level of analysis: Detailed.
Your good record keeping means a detailed analysis was possible for your herd.

Report date:	27/11/17
PTPT:	
Herd Code:	5/4124
Calvings up to this date requested for analysis:	04/05/15
No of cows included:	248
These cows calved between:	07/06/14 and 13/12/14
Mating start & end date: (based on AB or pregnancy test data)	15/10/14 - 23/12/14

Part A) Herd records cross check

Check that the herd records in the table are complete and correct.

2014/15	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Total
No. of calvings		68	160	25									253
No. of AB matings					222	138	26						386
No. of preg tests	2							62	184				248
No. of non-aged/late aged positive preg tests									2				2
No. of cows culled or died	13		2	1	2	2			11	27	12		70

Part B) Notes on the calculations

Use the following notes to see how your results were calculated.

1 Overall herd reproductive performance

6-week in-calf rate

Your report has been based on the mating and pregnancy test results you supplied. The ACTUAL 6 week in-calf rate is shown for your herd.

Records available for not-in-calf rate

Recorded pregnant	223
Recorded empty	19
Doubtful/recheck*	1
Culled without pregnancy test	3
No record of cull or pregnancy test	2
Cows analysed	248

*Includes cows whose most recent empty diagnosis was less than 35 days after mating end date.

2 Drivers of the 6-week in-calf rate

3-week submission rate

248 cows had calving dates in the required range and were not culled before day 21 of mating and 94% of these were submitted during the first 21 days of mating.

Non-return rate

Non-return rate is not calculated when pregnancy test results provide an accurate estimate of conception rate.

Conception rate

The conception rate was calculated for 340 AB inseminations on and between 15.10.14 and 23.12.14.

3 Key indicators to areas for improvement

Calving pattern of first calvers

67 cows with eligible calving dates were recorded as calving at less than 34 months of age. The calving pattern of first calvers was calculated from their records.

Calving pattern of whole herd

253 cows had calving dates that were eligible for this report.

3-week submission rate of first calvers

65 first calvers had calving dates in the required range and were not culled before day 21 of mating and 94% of these were submitted during the first 21 days of mating.

Heat detection

118 cows at least 4 years old at calving had calved at least 8 weeks before mating start date and were not culled before day 21 of mating and 98% of these were submitted during the first 21 days of mating.

Pre-mating heats

248 cows had calving dates in the required range and were not culled before day 21 of mating and 222 of these had a pre-mating heat recorded.

Non-cycling cows

No cows were identified as being treated for non-cycling. If you did treat non-cycling cows, please supply records to ensure those cows are identified.

Performance after week 6

Your herd's not-in-calf rate and 6-week in-calf rate were used to determine the success of your herd's mating program after the first six weeks. If bulls were used after week 6 of mating, this gives an assessment of how well they got cows in calf.

Induced cows

No cows were identified as having induced calvings. If cows were induced, ensure all inductions are recorded.

ago. Any intervention resulting from this assessment is only going to influence the heifers that will be calving in two seasons time as the heifers that will be calving in the next season have already been bred. This highlights the importance of monitoring heifer weights as this is the best way of ensuring that heifer fertility is optimal. The second heifer measure, heifer 3-week submission rate, separates out first lactation heifers from the main herd because poorly grown heifers often fail to show oestrus quickly after calving for the first time.

As discussed earlier, calving pattern is crucial as late calving cows have less time to get pregnant. The fertility focus report thus provides an overall calving pattern as well as the heifer one. The next two factors, heat detection and premating heats, focus on heat detection. The heat detection measure used in the fertility focus report is an attempt to identify the proportion of false negatives (i.e., how often a cow that was on heat is missed). The program identifies a group of cows that are highly likely to show heat – cows that were at least 4 years old at calving, which had calved at least 8 weeks before mating start date and were not culled before day 21 of mating. The assumption is then made that if these cows do not show heat, this is a failure of observation not of return to cyclicity. This measure does not identify false positives; this is best done using interoestrous intervals, which are not included in the fertility focus report.

Identifying the proportion of cows that show premating heats is the best measure of identifying cows that show anovulatory anoestrus. Unfortunately getting accurate results requires the farmer to record the heats (as they are not followed by mating); on many farms, such heats are not recorded or uploaded, or if they are, they are only recorded for a short period of time.

Timing of treatment of 'non-cyclers' (cows that do not have premating heats) is important because it strongly affects the economic benefit of such synchronisation. On average, treating non-cyclers increases days in milk by approximately 14 days per treated cow (McDougall et al. 2010). Much of this effect is because synchronised cows are inseminated on day 0, whereas untreated cows, which come into heat evenly across the whole of the first 3 weeks, are, on average, inseminated on day 10. If treatment is delayed until after the start of the breeding season, the treated cows lose this advantage as they cannot be inseminated until treatment is complete, 10 days later. So, for example, if treatment starts on the first day of the breeding season, then both treated and untreated cows will be inseminated, on average, on day 10.

The final measure on the fertility focus report, performance after week 6, is an attempt to measure the performance of the bulls talking into account the 6-week in-calf rate; so for farms with a poor 6-week in-calf rate, the target not-in-calf rate is increased. As with the 6-week in-calf rate, this calculation assumes that the conception rate and submission rate remain at 60% and 90%, respectively. This is always likely to be an overestimate as it assumes that cows that have failed to get pregnant during the first 6 weeks have the same underlying fertility as cows that did get pregnant.

Autumn or Split Block Calving

Seasonal calving systems other than spring calving at pasture are relatively common in many areas of the world. Compared with pasture-based spring calving herds, autumn calving herds are generally more intensive, with the aim of achieving the group feeding benefits of a seasonal calving pattern while feeding supplementary feed (often a total mixed ration) rather than being dependent on grazing. Nevertheless, autumn calving herds often make use of spring grazing to support the later part of lactation, reducing feed cost. The principles of managing and monitoring fertility in this system are broadly similar to those in a spring calving system. However, under European conditions the increased milk yield is often associated with reduced fertility, so targets (especially for conception rate) need to be adjusted accordingly, and the expectation will be that calving period will be slightly longer than in spring. In contrast, under Australasian conditions, the fertility of autumn calving herds is often higher (and they often have shorter calving periods). This is because of the greater consistency of feed intake, both after calving (supplementary feed not just pasture) and in mid- to late lactation (spring/summer grass), which results in better body condition score.

In many farms split (or 'double') block calving systems are used. Such systems maintain the management and efficiency benefits of block calving while maintaining a relatively stable milk production through the year. Again, the key principles of monitoring and management discussed for spring calving herds apply here, although if only one set of data is available for the two herds, performance measurement can be challenging. For this reason the fertility focus system produces two reports (separated based on calving date) for block calving herds. Maintaining a sufficiently short calving period length so that there are some 'rest' times in the year can be challenging; when calving blocks are both 12 weeks long (the conventional target), there is very little of the year in which there are not cows either calving or being bred. In some cases, this leads to inappropriately short breeding periods and too many cows 'rolling over' from the autumn to the spring calving herd or vice versa, which is likely to have a substantial effect on profitability.

Veterinary Control of Reproduction in Beef Herds

NEIL SARGISON AND COLIN PENNY

Basic Economics and Targets of Suckler Beef Calf Production

Suckler beef cattle fulfill a role in food production from marginal agricultural settings that are poorly suited to arable farming and cereal-based livestock production. The economic stability of systems of suckler beef production is driven by the efficiency of herbage growth and optimisation of its conversion into beef meat. At an animal level, this equates primarily to 'weaning the optimal total weight of calves per unit of cows'. Differential calf market values per kilo, depending on conformation and integration with other farm management, are secondary considerations. These production objectives differ greatly from intensive dairy production (see Chapter 25) in which there is a strong emphasis on efficiency of supplementary feeding to meet the nutritional demands of milk production, but there are many similarities to pastoral dairy farming.

Cattle must be cared for over the winter months when herbage availability and quality in marginal areas is poor. This incurs high costs of housing, labour, machinery, conserved forage, supplementary concentrate feeds, and disease management (Fig. 27.1). Therefore, in the absence of differential value chains, the most economically efficient systems are those that minimise these costs by matching the nutritional requirements of the suckler beef cattle production cycle to the seasonal availability of and access to herbage. The peak metabolic requirements of suckler cows arise during lactation, whereas the lowest needs are after weaning. These can be balanced by the cow to some extent through mobilisation of body reserves during late pregnancy. Hence calving in the spring coordinates lactation with herbage growth and availability, and allows cows to accumulate body reserves to tide them over late pregnancy. This allows calves to be weaned in the autumn or early winter at 6 to 8 months old, matching the dry cows' more modest nutritional requirements with poorer herbage availability and quality. Spring calving is amenable to precise management of nutrition, housing, and disease during the second half of pregnancy. Conversely, autumn calving is expensive in terms of feed management and the need for housing and incurs greater costs of disease prevention in growing calves because precise nutritional management is problematic during later stages of pregnancy on pasture. Nevertheless, autumn calving does allow utilisation of conserved forage and can complement general mixed farm management in some circumstances. This chapter will focus on spring calving, suckler beef cattle herds (Fig. 27.2) as an efficient model system that is suited to upland western European settings.

Historic 'headage-based' subsidy payments and traditional small scale mixed farming systems encouraged the achievement of a 100% pregnancy rate as the primary reproductive management target for beef suckler cow herds. Provided that periparturient disease and infectious causes of infertility such as venereal campylobacteriosis were absent, this target can be achieved by running sound bulls with the herd all year round. However, such management inevitably resulted in mean calving intervals of individual cows greatly exceeding 365 days, and consequently, they will be calving all year round. Failure to match herbage availability to the cows' metabolic requirements created a need for longer housing periods and greater labour inputs to meet the complicated nutritional management needs of multiple small groups of individual animals. The greatest economic effect resulted from calves having mixed ages and weights at fixed weaning times and sale dates, with the mean weight being lower than if the calving period had been compact. Although the system worked for small herds finishing their own calves in small batches, it is not conducive to efficient management of large groups of animals with economics of scale. A compact calving period is therefore necessary both to optimise the utilisation of herbage growth and to ensure the maximum total weight of calves at weaning on a fixed date. A mean calving interval of 365 days is a prerequisite to maintain this year-on-year.

The traditional model of suckler cow beef production encouraged added value of individual calves through better conformation. Throughout the 1970s and 1980s, typically small Hereford, Aberdeen Angus, or Shorthorn-cross dairy cows were replaced by larger beef bred animals, and traditional purebred early maturing bulls were replaced by larger, late maturing Continental European breeds, in particular the Charolais, Simmental, Limousin, and Blonde D'Aquitaine, among various other breeds. Early maturing breeds were well suited to extensive, pastoral production systems, whereas later maturing animals required intensive management to allow them to grow quickly and to achieve target weights for their age. When managed accordingly, the late maturing cattle had higher slaughter weights, higher carcass weights, better carcass conformation, and lower carcass fat scores than early maturing animals slaughtered at similar ages. However, this was achieved at the expense of a high reproductive cost of dystocia and associated consequences of extended postpartum anoestrous periods, failure to rebreed, and increased calf mortality (Fig. 27.3). Today,

VetBooks.ir

• **Fig. 27.1** The necessity to house beef suckler cattle over winter incurs high costs and creates opportunities for the spread of disease between cows and their calves.

• **Fig. 27.2** Spring calving is suited to the conversion of herbage into calf growth and affords an efficient model system for reproductive management.

• **Fig. 27.3** Severe dystocia risks death of the newborn calf and of its dam, whereas the consequences of moderate birth stress include poor calf growth and a prolonged postpartum anoestrous period. At a herd level, this reduces the value of calves weaned, extends the subsequent calving period, and, if the mating period is compact, increases the barren rate.

• **Fig. 27.4** A spring calved Angus crossbred cow with an easy calving Limousin sired calf.

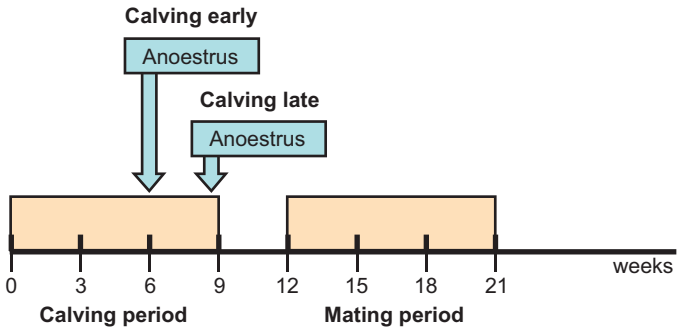
TABLE 27.1 Typical basic targets for spring calving beef suckler herds

Key Performance Indicator	Target
Barren cow rate	< 5%
Mature cows with difficult calvings	< 5%
Calf mortality (birth to weaning)	< 3%
Cows/heifers calved in first 3 weeks	≥ 65%
Calves weaned per cows/heifers mated	≥ 94%
Mating period for adult cows	9 weeks
Mating period for heifers	6 weeks
Calving period	< 10 weeks
Replacement rate	< 15%

compromises have been reached, in part driven by a move away from dairy-bred beef cows, which became unattractive due to an increasing Holstein influence. However, these still typically involve relatively large cows, commonly Angus or Limousin crossbreeds, with mature weights of 500 to 700 kg, coupled to selection of bulls for easier calving of their offspring (Fig. 27.4). These characteristics affect the reproductive management that is required to achieve a compact mating period and 365–day calving interval.

Some typical targets for UK and Irish spring calving beef suckler herds are shown in Table 27.1. When benchmarking beef suckler herd fertility performance, the two most useful key performance indicators (KPIs) are the weaned calf crop, expressed as a percentage of cows mated, and cows calved in the first 21 days, expressed as a percentage of all cows calving. The weaned calf crop is helpful as it factors in losses from the whole production cycle from conception through pregnancy loss to calf mortality. The percentage of cows calving in the first 21 days reflects both cow and bull fertility, and is an index of general cow reproductive and nutritional management and bull stud breeding soundness. Benchmark figures need to be calculated correctly to ensure comparable information. A standard gestation period for the farm, commonly 285 days, is added to the start date for mating to calculate the theoretical starting date for the calving period; then all cows calved in the 3 weeks after this date are counted, plus any cows calving before the calculated calving start date. Counting 3 weeks from the date, the first cow calves can reduce the benchmark figures and reduce the value of between-herd comparisons.

VetBooks.ir



• **Fig. 27.5** The effect of stage of calving of an individual cow within the herd calving period on rebreeding opportunities after a 42-day postpartum anoestrous period.

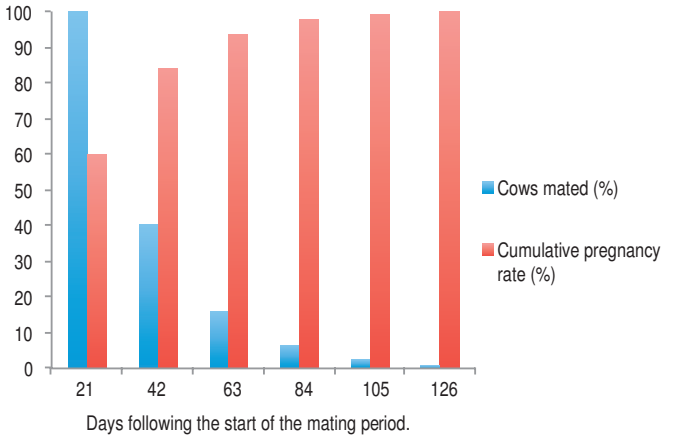
Although some UK and Irish beef farmers achieve the fertility and production goals shown in Table 27.1, many fall short. Actual benchmarking data shows average figures for cows calved in first 3 weeks of less than 50% and for weaned calf crops of 85% or less are commonplace. This demonstrates the scope for increasing fertility and production efficiency in beef suckler herds.

Theory of Beef Cattle Reproduction

The main annual reproductive target for spring calving suckler beef herds is to wean the maximum value of calves per hectare. This is achieved primarily by optimising the number of calves produced per group of cows while maximising the mean age, and therefore weight, of calves on a fixed weaning date. Maximisation of the value per kilogram of weaned calves is a secondary consideration to achieving ease of calving and rebreeding, but can be greatly influenced by selection of bulls with superior estimated breeding values (EBVs) for calving ease and growth.

The time interval between conception and calving in beef cows is between about 275 and 290 days (commonly assumed 285 days), generally being shorter for smaller, early maturing native breeds and longer for larger, late maturing Continental breeds. Beef cows that are in good body condition and calve easily without assistance have a postpartum anovulatory anoestrous period of between about 30 and 35 days; hence after a first silent ovulation, cows typically do not show first behavioural oestrus until 40 to 50 days postpartum (Crowe et al. 2014). In order to maintain a 365-day calving interval, bulls must be introduced about 80 days (365 minus 285 days) after the planned start of calving date. Hence with a target mating period of 63 days (three oestrous cycles) (Mossman & Hanly 1977), it is clear that, even in ideal conditions in which all cows have resumed oestrous cycles by 42 days postcalving, the later calved cows are unlikely to be cyclical at the start of the mating period. However, by calving the majority of cows in the first 6 weeks of the calving period, there will be sufficient recovery time to ensure most cows have up to three mating opportunities within the restricted mating period as shown in Fig. 27.5.

Economically efficient spring calving beef suckler herds all have a compact calving period, whereas most problem herds have calving periods longer than 12 weeks, not necessarily associated with low pregnancy rates due to extended mating periods. Maintenance of a compact calving period has additional benefits. Supervision of calving and calf disease management is easier because opportunities for the environmental build-up of pathogens are lower. Feed budgeting is more efficient for groups of late pregnant cows with known calving dates spread over a short time period.



• **Fig. 27.6** Theoretical pattern of mating and pregnancy over a six-oestrous cycle period.

Provided that heifers or cows are cycling and the bulls are reproductively sound or that artificial mating methods are effective, the average pregnancy rate after each behavioural oestrous event is around 60% (Mossman & Hanly 1977). Theoretical pregnancy rates resulting from mating periods spanning multiples of 21-day oestrous cycles can therefore be predicted at a herd level (Fig. 27.6). This theoretical model is consistently validated in practice (Hanly & Mossman 1977, Diskin & Kenny 2014).

This theoretical model shows that about 94% of the cows will be pregnant by the end of the 63-day mating period. Achievement of a compact calving interval using natural mating therefore potentially incurs a 6% barren rate. The model assumes that all of the cows were cycling when the bulls were introduced, in which case a 105-day mating period would be required for nearly 100% to become pregnant. However, in this scenario, 6% of the cows will not be calved, or cycling, when the bulls are introduced during the next year, thus increasing the length of the mating period required to achieve a 100% pregnancy rate, year-on-year. The subsequent extended calving period will result in poor weaning weights of later born calves and a lower average calf value at weaning on a fixed date. The extended calving period will allow for the build-up of environmental pathogens, increasing the requirements for disease management because nutritional management of cows calving over an extended period will be inefficient.

The fact that some very well managed beef suckler herds with compact 63-day mating periods can achieve pregnancy rates of

VetBooks.ir

95% or greater, even when it is biologically unlikely that 100% of cows are cyclical on Day 1 of mating, shows that conception rates to first mating in beef cows may potentially be 70% or higher.

Practical Management of a Compact Mating Period

The achievement of a 94% pregnancy rate after a 63-day mating period is dependent on the majority of heifers and cows cycling at the start of the mating period. Heifer management, cow nutrition and avoidance of postparturient disease are critical in this regard.

The onset of puberty in heifers is controlled by body weight ahead of age. Although there are differences between breeds and management systems, more than 90% of *Bos taurus* heifers will have displayed behavioural oestrus once they have reached 60% to 65% of their mature body weight (see Chapters 3 and 25). Fertility to the first pubertal oestrus is lower than to subsequent oestrous events (Byerley et al. 1987); hence puberty should ideally be attained at least 1 month before commencing mating. Furthermore, heifers that are mated and conceive before reaching a critical minimum weight will calve at lower body condition scores (BCS) and lighter weights than their contemporaries, thus with a high risk of dystocia and failure to rebreed due to prolonged postpartum anoestrus. Strategies to hasten onset of puberty in beef heifers include treatment with progestogens or progesterone products and exposure to vasectomised bulls, but neither option is commonly adopted in European beef herds and the response may be inconsistent (Diskin & Kenny 2014).

In spring calving herds, which source breeding replacements from homebred animals, or from other spring calving herds, practicalities dictate that heifers must calf for the first time at either 2 or 3 years old. Calving at 3 years old incurs higher maintenance costs of unproductive animals than calving at 2 years old and also reduces the potential productive lifespan and output of the female breeding herd. Conversely, calving at 2 years old provides a good basis for selecting replacement animals and potential for faster genetic gain. Hence most producers now aim to calve their heifers for the first time at 2 years old. This means that they must reach 65% of their mature weight by a mean age of 15 months. This equates to critical minimum mating weights of between 325 kg and 420 kg for small Angus and large Continental European bred animals, depending on the characteristics of their breed; this requires mean live weight gains of between 0.65 kg/day and 0.84 kg/day from birth. Achieving these targets is relatively straightforward for small early maturing animals but depends on high levels of supplementary feeding as part of a balanced ration for late maturing breeds. Overfeeding of early maturing breeds in particular, in an attempt to achieve critical minimum mating weights, compromises behavioural oestrus, conception rates, embryonic survival, and mammary gland development in fat animals, and increases the risk of dystocia and postparturient infections. Control of infectious diseases, such as bovine respiratory disease, roundworms, and liver fluke, in growing heifers is critical to ensure growth targets are achieved.

Failure to reach critical minimum weights at first mating of heifers results in high barren rates, whereas those that become pregnant calve at low weights and in poor body condition, with high levels of dystocia and postparturient disease. Subsequent barren rates of first calvers are high due to extended postpartum anoestrus in thin animals, resulting in less than three behavioural oestrous events during a compact three-cycle mating period.

The postpartum anoestrous period after first calving in heifers is about 20 days longer than that of cows in the same body condition. This means that if the heifers' three-cycle mating period is the same as that of the cows, then during the subsequent year, first calvers will only have two opportunities to show behavioural oestrus; therefore, on average, 16% will remain barren. Furthermore, those that become pregnant will calve correspondingly later and remain late calving cows for the remainder of their reproductive lifespan, with a higher risk of not becoming pregnant before the end of the mating period than in cows that calve early. Their calves that are born late in the calving period will be younger and lighter than those born earlier and therefore of lower sale value. In herds in which heifers are first calved at 3 years old, this problem is addressed by advancing the heifer mating period by 3 weeks compared with that of the main cow herd. However, in herds in which heifers are first calved at 2 years old, this strategy risks more animals failing to reach their critical weights at mating. A two-cycle (6 weeks) heifer mating period, starting at the same time as the three-cycle mating period for the main herd, offers a satisfactory compromise, allowing all of the heifers that calve to be cycling at the start of the subsequent mating period. The compromise involves mating more heifers than are required, as perhaps only 84% will conceive, but potentially 71.5% (60% x 100/84) of those that become pregnant will calve during the first 3 weeks of the calving period. In practice, if heifers have all reached their critical mating weights and are run with fully sound bulls, it is not unusual to achieve pregnancy rates of greater than 90% in a 6-week heifer mating period. The opportunities for alternative economically efficient management of less than 2-year-old barren maiden heifers are greater than those for older barren first or second calvers.

Heifer management dictates the reproductive performance of the whole herd and is key to achieving reproductive targets. Heifers need to be fed for maintenance plus 0.65 kg/day to 0.85 kg/day growth to ensure that they achieve critical minimum weights and are in good, but not excessively fat, body condition at mating. Heifers must be mated with bulls that have been selected for ease of calving. The same plane of nutrition must be maintained after mating to ensure that heifers calve in body condition of 3.0 on a scale of 1 (very thin) to 5 (very fat), based primarily on palpation of the transverse processes of the lumbar vertebrae. This is relatively straightforward for spring calving heifers at pasture (Diskin & Kenny 2014) but requires a carefully balanced winter feeding ration in autumn calving herds. Higher BCS predisposes to dystocia, whereas lower scores result in extended postpartum anoestrous periods. After calving, heifers that were first mated at 15 months old benefit from separate, beneficial management until their second calving at 3 years old. The differential disease and nutritional management of heifers and first calvers needs to be planned and affords opportunities for veterinary involvement in achieving beef suckler cow reproductive targets. Prebreeding scoring of heifer reproductive tracts by palpation or transrectal ultrasonography of the uterus and ovaries can be helpful to identify individual animals with abnormal tracts, e.g., freemartins (see Chapter 9) and those that that are prepubertal and therefore likely to fail to become pregnant in a restricted mating period (Holm et al. 2015).

The postpartum anoestrous period of mature cows is determined by the nutritional demands of the previous pregnancy and lactation and is related to BCS at calving, plane of nutrition, and the calf suckling and maternal bond. Temporary calf isolation or restricted suckling from around 30 days postpartum may significantly

VetBooks.ir

• **Fig. 27.7** An Angus cow at the beginning of the mating period in June with BCS 3.0 (1-5 scale).

shorten the time to first postpartum ovulation of beef cows (Stagg et al. 1998) but is impractical in most spring calving herds on pasture.

Cows calving in good BCS have the shortest postpartum anovulatory anoestrus. Low body condition (i.e., < 2.5 on a 5-point scale) leads to proportionally increased calving to conception intervals and later subsequent calving dates or to high barren rates. Increasing levels of feeding after calving has little beneficial effect in cows that calve below target BCS; hence it is important to manage pasture, forage, and supplementary feeding throughout the year based on monitoring of BCSs and comparison with target values.

In order to minimise the duration of postpartum anoestrus, the target BCS at calving is between 2.5 and 3.5 on a 5-point scale. For spring calving beef suckler herds, in which the objective is to maximise the utilisation of herbage growth during lactation, this dictates a minimum target BCS of 2.0 at mating and 3.0 at weaning (Fig. 27.7). For autumn calving beef suckler herds, which depend on expensive forage and concentrate feeding during the winter to meet the demands of lactation, minimum BCS targets of 3.0 at calving, 2.5 at mating, and 1.5 at turnout in the spring are appropriate, depending on the precise nature of the system (Lowman 1988).

In practice, a relatively inexpensive ration of ad lib straw and 2 kg of concentrate feed is sufficient for maintenance of a pregnant spring calving cow over winter, provided that she enters winter in the correct body condition. Management of herbage height controls nutrition during the summer but is less predictable than housed rations, commonly resulting in autumn calving cows being too fat at calving.

Pregnancy diagnosis and determination of fetal age by transrectal ultrasonography is useful in herds with a compact mating period to confirm that reproductive targets are met and instigate timely investigation if they are not. Good farm records of reproductive management are important in this regard, including: numbers of cows or heifers put to the bull; number of bulls used; dates that bulls were introduced and removed; number of cows or heifers diagnosed as pregnant; numbers of calves born alive; first and last calving dates; number of cows or heifers calving in each 3-week period; and details of animal deaths or culling. Pregnancy diagnosis allows barren animals to be identified early and informed decisions to be made concerning what to do with them. This can be particularly helpful in the case of heifers, allowing nonpregnant animals to be removed and economically managed for finishing. Simple analysis and benchmarking of KPIs can be undertaken using the same data discussed previously and allows ongoing monitoring of herd performance.

Other Factors Affecting Beef Suckler Herd Reproductive Performance

The basic reproductive management of spring calving beef suckler herds with a compact mating period first depends on appropriate heifer management and maintaining target BCS in cows. Another critical factor is bull fertility and, in individual herds, infectious diseases and specific nutritional deficiencies can also affect the achievement of economic reproductive targets.

Clearly, to achieve and maintain reproductive targets in beef suckler cattle, it is crucial that the herd bull stud is fully fertile and capable of delivering conception rates of 60 to 70% to each service throughout the mating period (Fig. 27.8). In many herds, the presence of subfertile and unsound bulls due to factors such as lameness and poor semen quality will contribute to reproductive failure. Published surveys have consistently found that in an unselected population of beef stock bulls, the failure rate when subjected to a full breeding soundness examination can be 20% or higher. It is therefore important that all bulls are subjected to a breeding soundness examination before each mating period (see Chapter 35). Healthy, mature bulls that have passed a breeding soundness examination can be run with breeding groups of 30 to 40 cows, whereas younger bulls must be limited in their first breeding period to groups of 15 to 20 females. Consideration also needs to be given to the terrain and size of fields used to accommodate the breeding group during the mating period of spring calving herds, e.g., avoiding steep slopes and large enclosures. It is common practice to rotate bulls around breeding groups halfway through the mating period to help limit the effect of possible bull subfertility or infertility; however, farmers should have confidence to run a single sire with mating groups if they have had a prebreeding examination. Introduction of bulls that have previously been used for breeding, especially hire bulls, should be avoided as it can have severe biosecurity implications, risking introduction of venereal diseases such as campylobacteriosis and trichomonosis.

Generalised infectious diseases caused by bovine viral diarrhoea pestivirus (bovine viral diarrhoea – BVDV) or bovine herpes virus-1

VetBooks.ir

(infectious bovine rhinotracheitis – IBR) can result in failure of conception or maintenance of pregnancy. Specific pathogens, such as *Salmonella* Dublin and other serovars, *Leptospirahardjo,* and variants of *Campylobacter fetus* subsp. *venerealis,* cause reproductive loss in European beef suckler herds through abortion or embryonic losses. Introduction of these diseases to naïve herds can have a large effect on reproductive performance, and their presence in endemically infected herds can compound reproductive losses due to other causes. The pathogenesis of these diseases is described in Chapter 24. The control of BVDV, BoHV-1, salmonellosis, and leptospirosis in endemically infected suckler herds can involve eradication and vaccination. Nonspecific pathogens, such as *Listeria monocytogenes* and *Bacillus licheniformis,* cause sporadic abortion losses as a consequence of feeding of spoilt silage. In beef suckler herds, *Neospora caninum* is generally only diagnosed as a cause of abortion in association with other infectious diseases or poor nutrition.

Venereal campylobacteriosis has been shown to be economically important when identified in beef suckler herds (Truyers et al. 2014), causing embryonic mortality and occasional abortions. However, without good farm records as a stimulus for the investigation of poor reproductive performance and availability of practical sensitive and specific diagnostic tests, the true prevalence of this infection is unknown. It is possible that a high prevalence of venereal campylobacteriosis may be responsible for failure to reach reproductive targets in many beef suckler herds. Artificial insemination has been proposed as a simple control method for bovine venereal campylobacteriosis, but it is impractical for most spring calving beef suckler herds when breeding takes place at pasture. Commercial vaccines are unavailable in Europe but are widely used in other continents, and the efficacy of autogenous vaccines using a bacterial isolate from infected animals on a specific farm is at best unproven. For most infected herds, control requires good record keeping allowing biocontainment of the disease by segregation of potentially infected and uninfected animals in combination with culling or treatment.

Prevention of infectious causes of poor reproductive performance in naïve beef suckler herds depends on good biosecurity in conjunction with good general farm management. Most beef suckler herds are comprised of crossbred cows mated to purebred terminal sire bulls. In these situations, maintenance of totally closed, and therefore biosecure, herds is impractical without artificial control of reproduction; consequently, most beef suckler herds regularly introduce new bulls. Many herds also buy in replacement crossbred breeding heifers. Trade in calved heifers and cows is commonplace but is strongly discouraged due to the disproportionately high risk of introduction of generalised or specific infectious diseases, such as BVDV and BoHV-1 or venereal campylobacteriosis, respectively. Attempts must be made to purchase replacement heifers or bulls from herds with similar disease status, albeit this is often unknown. Introduction of animals to bovine tuberculosis-free areas from endemically infected regions is strongly discouraged. Purchased animals need to be quarantined on arrival for sufficient time – usually 1 month – to allow them to be tested for specific diseases, vaccinated against those infectious diseases that are endemic in the new herd, or show clinical signs caused by infections that were latent on arrival.

Deficiencies in copper, selenium, and iodine are frequently implicated as causes of poor reproductive performance in pastorally managed beef suckler herds, but in many cases, these problems arise secondary to poor basic nutritional management. The pathogenesis and management of trace element deficiencies is in Chapter 22.

Artificial Breeding Management of Beef Suckler Herds

Artificial insemination (AI) has been used for many years in pedigree beef breeding herds along with other breeding technologies, such as multiple ovulation embryo transfer; but current estimates from US and Europe suggest that only around 10% of commercial suckler beef cattle are bred by AI. Economic arguments for AI in commercial beef herds revolve around the ability to inseminate large numbers of cows or heifers on Day 1 of the mating period and to utilise superior sire genetics suited to the production system. Assuming acceptable pregnancy rates to AI (target 60%–65%), this can lead to economic gain by having a high percentage of the herd (typically > 70%) calved in 21 days, resulting in an increased mean value of weaned calves from a combination of extra age growth and superior genetics. A well-managed, fixed-time AI (FTAI) programme in beef cows will consistently deliver a superior calving pattern to a natural service alone as it takes at least 21 days for every female to be exposed to the bull, as opposed to service on 1 day by FTAI.

Field studies have demonstrated that by using oestrous synchronisation and FTAI for first service followed by sweeper bulls, beef cows can have superior reproductive performance and economic gain compared with using natural mating alone (Rodgers et al. 2012). Another common reason for using AI in beef cows or heifers is to access sires with suitable maternal trait EBVs, helping to breed superior replacement heifers. Keeping heifer calves that have been bred from terminal sire stock bulls as replacements may be unwise as it can lead to an unsuitable cow type with poor milk production. The growing availability of sexed semen opens up further opportunities to breed heifers from heifers or increase the proportion of male calves born.

The ability to synchronise oestrus, leading to single FTAI with minimal labour inputs and handing protocols, is crucial. Many protocols have been described that allow synchronisation of the oestrous cycle in beef cows and heifers for FTAI involving use of prostaglandin $F_{2\alpha}$ (PG) and gonadotrophin releasing hormone (GnRH) injections, intravaginal progesterone implants and oral progestins (see Chapter 8). In general, the use of double PG injection or GnRH/PG/GnRH protocols is less successful than reported in dairy cattle, because a proportion of animals will be in anovulatory anoestrus in beef suckler herds. Progesterone-based programmes are therefore the method of choice, as progesterone treatment alone or in combination with 400 to 500 IU equine chorionic gonadotrophin (eCG) has been shown to overcome anovulatory anoestrus in beef cows and lead to a normally fertile oestrus in most cases (Patterson 2016). This allows cows to be synchronised and bred by as early as 40 days postpartum, and achieve pregnancy much earlier than had they been exposed to bulls alone. Reproductive tract scoring of groups of heifers to ensure that they are all cyclic before synchronisation can further improve pregnancy rates after FTAI. When sweeper bulls are introduced to cover repeat services, sufficient bull power must be employed to allow for synchronisation over a period of about 7 days (Fig. 27.9). Repeated oestrus synchronisation and AI protocols have been described, allowing suckler beef cows to be bred entirely without the need for bulls (Penny et al. 1997), but as these involve multiple handlings, they are considered by some to be impractical.

For protocols utilising intravaginal progesterone implants, the decision on which to use is often guided by previous experience and the number of handlings that are considered acceptable. It is

VetBooks.ir

• **Fig. 27.9** Sweeper bull power (both breeding soundness and numbers) needs to be sufficient to take into account that, if not pregnant to their first service or mating, heifers or cows synchronised for their first cycle will all return to a second behavioural oestrus within a short time period.

noteworthy that, even using identical protocols, the between-farm variation in results can be large, showing the importance of other management factors in success. Most product data sheets suggest PG injection at least 24 hours before progesterone implant removal, which ensures that any existing luteal tissue is already lysed, thus tightening synchrony. In the US, it is more normal to use 'Co-Synch' protocols (Patterson 2016) in which PG is administered on the same day as progesterone implant removal, thus reducing a handling. Examples of typical progesterone implant based protocols for beef cows or heifers are shown in Fig. 27.10. Administration of GnRH injection at progesterone implant insertion may be beneficial as it reduces the risk of dominant follicle persistence and starts a fresh follicular wave in the majority of females.

Consistent results can be achieved with FTAI in beef cows and heifers by:

i) Ensuring good forward planning and compliance with the protocol;
ii) Ensuring that cows and heifers are in suitable BCS and target mating weights so that majority are cyclic at start of programme;
iii) Having suitable handling facilities and avoiding stressful management such as administration of vaccines close to the AI date;
iv) Maintaining a steady or rising plane of balanced nutrition;
v) Controlling infectious diseases and nutritional deficiencies that could affect fertility; and
vi) Using skilled technicians and quality semen.

Fertility and Infertility in *Bos indicus*

ROBERTO SARTORI, JÉSSICA NORA DRUM AND ALEXANDRE BARBIERI PRATA

Introduction

Over the years, cattle have been raised and selected especially for meat and dairy production; the majority of breeds are either *Bos taurus* (*B. taurus*) or *Bos indicus* (*B. indicus;* Zebu), see Fig. 28.1. Some of the *B. taurus* breeds, such as Holstein and Jersey, have been selected for high milk production, and others, such as Angus and Hereford, for beef production. Due to the intensive selection, *B. taurus* breeds are very efficient for food production compared with other breeds; however, they are not adapted to tropical environments and cannot make use of their entire potential for production in the tropics. The main problem with the husbandry of *B. taurus* in the tropics is their very low tolerance to heat stress; compared with *B. taurus,* Zebu breeds experience a less severe reduction in feed intake, growth rate, milk yield, and reproductive function in response to heat stress (Adeyemo et al. 1979, Bennett et al. 1985, Pegorer et al. 2007, Satrapa et al. 2011).

Although *B. taurus* breeds are more precocious, Zebu cattle are extensively used in the tropics, due to their thermo tolerance and resistance to parasites. The extensive systems of management, which predominate in South America, have continually exposed them to a tropical climate and nutritional environment, resulting in increased tolerance to that environment through selection pressure. This environmental tolerance means that Zebu cattle can thrive, whereas *B. taurus* animals may not. However, regarding reproductive management, difficulties of oestrous detection in Zebu cattle is one of the major factors that limit the widespread use of AI in these breeds. This can be overcome with the use of fixed-time artificial insemination (FTAI) protocols, developed or adapted specifically for Zebu cattle. Additionally, embryo production and transfer has been increasing around the world, especially in tropical countries such as Brazil, particularly because of the use of *in vitro* production in Zebu breeds or crossbreeds (Viana & Camargo 2007, Viana et al. 2017).

To overcome or minimise problems related to decreased production of pure bred *B. taurus* cattle in tropical regions, one strategy has been to produce *B. taurus* x *B. indicus* crossbreeds. Zebu cattle are known to be less fertile and have lower levels of milk production than *B. taurus* breeds, but their better adaptation to the environmental conditions make them more likely to reproduce successfully in the tropics. Crossbreeds incorporate the environmental adaptation of Zebu cattle, with the higher production of *B. Taurus* (Negussie et al. 1999), as well as the benefit of hybrid vigour.

Because most of the reproductive physiology studies in cattle have involved *B. taurus* breeds in countries with a temperate climate, strategies for reproductive management that have been used in Zebu cattle have been adapted from those studies and may not be ideal for *B. indicus.* Although the majority of studies reported in the literature have used *B. taurus* cattle to study ovarian physiology, there are an increasing number of reports involving *B. indicus* breeds, such as Brahman and Nelore. These recent studies have gained a great deal of knowledge on the reproductive physiology of *B. indicus,* enabling direct comparisons with *B. taurus* under similar environmental, nutritional, and management conditions to be made. These studies have identified considerable differences in ovarian morphology and function, as well as circulating hormones and metabolites between these two genetic groups.

Currently, researchers are using this acquired knowledge to optimise protocols for FTAI and production of *in vivo*-derived (IVD) embryos by multiple ovulations or by *in vitro* embryo production (IVP). Accordingly, this chapter is divided into sections that describe: 1) physiological differences in reproductive cycles of *B. taurus* and *B. indicus;* 2) nutritional and metabolic effects on reproductive physiological parameters and performance; and 3) assisted reproductive technologies (ARTs) applicable to *B. indicus.*

Physiological Differences in the Oestrous Cycle of *B. taurus* and *B. indicus*

Puberty

Puberty is defined by the animal's ability to reproduce as a result of the development of hypothalamic neurones, which secrete GnRH at the appropriate frequency and in sufficient quantities to release gonadotropins and promote gametogenesis (see Chapter 3). Although the first ovulatory oestrus is the main marker of puberty (Rawlings et al. 2003), heifers usually only reach maximum fertility at their third oestrus (Byerley et al. 1987).

Increased LH pulse frequency in the circulation, which is the determining factor for sexual maturity of heifers, is due to decreased hypothalamic sensitivity to the negative feedback of oestradiol (E2; Day et al. 1987), which is influenced by genetic and environmental factors (Martin et al. 1992, Nogueira 2004).

Most heifers reared in the tropics have access to low quality forages and suffer from protein, energy, and/or mineral deficiency. Therefore they do not reach puberty until 2 years old, whereas those in a temperate climate reach puberty around 9 to 12 months of age (Fajersson et al. 1991). Independent of nutrition, there also seems to be a genetic factor associated with puberty in Zebu cattle because 30% of Nelore heifers (12 of 37) became pregnant at 16 months of age but with no difference in age or weight from

VetBooks.ir

• **Fig. 28.1** Zebu Cattle. (Courtesy of Roberto Satori).

the group mean at first ovulation (Nogueira 2004). In addition, when comparing precocious with nonprecocious sires, daughters of nonprecocious sires at puberty onset are heavier and older than precocious heifers (Ferraz et al. 2014).

There are clear differences in age at puberty between *B. taurus* and *B. indicus* cattle. Generally, Zebu heifers are less precocious than *B. taurus* heifers. This was elegantly demonstrated in the study by Rodrigues et al. (2002), in which the cessation of inhibition of E2 on LH pulses occurred simultaneously with the onset of puberty in heifers of both genotypes but occurred earlier in *B. taurus* heifers, especially during the initial period of weight gain (16–18 months of age). The estimated age at puberty for Zebu in the tropics and subtropics is between 16 and 40 months, with a mean of 25 months, i.e., 6 to 12 months later than *B. taurus* (Abeygunawardena & Dematawewa 2004, Nogueira 2004). Moreover, smaller breeds such as the Zebu normally reach puberty at an older age and heavier body weight than *B. taurus* heifers (Martin et al. 1992, Bagley 1993). Finally, regardless of size and nutrition status, Zebu cattle are less precocious because the selection pressure for early onset of puberty has been much less intensive than in *B. taurus* cattle (Eler et al. 2002), even though there is a high correlation between scrotal circumference in *B. indicus* bulls and young age of puberty in their heifer offspring (Forni & Albuquerque 2005, Eler et al. 2006). Moreover, age at first conception was highly heritable (h2 = 0.44–0.67; Pereira et al. 2006) as was heifer pregnancy (h2 = 0.58–0.66; Eler et al. 2006). There was also a high genetic correlation between age at first calving and the interval from the onset of the breeding season to calving in the subsequent year (Forni & Albuquerque 2005). Therefore the potential to advance the age of puberty and shorten the postpartum anoestrous interval through selection in *B. indicus* cattle exists.

Oestrous Cycle Overview: Follicular Wave Patterns and Ovulation

After puberty the female bovid has recurrent oestrous cycles that continue throughout most of their productive life unless she becomes pregnant or undergoes a period of negative energy balance that would induce anoestrus (Diskin et al. 2003). One of the first studies performed in Nelore cattle reported that oestrous cycle length was on average 20.7 (n = 20) and 22.0 (n = 14) days for two and three follicular wave animals (see Chapter 1), respectively; the majority of cows having two (83.3%, n = 18) and heifers three (64.7%, n = 16) waves (Figueiredo et al. 1997). Similar differences in oestrous cycle length between two and three wave animals have been reported in Holstein cattle (Sartori et al. 2004). Other studies in *B. taurus* have described the occurrence of two to four follicular waves during the oestrous cycle, with predominance of two waves, and very rarely four waves (Sirois & Fortune 1988, Townson et al. 2002). These authors also reported that 70% of Nelore females (n = 10) observed during two consecutive oestrous cycles repeated the same pattern of follicular waves of the previous cycle (i.e., two or three waves). After evaluating 117 interovulatory intervals (oestrous cycles) from 17 Brahman heifers, Rhodes et al. (1995) recorded that 26.5%, 66.7%, and 6.8% of cycles had either two, three, or four follicular waves per cycle, respectively; and the oestrous cycle length lasted, on average, 20.9 days. In five Brahman heifers examined over more than 12 oestrous cycles, it was reported that the same follicular wave pattern was repeated 60% to 87.5% of the times. Other studies in Nelore heifers (Sartorelli et al. 2005, Mollo et al. 2007), Gir cows (Gambini et al. 1998, Viana et al. 2000) and Brahman cows (Zeitoun et al. 1996) have reported a predominance of three wave cycles but also observed animals with two, four, and even a few with five waves per oestrous cycle.

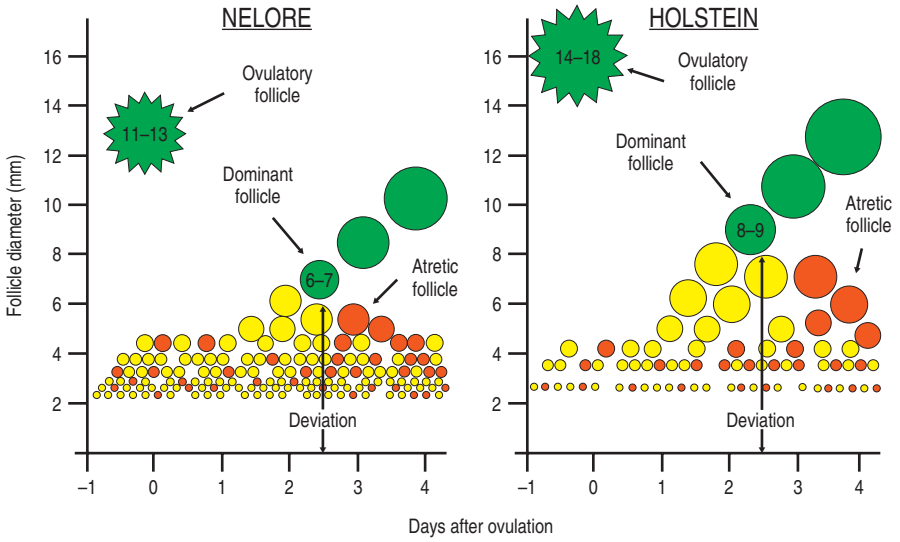
The average ovarian antral follicle count (AFC) in *B. indicus* is twice the number observed for *B. taurus* (Fig. 28.2; Table 28.1). For example, at wave emergence the number of 2 to 5 mm follicles present in the ovaries was 42.7 (ranging from 25–100) in Nelore and 19.7 (ranging from 5–40) in Holstein cows (Bastos et al. 2010). Greater AFC has been associated with greater circulating anti-Müllerian hormone (AMH) in *B. indicus* compared with *B. taurus* (Baldrighi et al. 2014, Batista et al. 2014).

Another observed difference between *B. taurus* and *B. indicus* was the size of the largest follicle at deviation. In Holstein cattle the diameter of the future ovulatory follicle at the time of deviation was between 8.3 and 9.8 mm (Ginther et al. 1996, Sartori et al. 2004, Bastos et al. 2010). In Nelore heifers, deviation happened when the largest follicle reached 5.4 to 6.2 mm (Sartori et al. 2005, Gimenes et al. 2008) and in nonlactating Nelore cows between 7.0 and 7.4 mm of diameter (Bastos et al. 2010, Sartori et al. 2016). Nevertheless, the time after ovulation or after wave emergence for follicle deviation was similar for *B. taurus* and *B. indicus* (Sartori et al. 2010, Sartori et al. 2016) due to a slower growth rate of the follicles in Nelore (0.8–1.2 mm/day; Gimenes et al. 2008, Sartori and Barros 2011) compared with Holstein cattle (1.2–1.6 mm/day; Sartori et al. 2001).

Although follicle deviation occurs in *B. indicus,* when the dominant follicle reaches 5 to 7.5 mm in diameter compared with 8 to 10 mm in *B. taurus,* it is possible that additional growth is necessary for the dominant follicle to acquire ovulatory capacity in both breeds. Sartori et al. (2001) observed that Holstein cows with follicles 7 or 8.5 mm in diameter did not ovulate, even after administration of high doses of pLH (40 mg). However, 80% of the cows with follicles equal to or larger than 10 mm ovulated after pLH administration. Conversely, Gimenes et al. (2008) reported that administration of 25 mg pLH to *B. indicus* heifers induced ovulation in 33.3%, 80.0%, and 90.0% of animals, with follicles that were 7.0 to 8.4, 8.5 to 10 and larger than 10 mm in diameter, respectively.

The decrease in progesterone (P4) and increase in E2 near the time of ovulation are responsible for overt oestrous behaviour and

VetBooks.ir



• **Fig. 28.2** Schematic representation of follicle development in Nelore (*B. indicus*) and Holstein (*B. taurus*) cows based on data from the literature and personal data. Nelore have a greater population of small (2–5 mm) follicles in the ovaries throughout the entire oestrous cycle than Holstein cattle. Moreover, although both breeds have follicle deviation between Day 2 and 3 after ovulation, the diameter of the future dominant follicle at deviation is greater in Holstein cattle. The diameter of the ovulatory follicle is also greater in Holstein than Nelore cows. (From Sartori et al. 2010.)

[a]From Segerson et al. (1984), Alvarez et al. (2000), Bó et al. (2003), Carvalho et al. (2008), Gimenes et al. (2008), Sartori et al. (2010), Sartori & Barros (2011), Sartori et al. (2013), Baldrighi et al. (2014), Batista et al. (2014), Sartori et al. (2016).

for the preovulatory GnRH/LH surge. Oestrus, the period of sexual receptivity, lasts between 30 minutes and 27 hours in *B. taurus* (Lopez et al. 2004) and between 1 and 20 hours in *B. indicus* (Bó et al. 2003). The onset of oestrus coincides with the preovulatory surge of LH followed by ovulation, on average, 26 to 28 hours later (Walker et al. 1996, Pinheiro et al. 1998, Mizuta 2003).

Studies in Nelore cattle have observed some specific characteristics regarding oestrus in this breed. The interval between the onset of oestrus and ovulation was 27.7 ± 2.4 and 26.1 ± 1.2 hours after $PGF_{2\alpha}$-induced and natural oestrus, respectively in nulliparous heifers, and in cows it was 26.8 ± 0.8 and 28.0 ± 0.9 hours after $PGF_{2\alpha}$-induced and natural oestrus, respectively (Pinheiro et al. 1998). Additionally, the oestrous behaviour, when detected (< 50% of the cows), was shorter (10.5 ± 1.0 and 13.6 ± 1.0 hours) after $PGF_{2\alpha}$-induced and natural oestrus, respectively compared with reports in European breeds, and there was a high incidence of oestrus at night.

Combined data from two other studies, in which oestrus was synchronised in 90 cyclic Nelore heifers and ovulation was confirmed by ultrasonography, were analysed. Although the majority of the heifers (76.7%) ovulated within 7 days after $PGF_{2\alpha}$ treatment, 50% of them were not observed in standing oestrus, even with continuous 24 hour-a-day visual monitoring along with the aid of heatmount detectors. Moreover, out of the 45 heifers that were not detected in oestrus, 25 (55.6%) ovulated, and only one (2.2%) that was seen in oestrus did not ovulate. Some of the possible reasons for the lack of oestrous behaviour in these studies, besides an inherent breed effect, were excessive animal handling for daily transrectal ultrasound evaluation and blood collection and/or a relatively steep fall in ambient temperature during some of the nights during the study.

One study that directly compared oestrous behaviour in Nelore cows with a European breed (Angus) was performed by Mizuta (2003). Using a radiotelemetric oestrous detection system (HeatWatch), the study verified that average oestrous duration in Nelore was shorter than in Angus cows (12.9 ± 2.9 vs 16.3 ±

VetBooks.ir

4.8 hours). However, the interval between the onset of oestrus and ovulation was similar: Nelore 27.1 ± 3.3 hours and Angus 26.1 ± 6.3 hours.

The effect of a high percentage of Nelore females displaying no signs of oestrus before ovulation, short oestrous duration, and a high percentage of cows that exhibit the start and end of standing oestrus during the night makes it difficult to detect signs; this, consequently, impairs the efficacy of AI in Nelore cows. This can be significantly reduced if FTAI, without the need for oestrous detection, is performed. Consequently, several hormonal treatments have been developed to allow FTAI in zebu cattle, including protocols for FTAI in embryo donors (Barros & Nogueira 2001, Fernandes et al. 2001, Baruselli et al. 2004, Bó et al. 2007).

The diameters of the largest ovulatory follicle and of the corpus luteum (CL) also differ between *B. taurus* and *B. indicus*. The ovulatory follicles of *B. taurus* have a larger diameter (see Fig. 28.2) and greater CL volume than *B. indicus*. However, circulating concentrations of steroid hormones in *B. taurus* are lower than in *B. indicus* (Sartori & Barros 2011, Sartori et al. 2016). In studies with Nelore cattle the diameter of the ovulatory follicle was 11 to 14 mm (Figueiredo et al. 1997, Sartorelli et al. 2005, Sartori et al. 2016), and the maximum diameter of the ovulatory follicle in Holstein cattle was 13 to 19 mm (Ginther et al. 1989, Sartori et al. 2002, Sartori et al. 2004). Similarly, the CL diameter of *B. indicus* ranged from 17 to 22 mm or approximately 2.5 to 5.0 cm^3 (Segerson et al. 1984, Rhodes et al. 1995, Figueiredo et al. 1997, Bó et al. 2003, Sartori et al. 2016), whereas the CL diameter of *B. taurus* ranged from 20 to 30 mm or approximately 4.0 to 14.0 cm^3 (Ginther et al. 1989, Bó et al. 2003, Sartori et al. 2004, Sartori et al. 2016).

Despite having larger follicles and CL, *B. taurus* have lower circulating steroid hormone concentrations. For example, nonlactating Holstein cows had larger ovulatory follicle diameter (14.2 vs 12.9 mm) and CL volume (5.2 vs 3.9 cm^3) than nonlactating Nelore cows (Sartori et al. 2016); however, Holstein cows had a lower preovulatory peak of circulating E2 (12.5 vs 16.2 pg/mL) and circulating P4 concentrations (1.9 vs 2.7 ng/mL) on Day 7 of the oestrous cycle, compared with Nelore cows.

This inverse relationship between the size of ovarian structures and circulating steroid hormones may be related to the reported differences in circulating insulin, IGF1, and cholesterol between breeds. Most of the studies have described greater circulating insulin and IGF1 in *B. indicus* than in *B. taurus* (Alvarez et al. 2000, Sartori & Guardieiro 2010, Sartori et al. 2013). Moreover, it has also been reported that, under similar nutritional management conditions, Nelore heifers have approximately 60% greater circulating cholesterol (precursor for the biosynthesis of steroid hormones) than Holstein heifers (196.8 vs 123.5 mg/dL; Gandra et al. 2011). Besides greater production of steroid hormones, there may be also reduced metabolic clearance rate for E2 and P4 in *B. indicus* compared to *B. taurus* (Sartori et al. 2016).

Nutritional and Metabolic Effects on Normal Reproductive Physiology and Reproductive Performance

The body condition score (BCS) in the first weeks postpartum exerts influences on metabolic hormones such as IGF1, insulin, glucose, NEFA, and thyroxine in *B. taurus* (Ciccioli et al. 2003). The same authors also reported that cows that maintain or lose BCS during lactation had a longer interval between calving, delayed first oestrous manifestation, and lower fertility (Ciccioli et al. 2003). In addition, *B. taurus* crossbreed cows (Charolais x Angus) maintained on pasture with BCS higher than 3 at calving had a lower postpartum anoestrous period compared with cows with BCS of 3 or lower, which presented the first ovulation postpartum later than 80 days (Houghton et al. 1990). These studies have shown that cows with moderate to good BCS at calving had a faster resumption of cyclicity (Whitman 1976, Graham 1982). In fact, in beef cattle, cows that lost less BCS before calving had fewer days open and higher pregnancy rates (Selk et al. 1988).

Few studies have directly evaluated the influence of nutrition on the reproductive variables of *B. taurus* versus *B. indicus*. In one study, using nonlactating Nelore (n = 12) and Holstein (n = 12) cows submitted to high or low feed intake, in a completely randomised design with a 2 x 2 factorial arrangement of treatments, cows were randomly assigned into two groups within each breed receiving 180% (1.8 M) or 70% (0.7 M) of a maintenance diet in a crossover design. Two weeks after the start feeding experimental diets, oestrus was synchronised and the cows were monitored twice a day by ovarian ultrasonography and blood samples collected once a day for hormone assays. Independent of diets, Holstein had fewer follicles at wave emergence than Nelore cows (12.7 ± 5.8 vs 31.8 ± 5.7 AFC). Results regarding all variables related to the size of ovarian structures were consistent with previous reports, in which Holstein cows had larger ovulatory follicle diameters (14.2 ± 0.4 vs 12.9 ± 0.4 mm) and CL volume (5.2 ± 0.3 vs 3.9 ± 0.3 cm^3) than Nelore cows. However, Holsteins had lower preovulatory peaks of circulating E2 (12.5 ± 1.4 vs 16.2 ± 1.3 pg/mL), plasma P4 concentrations on D7 (1.9 ± 0.3 vs 2.7 ± 0.3 ng/mL), and plasma insulin on D7 (2.3 ± 1.9 vs 7.6 ± 1.8 µIU/mL) than Nelore cows. Independent of breed, overfed cows had larger ovulatory follicle diameters (14.6 ± 0.3 vs 12.4 ± 0.3 mm) and larger CL volumes (5.2 ± 0.3 vs 3.9 ± 0.3 cm^3). However, they had lower plasma E2 preovulatory peaks (12.7 ± 1.2 vs 16.0 ± 1.3 pg/mL) and plasma insulin values on D7 (7.2 ± 1.6 vs 2.6 ± 1.9 µIU/mL) than those in low feed intake, although plasma P4 concentrations on D7 did not differ (2.2 ± 0.2 vs 2.4 ± 0.2 ng/mL, high vs low, respectively) between diets. Interestingly, regardless of genetic group, overfed cows had follicle deviation occurring later in the cycle (2.9 ± 0.2 vs 2.5 ± 0.2 days after ovulation), and the diameter when the largest follicle reached deviation was also greater (8.1 ± 0.4 vs 7.4 ± 0.4 mm) than those on low feed intake. Finally, independent of all the differences observed between breeds, the effect of nutrition on the analysed variables was similar for Nelore and Holstein cows.

It is known that the liver metabolism of steroid hormones is correlated with the dry matter intake (Sangsritavong et al. 2002, Vasconcelos et al. 2003). However, studies in which cows were fed the same maintenance diet and dry matter intake per kilogram of body weight was 1.37% for Nelore and 1.54% for Holstein cows (according to NRC 2001 recommendations), there was no body weight gain or loss in any of the studies for both breeds. Therefore, based on these results, a possible higher steroid metabolism in Holstein cows may be inherent to the breed and not only a consequence of higher feed intake. Moreover, despite contrasting data from previous studies (Randel 1976, Segerson et al. 1984), tropical cattle (mainly represented by the Nelore breed) may have lower liver steroid metabolism and increased steroid production by the ovaries than temperate cattle (represented here by the Holstein breed); this may be associated with higher circulating insulin and IGF1 in *B. indicus*.

VetBooks.ir

Influence of Dry Matter or Energy Intake Associated With High Plasma Insulin Concentrations on the Yield and Quality of Embryos

Most researchers who have studied the effect of feed intake on embryo production of *B. taurus* cows or heifers have reported negative results on the reproductive function of overfed cattle compared with those fed restricted diets. The causes of impaired embryo production related to feed intake are still not well understood. However, changes in liver blood flow, local and circulating metabolites (glucose and IGF1), hormone concentrations (insulin and steroids), and different sources of volatile fatty acids may be involved in these processes. Moreover, we hypothesised that the effects of dietary intake on embryo quality may differ between *B. taurus* and *B. indicus,* which consistently show different concentrations of circulating insulin and IGF1 concentrations. As shown later in this chapter, it is tempting to speculate that Zebu cattle may be more resistant than European breeds to the effects of changes in feed intake on embryo production and quality.

Bastos et al. (2007) did not detect any effect on the superovulatory response, embryo production, or embryo quality in Nelore heifers (n = 36) with higher or lower BCS fed maintenance (M) or flushing (1.8 M) diets for 14 days before the superovulatory treatment. However, there were clear differences in nutritional effects on cows subjected to OPU and *in vitro* production (IVP) of embryos compared with superovulation and *in vivo* development of embryos (Sartori et al. 2017). Thus all cows went through all treatment groups (n = 32 per group) and both types of embryo production systems.

Embryos (n = 274 vitrified embryos) were subsequently transferred to evaluate the effects of *in vivo* treatments on subsequent pregnancy per fixed-time embryo transfer (P/ET) in Nelore recipients. As expected, preprandial circulating insulin measured in blood collected on Day 32 (at the onset of superstimulation treatments) was greater in the E group compared with the 0.7M and M groups (8.7 ± 0.9, 4.6 ± 0.9, and 5.3 ± 0.85 μIU/mL respectively), but did not differ from that in the 1.5M group (6.6 ± 0.9 μIU/mL). Superovulation (as determined by the number of CL) was less in donors fed the E diet compared with cows receiving the standard (0.7M, M and 1.5M) diets (9.7 ± 1.2, 13.0 ± 1.3, 14.2 ± 1.2, and 13.9 ± 1.2, respectively), with a negative correlation between circulating insulin and CL number ($r = -0.32$). Nevertheless, there was no difference between groups for number of ova or embryos (~6), viable embryos (~3), or freezable embryos (~2.7). Regardless of treatment, circulating insulin was negatively correlated with the number of viable embryos (r = −0.22). There was a lower P/ET at 60 days in the 97 cows receiving embryos from donors fed the E diet (29.4%) compared with the 177 cows receiving embryos from donors fed the standard (0.7M, M or 1.5M) diet (43.3%). Moreover, probability of P/ET at 60 days, evaluated by logistic regression, decreased as circulating insulin concentrations of donor cows increased from 0.64 to 25.0 μIU/mL. Therefore high circulating insulin in the donors was associated with a reduced superovulatory response, fewer viable embryo, and poorer P/ET at 60 days.

In the same study for IVP, cows with low energy intake (0.7M) differed from cows fed the M or E diets, but not those fed the 1.5M diet (which exhibited intermediate values), with more oocytes recovered (23.0 ± 2.3, 20.2 ± 2.0, 21.5 ± 2.2, and 20.1 ± 2.0 for the 0.7M, M, 1.5M, and E groups respectively), and a greater number of viable oocytes per OPU (17.0 ± 1.9, 14.4 ± 1.6, 15.7 ± 1.7, and 14.1 ± 1.6 for the 0.7M, M, 1.5M, and E groups respectively). The number of cleaved oocytes per OPU was also greater in cows fed the 0.7M diet compared with the M diet (13.4 ± 1.7, 10.7 ± 1.4, 12.6 ± 1.6 and 11.7 ± 1.5 for the 0.7M, M, 1.5M, and E groups, respectively). However, the study did not detect an effect of diet on the number (6.9 ± 0.9, 5.4 ± 0.8, 5.9 ± 0.8, and 6.6 ± 0.9 for the 0.7M, M, 1.5M, and E groups respectively) or percentage (30.6, 31.9, 31.1, and 34.0% for the 0.7M, M, 1.5M, and E groups respectively) of blastocysts produced *in vitro.* Thus negative effects of high energy intake appear to be exerted at the later stages of follicle development or during early embryo development, and not during the early stages of follicle development, because high energy negatively affected embryo production and quality in cows that were superovulated and underwent *in vivo* embryo production but not in the case of oocytes collected from small follicles.

However, another study (Sales et al. 2015) has shown that nonlactating Gir cows, in which 1.7M diet was offered for more than 60 days, had a decrease in blastocyst rate over time (46.9 vs 25.7%). Nevertheless, in the same study, blastocyst rate was the same in nonlactating Holstein cows before or after being overfed for more than 60 days (6.5 vs 9.8%).

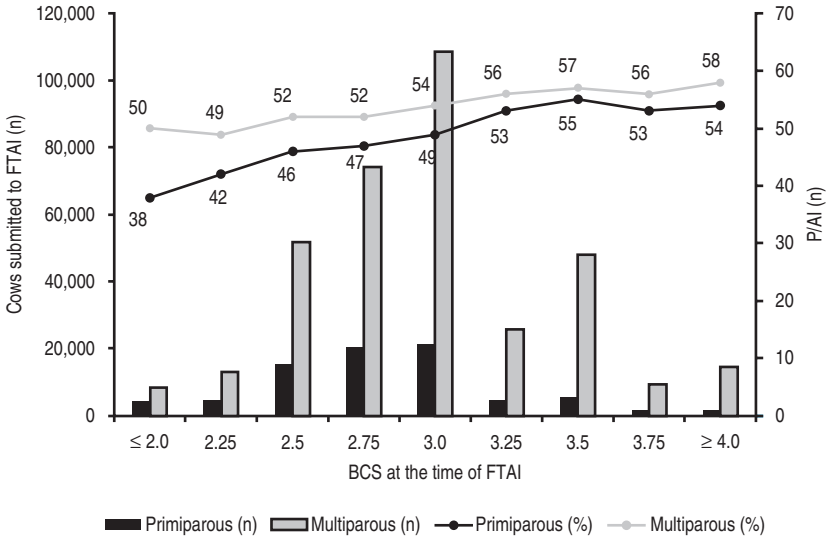
With the purpose of investigating the effect of fat supplementation on embryo production, Guardieiro et al. (2014) supplied concentrate with or without rumen-protected fat (Megalac-E, Elanco Animal Health, São Paulo, Brazil), rich in linoleic acid, to 40 Nelore heifers, starting 50 days before superovulation in a crossover experimental design. Supplemental diets were isocaloric and isonitrogenous. The superstimulatory response, the number of total embryos/ova, viable embryos, degenerate embryos, or unfertilised oocytes recovered were similar between groups. However, there was negative effect of unsaturated fatty acids on the superovulatory response (15.7 ± 1.2 vs 18.0 ± 1.3 CL), hatching rate at 48 hours (17.3 ± 3.3%; n = 137 vs 33.1 ± 4.0%; n = 148), and at 72 hours (30.9 ± 4.0%; n = 137 vs 44.3 ± 4.2%; n = 148) of *in vitro* culture after thawing. This negative effect associated with a rumen bypass fat diet may have been influenced by lower plasma concentrations of IGF1 observed in this experimental group compared with control (374.3 ± 27.2 vs 483.8 ± 26.5 ng/mL, respectively).

Assisted Reproductive Technologies (ARTs) Applied to *B. indicus*

Most of beef cattle herds in the tropics, especially in Brazil, are composed of *B. indicus* that have a longer postpartum anoestrus and low BCS when kept at pasture (Bó et al. 2003). This results in economic losses because of the increased calving to conception interval and reduced pregnancy rates (PR; Bó et al. 2007). In a pasture-based cow–calf production system, the use of reproductive management programmes, such as synchronisation of ovulation for FTAI (synchronisation protocols based on P4 and E2), is essential to achieve high PR in the breeding season, and it has been increasingly incorporated in cow–calf operations (Pessoa et al. 2016).

Data generated by the GERAR group (Specialised Group in Applied Reproduction to the Herd) in Brazil show the improvements in pregnancy rates from AI using P/AI from 2007 to 2015 in millions of heifers and cows submitted for FTAI. The main FTAI protocol used during the period of the study was the following: (1) D-11: Progesterone insert + 2 mg EB; (2) D-4: 12.5 mg dinoprost trimethamine; (3) D-2: P4 insert removal + 0.6 mg

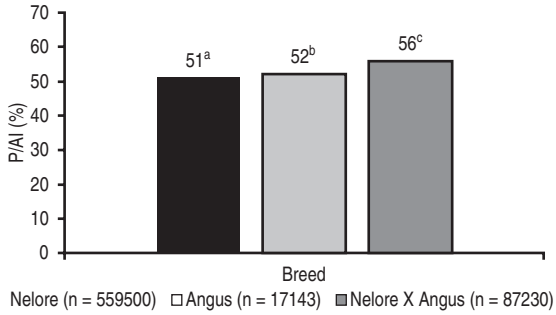
VetBooks.ir



• **Fig. 28.3** Number and P/AI of primiparous and multiparous beef cows submitted to FTAI according to BCS.

ECP + 300 IU equine chorionic gonadotropin (eCG) or calf removal for 48 hours; (4) D-0; FTAI (Meneghetti et al. 2009, Peres et al. 2009, Sa Filho et al. 2009). The fertility in all types of beef cattle has been relatively constant (~50%) during recent years. Nevertheless, there is likely to be room for improvement in many of the herds because some herds (~24%) had average P/AI greater than or equal to 60%. These herds are likely to have more intensive reproductive programmes: better nutrition with fewer cows with low BCS that could impact on fertility, especially in primiparous cows (Fig. 28.3); the cattle may also have better fertility traits, such as Nelore x Angus crossbreeds that also have an effect on P/AI results (Fig. 28.4).

Sex-sorted sperm has been widely and increasingly used in Brazil, especially for AI or IVP. Unfortunately, epidemiological data on the use of sex-sorted sperm in Brazil are not available.



• **Fig. 28.4** Breed effect on P/AI of cows submitted to FTAI. ($^{a,b,c}P < 0.01$.)

Breeding Season

One of the strategies commonly used for reproductive management of *B. indicus* is the establishment and incorporation of a breeding season (BS) in the management systems. A specific BS facilitates the concentration of calving and calf rearing, allowing breeding to occur when favourable nutritional and environmental condition for tropical environments are present, due to better forage availability. Usually, the BS occurs throughout spring and summer, lasting on average 3 months, and as a consequence, calving is concentrated during seasonal dry periods.

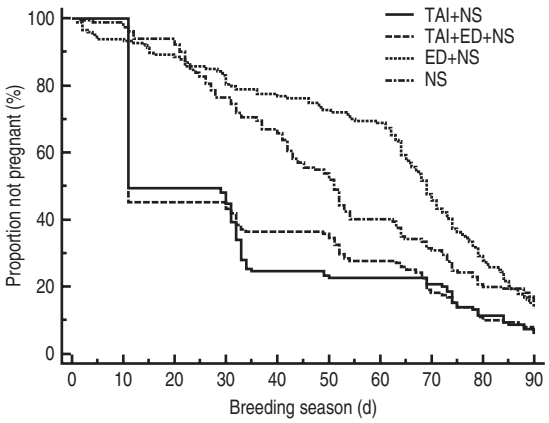
One of the best methods of increasing the number of females that are inseminated during the BS is the use of FTAI protocols. There are many strategies used in the reproductive management of *B. indicus* herds during the BS, with the objectives of improving pregnancy rates, accelerating genetic gain, and having as many females as possible pregnant at the end of the BS. Among the strategies that can be highlighted are: FTAI, improved oestrous detection, and use of natural service. Ideally, it is important to maintain a 365-day calving interval, in which cows conceive on average at least by 70 to 80 days postpartum.

Sá Filho et al. (2013) compared different reproductive management strategies during the breeding season and showed that cows submitted for their first postpartum AI after oestrous detection, followed by natural service, or just natural service during the entire BS had a decreased chance of pregnancy compared with cows in the two groups that had been bred only by FTAI at the onset of the BS. Moreover, cows bred by FTAI (~93%) had higher pregnancy rates at the end of the BS compared with cows not bred by FTAI (~84%). They also concluded that cows submitted for FTAI became pregnant sooner during the BS than cows submitted for AI after oestrous detection or natural service (Fig. 28.5).

Fixed-Time Artificial Insemination Protocols

The fixed-time artificial insemination (FTAI) protocol allows for a large number of cows to be inseminated on the same day, with high reproductive efficiency and at relatively low cost. Nevertheless, the success of the FTAI programme depends on several factors, such as synchronisation of follicular waves to optimise the period of follicular dominance, in order to reduce the chance of follicles ovulating too late (Cerri et al. 2009, Peres et al. 2009) or too early (Vasconcelos et al. 2001). This can be achieved by: synchronisation

VetBooks.ir



• **Fig. 28.5** Survival curves for proportion of nonpregnant cows by days of BS for various breeding strategies during a 90-day breeding season. TAI + NS (n = 150): cows received TAI on Day 11 of the BS, followed by NS until the end of the BS; TAI + ED + NS (n = 148): cows received TAI at Day 11, then were observed for oestrus twice daily, with AI 12 hours after ED until Day 45 of the BS, followed by NS until the end of BS; ED + NS (n = 147): cows were bred by AI 12 hours after ED during the first 45 days of the BS, followed by NS until the end of BS; NS (n = 149): cows were bred by NS throughout the BS. BS, breeding season; ED, oestrous detection; NS, natural service; TAI, timed AI. (From Sá Filho et al. 2013.)

of CL function and circulating P4; complete luteolysis at the end of the protocol; and synchronisation of final ovulation with optimally scheduled FTAI.

There are two main methods for the synchronisation of follicular wave emergence in dairy and beef cattle: (1) GnRH-based protocols, in which in the presence of a dominant follicle, GnRH induces ovulation and a new follicular wave begins; (2) E2/P4-based protocols, which after induced regression of all follicles, there follows a new wave commencing within the following days, depending on which E2 ester is used (Bó et al. 2003).

There are several factors that influence the proportion of cows ovulating after a GnRH/LH surge at the initiation of a FTAI protocol, such as the day of the oestrous cycle (Vasconcelos et al. 1999) or follicle diameter (Sartori et al. 2001, Gimenes et al. 2008). Although GnRH-based protocols have been successfully used in *B. taurus* cows (Pursley et al. 1995, Pursley et al. 1997, Bridges et al. 2008) but not necessarily in *B. taurus* heifers (Pursley et al. 1995, Pursley et al. 1997), there are conflicting data regarding their effectiveness in *B. indicus* cows (Fernandes et al. 2001, Bó et al. 2003, Baruselli et al. 2004, Ferraz et al. 2016).

Because it has been shown that *B. taurus* did not have consistent ovulations after GnRH treatment even in the presence of a dominant follicle larger than 10 mm in diameter (Martinez et al. 1999, Perry and Perry 2009), factors other than follicle size, such as circulating concentration of P4, may affect the ovulatory response to GnRH. For example, one study (Biehl et al. 2013) compared the response to the first GnRH (100 μg gonadorelin) treatment of the 5d CO-Synch + CIDR (5-d CS) programme in Nelore heifers. The treatments were: HiP4 (n = 62; GnRH in heifers with a CL present at P4 device insertion); LoP4 (n = 35; GnRH in heifers with no CL present at P4 device insertion); PGF-LoP4 (n = 65; GnRH in heifers that had a CL, but were treated with 25 mg of dinoprost (PGF) 2 d before GnRH treatment and P4 device insertion). Ovulation to GnRH was greater for the LoP4 (85.7%) and PGF-LoP4 (95.4%) compared with the HiP4 (25.8%). Moreover, it is possible that different analogues of GnRH may produce different outcomes because it has been reported, for example, that gonadorelin induced a lower LH surge compared with other analogues of GnRH, such as lecirelin, fertirelin, or buserelin (Chenault et al. 1990, Picard-Hagen et al. 2015).

Thus GnRH-based protocols are likely to result in poorer synchronisation of the first follicular wave when they are initiated in the presence of a CL, primarily due to lack of ovulation of a dominant follicle at the initiation of the protocol. This is clearly related to the greatly reduced magnitude of the LH surge, induced by GnRH in the presence of elevated P4. In addition, due to the natural growth and regression of follicular waves during the luteal phase, there are many times when an LH-responsive dominant follicle is not present, and therefore ovulation would not occur even with an optimised LH surge. Furthermore, the presence of elevated P4 may reduce LH receptor expression in the dominant follicle, and this could reduce responsiveness to an LH surge in dominant follicles (Dias et al. 2014).

Many GnRH-based protocols in *B. taurus* now use presynchronisation strategies to assure that cows are at a stage of the oestrous cycle that optimises ovulation to GnRH treatment. For example, double Ovsynch uses an Ovsynch protocol to presynchronise the cows, so that almost all cows (~94%; Herlihy et al. 2012) are cycling and at Day 6 or 7 of the oestrous cycle at the start of the breeding Ovsynch protocol. This produces a high ovulation rate to GnRH and high fertility during the protocol. These presynchronisation strategies have not been adequately tested in *B. indicus* but are likely to be too complicated for most *B. indicus* management systems. Unfortunately, studies have not yet been performed that directly tested the ovarian responses and fertility of *B. taurus* versus *B. indicus* in response to the same GnRH-based protocols.

Early studies that established the physiological basis for these protocols utilised *B. taurus* beef heifers and found that treatment with different esters of E2 simultaneously with P4 treatment led to suppression of the gonadotropins, regression of growing follicles, and emergence of a new follicular wave about 4 days after E2 treatment (Bó et al. 1993, Bó et al. 1994, Bó et al. 1995). Although E2/P4-based FTAI protocols are widely used in *B. taurus* and *B. indicus,* the metabolism of E2 is different between *B. taurus* and *B. indicus*. It was concluded that the timing of follicle wave emergence after treatment with EB + P4 was EB dose-dependent for both breeds.

The results presented previously are somewhat contradictory because, despite a very different clearance rate of E2, the behaviour of wave emergence after EB + P4 treatment was not different between breeds. Therefore based on differences in circulating E2 after EB treatment between breeds, one might expect that lower EB doses should be used for Nelore and higher EB doses should be used for Holstein cattle at the initiation of an E2/P4-based FTAI protocol in order to optimise synchronisation of follicle wave emergence. In contrast, based on the similar responses of both breeds to EB treatments in terms of follicle wave emergence, a similar E2 dose might be optimal for Nelore and Holstein cows.

Pessoa et al. (2015) compared 1 mg with 2 mg EB at the onset of a resynchronisation protocol starting 22 days (Day 22) after the first FTAI and evaluated P/AI, pregnancy loss and induction of new follicular wave emergence in 1426 suckled beef cows (768 *B.taurus* and 728 *B.indicus*). They concluded that 2 mg EB produced a more uniform emergence of the follicular wave and greater P/AI after resynchronisation without compromising the pregnancy established at the first FTAI.

VetBooks.ir

Regarding induced luteolysis by exogenous treatments, the responsiveness of the CL to $PGF_{2\alpha}$ seems to be very similar between *B. indicus* and *B. taurus.* To test the effect of the dose of a $PGF_{2\alpha}$ analogue and day of the oestrous cycle at the time of treatment, Ferraz et al. (2016) performed an experiment with nonlactating Nelore cows in a factorial design 3 x 2, in which three different doses of dinoprost tromethamine (12.5, 25, and 50 mg) were used on Days 5 or 7 of the oestrous cycle. In this study, luteolysis was dose-dependent. Therefore increasing the dose of $PGF_{2\alpha}$ increased the proportion of cows detected in oestrus and augmented the percentage of cows with circulating P4 concentration less than 1 ng/mL at 72 hours after $PGF_{2\alpha}$ treatment. In addition to the dose of $PGF_{2\alpha}$, it is well known that the day of the oestrous cycle influences the proportion of cows that undergo luteolysis after $PGF_{2\alpha}$ (dinoprost tromethamine) treatment. Ferraz et al. (2016) observed that Nelore cows, with a CL on Day 5 of the oestrous cycle, were more refractory to $PGF_{2\alpha}$ than those on Day 7 of the cycle. Moreover, in lactating Holstein cows a second treatment of dinoprost tromethamine (+ $PGF_{2\alpha}$; 24 hours apart) increased the percentage of cows that had complete luteal regression (95.6%), compared with control cows (84.6%). Although one study found no detectable effect of the additional $PGF_{2\alpha}$ on P/AI (control = 41.5% vs + $PGF_{2\alpha}$ = 44.7%; P = 0.34; Brusveen et al. 2009) and recent studies have found significant improvements in P/AI when a second $PGF_{2\alpha}$ treatment is given, particularly in multiparous cows (Carvalho et al. 2015, Wiltbank et al. 2015). Therefore complete luteolysis is essential to optimise ovulation and fertility in a FTAI protocol. In fact, more lactating Holstein cows with P4 < 0.1 ng/mL, compared with P4 of 0.1 or higher and less than 0.22 ng/mL at the time of AI, ovulated to a E2/P4-based FTAI protocol (81.2 vs 58.0%) and had increased P/AI (47.4 vs 21.4%; Monteiro et al. 2015). Similar results were observed by Pereira et al. (2013) when lactating dairy cows were also synchronised with an E2/P4-based protocol and were either inseminated or served as embryo recipients (ET). The P4 concentration at the time of AI or 7 days before ET altered fertility in FTAI cows with higher P/AI in cows with P4 concentration less than 0.1 ng/mL compared with cows with P4 concentration of 0.1 ng/mL or more, and in ET cows with higher P/ET in cows with P4 concentration less than 0.22 ng/mL compared with cows with P4 concentration of 0.22 ng/mL or higher.

Embryo Technologies

The physiological differences between *B. indicus* and *B. taurus* described previously need also to be considered when managing females for *in vivo*–derived (IVD) embryos by multiple ovulation and embryo transfer (MOET) or *in vitro* embryo production (IVP).

One of the protocols most frequently used in *B. indicus* cows and heifers for MOET was developed by Barros and Nogueira (2005) and was called P-36. The protocol included the use of an intravaginal P4 device for 36 hours after $PGF_{2\alpha}$ administration and the induction of ovulation with exogenous LH, administered 12 hours after the P4 device removal (48 hours after $PGF_{2\alpha}$ administration). The FTAI was performed 12 and 24 hours later because ovulation occurs between 24 and 36 hours after LH administration. The effectiveness of the P-36 protocol has been confirmed (Baruselli et al. 2006, Nogueira et al. 2007). A variation of the P-36 protocol, in which the P4 device is removed 24 hours after $PGF_{2\alpha}$ (protocol P-24) and LH is administered 24 hours later (48 hours after $PGF_{2\alpha}$), has been utilised in Nelore cattle, apparently with comparable results to those obtained with P-36 protocol (Baruselli et al. 2006).

The use of the P-36 protocol in *B. taurus* breeds, however, has resulted in decreased numbers of viable embryos in comparison with conventional protocols using oestrous detection. In Holstein (Baruselli et al. 2006) and Angus (Bó et al. 2006) donors, viable embryo production was increased with the P-36 protocol, when the ovulation induction treatment (LH or GnRH) was administered at 60 hours (P-36/LH60) rather than at 48 hours (P-36/LH48) after $PGF_{2\alpha}$ administration. On the other hand, even though delaying ovulation for 12 hours in the P-36 protocol in *B. taurus* breeds (P-36/LH60 protocol) had positive effects on embryo production, the opposite occurred when used in *B. indicus* breeds. The P-36/LH60 protocol caused a decrease in embryo production compared with P-36/LH48 protocol (Baruselli et al. 2006). Therefore it can be inferred that ovulation in superstimulation protocols must be induced earlier in *B. indicus* donors, whereas in *B. taurus* donors, it seems necessary to delay treatment with an ovulation inducer, thereby allowing an increase in follicle size and acquisition of LH receptors. *Bos indicus* breeds have a reduced capacity for LH secretion and a greater sensitivity to exogenous gonadotropins than *B. taurus* (Randel 1984).

Because of the greater AFC and better oocyte quality in *B. indicus* in comparison with *B. taurus,* IVP is much more successful in *B. indicus.* For example, Gir (*B. indicus*), Holstein, and crossbreeds (1/4 Holstein x 3/4 Gir or 1/2 Holstein-Gir) were compared for total and viable oocyte yield and IVP of embryos (Pontes et al. 2010). The number of total and viable oocytes and embryos produced was greater in Gir than in Holstein cattle (17.1 vs 11.4; 12.1 vs 8.0; 3.2 vs 2.2, respectively). Moreover, embryo production (5.5 blastocysts) was even greater in Holstein-Gir crossbreeds compared with the other breeds. Another study was conducted to compare IVP between Nelore and Holstein heifers (Gimenes et al. 2015). More oocytes were recovered (37.1 vs 15.4), more embryos were produced (7.3 vs 1.1), and a greater blastocyst rate was obtained (28.3% vs 14.1%) from Nelore than Holstein heifers. In another study (Sales et al. 2015), Gir cows had a greater number of oocytes recovered by ovum pickup (OPU; 23.4 vs 14.9), better quality of oocytes as demonstrated by greater cleavage rates (73.6% vs 40.8%), greater number of blastocysts (3.8 vs 0.7), and better blastocyst rates (36.7% vs 12.1%) than Holstein donors.

Overall, the main findings of the studies described previously indicate that *B. taurus* yielded fewer oocytes as well as produced fewer blastocysts per OPU than *B. indicus* donors. This pattern seems to occur even when other *B. taurus* breeds are studied. Sudano et al. (2014) conducted an experiment in which nonlactating Simmental (*B. taurus*) and Nelore cows were compared for *in vivo* embryo production and IVP. The total number of recovered ova/embryos per cow (5.5 vs 3.7) and transferable IVD embryos per cow (3.8 vs 2.3) were not different between Nelore and Simmental, respectively; however when IVP was performed, Nelore produced more oocytes per OPU (14.9 vs 8.1) and had greater blastocyst rates per OPU (41.5% vs 23.4%) than Simmental cows.

Nelore cows (with or without a calf) were synchronised with the same protocol within a 3-month period. For FTAI, 346 cows were bred on Day 0 using frozen/thawed semen of five bulls. For ET, cattle received IVD (n = 274) or IVP (n = 573) vitrified embryos (produced with semen from seven bulls, of which three were the same bulls used for FTAI) on Days 6, 7, or 8 of the protocol after confirming the presence of a CL. The same groups of cows were used for all treatments. When this variable was used for analysis, more healthy calves were born per cow submitted to a synchronisation protocol for the FTAI group and less for the IVP group (Table 28.2).

VetBooks.ir

TABLE 28.2 Pregnancy per AI or P/ET, pregnancy loss, abortion, and peripartum loss in Nelore cows that received fixed-time AI (FTAI) or vitrified *in vitro* produced (IVP) or *in vivo* derived (IVD) embryos

	FTAI	IVD	IVP
30 d pregnancy, % (n/n)	50.3[a] (174/346)	39.4[b] (108/274)	34.0[b] (195/573)
60 d pregnancy, % (n/n)	47.7[a] (165/346)	35.4[b] (97/274)	28.6[c] (164/573)
Embryo/foetal loss (30–60 d), % (n/n)	5.2[b] (9/174)	10.2[ab] (11/108)	15.9[a] (31/195)
Later pregnancy loss (60 d to calving), % (n/n)	15.2[a] (25/165)	6.3[b] (6/96)	16.5[a] (27/164)
Peripartum loss, % (n/n)	2.1[b] (3/140)	4.4[ab] (4/90)	9.5[a] (13/137)
Total loss, % (n/n)	21.3[b] (37/174)	19.4[ab] (21/108)	36.4[a] (71/195)
Healthy calf born per synchronization protocol, % (n/n)	39.6[a] (137/346)	25.4[b] (87/342)	17.3[c] (124/716)

Infertility and Abortion in Sheep and Goats

PEERS DAVIES

Sheep

Three factors influence the numbers of lambs sold: fertility, i.e., whether the ewes are pregnant and lamb; fecundity, i.e., the number of lambs born per pregnancy; and survival rate of lambs to weaning.

The level of fertility in sheep is usually expressed as the reproductive performance of the flock. This can be defined as the number of lambs born per 100 ewes put to the ram (i.e., true lambing percentage). The breeding season commences with the introduction of rams, and all physical and financial performance should be calculated from this point, taking into consideration ewes that die, those that are culled, and those that abort or are barren. Empty ewes are a cost to the flock but are often not included in costings, making between-flock comparisons difficult and, in some cases, giving an overoptimistic impression of reproductive performance when the denominator for lambing percentage only includes those that have conceived, as measured at scanning, or those which gave birth to lambs. Attention should be paid to both the empty ewe % at pregnancy diagnosis (midpregnancy) and the aborted % that itself includes both the observed abortions and also unobserved abortions (those ewes that were confirmed pregnant and subsequently did not lamb, sometime termed 'wet-to-dry' ewes). Ewe conception rate per cycle is normally accepted to range from 80% to 90% in well managed flocks during the prime breeding season for the breed. This is commonly calculated from lambing records with the assistance of raddle mark information in some cases. Based on this conception rate after a mating period of two cycles, it would be expected that the physiological empty rate should not exceed 4% of the flock or 0.8% after 3 cycles.

The most recent published figures for ewe productivity in lowland (non-SDA) and upland/hill (SDA) flocks in England published in 2016 revealed scanning percentages of 170% and 164% respectively with empty rates of 6% and 4.6% respectively. The abortion rates (observed and unobserved) were 10% and 6% respectively (AHDB Stocktake Report 2016). However, the observed abortion rate is typically far lower than this given the extensive nature of most sheep production systems in the UK and worldwide. Empty or aborted ewes are frequently culled and, as a consequence, there is some genetic selection against poor fertility. Fecundity is influenced by genetic selection, age of the ewe, nutritional status, and environment. Lamb survival rate will be influenced mainly by management factors, the environment, and also genetic selection for such traits as good mothering behaviour.

Ewes are generally allowed to run with the ram during the breeding season and not segregated; thus oestrus detection problems are not frequently encountered. Furthermore, most breeds of sheep have a long period of acyclicity after parturition, allowing the reproductive system time to recover from the effects of pregnancy. Published information on normal conception rates in British lowland ewes is vague. However, the fertility of ewes, as measured by pregnancy (conception) rates to first service by Smith (1991) was 91.6%. In the same study, 99.4% had conceived by the third mating. Conception rates are influenced by a number of physiological and managemental parameters as well as pathological processes that may prevent conception but are more commonly associated with abortion. Structural or anatomical factors are of limited importance.

True anoestrus is uncommon in sheep; Smith (1991) identified the condition in 0.3% of 5488 lowland ewes. In fact, when the rams are turned out with the flock, it is usual for most of the ewes to be mated within a month. The first oestrus of the breeding season in some ewes is anovulatory and, according to Dutt (1954), more frequently ewes fail to become fertilised at these early matings compared with later ones. Ovarian follicular cysts, commonly encountered in cattle, are of limited importance in sheep. Smith (1996) identified follicular cysts in 2.9% and 10.02% of abnormal parous and nulliparous genital tracts respectively. Luteal cysts were rare.

Embryonic death, or resorption, is a conspicuous feature of sheep infertility and is more often associated with multiple than with single conception. It is suggested that a greater degree of embryonic death follows early matings. Using laparoscopy and comparing the number of corpora lutea with the number of fetuses the incidence of the condition has currently been estimated at 20% to 33% (Wallace & Ashworth 1990, Bruere & West 1993).

Early embryonic death has also been associated with infectious diseases such as toxoplasmosis, Border disease, and Schmallenberg disease (see later in this chapter). In a survey by Johnston (1988), 35.2% of barren ewes had elevated antibody titres to *Toxoplasma* compared with 19.2% of fertile ewes.

Noninfectious Causes

Nutrition

Ewe nutrition plays an important role in both fertility and fecundity. The effects of nutrition on fertility and fecundity

VetBooks.ir

are not restricted to the period around mating but are influenced by the nutritional experience of the individual during its own development. For example, recent research in ewes has demonstrated that during its early development the fetal ovary is remarkably sensitive to maternal nutrition with subsequent lifetime effects on ovulation rate (Robinson et al, 2006). The timing of puberty in both sexes and adult ovulation rates in ewes are influenced by postnatal nutrition. Nutrition during the period when ovarian follicles emerge from the primordial pool (approximately 6 months before they ovulate in ewes) can influence ovulation rate in ewes. The role of nutrition can be considered in the form of energy, micronutrients/trace elements, and finally bioactive chemical compounds that act directly upon the reproductive tract derived principally from varieties of legumes, especially red clover grown as a high protein, draught tolerant, nitrogen-fixing forage crop for grazing or conservation as hay or silage.

Energy

It is important that ewes are in good bodily condition at mating. Increasing the energy intake several weeks before tupping so that the ewes are gaining weight (flushing) has been common practice for decades as a means to increase the fecundity in those ewes with the genetic potential. However, it has been demonstrated that maintaining ewes at body condition score (BCS) 3.5 to 4 (1–5 scale) before mating has the same effect as 'flushing' lower BCS ewes by increasing the energy intake in and weeks preceding mating. Studies conducted in Australian sheep flocks have demonstrated a normal distribution of fetal numbers with BCS an optimum conception rate at a BCS of 3.5 determined by ultrasound pregnancy diagnosis.

Trace Elements

It has been demonstrated that the cobalt/vitamin B12 status of donor ewes in superovulation protocols affected ovulation rate. In a study by (Mitchell et al. 2007), ewes with mean circulating B12 concentrations of 1483 and 182 pmol/l had mean ovulation rates of 14.4 ± 1.28 and 9.9 ± 1.55, respectively.

Selenium has been demonstrated to have a significant effect on ram fertility (Kendall et al. 2000); however, the significance in ewes is less clear. The importance of copper and zinc to fertility and fecundity is also unclear; however, in the developing fetus the importance of sufficient bioavailable copper in the maternal diet is well known in order to prevent inadequate axonal myelination leading to enzootic ataxia in lambs 'swayback'.

Iodine supplementation of ewes and rams grazing severely deficient pastures has been associated with a significant improvement in fertility (Ferri et al. 2003, Clark et al. 1998). Iodine sufficiency of the maternal diet has also been associated with lamb survival (Clark et al. 1998).

Bioactive Agents – Red Clover

Since the 1950s, studies conducted in Australia have demonstrated temporary and, in some cases, permanent infertility induced in ewes by the prolonged grazing of red clover pasture. This led to a number of chemical and biological studies, mostly conducted on red clover grown in Australia, indicating that red clover contained oestrogen-like compounds (Marley 2011). Later, researchers identified that red clover with high levels of the phytooestrogens formononetin (7-hydroxy-4'-methoxyisoflavone) and biochanin A (5,7-dihydroxy-4'-methoxyisoflavone) indirectly caused the infertility.

Sheep grazing pastures with red clover at less than 25 % of total dry matter could not be guaranteed not to cause fertility problems as it has been shown that sheep will selectively graze clovers over grasses in mixed swards.

The phytooestrogen content of red clover is primarily under genetic control, but environmental factors can also have an effect. Different cultivars have been shown to contain different concentrations of phytooestrogens (Marley 2011), and plant breeders have developed many new varieties of red clover, recognised for their lower levels of the oestrogenic compounds (e.g., the variety AberRuby). In Australia and New Zealand, pasture contains higher levels of phytooestrogen in spring, with oestrogen content declining after flowering. Nutrient deficiencies that impair plant growth have also been shown to increase the concentrations of formononetin, and hay and silage have been shown to retain oestrogenicity in some cases (Marley 2011). In particular, one study highlighted that the oestrogen content of red clover silage was higher than that of the raw material and that the type of silage inoculant used during ensiling could affect phytooestrogen levels (Sarelli et al. 2003).

Management Factors

The management of ewes before, during, and after mating can all play a key role in the reported fertility and fecundity of the flock. These can be divided crudely into ewe and ram management factors. For both ewes and rams, management of mating to coincide with the degree of breed seasonality is essential. The general trend is for tropical or equatorial native breeds such as the Cameroon to be aseasonal and polyoestrous whereas seasonality generally increased with latitude whereby the native primitive and commercial hill breeds of Britain may only experience three oestrous cycles in a brief autumn mating period.

There are exceptions to this general relationship between latitude and seasonality, most notably the Dorset and the Romanov. The Dorset is still somewhat influenced by photoperiod: fecundity of Dorsets mated 'in season' during the typical shortening day mating period is normally higher (lambing % of 150%–175%) compared with out of season mating in which fertility and fecundity can be 20% to 30% lower.

For ewes of any breed, puberty and body weight are important limiting factors on ovarian activity. Puberty occurs early for many of the highly fecund breeds, such as the Romanov, at 3 to 4 months of age whereas 6 to 8 months of age is more typical for the majority of British or continental European breeds. If ewe lambs experience nutritional or parasitical challenges that restrict their growth rate, it is expected that puberty may be delayed in many individuals. The target of 60% to 70% of mature bodyweight is commonly used as a suitable threshold for the mating of ewe lambs as this is the point by which the majority of individuals would be expected to cycle and have also reached puberty by this time, given the expected growth rate in most sheep systems.

The management of multiparous ewes is also critical, especially the interval between weaning and mating. In sheep, locational anestrus driven by prolactin production can present problems in dairy flocks in which lactations may depress fertility and lead to ewes failing to lamb annually or in accelerated lambing protocols in which ewes are managed to lamb more frequently, most typically targeting three lamb crops in 2 years (8 month interval between lambing). In these systems a combination and interaction between both nutritional sufficiency and hormonal control reduce the fertility of ewes under these

VetBooks.ir

management systems. However, selection for ewes that are fertile during lactation has demonstrated that the trait is heritable (Cornell 'STAR' system).

The fertility and fecundity of ewes vary over the course of their life with the lowest fertility and fecundity apparent as ewe lambs, partly for reasons of variable levels of mature body weight as discussed previously. However, variation with age continues into maturity with third and fourth parity ewes demonstrating the highest fertility in most breeds and farming systems although significant variation exists between flocks due to management practices.

Oestrus Detection and Artificial Insemination

The best method of oestrus detection is with a raddled vasectomised ram, very few visible signs being detectable in the ewe. Artificial insemination (AI) in sheep has not assumed the popularity achieved in cattle; however, numbers are increasing. A number of factors have been responsible, notably the disappointing results using frozen/thawed semen deposited intravaginally or intracervically to a synchronised oestrus. The spermatozoa are unable to colonise or traverse the length of the cervix and are rapidly lost from the ewe's reproductive tract. However, lambing rates of 72% have been observed using this technique in response to natural observed oestrus as opposed to an artificial oestrus (Paulenz et al. 2005). Globally, the use of intrauterine insemination by laparoscopy has been much more successful and commonly adopted for high value breeding stock, with pregnancy rates of over 70% using both fresh extended semen and frozen–thawed semen (McKelvey 1999). Artificial insemination is best used in midoestrus or 12 to 14 hours after its onset.

Ram Effect and Teasing

Use of vasectomised or epididymectomised rams before the introduction of fertile rams is a common management practice whereby the pheromone and behavioural stimuli provided by the rams trigger ovulatory activity in the ewes resulting in a degree of synchronisation of oestrous activity. At the onset of the breeding season, when ewes are approaching the end of their anoestrous period, the use of teaser rams can allow the ewes to experience the normal first short, silent oestrus that is caused by the formation of an abnormal corpus luteum, as early as possible then allowing the first fertile oestrus to occur earlier and more synchronously for the flock than would otherwise be possible (Rosa & Bryant 2002). It has been demonstrated that 84.8% of teased ewes exhibited oestrus in the first 16 days after exposure to the fertile ram, whereas two cycles were required for the unteased ewes to show comparable activity (Smith 1991). Teasing is only effective if the ewes and rams have been isolated from any sensory contact for several weeks or months previously. The period of teasing contact is also important; once introduced to the ewes, the teaser rams should be allowed contact for 12 to 14 days before they are replaced with fertile rams.

Hormonal Manipulation of Fertility and Fecundity

Exogenous progesterone can also be used to overcome the first silent oestrous effect of abnormal anoestrous transition CL. This is most commonly supplied by intravaginal sponges impregnated with progesterone that are implanted for 12 to 14 days. They can be used in conjunction with exogenous PMSG as the most common artificial synchronisation protocol in sheep. The dose of PMSG administered varies from 100 to 900 IU, depending on the breed seasonality, the mating period, and the desired fecundity effect. Other synchronisation protocols involving GnRH and $PGF_{2\alpha}$ have also been demonstrated to be effective alternatives (Haile et al. 2016). Similar protocols are used for natural mating as for artificial insemination.

Melatonin implants are also used to advance the breeding season in moderately seasonal breeds in both rams and ewes. Melatonin implants have also been demonstrated to increase fetal numbers (Scott et al. 2009) as well as advance the breeding season.

Ram to Ewe Ratio

The number of rams per ewe will vary, depending on a number of factors: age of the ram; age of the ewes; whether more than one ram is to be used with the group of ewes; the terrain; and the size of the enclosure. Ram to ewe ratios of 1 to 25 to 1 to 40 are traditionally regarded as suitable in nonsynchronised flocks. When synchronisation is attempted, a ratio of at least 1 to 10 is commonly advised. However, far higher ratios are frequently used when rams are capable: 1 to 80 and 1 to more than 100 are not uncommon in some UK and NZ flocks. The number of rams in the mating team is also important; single sire mating groups should be avoided unless essential for parentage assignment, as transient subfertility or low libido of a single ram in single sire mating groups can present as high empty rates among ewes. It can also present as an extended lambing pattern with an unexpectedly high proportion of lambings occurring in the second or even third cycle.

Genetic Potential

Significant breed variation is observed in both fertility, fecundity, and seasonality in sheep. The modes of inheritance of the different prolificacy genes include: autosomal dominant genes with additive effects on ovulation rate (BMPR-1B; Lacaune); autosomal overdominant genes with infertility in homozygous females (GDF9); X-linked overdominant genes with infertility in homozygous females (BMP15); and X-linked maternally imprinted genes (FecX2). The size of the effect of one copy of a mutation on ovulation rate ranges from an extra 0.4 ovulations per oestrus for the FecX2 mutation to an extra 1.5 ovulations per oestrus for the BMPR-1B mutation. DNA tests enable some of these mutations to be used in genetic improvement programs based on marker assisted selection.

Noninfectious Abortions

Noninfectious abortions may be caused by rough handling (winter shearing, prehousing dipping, vaccination procedures), metabolic diseases (especially twin lamb disease), and transportation. Dog worrying is also commonly blamed for sheep abortion. Vaginal prolapse producing excessive straining, especially when infection has softened the cervical plug, may lead to abortion. Congenital goitre in lambs has also been implicated as a cause of abortion.

Noninfectious abortions rarely result in more than 2% of the flock aborting, and when the percentage is higher, it is highly likely that an infectious cause of abortion is present and should be fully investigated (see later in this chapter).

Structural Defects

Structural defects of ovine genital organs are uncommon. In a recent and extensive survey involving 33,506 ovine genital tracts

(9970 parous) from two UK abattoirs, Smith (1996) identified 6.57% of parous and 1.95% of nulliparous tracts with pathological lesions. Most involved the ovaries and their associated bursae, with fibrin tags and paraovarian cysts being most frequently identified. However, it is unlikely that these lesions alone would cause infertility. There is no doubt that many of the other lesions identified in this survey would have caused infertility or sterility (e.g., ovarian aplasia, ovarian hypoplasia, bilateral hydrosalpinx, aplasia of the paramesonephric ducts, freemartinism, hermaphrodism, and pseudohermaphrodism).

Owing to the rarity of anastomoses of the adjacent allantoic vessels of twins, the freemartin condition is likely to be rare, but incidences of 0.23% to 1.22% have been recorded (Smith 1996). Even higher levels have been detected in the more prolific breeds: for example, 6.85% in Booroola F ewes (Cribiu et al. 1990). True hermaphroditism has been recorded in sheep. Frayer-Hosken et al. (1992) both reported ewes with an ovotestis, whereas Smith et al. (1996) reported a ewe with one active female gonad and an inactive testis with a pampiniform plexus. Cases of intersexuality are seen mainly at lamb castration. They are male pseudohermaphrodites referred to by shepherds as 'wilgils'. The fact that several may be seen at once in a flock tends to point to a possible hereditary cause. Other developmental defects of the genital organs of sheep are rare, although there is good evidence of an association between ovarian hypoplasia and breeds with high fecundity (Davis et al. 1992, Vaughan et al. 1997).

Infectious Agents

It should be noted that all the insidious production limiting disease of sheep that lead to weight loss and ill thrift will also reduce fertility and fecundity. These include maedi visna, ovine pulmonary adenomatosis, Ovine Johnes disease, parasitical gastroenteritis, fascioliasis, haemonchosis chronic pneumonia, and caeseous lymphadenitis in advanced cases. Recent proportional distribution of abortion diagnoses (2008–2015) from sheep submissions to surveillance laboratories in the UK are summaries in Table 29.1.

Nonspecific infections of the genital tract, especially the uterus, are of minimal importance in ewes, probably because in most breeds of sheep there is a long period of anoestrus after lambing. In the small number of ewes in which bacterial contamination occurs at lambing or postpartum, which is less than 20%, they are rapidly eliminated within a week (Regassa & Noakes 1999) and thus before the genital tract can be exposed to a period of progesterone influence; this will occur at the next dioestrus, which will normally be many months away. In the cow, retention of the fetal membranes (RFM) postpartum is quite common, and this is a major risk factor in the development of endometritis and subfertility. RFM is relatively uncommon in ewes; when it does occur, attempted removal by applying traction to the exposed portions of the membranes can be attempted. If left, they will usually separate and be shed within 5 to 6 days. If an affected ewe shows signs of systemic illness due to the development of metritis, she should be treated with an appropriate broad spectrum antibiotic. However, there are a number of specific infectious agents that can have a profound effect upon fertility, particularly by causing abortion and perinatal mortality.

A number of infectious agents have a predilection for the gravid reproductive tract of sheep, frequently resulting in abortion. Abortion per se is only aspect of the phenomenon, in some instances barren ewes may be involved, as are weak nonviable lambs, either being born to time or prematurely.

All abortions occurring in a flock should be regarded as infectious unless proved otherwise.

VetBooks.ir

Those specific infectious agents that cause infertility and subfertility in sheep, especially fetopathy with abortion, will be described later in order of prevalence.

Enzootic Abortion of Ewes

Enzootic abortion of ewes (EAE), also known as ovine enzootic abortion, is consistently the most commonly diagnosed cause of infectious abortion in the UK. Infection is caused by *Chlamydia abortus* (previously classified as *Chlamydophila psittaci* immunotype 1), which has a predilection for the pregnant uterus. It may also infect goats, cattle, deer, and humans. For many years, in Scotland and the English border counties, shepherds and veterinarians were familiar with an enzootic abortion in flocks. The causal organism was identified by Stamp et al. (1950). The disease is now widespread in Britain and common in Europe and the western US but absent from Australia and New Zealand. *C. abortus* has a highly specialised life cycle involving alternate intra- and extracellular phases that confer advantages for evasion of host immune responses and facilitate the maintenance of low grade, asymptomatic infection. It occurs most commonly in flocks that are intensively managed over the parturient period.

Epidemiology

The major source of infection, responsible for over 80% of new outbreaks in clean flocks, is the purchase of infected ewes of any age (Greig 1996). Spread may also be by wildlife, e.g., foxes, gulls, and crows. Sheep-to-sheep spread is the commonest route, and lambing time is the greatest time of risk when infected ewes shed large numbers of infectious particles into the environment. Susceptible ewes inhale or ingest *C. abortus* from infected placentae and fetal fluids from aborting ewes, which are heavily contaminated and are the main source of infection for susceptible sheep (Aitken et al. 1990); dead lambs and contaminated bedding can also be implicated. Infective particles (elementary bodies) may survive for weeks at low environmental temperatures. Ewes infected early in pregnancy usually abort; otherwise the organisms lie dormant until the next pregnancy, or occasionally a subsequent pregnancy. *C. abortus* is not transmitted in the milk of infected ewes. However, lambs may acquire infection from uterine discharge on the teats. Of the lambs infected by the ewes, field evidence suggests that around 30% may develop placentitis in their first pregnancy (either as lambs or shearlings), a proportion of which may abort (Greig 1996).

Chlamydia acquired outside pregnancy lie dormant. However, they can be reactivated from their 'latent' state during pregnancy. Neither the site of latency nor the precise triggers of reactivation have been identified. Latently infected flocks are unrecognisable by immunological methods. The work of Buxton et al. (1990) demonstrated that ewes were susceptible to infection from early gestation onwards. The tonsil and lymphoid tissue of the pharynx has been shown to be a primary site of infection, with subsequent blood-borne spread to major organs and lymph nodes. Thereafter, until 60 to 90 days of pregnancy, the site of *Chlamydial* persistence has not been ascertained and, although infection of the placentae and fetuses occurred from 60 days gestation, pathological changes were not observed until after day 90. Rapid replication of *C. abortus* leads to local necrosis and contiguous spread of infection involving the cotyledonary and intercotyledonary placenta and apposing endometrium, resulting in abortion that usually occurs in the last 2 weeks of pregnancy. The macroscopic signs of a placentitis are similar to that after *Brucella abortus* infection in cattle. The intercotyledonary allantochorion is oedematous, thickened, and leathery in appearance; there is degeneration and necrosis of the fetal cotyledons and a thick yellow deposit on the chorion.

Those ewes that are infected late in pregnancy do not abort until the next pregnancy. In split lambing flocks, late lambing ewes may acquire infection from infected ewes in the earlier lambing flock and abort in the same season. Infected brought-in sheep may abort in the first year, spreading infection at lambing time to susceptible ewes and lambs, resulting in an abortion storm the next year.

Most aborted lambs are well developed, fresh, and show no autolytic changes, indicative of recent death in utero; some infected ewes may produce both dead and live lambs. However, lambs born alive may be weak, fail to survive, and, in spite of good nursing, contribute to the overall losses from EAE. A small number of ewes may develop postabortion metritis. Abortion rates vary from 5% to 30%, the upper level most likely to occur in the first or second year after the introduction of infection, and thereafter at a rate of 5% to 10%. However, these figures do not take into account lamb losses in the neonatal period, which may be as high as 25% (Greig 1996).

Although rams can become infected and may develop epididymitis, there is no evidence that they play any significant role in the transmission of EAE. In the UK, rams rarely run with ewes during lambing/abortion times and therefore are not exposed to *Chlamydial* infection.

Diagnosis

Clinical Signs. There are no premonitory signs of impending abortion. Ewes are not ill. However, a few ewes may show evidence of a vaginal discharge for several days beforehand and possibly behavioural changes. There may be abortions, premature lambs, weakly live lambs, and normal lambs with infected membranes. Ewes may retain fetal membranes leading to metritis, but no other clinical signs are seen.

Placental Lesions and Staining. The placenta is usually acutely inflamed, thickened, and necrosed showing typical signs of a placentitis (Fig. 29.1). Smears from infected intercotyledonary areas and the wet skin of the fetus can be stained by the modified Ziehl-Neelsen method to detect intracellular inclusion bodies, which occur as small, acid-fast cocci; they may be seen intracellularly as clumps or singularly scattered throughout the smear, and these may be confused with *Coxiella burnetii* organisms, which are larger.

Serology

The demonstration of specific *Chlamydia* antibody in fetal fluids or precolostral lamb serum with a fluorescent antibody test is specific evidence of *Chlamydia* infection.

The complement fixation test is the routine diagnostic test used, titres of at least 4/32 generally being accepted as positive. Paired samples should be taken at the time of abortion and 3 to 4 weeks postaborting; in positive ewes, samples show a significant rise in antibody titres. An enzyme-linked immunosorbent assay (ELISA) and indirect immunofluorescent antibody test are also available.

Treatment

Antibiotics, which will reduce rather than eliminate abortions, can be used in flocks with extended lambing seasons in the face of an epidemic outbreak in a previously uninfected flock. For the best results, treatment should be given as soon after 95 to 100 days of gestation as possible, at which time possible cases of placental

VetBooks.ir

• **Fig. 29.1** Ovine placenta infected with *C. abortus* showing evidence of acute placentitis and thickened and necrotic placentomes.

infection will have commenced. Long-acting oxytetracycline, at a dose of 20 mg/kg repeated every 10 to 14 days until lambing, has been used to arrest or retard the progress of the infection. This treatment will reduce the number of organisms shed but does not eliminate infection, nor can it reverse pathological changes already present in a heavily infected placenta; hence some abortions will still occur despite treatment. It must be emphasised that in flocks with a history of EAE or at high risk of acquiring disease through purchased replacement ewes, the routine, prophylactic antibiotic use for the control of the disease is neither appropriate nor responsible use of antibiotic agents when highly effective vaccines are available and economical.

Control

Live attenuated vaccines are very successful in preventing disease and should be regarded as the preferred means of control in flocks with endemic disease in which the early vaccination of uninfected female replacements over the generational cycle of the flock will eradicate the disease in many cases. Vaccinated ewes will have lower titres with no evidence of a rise and have occasionally been associated with abortion due to the vaccine stain potentially due to reversion to virulence; however, these cases are believed to be exceptionally rare.

Ewes that have been infected do not develop positive titres until after they have aborted, thus it is not possible to screen a flock for a latent infection. Protection by vaccination, using either Enzovac (Intervet UK) or Cevac Chlamydia (Ceva), both of which contain a temperature-sensitive strain of *C. abortus*; thus both require a 2-month time interval after vaccination before they have developed protective antibody levels. Vaccination can be used from 5 months of age, and also in older animals between 1 and 4 months pretupping. The vaccine will protect lambs from transplacental infection. High-risk flocks, i.e., those who source replacement sheep from nonaccredited flocks, should have vaccination repeated yearly or biannually. An inactive preparation, Mydiavac (Novartis UK Ltd), has also been developed, and experimental data indicates that it may reduce the level of abortion in previously infected ewes during an outbreak of infection.

Biosecurity and Biocontainment of Infection Risk

Strenuous efforts must be made to prevent infectious abortion agents from gaining entry using the following management strategies:

- Maintain a closed flock and purchase rams from known sources, or purchase replacements from EAE-monitored flocks.
- Purchased ewes should be lambed separately from the indigenous flock in the first year, and all abortions and barren ewes should be investigated.
- Isolate for up to 3 weeks, and mark all ewes that abort.
- Send further dead lambs and membranes to a laboratory for diagnosis as more than one cause of abortion may be present in the flock.
- Reduce risk of spread to other ewes.
- Dispose of dead lambs and membranes not needed for diagnosis.
- Clean lambing area and cover with clean straw.
- Discourage use of ewes to foster lambs as infection may be picked up from vaginal discharges and infected fleeces. If lambs are fostered they should not be used for breeding.

Zoonotic Risks

C. abortus from sheep can be extremely dangerous to pregnant women, growing rapidly in the unborn baby's placenta. Initial mild, influenza-like symptoms become progressively more severe, and abortion occurs within a week. Disseminated intravascular coagulation may develop in the mother, causing critical illness.

Toxoplasmosis

Toxoplasma gondii infection is the second most common cause of abortion in the UK and also in New Zealand; it has been shown to cause early embryonic mortality, abortion, stillbirths, and weakly offspring in many domestic species, including sheep, and has a worldwide distribution in animals and humans. Infection in nonpregnant sheep is typically mild and unapparent, but in pregnancy, it is essentially a disease of the conceptus and the gestational age at infection affects the nature of the disease process.

The causal organism has a complex life cycle, involving an asexual cycle that can occur in any species of mammal or bird and a sexual cycle that can only be completed in cats and wild Felidae. In the cat family, the parasite multiplies within the epithelial cells of the intestine, and as a consequence, oocysts will be excreted in the faeces for about 8 days, during which time tens of thousands of oocysts can be shed. These sporulate within a few days and are then ingested by sheep.

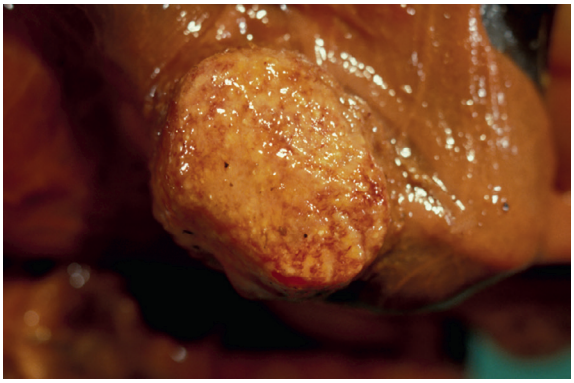
Epidemiology

The principal vector in the spread of toxoplasmosis is the cat and its related wild species. Infective toxoplasma oocysts may survive up to 2 years on pasture, feed, or bedding. They are passed in the faeces of young cats, which become infected when they first begin to hunt. Although toxoplasms have been demonstrated in the semen of experimentally and naturally infected rams, infection of the ewe at tupping would be unlikely to cause abortion. Toxoplasms can also be passed in milk during acute infections. Lateral spread within a flock from aborting ewes is likely to be relatively unimportant. However, lambs born alive that survive from infected ewes can be congenitally infected. As few as 200 oocysts will infect one ewe, and as many as 1 million may be present in 1 g of cat faeces. Once ingested sporozoites are released, they penetrate the intestines and are distributed to many organs, where tissue cysts form; a febrile response occurs after 5 to 12 days in conjunction with a parasitaemia. Toxoplasma can be detected in the uterine caruncular septa 10 days after oocyst ingestion and in placental trophoblast cells after 10 to 15 days; toxoplasma-specific fetal antibody is present after 30 days.

After infection, sheep are considered to remain persistently infected for life, to be immune to the parasite, and therefore unlikely

VetBooks.ir

• **Fig. 29.2** Mummified ovine fetus surrounded by fetal membranes showing cotyledons associated with infection with *T. gondii*.



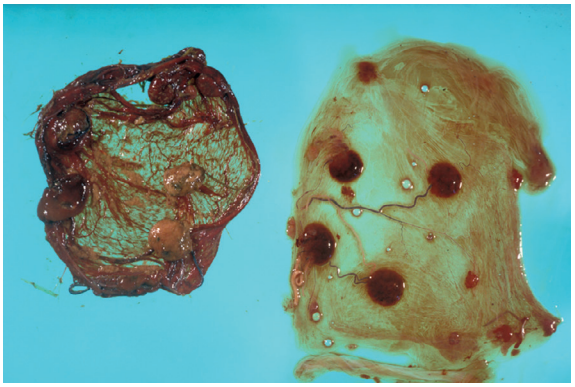
• **Fig. 29.3** Ovine cotyledon infected with *T. gondii* showing the typical 'frosted strawberry' appearance.

to abort again with toxoplasmosis (Buxton et al. 2006). However, it has been reported that a small proportion of persistently infected ewes may, in subsequent pregnancies, transmit toxoplasms to the fetus and abort; it has been suggested by Duncanson et al. (2001) that this may be due to a recrudescence in the ewe, causing a vertical transmission to the fetus. More research work is necessary to confirm this.

Clinical Signs

The effect upon reproduction depends on the stage of pregnancy when infection occurs. If early in gestation, i.e., before 60 to 70 days, fetal resorption usually occurs, with ewes returning to oestrus or remaining barren. Unlike the case with EAE, numerous barren ewes that have not been seen to abort may be detected in the flock at scanning or lambing time. With early embryonic mortality, providing a ram is still present and the breeding season has not ended, ewes are capable of conceiving, now with a good immunity. Infection in midgestation results in abortion or mummification; in the latter case, only one member of a set of twins or triplets may be involved (Fig. 29.2). Infection after 120 days usually results in stillbirth, or weakly or normal lambs.

The gross appearance of the placenta, particularly the cotyledons, is fairly typical of the disease. Cotyledons are bright to dark red with multiple small white necrotic foci 1 to 3 mm in diameter (so called 'frosted strawberries') (Fig. 29.3). These nodules may be sparse or so numerous that they become confluent; sometimes normal cotyledons are present. The intercotyledonary areas of the allantochorion appear normal (unlike infection with *C. abortus*) (Fig. 29.4).



• **Fig. 29.4** Photograph of normal allantochorion *(right)* and one infected with *T. gondii (left)*. Note that although the cotyledons appear different, the intercotyledonary allantochorion is similar in both specimens: clear and transparent.

Diagnosis

The condition is characterised by barren ewes, abortions, stillbirths, and mummified and weakly lambs. The appearance of the placenta is diagnostic.

Confirmation can be made using Giemsa- or Leishmann-stained smears of those cotyledons containing the white nodules. Alternatively, histological sections of the cotyledons may be required to demonstrate the presence of the parasite. Examination of the brain, especially in those lambs that die soon after birth, may reveal foci of glial cells and leukoencephalomalacia, which are characteristic of the infection. Immunofluorescent staining of cotyledon sections can also be used.

A number of satisfactory serological tests on the maternal serum have been used including the dye test of Sabin and Feldman, the indirect fluorescent antibody (IFA) test, radioimmunoassay, and the ELISA test. The ELISA test has been modified to detect anti-*Toxoplasma* immunoglobulin G (IgG) in body fluids. The indirect haemagglutination test (IHA) has been developed so that kits are available for use by veterinarians in practice laboratories. A single serum sample with an elevated titre may well only indicate past infection. However, serology of ewes is difficult to interpret as antibodies remain elevated for years. Paired samples may prove beneficial; when retaken after a 14-day interval, a rising titre is indicative of an active infection. Infected lambs will have precolostral antibodies, and serology can be performed on pleural, pericardial or peritoneal fetal fluids, or lamb serum. If postcolostral samples only are available, it is necessary to demonstrate IgM and IgG antibody.

Treatment and Control

Although there is virtually no danger of lateral spread from aborting ewes, isolation in the early stages of an abortion outbreak should be implemented because there is a possibility that other infectious agents may also be present.

Ewes that have aborted will be immune (see previous mention of possible recrudescence) and should be retained in the flock, and new additions should be exposed to possible infection with oocysts from contaminated food or bedding as early as possible before the start of the breeding season.

An effective vaccine (Toxovax, Intervet, UK) has been developed using living tachyzoites of the S48 strain of *T. gondii* (Buxton et al. 1991). Ewe lambs should be vaccinated from 5 months of age, and ewes and shearlings should be vaccinated during the 4-month period before tupping; pregnant animals must not be vaccinated. Recent

VetBooks.ir

studies show that the degree of protection produced by the S48 tachyzoites was as good at 18 months as 6 months after vaccination. The manufacturers state that other live vaccines should not be administered within 4 weeks of the administration of Toxovax.

Decoquinate, the anticoccidial drug fed daily at 2 mg/kg body weight, also significantly reduces the effect of *T. gondii* oocysts ingested by pregnant sheep and is licensed in the UK for this use. Both these products work best if they are being fed at the time sheep encounter infection rather than after infection has been established (Buxton et al. 1996). However, due to the nature of flock management systems and the difficulty and expense of incorporating decoquinate into a feed stuff that reliably delivers the required dose to every sheep, it is seldom if ever practical or preferable to use this approach as an alternative to vaccination.

Transmission and Pathogenesis

Without doubt, the principal vector in the spread of toxoplasmosis is the cat and its related wild species. They excrete oocysts in their faeces and contaminate pasture, forage, and other foodstuffs. Young cats and older breeding cats are the main problem. Old neutered cats on a farm are helpful, not only in reducing levels of vermin but in keeping feral cats away. Foodstuffs should be protected from faecal contamination by cats. Wild rodents, especially mice, are the main source of infection for cats.

Infection of ewes outside pregnancy produces a good immunity. Replacement ewes should be exposed to the farm environment as soon as possible after purchase so that they can ingest oocysts and acquire immunity before tupping (see previous section).

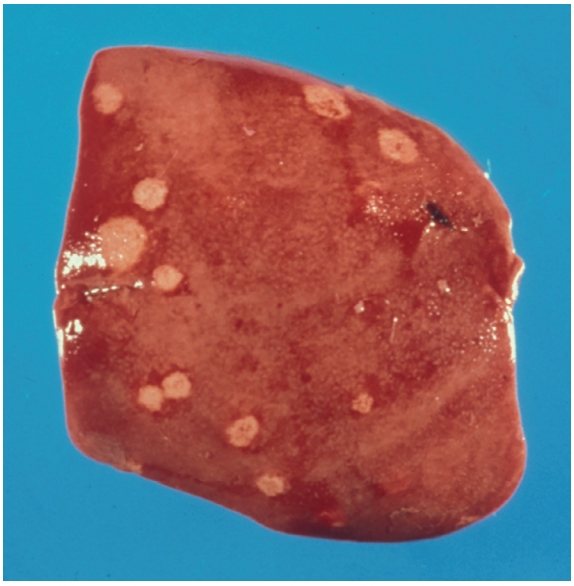
Toxoplasma gondii can affect humans but usually does not cause clinical disease. The exceptions are women who become infected for the first time during pregnancy. Placental and fetal infection results in severe damage to the unborn child. Other people at risk are those who are immunosuppressed, and they, like pregnant women, should not assist at lambing time.

Campylobacteriosis

Campylobacter is the third most common cause of abortion in the UK and the most common cause in New Zealand; both *C. fetus fetus* and *C. jejuni* cause abortion in ewes, the former being the most commonly isolated organism.

Epidemiology

Infected, and often symptomless, animals excrete these organisms in faeces. *C. jejuni* is mainly from a wildlife source and *C. fetus fetus* from carrier sheep. Unlike in cattle, in which the route of infection is mainly venereal, in sheep it is by ingestion and mainly intestinal. Once abortions occur, there is lateral spread to other susceptible pregnant ewes. The organism survives well in cold, moist conditions but soon perishes in hot, dry weather. The only clinical signs of the disease are abortion, usually in the last 6 weeks of gestation; lambs at full term may be born dead or in a weak condition. Apart from some vulvar swelling and the presence of a reddish-coloured vulvar discharge, ewes rarely show any other clinical signs. Metritis may develop after abortion, with some ewes becoming ill and even dying. Aborted material is infective. Ewes infected less than 3 months into pregnancy are not affected. If ewes are infected more than 3 months into pregnancy, a bacteraemia develops, with placentitis being the main lesion. In late pregnancy, abortion occurs between 1 and 3 weeks after infection. Flocks infected for the first time may have levels of abortion varying from 5% to 50%. There is a strong immunity after infection, but this is serotype specific. Symptomless carriers may excrete the organism for up to 18 months. In the UK, the disease dynamic appears to follow a national 4 to 7 year cycle in which campylobacteriosis alternates between being the second most commonly identified infectious abortion agent behind *C. abortus,* and low prevalence years in which it may lie fourth behind toxoplasmosis and listeriosis (VIDA surveillance data from Animal and Plant Health Agency, APHA). This pattern suggests a possible climatic effect increasing the relative risk of infection between farms as well as within a farm, dynamic susceptible population flux over time as previously infected individuals are culled and replaced with naïve individuals as part of the normal production cycle.



• **Fig. 29.5** Ovine fetal liver showing the characteristic circumscribed grey necrotic foci.

Diagnosis

- There are signs of placentitis with oedema and necrosis of the fetal cotyledons; the intercotyledonary membrane is oedematous, hyperaemic, and slightly opaque. However, these lesions are not pathognomonic. The aborted fetus looks fresh, with no specific visible gross pathology; however, in approximately 25% of the aborted fetuses, there are characteristic circumscribed, grey, necrotic foci in the liver (Fig. 29.5), 10 to 20 mm in diameter (Dennis 1991).
- Disease is most common in young ewes or older ewes that have lost their immunity.
- The organism can be identified in Gram- or modified Ziehl-Neelsen-stained smears from the placenta and fetal stomach contents and cultured from the placenta, fetal stomach, or liver.
- Serology is not useful.

Treatment and Control

- As soon as campylobacteriosis is suspected, aborting ewes should be isolated from pregnant ewes.
- Dispose of aborted materials as the disease is zoonotic. Avoid infecting sheep over 3 months in lamb or wildlife that can later act as reservoirs of infection.
- When campylobacteriosis has been confirmed, mix aborted ewes with those already lambed to stimulate production of a

VetBooks.ir

strong immunity. The disease is self-limiting, and most ewes from an infected flock acquire an immunity in the first year, irrespective of whether or not they have aborted. This acquired immunity lasts about 3 years in most circumstances, equal to the expected breeding life of the ewe.
- Turn over feed troughs, preventing birds from feeding at them.
- Try to keep the flock closed. Brought-in ewes should be mixed with the resident sheep for as long as possible before midpregnancy, then separated in late pregnancy and lambed separately.

In the US, New Zealand, Australasia, and Europe, a formalin-killed adjuvant vaccine incorporating the most prevalent serotypes (Campvax4, MSD) is commonly used. There is some evidence that, in the early stages of an outbreak of campylobacteriosis in a flock, vaccination of all remaining pregnant ewes might be worthwhile. Because there is a 10- to 14-day delay before immunity develops after vaccination, early diagnosis is imperative. In New Zealand, campylobacteriosis is the most important abortion agent; 88% of sheep farms are suspected to be infected and use of the multivalent vaccine for the four most prevalent fetus serotypes has been suggested to increase lambing rates by an average of 9%. There is considerable debate in the UK over the potential usefulness of this vaccine. This is because the serotype distribution differs from that found in NZ, abortion outbreaks are less common and flock prevalence is thought to be lower. Currently the vaccine is not licensed in the UK but is imported on special license for use in some flocks.

Listeriosis

Listeria has a worldwide distribution in several domestic species, especially ruminants, and is the fourth most common diagnosed cause of ovine abortions in the UK. Two species and multiple strains of *Listeria* produce disease in sheep, *L. monocytogenes* and *L. ivanovii,* and the disease may be presented in one or more of the following forms, relating to the strain of the bacteria involved:
- Encephalitis
- Abortion
- Diarrhoea and septicaemia
- Keratoconjunctivitis, iritis, and mastitis
- Septicaemia and death in young lambs
- Chronic mastitis

The incidence of listeriosis has increased in the UK in recent years, with encephalitis being the most common form. Neurological signs characteristic of listerial encephalitis are circling with evidence of unilateral facial paralysis, head tilting, and turning. Abortions in sheep are produced by both *L. monocytogenes* and *L. ivanovii,* and although they may occur at any stage, they are most frequent in late pregnancy. Initially, sheep may be pyrexic. There are no distinguishing characteristics to the abortion and usually no typical complications after expulsion of the fetus, which may be autolysed. Weakly lambs are often born, and grey/white miliary foci of necrosis may be seen in the fetal liver (so-called 'sawdust liver'). The placental villi are necrotic, and the chorion is covered with a brownish red exudate; there is a heavy brown vaginal discharge, and rarely death of the ewe occurs from metritis or septicaemia. It is rare for the nervous disease and abortions to occur together. Abortions under field conditions have been reported as soon as 7 days after the feeding of suspect silage.

Transmission and Pathogenesis

L. monocytogenes is ubiquitous, frequently found in soil but also isolated from foodstuffs and faeces of healthy animals. Soil is the most likely source of infection, principally after the feeding of soil-contaminated baled silage when poor fermentation conditions promote bacterial multiplication. Sheep are probably frequently exposed to infection, but presumably it requires some other factors to precipitate clinical listeriosis. After ingestion in late pregnancy, the organism penetrates the gut mucosa and infects the fetus, causing a septicaemia and placentitis, both of which may kill the fetal lamb. As a consequence, abortion occurs.

Diagnosis

Diagnosis is based on isolation of the organism from vaginal swabs, fetal membranes or the fetus, and fetal liver lesions. Fluorescent antibody techniques have also been used for diagnosis.

Treatment

Penicillin and amoxicillin are the most appropriate and commonly prescribed antibiotics for listeriosis. However, the promptness of treatment is critical in order to achieve clinical recovery in neurological cases. Abortion cases rarely show systemic signs in the ewe before the abortion, and the prevalence of disease during an outbreak seldom justifies the prophylactic treatment of the whole group or flock, unlike cases of EAE outbreaks.

Control

The incidence of listeriosis in all its forms has increased dramatically with the practice of feeding silage to sheep, especially that stored in round bales. In a survey carried out in Scotland, *L. monocytogenes* was isolated from 2.5% and 5.9% of clamp silage examined in 1983 and 1984 respectively, and from 22% and 4% samples of big bale silage. A more recent survey in Scotland showed that 10% of flocks had cases of listeriosis, and 80% of these were fed silage (Martin & Aitken 2000).

Attempts should be made during silage production to develop conditions that are not favourable for the multiplication of the organisms.
- Use additives to reduce the pH of the silage; make high-quality silage with a pH below 5, avoiding gross soil contamination (when the ash content exceeds 70 mg/kg dry matter), i.e., avoid mole hills and having forage harvesters set too low.
- Compact and seal silage the same day as made, making sure that round bales are securely tied and not punctured.
- Avoid feeding obviously mouldy or poor quality silage that can be smelled or has come from the top or sides of the pit.
- Remove any silage that has not been eaten by sheep after 48 hours.
- On farms where listeriosis occurs annually, it would be advisable not to graze any fields with livestock that are intended for silage making.

Listeriosis also has zoonotic implications.

Border Disease

This disease was first recognised in flocks along the English–Welsh border in the 1950s (Hughes et al. 1959), affecting newborn lambs that showed neurological symptoms such as tremor and a coarse fleece (so-called 'hairy shakers') and were generally weak with a high mortality rate. Since then, it has been recognised throughout the northern and southern hemisphere. It has also been shown to cause reproductive failure and may initially present as an unexpectedly high return to oestrus rate (identified by raddle marking) or as a high empty rate at ultrasound pregnancy diagnosis.

VetBooks.ir

Aetiology
The disease is due to infection with a pestivirus similar to that which causes bovine viral diarrhoea (BVD) in cattle and European swine fever.

Clinical Signs
The clinical signs in lambs are well documented elsewhere, so called 'hairy shakers' or 'fuzzy lambs' (Nettleton 1990). In adult ewes, infection results in a mild pyrexia that would probably go undiagnosed. However if ewes have been mated, the subsequent pyrexia may reduce conception rates and increase the risk of embryonic or fetal death, with subsequent mummification, abortion, or the birth of weakly lambs. Abortion can occur at any stage of gestation, although it is most common around 90 days with the voiding of a brown, mummified or swollen anasarcous fetus. The conceptus is most susceptible to experimental infection within the first 60 days of gestation, and if infection occurs at an early stage, the only clinical sign will be barrenness. The fetus becomes responsive to antigenic stimuli between Days 60 to 80 of gestation, after which other signs may become detectable in the lambs (Nettleton 1990).

Diagnosis
This can be made on clinical signs in lambs, supported by histopathological examination of the brain and spinal cord, virus isolation from the lamb, or a fluorescent antibody staining technique. Usually, there are no gross lesions detected in the placenta. Serological tests on ewes that abort or are barren have to be examined in relation to the antibody levels present in other ewes in the flock.

Transmission
The most likely source of infection is from either transiently or persistently infected individuals. The common route is via the purchases of female replacements from an infected flock that are then mixed with the existing naïve flock at or before mating, resulting in ongoing transmission during the mating/gestation period. Transiently infected individuals are those which have been infected by the virus and are viremic and infectious for a period of days or weeks before establishing a neutralising immune response and clearing the infection. Persistently infected (PI) animals are those infected *in utero* before the development of a functioning immune systems, where the virus is then misrecognised as 'self'. Thereafter, these animals never raise an antibody response to the infection and are continuously viremic. PI's are a particular risk as they continuously excrete virus although they may appear healthy (important to recognise that not all 'hairy shakers' are PI's and not all PI's are 'hairy shakers'). Although PI's are likely to have reduced fertility, they can give birth to infected progeny that themselves are a source of infection. However, PI's are generally present in only small numbers 0% to 2% of a lamb crop, so the importance of transiently infected individuals in a large group of mixed exposure can lead to 'rolling' transmission that maintains a source of infection for some indeterminate time until sufficient proportion of the flock is exposed and naturally immune to prevent further transmission. Some ram lambs can excrete the virus in their semen, and they may have poor fertility associated with small, soft testes. However, high value rams of perfectly normal appearance can be both transiently and persistently infected and should be quarantined and tested before use.

Pestiviruses from other species can also, under experimental conditions, cause border disease in sheep so that, among domestic animals – cattle in particular but also goats – represent potential sources of infection. Carlsson (1991) reported two natural outbreaks of border disease in which sheep were housed in close confinement with calves persistently infected with noncytoplasmic BVD virus.

Treatment and Control
There is no treatment, and as yet, there is no commercially available vaccine, although one may become available eventually. The disease is best controlled by ensuring that the flock remains closed, and hence the disease does not gain entry. Once it is present in a flock, it is important in the early stages of the outbreak to attempt to segregate pregnant ewes from those that have given birth to clinically affected lambs. At the same time, to ensure that nonpregnant ewes develop an immunity, they should be exposed to infection before the next mating period, and thereafter, any surviving lambs from the infected flock should not be retained for breeding and should be sent for slaughter, so that symptomless carriers do not remain.

Salmonellosis
Several serotypes cause ovine abortion, including *Salmonella abortus ovis, S. typhimurium, S. dublin,* and *S. montevideo.* Occasionally, exotic strains have been isolated, often associated with imported foreign protein.

Epidemiology
Many species of animal, including humans, may act as sources of infection, which may result in early pregnancy in barren ewes and in late pregnancy in abortions, and dead and weak lambs. Depending on the serotype, affected ewes may become ill and losses may be catastrophic in both ewes and lambs; meanwhile, those that recover may act as symptomless carriers.

Clinical Signs
These will vary with the serotype of organism and are summarised here.

Salmonella Abortus Ovis. This is a host-specific strain, once common in the southwest of England but now rarely isolated. Few systemic clinical signs occur in ewes other than abortion, which usually occurs in the last 6 weeks of pregnancy. Two distinct clinical pictures may be observed in the lambs:

- They may be born weak and die within a few hours of birth.
- They may be born healthy, suddenly become ill, and die in the first 10 days of life.

Salmonella Montevideo. This strain has been a problem in southeast Scotland for several years. Apart from abortion, there has been little evidence of systemic illness. During the severe winter of 1982, an abortion rate of 10.1% was noted in 11,500 breeding ewes. Severe weather with prolonged cold stress necessitated close congregation of these sheep for the early provision of foodstuffs. These arrangements may have compounded the problem and led to water courses being polluted, resulting in animals downstream becoming infected. However, it was eventually thought that seabirds had a major part to play. The disease is not as severe as cases of *S. typhimurium* and *S. dublin* infection, and diarrhoea is not a feature in lambs born alive (Linklater 1983).

Salmonella Typhimurium. The clinical picture in the ewe is totally different from those previously described. Anorexia, pyrexia

VetBooks.ir

(up to 41°C, or 106°F), and profuse scour are usual. A foul smelling vaginal discharge may be present. Death may occur from septicaemia or dehydration in 6 to 9 days. Lambs may be born dead, and those that are born alive may show signs of severe illness with diarrhoea and a high mortality rate. Severe losses among the ewes are not unusual. Numerous observers have commented that the disease often follows times of stress, e.g., after gathering, winter shearing, housing, and vaccination.

Salmonella Dublin. The clinical signs are not normally as severe in both ewes and lambs as with *S. typhimurium* infection. Death is usually from septicaemia or dehydration, and mortality rates are usually much lower.

Diagnosis

It is important to stress that *Salmonella* strains, other than *S. abortus ovis,* are zoonoses; hence care should be exercised when dealing with infected material.

- The clinical picture is that of scouring and pyrexic ewes. Before or in association with abortion, a foul smelling vaginal discharge may be present.
- Lambs born alive may become ill with fatal septicaemia or pneumonia, especially in cases of *S. typhimurium* and *S. dublin* infection.
- Identification of the organism follows culture of fetal stomach contents, placental tissue, or vaginal discharges. In addition, fluorescent antibody techniques may also be used for the rapid diagnosis of organisms in the same tissues.
- Serological tests can be used to diagnose infection with *S. abortus ovis.*

Transmission and Pathogenesis

S. abortus ovis is host specific and is usually introduced into a flock by infected sheep. Other strains of *Salmonella* are not host specific and can be introduced through contaminated food, water, wild birds, or other infected livestock. Once the disease has become established, it will readily spread by ingestion of contaminated bedding, food, or water. There is always a danger that symptomless carriers may remain in the flock, providing a persistent reservoir of infection.

S. montevideo appears to have a predilection for sheep and could become endemic in the sheep population of the UK. It has been isolated from mesenteric lymph nodes of sheep at abattoirs all the year round, and thus the carryover of infection from year to year can occur in sheep themselves.

Treatment and Control

A number of general principles have been suggested for the control of *S. montevideo* that are applicable to other *Salmonella* strains:

- Isolate affected sheep that have aborted, or scoured profusely, and treat with an antibiotic to which the salmonellae are sensitive, thus limiting excretion of the organism.
- Keep aborted ewes separate from those yet to lamb.
- If birds are possibly the source of infection, turn over feed troughs when not in use; regularly change the feeding area and avoid feeding on the ground.
- Avoid stress situations arising within the flock, such as frequent moving, and make sure that foodstuffs are freely available with sufficient trough space to avoid competitiveness.
- Try to prevent sheep drinking from streams and open ditches by using piped fresh water.

Brucellosis

Sheep can be infected with both *Brucella melitensis* and *B. ovis.* The former is endemic in many Mediterranean countries, Africa, and Central America; it does not occur in the UK. The latter has been reported in parts of eastern Europe, South Africa, western states of the US, New Zealand, and Australia; it does not occur in the UK.

B. melitensis is primarily a disease of sheep and goats but can affect other species, including man (Malta fever). Transmission is by direct ingestion of the products of abortion or drinking infected milk. It causes abortions, stillbirths, or weak lambs in late pregnancy. The placental lesions are similar to those identified with *B. abortus* infection in cattle, and diagnosis is by direct examination or culture of placental smears, fetal stomach contents, or vaginal discharges. Serological tests, such as the complement fixation test, are used. The disease can be controlled by using *B. melitensis* or *B. abortus* S19 vaccines.

B. ovis's main effect is upon the ram, in which it causes an epididymitis and subsequent infertility or sterility (see Chapter 36). After experimental infection of the ewe, the organism causes a placentitis followed later in gestation by abortion or the birth of small weak lambs. However, under field conditions, abortion rarely occurs. Although a ram can be infected after serving a ewe previously served by an infected ram, the ewes themselves are not infected venereally. The method of infection of ewes is not fully understood. Until recently, it was thought that *B. ovis* was host specific; however, infection has been discovered in stags showing similar clinical signs to those seen in rams. Stags contract infection from infected rams or other infected stags (Ridler 2002).

Q Fever

This is due to infection with the rickettsia, *Coxiella burnetii.* Although of little significance in sheep farming, it has been associated with a small number of outbreaks of ovine abortion in the UK, although recent seroprevalence surveillance results estimate 1.0% of sheep are seropositive, between-flock prevalence of 10.2%, and within flock prevalence of 10.2% (Scottish Government, AHDA, VIDA 2008–2015). Its main importance is its public health implications, producing influenza-like symptoms, pneumonia, and cardiac lesions in humans, and thus it is important that the agent is recognised when fetal material is examined to avoid the possibility of human infection. Microscopically, it may easily be mistaken for *B. abortus* or *C. abortus.*

Placenta and vaginal discharges are heavily contaminated, allowing spread of infection at parturition or later by aerosol from the fleece or dust in the lambing area, acting as a source for human infection.

Tick-Borne Fever

This is limited to those areas where the sheep tick *Ixodesricinus* occurs because almost all ticks harbour the infective agent *Anaplasmaphagocytophilum.* The disease is known in the southwest of England, Scotland, Scandinavia, the Netherlands, and South Africa. Abortion in adult sheep previously unexposed to ticks occurs naturally after tick-borne fever infection in late pregnancy, usually 2 to 8 days after the commencement of a fever, which can be as high as 41-42°C (107°F). A proportion of pregnant ewes may die. Some fetuses may die *in utero,* become mummified, and be expelled weeks later. Recovery in nonpregnant ewes is generally uneventful.

VetBooks.ir

Diagnosis
Diagnosis can be confirmed by identifying the organism in the leucocytes of ewes that have aborted or during the septicaemic phase.

Treatment
Oxytetracycline can be used for the rest of the naive flock in the face of an outbreak.

Control
Infected ewes that survive develop an immunity; the majority of all sheep from tick-infected areas will have acquired an immunity at an early age. Newly purchased nonacclimatised sheep should be introduced to farms before tupping, preferably when tick numbers are at their highest. Ticks can also be controlled by adopting the appropriate dipping routine.

It is noteworthy that rams during the breeding season, when exposed to tick-borne fever for the first time, can have reduced fertility for several months due to poor sperm quality.

Bluetongue
The bluetongue virus (BTV) appears to have originated on the African continent, where it had adapted itself to both vertebrate and invertebrate hosts, and for many years it was accepted that it was confined to the central African continent (Bruere & West 1993). However, spread occurred to the north African countries surrounding the Mediterranean and into Cyprus and Turkey in the mid-1940s. Bluetongue was first diagnosed in Texas in 1948, and by 1960 it was present in 11 of the states of the US, where it was detected in cattle, sheep, goats, and wild ruminants (Bruere & West 1993).

It was first recognised in Europe in 1956, being seen in both sheep and cattle first in Portugal and then Spain. In the late summer and autumn of 2006, outbreaks of bluetongue in sheep and cattle occurred in northwest Europe. A total of 2056 cases were reported up to January, 2007; in September, 2007, the disease was reported for the first time in the UK. Bluetongue is caused by the bluetongue virus (BTV), which is transmitted by the *Culicoides* midge; it affects all ruminants, especially sheep, in which the infection can be serious, as in some wild ruminants, e.g., whitetail deer. The northern European outbreak was caused by bluetongue virus serotype 8 (BTV-8), not previously detected in Europe, and the vector was the midge *Culicoidesdewulfi.* Interestingly, some European breeds of sheep are more susceptible to infection than other breeds. The disease has been seen in the Mediterranean countries of Europe for some time where the climate is warmer, and the vector midge is able to overwinter or the virus survives longer in the susceptible host (Elliott 2007). The most serious clinical signs and reproductive losses were experienced in Greece and the Balkans due to BTV-4.

Epidemiology
This is about the relationship between the bluetongue virus, the vector (the midge), and the ruminant host, the interaction and outcome of which is dependent on climatic factors, especially temperature. Bluetongue does not spread by direct contact and is only spread by certain species of the biting midge (Elliott 2007). It is also possible that the virus may be transmitted by using the same needle on a flock of sheep during vaccination procedures. Cattle are important in the epidemiology of the disease, the main reservoir of infection, and may remain viraemic for up to 100 days.

Clinical
Signs are due to widespread damage of the endothelium of blood vessels; pyrexia occurs, lameness due to haemorrhages in the coronary band, and salivation due to hyperaemia of the muzzle, tongue, and buccal mucosa; purple-blue discoloration of the tongue may be seen, hence the disease name of bluetongue. Mortality rates are generally low – less than 5% – although very rare instances of high mortality higher than 50% have been reported. Morbidity is high, with transient period of pyrexia, inappetance, and lethargy, Poor conception rate may be seen, and reproductive losses may occur in pregnant sheep with early embryonic mortality, abortion, mummification, and the birth of stillborn or deformed lambs that may be blind and unable to stand. Milk yield is reduced; rams may be temporarily infertile.

No specific treatment is available, and it has to be symptomatic. Immunity after natural infection appears to be enduring but serotype specific, with little cross protection against other serotypes.

Diagnosis
Various serological tests are available to demonstrate antibodies to the virus; the virus can also be isolated from blood or lymphoid tissues.

Control
Serotype-specific vaccines have been developed, and their use in sheep has reduced morbidity and mortality.

Schmallenberg
In 2011 a novel orthobunyavirus, provisionally named Schmallenberg virus (SBV), was identified in Germany affecting cattle and shortly afterwards associated with an epizootic outbreak of congenital malformations, featuring an arthrogryposis hydranencephaly syndrome, in newborn lambs. In areas that reported congenital malformations due to SBV in France, a within-flock seroprevalence of 30% was detected. Between clinically affected and not clinically affected flocks, no significant differences in seroprevalences were found. Variable seroprevalence was confirmed in most European countries over the next 2 years reaching as high as 89% in the Netherlands. Transmission was via a range of midge hosts whose activity was highest during the warmer summer months, leading to the highest proportion of clinical signs being associated with early lambing flocks that were mated during the high transmission period. Late lambing flocks were exposed and derived some degree of protective immunity during this period and were not as susceptible to disease during their own subsequent pregnancy. However, data from the UK confirmed ongoing transmission throughout the winter (Davies et al. 2013), indicating that there was no true vector-free period, and reemergence of the virus during the autumn in a susceptible population could result in more widespread disease in the bulk of the national sheep flock. Wider reproductive effects of infection were investigated by Luttikholt et al. (2014), who identified an increased return to oestrous rate in infected flocks but no other significant reproductive effects such as abortion rate. The weaning rate of lambs per ewe encompasses all causes of reproductive and postnatal–lactational period losses, a 10% reduction associated with SBV diagnosis at a flock level was reported in Ireland during the epidemic outbreak (Barrett et al. 2015).

VetBooks.ir

Goats

In the absence of any major infectious cause of abortion, infertility in the goat is generally not a major problem, normally with only a small number of barren does remaining at the end of the breeding season.

Structural Defects

Abnormal sexual differentiation during embryological and fetal development, resulting in intersexes, is relatively common in the goat, especially in breeds such as the Alpine, Saanen, and Toggenburg. It is much more prevalent in polled individuals, in which 'polledness' is a simple dominant character with full penetrance but is also associated with a recessive hermaphrodite effect with incomplete penetrance. Intersexes can also occur as a result of freemartinism, in which placental fusion occurs in twins of dissimilar sex; examples of goat freemartinism have been reported. However, the incidence of hermaphroditism appears to be higher than that of freemartinism in this species; freemartinism in goats is much less common than in cattle (Jackson 2004).

Hermaphrodites that have been described in goats are mainly male pseudohermaphrodites, having testes and the accessory reproductive organs of the female; they are genetic females.

Intersexes vary in the degree of external structural abnormality. Most are generally female-like in appearance at birth, but as they grow and mature, there will be evidence of an enlarged clitoris, perhaps testes in the inguinal region, and the development of male secondary sex characteristics, including the typical male odour (see Chapter 9).

Functional Factors

The goat is a seasonal breeder responding to the effects of declining day length. It is not unusual to have irregular oestrous cycles at the beginning and end of the breeding season, especially in goatlings, with short cycles of between 5 and 7 days.

Anoestrus may be due to starvation, parasitism, or mineral deficiencies. In the case of the latter, phosphorus and the trace elements copper, iodine, and manganese as well as vitamin E have been implicated. It can also be influenced by chronic debilitating diseases.

Hydrometra or Pseudopregnancy ('Cloudburst')

Hydrometra is the accumulation of sterile secretions within the uterine lumen. The aetiology of the condition is not known precisely, but it is always associated with high progesterone levels secreted by a persistent functional corpus luteum (CL), cessation of cyclical activity, and variable degrees of abdominal distension. The incidence of the disease varies between herds and within the same herd from year to year. Studies involving 71 dairy herds in France found an overall incidence of 2% to 3% (Mialot et al. 1991), although on one farm in the study it was 20%. In Holland, Hesselink (1993a) found a mean incidence in three herds, totalling 550 does, of 9%. The disease occurs more frequently in older does and is uncommon in yearlings. A more recent study in the UK (Griffiths et al. 2006) detected an overall incidence of 5.74% (511 cases out of 8906 does). Other findings were similar to those of Hesselink, the incidence in maiden females (0.94%) being much less than the incidence in adults (6.64%).

In Hesselink's study (1993b), there also appeared to be an association with the use of progestogen sponges and eCG treatment to advance the onset of cyclical activity before the start of the normal breeding season.

One possible cause of hydrometra is early embryonic loss. However, not all animals will have been mated by the buck before the development of pseudopregnancy.

Two types of pseudopregnancy occur:

- Fertilisation after mating is followed by early embryonic death, the CL persists, and the doe acts as if pregnant. The abdomen becomes enlarged, and in some there is a degree of udder development if not the onset of lactogenesis. Those that are lactating may have a fall in yield. This type of false pregnancy generally lasts for the duration of the gestation period or even longer, until the CL has regressed spontaneously. The term 'cloudburst' is used to describe the voiding of large volumes of fluid from the uterus as the pseudopregnancy is terminated. After this, the abdominal distension disappears; some does may search for the 'missing' kids.
- After oestrus, when the doe was not mated, there is cessation of cyclical ovarian activity, but there is no marked hydrometra. At the end of the period of acyclicity, affected does expel a bloody discharge. Therefore any unbred does that do not return to oestrus after their first oestrous cycle in the autumn should be treated with $PGF_{2\alpha}$ for possible pseudopregnancy.

Differentiation of hydrometra from normal pregnancy can be made using transabdominal B-mode ultrasound imaging, demonstrating the presence of a fluid-filled uterus in the absence of a fetus or placentomes. After 50 days of anoestrus, pregnancy and pseudopregnancy can be differentiated on the basis of serum oestronesulphate levels (see pregnancy diagnosis in goats in Chapter 5). Treatment with 2.5 mg $PGF_{2\alpha}$ will be followed by expulsion of the fluid, and oestrus will occur in approximately 4 days. By using a second injection 12 days after the first, good levels of fertility can be achieved with 85% conceiving, compared with 95% of unaffected animals (Hesselink 1993b).

Cystic Ovarian Disease

Lyngset (1968) found an incidence of 2.4% ovarian cysts at necropsy. Most were unilateral, single, and varied in size between 1.2 and 3.7 cm. Jackson (2004) quotes an abattoir survey in which cysts were seen in 12% of does examined, but the nature of the cysts and their progesterone contents were not known.

Cystic ovarian disease has been described in dairy breeds and has been particularly evident where they have grazed oestrogenic clovers and legumes. A history of nymphomania may suggest follicular degeneration, and the typical clinical signs are those of continuous oestrous and short interoestrous intervals with a failure to conceive. They should be treated with 1500 to 2500 IU of human chorionic gonadotrophin (hCG), gonadotrophin-releasing hormone (GnRH), or progesterone treatment for 18 days.

Abortion in Angora Goats

Abortion has been recognised as a problem in Angora goats in the Eastern Cape province of South Africa since the turn of the century, and it has reached such proportions as to threaten the viability of the mohair industry.

Recent studies have identified two types of abortion:

- The most common is a 'stress-induced' abortion, which occurs in poorly grown and immature does. The abortus is fresh and

VetBooks.ir

TABLE 29.2 Frequency of isolation of pathogens from sheep fetopathies recorded by APHA and Scotland's Rural College on diagnostic submissions in Great Britain

Abortion Diagnosis	2008	2009	2010	2011	2012	2013	2014	2015
Bacillus licheniformis	0%	0%	3%	0%	0%	0%	0%	2%

Yersinia spp.	0%	4%	0%	0%	0%	0%	0%	0%
Other diagnosis	0%	8%	0%	4%	4%	0%	0%	3%
Diagnosis not reached	65%	56%	71%	86%	76%	89%	68%	77%

may be born alive. This is the major type of abortion loss in production operations. High metabolic requirements for fibre production in the Angora predispose the breed to nutritional and other forms of stress to a greater degree than goats of other breeds. It has been suggested that hypoglycaemia in pregnant does stimulates the immature fetal adrenal to produce oestrogen precursors, which result in the placental synthesis of oestrogens and subsequent abortions; blood glucose concentrations are influenced by short-term interruptions in food intake. Most abortions occur between 90 and 120 days of gestation, at the time of rapid fetal growth. It may be seen as a storm 1 to 2 days after stress.

- 'Habitual abortion' is probably a genetically determined hyperactivity of the maternal adrenal cortex, prematurely initiating the process of parturition. Fetuses, which are usually born dead, are often oedematous. Habitual aborters should be culled, together with any live offspring that may have survived. Does abort in the absence of stress, and levels as high as 5% may occur in flocks that do not practise culling.

Management Factors

Timing of Service or Artificial Insemination

Optimum pregnancy rates are obtained when does are mated towards the end of oestrus (which lasts 12–36 hours) and just before ovulation. Some goat owners serve their does only in the first 12 hours of oestrus, supposedly to increase the number of female kids but with a consequential reduction in pregnancy rates.

Nutrition

Vitamin A, certain minerals (manganese and iodine), and energy deficiencies reduce fertility and may be associated with abortion when the deficiency is chronic.

Stress

Stress-induced abortion has been described previously in Angora goats. However, there is evidence that other breeds of goat will abort if subjected to stress. This can result from being chased by dogs, inadequate feeding, transportation, and adverse weather, particularly during the fourth month of gestation.

Infectious Agents

Nonspecific infections appear to play a minor role in causing infertility in does, probably for similar reasons discussed previously for the ewe. However, specific infectious agents are important in causing abortion. Unfortunately, little information on their relative importance in the UK is available. Many of these specific infectious agents are also important in sheep. A survey of diagnoses recorded at VLA Regional Laboratories in England and Wales and Disease Surveillance Centres in Scotland listing the infectious causes of goat fetopathy identified in material submitted to their laboratories from 2008 to 2015 is summarised in Table 29.2.

Brucellosis

Brucella melitensis is the organism most frequently involved and is endemic in many Mediterranean countries, Africa, and Central America; it does not occur in the UK. *B. abortus* has occasionally caused abortion, but *B. ovis* has not been isolated from goats.

B. melitensis causes abortion in late pregnancy, stillbirths, or weakly kids; after the first exposure, abortion may be in the form of a storm. Few abortions occur in other years, and some does may become sterile from uterine lesions. Kids may become infected from does' milk. The disease can be diagnosed by bacterial culture from the fetus, fetal membranes, or vaginal discharges and can be controlled by routine vaccination. It is important to remember that *B. melitensis* is a zoonosis.

Campylobacteriosis

This is uncommon. It is caused by infection with *Campylobacter spp.,* probably *C. jejuni* and possibly *C. fetus fetus.* Does may or may not show evidence of a systemic illness and may abort in late gestation or produce stillborn or weakly kids and have a postabortion muco- or sanguinopurulent discharge. Multiple

VetBooks.ir

necrotic foci up to 2 mm in diameter may be seen in the liver of the aborted kids. Diagnosis, treatment, and control are similar to those described for sheep.

Chlamydophila *(Enzootic) Abortion*

This is an important cause of infertility in goats in many countries and is the most common cause of infectious goat abortion in the US. Infection is due to *Chlamydophila abortus,* which is similar to, or identical with, the strain responsible for enzootic abortion in sheep.

Abortions usually occur in the last 4 weeks of gestation, with levels as high as 25% to 60% in does kidding for the first time; stillborn and weakly kids can also occur.

Mathews (2007) states that a number of features different from those seen in sheep may be seen in goats:

- Abortion may occur at any time of pregnancy.
- Colonisation of the placenta may occur at any stage of pregnancy.
- From time of infection to abortion may be as little as 2 weeks.
- Vaginal secretions may occur as early as 9 days before abortion and last as long as 12 days after abortion.
- The doe may become ill with septicaemia and pneumonia postabortion.

Diagnosis and treatment are similar to those described previously for sheep. Does infected in late pregnancy usually abort during the subsequent pregnancy and can produce infected kids, which, after a latent phase, abort during their first pregnancy. The disease is best controlled by good hygiene to prevent lateral spread to susceptible animals, especially kids and young does, and the use of a vaccine, which has been made compulsory in some countries where the disease has become widespread. Enzovax, which is used in sheep, is not licensed for use in goats in the UK. *C. abortus* is a zoonosis.

Listeriosis

Encephalitis due to *Listeria monocytogenes* infection is quite common in goats. The same organism can cause abortion in late gestation or stillbirth. The does may show no signs before aborting but may develop a necrotic metritis and vaginal discharge shortly afterwards.

As in sheep and cattle, poorly fermented, soil-contaminated silage is a likely source of infection. The pathogenesis, diagnosis, treatment, and control are similar to those described for sheep.

Salmonellosis

There are no host-specific *Salmonella* species in the goat. However, the ubiquitous salmonellae have been reported to cause abortion.

Toxoplasmosis

Toxoplasma gondii is the most common cause of infectious goat abortion in the UK. It causes fetal death with resorption if infection occurs early in gestation, or abortion of kids, which may be stillborn, alive but weak, or normal, depending on the time in pregnancy that the doe was exposed to infection. However, unlike in sheep, fetal death is preceded in some cases by a period of severe illness with pyrexia, anorexia, diarrhoea, and muscle weakness. During an acute infection, toxoplasms may be excreted in the milk and be a source of human infection if the milk is drunk unpasteurised (Skinner et al. 1990). Also, experimentally at least, toxoplasms may be present in goat semen for a variable time after infection, but the epidemiological significance of this, as in sheep, may be very slight.

The placental lesions are very similar to those described in sheep. Diagnosis is dependent on identification of the organism in placental tissue or serological tests. Buxton (1998) states that, similar to sheep, the majority of does develop a protective immunity after infection and are protected against future challenges during pregnancy and should be retained within the herd, whereas young, nonpregnant does should be exposed to infection before they become pregnant. However, repeated abortion has been reported. Harwood (2007) states 'that immunity in goats following infection appears to be poor, or short lived, in comparison to sheep, and as a result some goats that have been previously exposed and considered to be immune may be susceptible to a new environmental challenge or to the reactivation of an existing latent infection during times of stress, disease, or injury'. (See Recrudescence under Toxoplasmosis in sheep (p. 519).)

Domestic cats and wild Felidae play a critical role in the spread of the disease, as in sheep.

Treatment and control measures are similar to those described for sheep (see previous mention). Toxovax is not licensed for use in goats.

T. gondii is a zoonosis and thus care should be taken in handling possibly infected material.

Border Disease

Border disease is only rarely recorded in goats in the UK. There appears to be only one single case of natural disease quoted in the literature, which occurred in Norway; however, Harwood (2007) states that two confirmed cases were investigated by the VLA, both of which had direct contact with known infected sheep.

After experimental infection, the disease presents a different clinical picture from that seen in sheep (Harwood 2007); early abortion, fetal resorption, and mummification occur more commonly whereas the delivery of weak, full-term kids or kids with tremors occurs less commonly. Marked placentitis is another notable feature.

Q Fever

Q fever, caused by *Coxiella burnetii,* can cause abortion and stillbirth in goats without previous clinical signs or after a few days of illness involving dullness, depression, and anorexia. The abortion rate can be very high in some infected herds (5%–50%). Large numbers of organisms are expelled into the environment from placental tissue, uterine fluids, colostrum, and milk (see Sheep section). Ticks have also been implicated in the spread of Q fever and may be the initial means of introduction into the herd. Between 2007 and 2010 a large scale zoonotic outbreak of Q fever led to over 4000 human cases. The most important risk factor for human Q fever was living close (< 5 km) to an infected dairy goat farm (van der Hoek et al. 2012). Occupational exposure of farmers and workers played a much smaller role. In 2009 several veterinary control measures were implemented, including mandatory vaccination of dairy goats and dairy sheep, improved hygiene measures, and culling of pregnant animals on infected farms (van der Hoek et al. 2012).

Diagnosis is made upon identification of the organism in smears of the placenta or the organs of the abortus and serological tests demonstrating a rising antibody titre.

Vaccination is possible but does infected before vaccination can remain chronic carriers of the organism; *C. burnetii* is a zoonosis and is excreted in milk.

Management of Breeding in Small Poultry Production Units

MICHAEL IAN CLARK

With the growing trend for keeping backyard/hobby poultry, it can be a daunting task for the new graduate to feel adequately equipped to deal with the veterinary requirement of owners. However, if new graduates draw together their anatomical, physiological, pathological, and medical knowledge of avian reproduction, then, subsequently, there is much that they can offer a client, whether there is a fertility or an egg production issue in a small flock.

This chapter will deal purely with the backyard chicken (Fig. 30.1), *Gallus gallus domesticus*. Though much that will be discussed will be pertinent to other kept poultry (turkey and waterfowl) and gamebirds (pheasant and partridge), there is some fundamental species variation.

Backyard poultry tend to be kept extensively, with the main purposes of companionship, egg production for human consumption, and occasionally breeding of replacement birds. Primarily, owners source their hens from pullet rearers or acquire former commercial laying hens. A female chicken is a 'pullet' once she is no longer a 'chick' (i.e., she has lost her feathery chick down and acquired adult feathering) but has not reached sexual maturity and laid an egg. Point-of-lay pullets are sold between 16 to 18 weeks of age, with the expectation that they will come into lay in the following month. The onset of lay is governed by three factors: the pullet being sufficiently old, being in adequate body condition, and subject to the correct light stimulation. There is a huge variation in the size of pullet rearing enterprises with many different breeds being reared, ranging from small silkies to the much larger Rhode Island Red. Former commercial hens will be acquired at the end of their commercial viability, which is typically 72 weeks of age. The four commercial systems used in the UK are: enriched cages, barn production, free range, and organic free range. Production can range from between 300 and 340 eggs per hen with the more intensive systems, resulting in the highest production figures. The commercial breeds commonly seen include Hyline, Lohmann, Bovan, and Novogen. The primary breed companies that produce these birds are a very good source of information on their husbandry and maximising their genetic reproductive potential (e.g., Hyline Website 2016, Lohmann Website 2011).

If there is no requirement for the backyard flock to produce progeny, then it is not necessary to have a cockerel. In fact, they are often perceived as a nuisance due to their early morning crowing and aggressive/protective behaviour. Many owners do put up with these inconveniences and have a cockerel in the flock, as there is a perception that this maintains a more natural flock dynamic. If fertilisation of eggs does occur but there is no incubation either naturally with broody hens or artificially with incubators, then there is no embryonic development, and the eggs are fit for human consumption. A few backyard flock keepers have birds that are intended to produce fertile eggs for incubation and chick production. For the amateur enthusiast, this can be frustrating because veterinary intervention is required to investigate any combination of low egg production, low fertility, low hatchability, and poor chick viability.

Anatomy of the Female Reproductive System

In the majority of avian species, only the left ovary is functional, and this holds true for chickens. Although the right one is present embryologically, it regresses during development and is vestigial in the adult bird. If the functional ovary is removed surgically or is destroyed by disease, the right rudiment enlarges and becomes functional. The age at which the removal of the functional ovary occurs determines the future development of the rudiment. If the ovary is removed from chickens younger than 20 days old, the rudiment hypertrophies into a structure resembling a testis and is capable of spermatogenesis. However, because the Wolffian duct system does not develop in genetic females, there is no duct connection between the testis and the copulatory organ in the cloaca. The structure of the normal poultry reproductive tract is shown in Fig. 30.2.

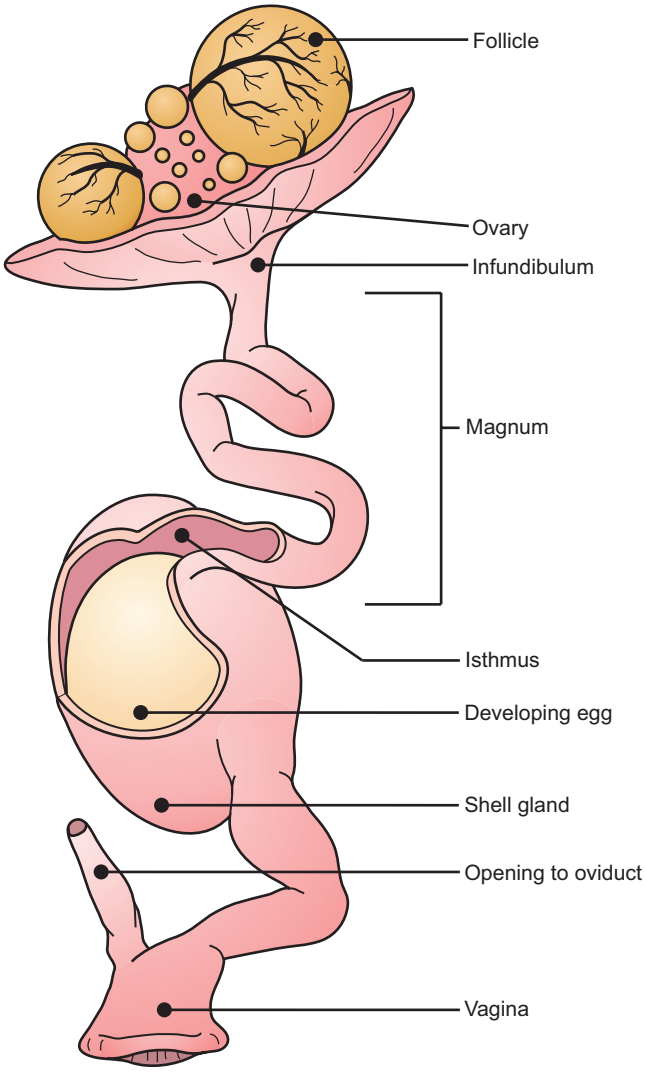
Ovary

Immature left ovaries are amorphous, granular, grey, triangular structures ventral to the cranial lobe of the left kidney. An active left ovary can take up a significant part of the mid coelom. Numerous developing follicles can be seen ranging from the smallest white pin head sized to the most mature follicles that are the size of egg yolks (as that is what they become) and are a rich yellowy/orange in colour. This is a single cell, and the yolk represents a very large lipid inclusion in its cytoplasm.

On hatching, a female chick has millions of oocytes, most of which become atretic. The remaining few follicles slowly grow for months or years. Neutral lipids are deposited as yolk in the

VetBooks.ir

• **Fig. 30.1** Backyard chickens: *Gallus gallus domesticus*.



• **Fig. 30.2** A diagram of the female poultry reproductive tract.

oocytes, 8 to 9 weeks before onset of lay; then a small number oocytes start to enlarge, depositing more white, primordial yolk. They then enter the final rapid growth phase, with deposition of yellow yolk, which has lipids along with water, proteins, minerals, and vitamins. Follicles grow to larger than 35 mm in 7 to 11 days in the domestic hen. Developing follicles are an oocyte, surrounded by granulosa cells, and an outer layer of thecal cells. There is no fluid-filled cavity; the entire follicle is filled with yolk material. In the avian ovary, follicles do not mature synchronously; there is a hierarchy of maturation with the largest most orange coloured follicle being the next to ovulate. The next largest follicle will ovulate 25 hours later, and so on. Usually a hen's ovary has up to 10 follicles containing yolk, a larger number of small yellow follicles, and numerous small white follicles awaiting recruitment or atresia.

Oviduct

Anatomically, the oviduct is relatively complicated as it is not just involved in transporting the ovum. Spermatozoa enter the oviduct and are either stored or ushered up the oviduct to fertilise the ovum. The fertilised ovum is enveloped by the nutritious albumin and numerous membranes added before it being encapsulated by the protective shell as it journeys through the oviduct to the cloaca. The oviduct has several components: the infundibulum, magnum, isthmus, shell gland, and vagina. In immature or out of lay hens, the oviduct is a relatively small structure, but in a sexually active hen, it can be a 60 cm coil of glandular tissue of varying diameters traveling on a circuitous route from the left ovary through the left, dorsal, caudal body cavity to the cloaca.

Infundibulum

As the follicle is released from the ovary, it has to be captured by the infundibulum. The infundibulum is attached to the body wall and closely associated with the left abdominal air sac. The fluted part to the infundibulum grasps the oocyte before its passing through the infundibulum in 15 minutes.

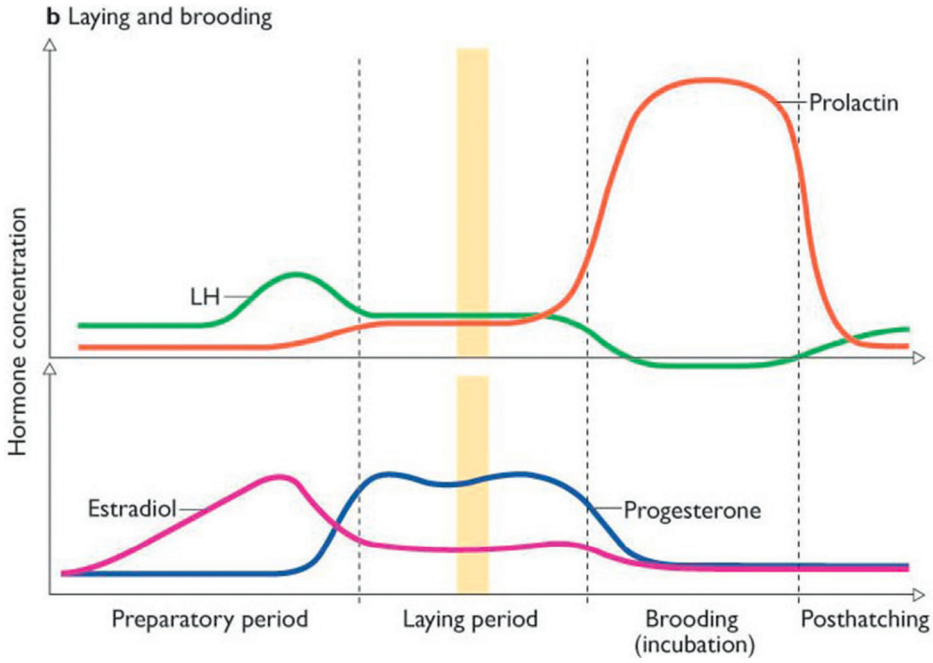
Magnum

The magnum is highly coiled and the longest part of the oviduct. There are massive mucosal folds that add about half the egg's total albumin during its 3-hour passage through the magnum.

Isthmus

After a narrow aglandular zone, there is the isthmus that is thinner and has fewer mucosal folds than the magnum; further albumin is added and the two subshell membranes are applied to the egg during its 1-hour passage.

VetBooks.ir



• **Fig. 30.3** Hen Egg Laying Endocrinology The four hormones – luteinising hormone, prolactin, oestradiol, and progesterone – are graphed through the four phases – preparatory period, laying period, brooding, and posthatching. (From Sjaastad OV, Sand O, Hove K, *Physiology of Domestic Animals*, 2003. Scandinavian Veterinary Press. http://www.scanvetpress.com.)

Shell Gland

During the egg's 20-hour presence in the shell gland (uterus), further albumin is added from the flattened mucosal cells. There is deposition of the shell, its glaze, and the outer cuticle.

Vagina

The egg passes through the vagina in a few seconds. The vagina ends at a slit-like opening in the lateral wall of the middle chamber of the cloaca (urodeum). When the egg is laid (air cell end first), the vaginal opening protrudes through the vent, minimising contact with faeces (Dyce et al. 2002).

Female Reproductive Physiology

There are major endocrine differences in the reproductive cycle of avian species compared with mammals. For example, in birds, granulosa cells (cells surrounding the vesicular ovarian follicle) produce progesterone (rather than oestradiol as occurs in mammals). Most of this diffuses to thecal cells (cells making up the envelope of condensed connective tissue surrounding the ovarian follicle) and is converted to oestrogen.

Fig. 30.3 illustrates the hormonal changes (for luteinising hormone (LH), prolactin, oestradiol, and progesterone) encountered by a hen through the four phases:

- Preparatory period
- Laying period
- Brooding
- Posthatching

As with any endocrine cycle, it is difficult to conceptualise a starting point. However, it is sensible to focus initially on the rising oestradiol levels in preparation for the onset of lay:

1. Synthesis of calcium ATPase in the shell gland;
2. Changes in bone composition – 10 days before egg formation, calcify medullary spaces of long bones, especially tibia and femur; this will mobilise calcium for use in shell formation;
3. Production of very low density lipid protein (VLDL) by the liver, which is a major precursor of yellow yolk, and is transported to the ovary and deposited in yolk;
4. Increased size of the oviduct (important for egg formation); and
5. Together with male sex hormones causes changes to plumage, comb size, sexual receptivity to males

As follicles mature, enzyme activity decreases in the theca cells but increases in the granulosa cells, resulting in a shift to increased progesterone synthesis near the time of ovulation. This can be seen in the rising blue line just before laying in Fig. 30.4.

The ovulation positive feedback loop that occurs in poultry (Fig. 30.5), superficially, may look similar to that of mammals; however, there are differences:

- It is progesterone, not oestrogen that is involved in this positive feedback loop.
- Ovulation of the dominant follicle (given the nomenclature F1) in birds is preceded by an increase in progesterone and LH.
- LH stimulates secretion of more progesterone from the granulosa layer of the mature ovulatory follicle.
- In experiments, administration of exogenous progesterone results in an LH surge and ovulation, so many believe it is progesterone that triggers the LH surge, not oestrogen as it does in mammals.

In both mammalian and avian species, LH and oestradiol increase before ovulation. The big difference is that in mammals, progesterone only increases after ovulation, whereas in birds, progesterone

VetBooks.ir

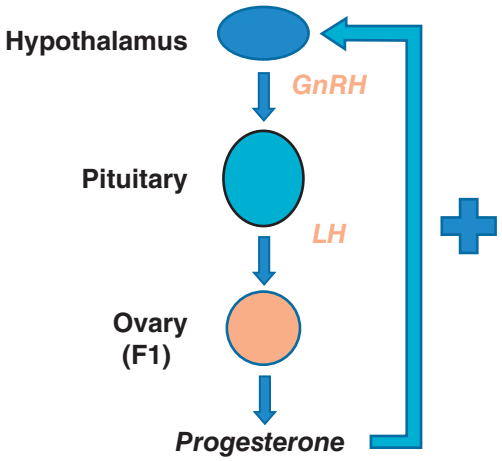
• **Fig. 30.6** Avian hormone changes around the time of ovulation.



• **Fig. 30.5** The avian ovulation positive feedback loop. N.B. it is progesterone that is involved with this loop. (With the permission of Yon L. Avian Reproduction. Unpublished lecture notes, 2017.)

increases before ovulation (Fig. 30.6) and is actually responsible for the LH surge which triggers ovulation.

There is an 'open period', which is a window of time each day when LH release can occur. It is usually 8 to 10 hours long and is from the onset of darkness to about 1 hour after the onset of light. Dusk signals the hypothalamus to set the circadian clock, which then sets the timing of the open period.

If the largest follicle (F1) produces and releases enough progesterone during the open period, then an LH surge and ovulation occur. After ovulation, unlike in mammals, no corpus luteum is formed in birds as there is no requirement to sustain a pregnancy. Synthesis of progesterone is restricted to the few mature follicles that are present because progesterone is responsible for the positive feedback cycle that triggers LH surge and ovulation. If it is too high, it will suppress GnRH and LH.

In domestic hens, ovulation occurs 6 to 8 hours after the LH surge, and then approximately 25 to 26 hours after ovulation, the egg is laid. Ovulation usually occurs 15 to 75 minutes after oviposition (time of lay is a practical guide to time of ovulation). Each ovulation occurs slightly later on subsequent days; as a consequence the hen eventually 'misses' the open period for that day's ovulation, resulting in a pause of 1 day in egg production.

Male Reproductive Anatomy

Testes

Chicken testes (left and right) can be seen during embryonic development at the cranial poles of the kidneys. Unlike mammals, there is no migration from this position during sexual maturation. Before sexual maturity the testes resemble grains of rice. In sexually active cockerels the testes are large white structures up to 5 cm long; in the quiescent period, they shrink to about half that size (Fig. 30.7). The seminiferous epithelium contains developing germ cells in distinct associations referred to as 'stages'. The stages are arranged sequentially in a helix that extends along the length of the seminiferous tubule (Scanes 2015). There are no accessory sex glands in cockerels, resulting in a modest ejaculate of approximately 1 ml of semen.

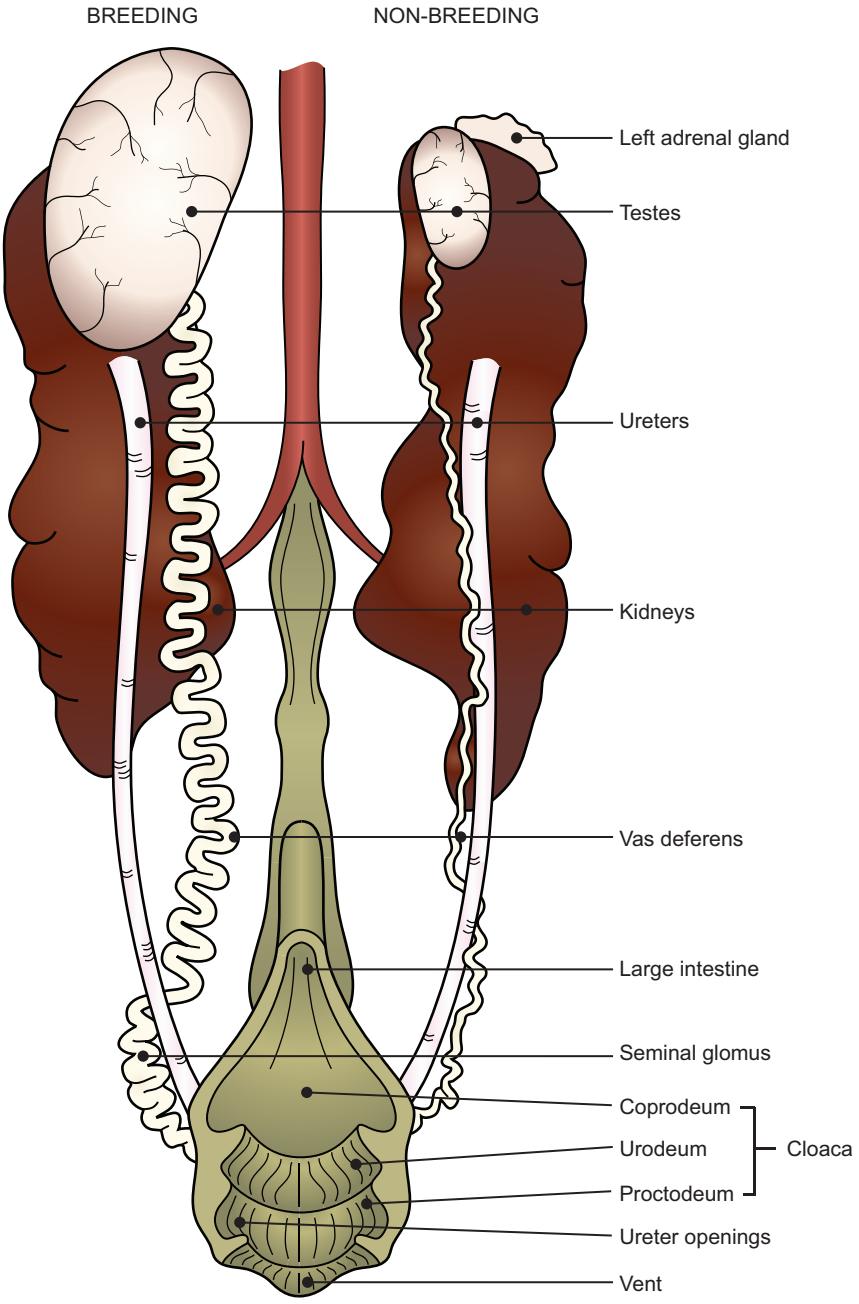
Epididymis and Ductus Deferens

There is an epididymis and ductus deferens, but there is no head, body, or tail to the epididymis, which appears as a slight bulge on the testis. The tightly packed efferent ductules join to form the deferent duct, which arises from the caudal end of the epididymis; the ductus deferens closely follows the ureter to the middle chamber of the cloaca (urodeum). In sexually active cockerels the ductus deferens is full of spermatozoa and thus is whitish in colour. The copulatory apparatus (phallus) of the chicken consists of two papillae and a rudimentary copulatory organ that is located in the vent (Scanes et al. 2004).

Male Reproductive Physiology

Each testis is surrounded by a layer of connective tissue containing the seminiferous tubules and Leydig cells, which are dispersed in the spaces between the tubules. The interstitial cells produce several androgens, but the major hormone is testosterone. As sexual maturity is attained, the production of testosterone is stimulated by the rising blood concentrations of LH. In the sexually mature cockerel, the blood concentration of LH is maintained by a negative feedback loop in which the elevated concentrations of testosterone inhibit

VetBooks.ir



• **Fig. 30.7** A diagram of a cockerel's reproductive anatomy with the structures shown during breeding on the left and nonbreeding on the right.

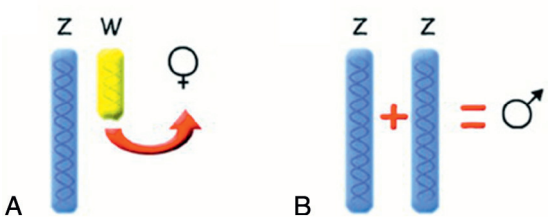
the secretion of GnRH, which in turn inhibits the secretion of LH. As the secretion of LH declines, the concentration of androgens declines, and hence the secretion of GnRH and LH is enhanced.

The Sertoli cells provide the microenvironment in which differentiation can take place and act as nurse cells to the developing sperm; the duration of spermatogenesis is approximately 14 days.

Sperm Storage

There are sperm storage tubules at the junction of the vagina and shell gland (uterus). Sperm are ejaculated into the cloaca or vagina and rely on their motility to reach the sperm storage tubules (SSTs). Some then enter the uterus and are carried passively to the infundibulum where fertilisation occurs; sperm storage tubules can store sperm for a long time (10 days) because bird sperm remains viable at body temperature (41°C) for up to 2 weeks in the female's genital tract, resulting in successful fertilisation. For comparison mammalian sperm remains viable in the female reproductive tract for a few days at most and then only under ideal conditions. After an egg is laid, some of these sperm may get 'squeezed out' of the tubules into the lumen of the tract, from where they may migrate further up to fertilise another egg.

VetBooks.ir



• **Fig. 30.8** (A) The heterogametic female avian chromosomes Z & W. (B) The homogametic male avian chromosomes Z and Z.

Fertilisation

Ovulation results in the release of an egg from a mature follicle on the surface of the ovary. At ovulation the ovum is captured by the infundibulum, which is covered with a ciliated simple columnar epithelium. The beating of the cilia is important in moving the egg into the funnel shaped/fluted upper end of the tube. After passive entry into the infundibulum by the egg, there is fertilisation when the sperm penetrates the ovum and there is fusion of the male and female pronuclei (syngamy). From here, the egg further develops during the 25-hour journey through the oviduct, with the end result being a fertile, shelled egg.

Sex Determination

Because all male birds are ZZ (homogametic unlike the heterogametic mammalian male XY), all spermatozoa will carry the Z chromosome (Fig. 30.8), whereas at the end of the second meiotic division, the Z and W chromosomes of the heterogametic avian female will have segregated into 50% of the ova. At fertilisation any of the ova carrying the Z chromosome will develop into male chicks, whereas any ova carrying the W chromosome with develop into the female chicks.

Egg Development

The infundibulum also has a secretory function. It produces the first of the egg coats, the chalazae. These are the whitish string-like structures on either side of the yolk that keep the embryo in proper position during development (University of Illinois Extension). Around the yolk, there are four distinct layers of albumen (Fig. 30.9):

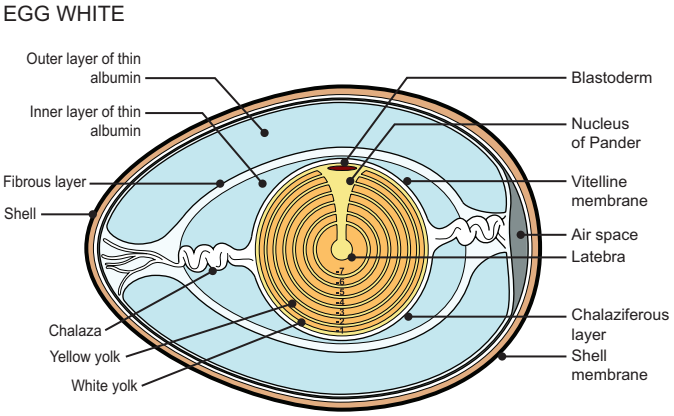
1. The chalaziferous (inner thick) layer attached to the yolk (3% by weight) – produced in the infundibulum
2. The inner thin (liquid) layer (~17% by weight) – produced in the infundibulum
3. The outer thick layer (~55% by weight) – produced in the magnum
4. The outer thin (fluid) layer (~25% by weight) – produced in the magnum

The inner and outer shell membranes are produced in the isthmus. There are three calcified layers to the eggshell.

The organic shell matrix is a series of layers of proteins and mucopolysaccharides in which calcification occurs. Just before oviposition (expulsion of the egg), the cuticle (a thin waxy layer) is applied to the shell.

Brooding/Broodiness

A backyard hen that lays 5 or 6 eggs, whether they have been fertilised or not, is likely to become broody if the clutch of eggs



• **Fig. 30.9** The anatomy of a poultry egg.

is not removed from her. The daily removal of laid eggs and the reproductive physiology of an indeterminate layer can result in over 300 eggs per hen being laid over a 12-month period. Physiologically, she is striving to establish a clutch of eggs but is being thwarted on a daily basis by the stock keeper. After a clutch of eggs are laid, a hen's behaviour changes, and she becomes broody. This may be a desired quality if the owner wishes a hen to incubate her own fertilised eggs; it may be an undesirable trait if the purpose of the hen is to lay eggs for human consumption or to produce fertile eggs for artificial incubation. To prevent broodiness, eggs should be collected daily, and there should be few dimly lit hiding places for a hen in her enclosure. From an endocrinological perspective the following is occurring:

- In the ruptured follicle, granulosa cells synthesize progesterone, and, if sufficient, it inhibits further ovulation.
- The ovary, oviduct, and comb regress.
- LH levels decrease during incubation and hatching but increase if the hen lays a second clutch of eggs.
- Gonadal steroids decrease, whereas prolactin increases.
- Prolactin increases in males and females during egg laying, peaks during incubation, and declines when chicks hatch.

The purpose of brooding is to keep the eggs warm. The hen develops a brood patch (Fig. 30.10) towards the end of the egg laying period, and the skin becomes oedematous and highly vascularised. Brood patches develop in response to ovarian steroid exposure. The tactile simulation of the defeathered, oedematous brood patch triggers transition from egg laying to brooding due to prolactin release. The blood flow to the brood patch is greatly increased, such that the heat from skin in this area incubates the eggs. Sensory fibres detect skin temperature where there is skin-to-egg contact. If the hen's body temperature falls she will shiver to generate heat and increase her metabolism to ensure that eggs are at the optimal temperature for incubation. The brooding period ends when prolactin levels decline.

Moulting

Moulting is a natural process in which the laying hen's reproductive function goes into abeyance and coincides with seasons of the year that are suboptimal for chick rearing. This is not a desirable trait for birds kept for egg production, but it may be of use to a small flock keeper who wishes to synchronise egg production. If that is the case, a flock moult can be induced by reducing the

VetBooks.ir

• **Fig. 30.10** The ventrum of a hen with a prominent red brood patch.

day length to 8 hours and restricting (but not withholding) feed. After a rest period, production can be resumed by then increasing the day length to 14 hours over 4 weeks before raising it to 16 weeks, and increasing the ration. If hens in a flock appear to be losing feathering commencing at the neck followed by breast, body, wings, and tail, in that order, in conjunction with a drop in flock egg production, then a moult is occurring.

Hatchery Management

Egg Storage

The aim of egg storage is to stop embryo development**,** and this requires a cool temperature: 17°C to 21°C (63°F–70°F), which should be ensured with careful monitoring using a minimum/maximum thermometer. However, there are still potential problems, such as hot spots in the egg store. Temperature fluctuation during storage can cause a decline in hatchability of up to 3.5%, and eggs stored for longer than 10 days have a decreasing hatchability of 1% per additional day. However, judicious use of an egg store allows pooling of eggs before setting.

Incubation/Setters

Fertilisation of the follicle is the first step in the production of a hatching egg.

The egg membranes and shell are then added over a period of approximately 24 hours, which is achieved *in vivo* at the hen's body temperature of 41°C. Therefore at the point of laying, the embryo is 24 hours old, and 1 day should be 'added' to the standard incubation periods for all species (i.e., 21 + 1 days for a hen egg). During this egg development period, the embryo progresses from one cell to 20,000 to 40,000 cells.

Incubation is divided into two processes: the 'setters' receive the eggs for the first 18 days, then for the final 3 days the eggs enter the 'hatchers'. For very small incubators (Fig. 30.11), eggs

• **Fig. 30.11** A small incubator.

are laid on their side, and the machine is a combined setter and hatcher. Such machines require a temperature of 38°C.

Single Stage Versus Multistage Incubators

A single stage incubator has all eggs at the same stage of incubation. The advantage of this design is that, potentially, the incubator can provide the optimum environment for development and hatching for each day of incubation. There is also improved biosecurity, as the incubator will be empty periodically for thorough cleaning and disinfection. A disadvantage is cost, as these incubators are often large, and they need either to supply heat to the eggs or to remove heat or cool them.

A multistage incubator has eggs at various stages of incubation. This reduces the cost of the operation, as some eggs need to be supplied with heat, whereas others need to dissipate heat. However, the machine is providing 'average' conditions for the age range of eggs. There is also a biosecurity compromise, as the capacity of the machine is being maintained at its maximum with more recently laid eggs.

Temperature Control

When monitoring a hatchery, the critical issue is embryo temperature; however the incubator air temperature may not necessarily reflect embryo temperature. It is known that egg shell temperatures correlate well with embryo temperatures if taken correctly with an infrared thermometer at the equator of the egg and therefore is better than a hatchery air temperature thermometer. The downside is that measuring the egg shell temperature may require opening of the machine, with a resultant dissipation of heat. From about halfway through incubation, an embryo changes from a net absorber of heat to a net producer of heat, though the optimal temperature for the embryo remains in the range 37.8°C to 38°C. This is a challenge for an operator of a small machine, as the focus changes from heat supply to heat dissipation. If the temperature is slightly suboptimal, then development is delayed, and if the temperature is slightly higher, target chick viability is compromised; if it goes even higher hatchability is also affected.

Humidity Control

The optimal operating humidity for a hatchery is 55% to 60%. When incubated correctly, eggs will lose 11% to 12% of their

VetBooks.ir

weight from the time of laying to day 18 of incubation. Small amounts of moisture loss occur during storage (approximately 0.5% per week), which need to be deducted from the incubation value. Egg weight monitoring is a valuable tool, but not commonly used (Aviagen Website). If the humidity is too high, then the egg's rate of moisture loss will be too low and the air cell too small; ultimately, the embryo cannot inflate its lungs. If the humidity is too low, then the rate of moisture loss will be too high, and thus there is a risk of embryo dehydration.

Movement Control

Egg turning is paramount for proper embryo development, as it prevents the embryo adhering to shell membranes. There is also better yolk sac and allantoic vascular development, better albumen protein utilisation, better hatch weight, and better embryo positioning before hatching. Turning in the first week is more important than in the second week and should be done at least 5 to 6 times per day. The eggs should not be turned in the last 3 days of incubation after transfer from the setter to the hatcher.

Ventilation Control

Air exchange is essential to prevent suffocation of the embryo. Removal of carbon dioxide (CO_2) is required as a concentration of 1% CO_2 has a marked detrimental effect on hatchability. However, in normal avian nests, CO_2 is 10 times higher than atmospheric CO_2 levels (0.4%–0.6% vs 0.04%). The operator's aim should be to ensure as much ventilation as possible can be provided while maintaining adequate temperatures. Ventilation is a major method of temperature control for the hatching egg; if it is too hot, this increases the rate of embryonic development, potentially affecting chick quality. If it is excessively too hot, there will be embryo mortality, resulting in reduced hatchability. Too cool a hatchery delays the rate of embryonic development.

Temperature fluctuations cause embryo 'stress' – reduced hatchability, reduced chick viability. Hot and cool spots (e.g., due to egg size variability, air movement issues) will result in an increased hatch window (the duration of the interval from the first to the last egg to hatch), which influences chick viability (Engormix Website).

Microbial Control

If eggs have a low total viable count of bacteria before incubation, then contamination should decline during the process (Fig. 30.12). Highly contaminated eggs placed in dirty machines will result in bacterial proliferation, with detrimental consequences on hatchability and chick viability.

Candling

A bright light can be shone through the egg (Fig. 30.13) enabling the viewer not only to see if the egg is fertile and developing but also whether it has the correct amount of humidity. This is done by assessing the relative size of the air cell.

	Pre-incubation	At transfer to hatcher
Clean Egg	5×10^2 - 1×10^4	$< 1 \times 10^2$
Dirty Egg	2×10^4 - 2×10^6	2×10^7

• **Fig. 30.12** Low egg bacterial contamination will get lower during incubation whereas high levels of egg bacterial contamination will get higher during incubation.

Incubation/Hatcher Settings

Candling is often carried out before transferring eggs from the incubator to the hatcher at day 18 of incubation. This should be done with great care to avoid damage to the developing fetus. Once in the hatcher, the eggs no longer need turning. The temperature requirement is now lower for the egg, but the humidity requirement is higher. With gas production and bacterial contamination, there is always a risk of what are described as 'bangers', namely exploding contaminated eggs with the consequential risk they pose to other eggs in the hatcher. With each batch of eggs being hatched, there should be an aim to have a short period of time when there are no eggs in the hatcher; this is referred to as a 'hatch window'. The longer the hatch window, the greater the welfare compromise and the disease risk to the first hatched chicks. A hatch window of 24 hours should be achievable. Excessive amounts of meconium present in a hatch basket would alert a veterinary surgeon to there being a long hatch window.

Sexing

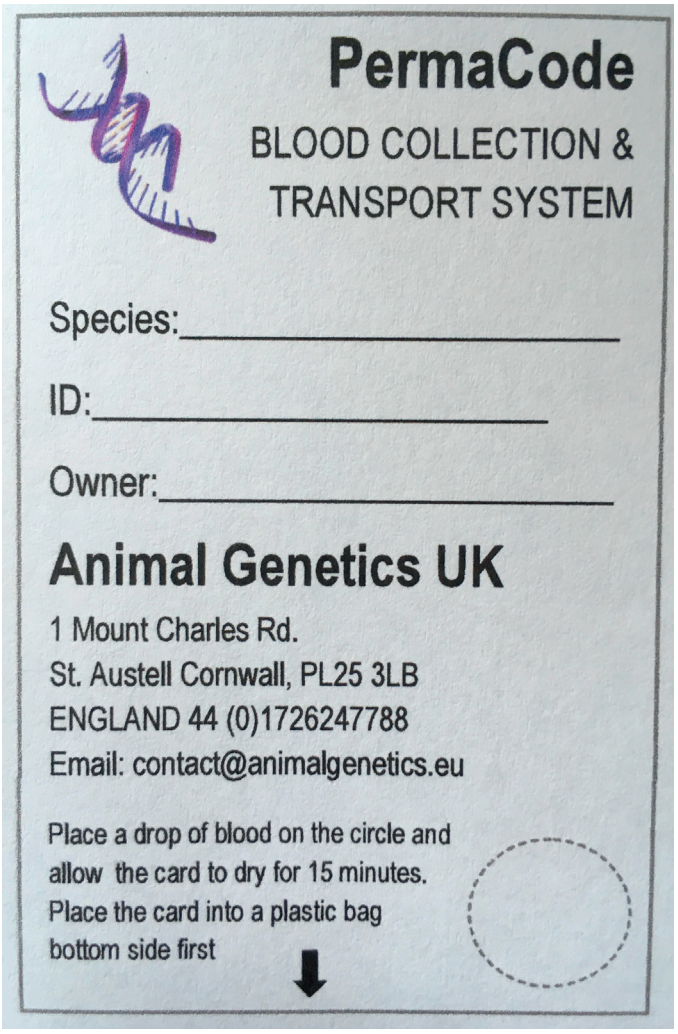
DNA Sexing

It is possible to harvest tissue from the young chicken for karyotyping. There are several laboratories in the UK that offer this testing service. Sampling techniques include:

1. Blood collection by venipuncture or clipping a toe nail so that a few drops of blood can be placed on a permacode card (Fig. 30.14); the card should be left to dry for approximately 20 minutes at room temperature. Once the card is dry, it should be placed in a small envelope with the submission form and sent to the appropriate laboratory.
2. Two or three feathers can be plucked from the bird (they cannot be naturally shed feathers, as they have only keratinised material with no DNA). Although any feather can be selected, as a general rule, they should be between 5 to 10 cm (2–4 inches) long. They are then placed into a sealed plastic bag to be sent to the laboratory.
3. After hatching, the shell remnant can be used for sexing the hatched chick. Allow the eggshell membrane to completely dry before submission. Shells may be left in the incubator or removed and allowed to air dry for 24 hours or until the egg membrane is no longer moist; removing the moisture will

• **Fig. 30.13** Candling of fertile egg. (Courtesy of Boehringer Ingelheim.)

VetBooks.ir



• **Fig. 30.14** A permacard for submitting a blood sample for DNA sex determination testing.

slow down the decay of the DNA required for testing. DNA is extracted from the vascular material lining the eggshell membrane. This testing method is very accurate.

Surgical Sexing

It is possible to surgically sex birds, although not in very young birds, and it is not without risk. The patient requires general anaesthesia before the insertion of an endoscope through a surgical incision between the ribs at the level of the caudal thoracic air sac.

Faecal Hormone Measurement

Fresh faecal samples can be assayed for testosterone and oestrogen concentrations in sexually mature birds. The chickens being tested must be healthy and the sampled faeces assigned to the correct individual; the test is safe and inexpensive.

Vent Sexing

Due to the slight anatomical difference in the male and female vent, it is possible to determine the sex of day old chicks with this technique. However, it needs much training to become proficient, as the anatomical differences in male and female vents are far subtler than other species such as ducks in which even at a day old the male phallus is quite obvious.

• **Fig. 30.15** Autosexing: comparing flight feathers of female (on the left) to male (on the right) chicks. (From Aviagen Ltd.)

Autosexing

In some breeds of chickens, there are some easily observable sex-linked characteristics allowing identification of the sex of the chick on hatching.

1. Colour sexing. For example, the Barred Plymouth Rock breed carries a gene for barring, which produces a white bar on a black feather. Males have a large white head spot that is smaller and narrower in females. Furthermore, if a gold coloured male is mated to a silver female, the progeny will consist of silver males and gold females.
2. Feather sexing (Fig. 30.15). This is possible due to rapid or slow feathering and the subsequent differences in wing feathering. If rapid feathering males are mated with slow feathering females, the result is slow feathering males and rapid feathering females (i.e., males have shorter wing feathers).

Failure to Lay/Egg Drop

There are numerous causes of reduced egg production, including infectious, nutritional, and environmental factors.

Egg Binding and Dystocia

Egg binding is an unhelpful term, as many practitioners and producers have different views on its precise definition. Hens can suffer from dystocia in which an egg becomes trapped in the vagina. The trapped egg may be visible on examination and will certainly be palpable. Large eggs (especially those with two yolks) are a contributing factor, as are hypocalcaemia, obesity, and early onset of lay. It may be possible to assist the expulsion of the egg with adequate lubrication. Initially, intramuscular calcium supplementation can help in the form of calcium gluconate followed by calcium glubionate or calcium carbonate orally. Some veterinary surgeons advocate breaking the offending egg. However, though this may rectify the immediate problem, it does predispose the bird to developing salpingitis. If the flock is laying a high percentage of double yolked eggs,

VetBooks.ir

a review of the lighting schedule is required. A nutritional review should also be considered to ensure the hens are not overweight and the egg weight is not higher than breed recommendations.

Salpingitis

Inflammation of the oviduct is often encountered due to ascending infections from the vent and cloaca. The incidence of this syndrome is increased in older hens, producing large eggs after a sustained period of production. Most commonly, *E. coli* are isolated from an infected oviduct. However, these may be opportunistic pathogens with a harder-to-isolate bacterium or virus being the primary pathogen.

Oviductal Impaction

An end point to dystocia or salpingitis can be oviductal impaction in which egg material (such as yolk, albumen, mucin) and purulent material occlude the oviduct and can ultimately lead to pressure necrosis of the oviduct wall. Birds that have oviductal impaction have been in lay before ceasing production and becoming progressively lethargic, depressed, and anorexic. It tends to be seen in older hens and may be regarded as a normal end point to production in the spent hen. Palpation or imaging of the caudal coelom can detect the caseous mass in the oviduct. Antibiotic treatment tends to be unrewarding and ovariohysterectomy a touch heroic.

Oviductal Prolapse

Excessive positive pressure in the coelom, such as a discrete mass or excessive straining, can lead to an oviductal prolapse. If it does so, the individual is at risk of cannibalisation by other hens in the flock. Former commercial laying stock tends to have been beak trimmed, which can limit the severity of the cannibalism, but this procedure is rarely performed on pedigree/pet poultry. Even if this does not occur, the condition is a surgical emergency; however, euthanasia should be considered on welfare grounds. If this condition is prevalent in a flock, consideration should be made to providing more available nest boxes.

Uterine Torsion

Uterine torsion occasionally occurs and normally proves fatal for the bird. There is often vascular compromise, and the oviduct will be oedematous, reddish black in colour, and friable.

Cystic Hyperplasia of the Oviduct

Numerous cystic structures can occur; they may contain clear or cloudy fluid and are lined by proliferative mucosa of the particular portion of the oviduct involved. This is probably an endocrinopathy, but the exact cause is not known.

Cystic Right Oviduct

It is not uncommon to see oviductal cysts of the vestigial right oviduct, although two Müllerian ducts are present in the developing chick embryo. The left duct develops normally into the oviduct, and the right duct regresses; occasionally regression does not occur, and it becomes a dilated fluid filled cyst. It can be especially pronounced in the sexually immature pullet, although it is an incidental finding as they do not appear to inhibit subsequent sexual development or cause disease.

Blind Layer Syndrome

Infectious bronchitis (QX strain) is known to cause blind layer syndrome (Pattison et al. 2008). For this to develop, the birds need to be infected when young chicks, before development of the oviduct. There may be partial, or almost complete, absence of the duct or vestiges that are nonpatent or cystic. Once sexually mature, the hen will ovulate, but the ovum is unable to pass normally through the oviduct and can be shed into the body cavity. The hen goes through the process of oviposition but fails to lay (hence blind layer syndrome). Affected hens have pendulous, fluid-filled body cavities and an obvious penguin-like gait. On postmortem examination, the ovary is normal but the affected oviduct is thin walled and cystic and can contain up to 1.5 litres of fluid.

Ectopic Ovulation

Ectopic eggs can be an incidental finding but can also be a cause of mortality, particularly if associated with peritonitis. Causes of this condition include oviductal rupture and reverse oviductal peristalsis.

Egg Peritonitis/Reproductive Associated Coelomitis

If the oocyte is not harvested by the infundibulum at ovulation, it may float freely in the body cavity. Rough handling of a hen may also dislodge other follicles from the ovary. It is possible that there is some reabsorption and no infection because free yolk is very irritating to the peritoneal lining of the coelom. This, or a progressively more severe salpingitis, can develop if egg material from the reproductive tract enters the coelom and becomes infected, leading to an egg peritonitis (Fig. 30.16). Affected hens are depressed and inappetant. If this condition becomes chronic, there may be involution of the ovary. Radiographs may show multiple radiopaque densities in the peritoneal cavity, though diagnosis is more frequently confirmed on postmortem examination. Coelomocentesis will yield fluid (unless the lesion is very consolidated) containing yolk material, inflammatory cells, and bacteria. If a flock is very hyperactive, husbandry measures should be taken to calm them; otherwise, egg peritonitis will occur at an unacceptably high level.

• **Fig. 30.16** Egg peritonitis with fibrin tags associated with a mature ovary.

VetBooks.ir

Vent Gleet

Infection of the vent is called 'vent gleet'. A vicious cycle can be established in which there is initial trauma to the vent with subsequent infection, resulting in cannibalistic behaviour and further trauma; it can occur in both hens and cockerels.

Oophoritis

Inflammation of the ovary can be secondary to infection of the peritoneal cavity or air sacs or associated with septicaemia. Viruses, bacteria, fungi, and mycobacteria are all possible causes. Ovarian lesions with intense blood vessel congestion and deformed shrunken ovules have also been associated with *Salmonella enteritidis* infection in laying hens (Pattison et al. 2008). If a salmonella species is isolated from infected birds, in the UK this must be reported to the Animal and Plant Health Agency (APHA), as part of the national control plan for salmonella; treatment with antibiotics is not permitted.

Ovarian and Oviductal Neoplasia

A drop or cessation in egg production could be attributed to ovarian neoplasia. Several different types of neoplasia have been reported, but they are rare. Some neoplasia can have a viral aetiology – for example Marek's disease. Confirmation of the diagnosis is made on histopathological examination of the affected ovary.

Egg Drop Associated With Lighting Pattern

Increasing day length stimulates reproductive development and production, whereas decreasing day length has the opposite effect; thus artificial lighting regimens are used to mimic these changes and stimulate production. This can be difficult in small flocks in which the housing provided often allows for light pollution, and the producer can be unsure of the optimal light duration and intensity.

Caged Layer Fatigue/Calcium Tetany

Affected hens show signs of paresis, and, although the hens may be in lay, they will have soft long bones. The flock will have a reduction in egg yields and poor shell quality. Supplementation with oyster shell can be beneficial.

Egg Eating

If the husbandry of a small breeding flock is suboptimal, it is possible for some of the hens to develop the vice of egg eating. It can be difficult to identify the culprits and to ascertain the action needed to stop the vice.

Fertility Issues

Keepers of small breeding flocks should be aiming for fertility levels of over 90% and hatchability levels of over 75%. If there is a failure to hatch, the first question is whether the egg is fertile. Breakout work on unhatched eggs (Fig. 30.17) can be useful as it is possible to ascertain at which point in time embryonic development ceased. However, the aviculturist is often unaware of embryonic death; thus the egg is left in the incubator beyond the time of death, leading to severe autolysis.

An infertile yolk is virtually homogenous in appearance apart from a small white area that is the blastodisc. The presence of large numbers of them should cast suspicion on the cockerel's fertility. Infertility can be due to lack, or poor numbers, of viable sperm or the inability to mate properly. In small flocks it is possible to identify hens that have been repeatedly mated; they will often have feather loss over their dorsum and neck, as well as damage to the integument. Conversely, it is also possible to identify those that have not been mated. A pullet that has not laid an egg will have a narrow gap between the points of the ischium. If a handler can position the width of two fingers or more between these points, the hen will have laid an egg.

After the monitoring of embryonic death, a late peak (18–21 days) close to hatching will be identified. Normally, there is also an early peak in embryo mortality (0–4 days) when there is the period of cell differentiation and this is commonly associated with egg handling (possibly before placement in the incubator). Excessively high incubation temperatures and excessive movement of the eggs can also be implicated in these deaths. Midterm embryonic death is relatively uncommon.

Late embryonic death is likely to be associated with the physiological complication changes of switching to pulmonary respiration. For an egg to hatch, it is critical that it loses a certain amount of moisture, which, if not achieved, will result in embryonic death. Very late embryo mortality is a hatching issue and is manifested as pipped shells in which the chick has attempted hatching but failed. These eggs may have been incubated beyond the range of acceptable temperatures.

A few days before hatching, the shell membrane contracts around the chick making the air cell larger, and 24 to 48 hours before hatching, the chick positions itself with its head in the air cell, allowing it to breathe. Abnormal positioning is potentially life threatening and can result from improper turning of the egg during incubation.

Orchitis

Inflammation of the testes is rare. However, if there is an infertility issue in a flock, it should be considered as a differential diagnosis. On postmortem examination of an affected cockerel, the testis/testes may be enlarged, reddened, and with multifocal lesions. Infectious causes of orchitis include fungal, bacterial (such as mycobacterium and chlamydia), and viral infections (e.g., infectious bronchitis).

Testicular Neoplasia

Though various types of testicular neoplasia have been reported in birds, they are rare in backyard poultry (Schmidt et al. 2015). In a small flock with one cockerel, it could explain a drop in fertility. Diagnosis would be on gross postmortem examination, when enlarged testes would be seen, followed by confirmation on histopathology.

Poor Libido

Immature cock birds, reared separately from females, will subsequently have a low libido when introduced to a breeding flock. Submissive cockerels in a flock can be bullied by both dominant males and females, thus influencing their breeding capability. Not only are male to female ratios important in a breeding flock (~1:8) but also the establishment of a nonviolent pecking order.

• **Fig. 30.17** Break out work on fertilised eggs showing fetal development during incubations. (From Aviagen Ltd.)

VetBooks.ir

• **Fig. 30.18** An ex-commercial layer showing upper respiratory tract clinical signs due to infectious bronchitis.

Infectious Causes of Reproductive Disorders

Infectious Bronchitis

A drop in egg production in a nonprotected flock caused by infectious bronchitis (IB) can be up to 50%. The pathogenicity is dependent on the strain of coronavirus causing the infection. Production can return 4 to 6 weeks after the initial challenge, though this often coincides with a rising number of pale, crinkled, weak shelled eggs; internally, the albumen will be watery. There can be concurrent respiratory signs (Fig. 30.18) and mortality. In immature flocks an early onset infection with IB QX strain is the cause of blind layer syndrome. On postmortem examination, birds from an infected flock may have lesions typical of egg peritonitis.

In situations in which it is not essential to isolate the virus, PCR is the test of choice for confirmation of diagnosis. Serological testing using either haemaglutination inhibition (HI) or ELISA can also be used. If a strain of IB is identified as the cause of a drop in egg production, there is no specific treatment. However, the flock keeper and veterinary surgeon should consider control by vaccination. Although commercial vaccines have 1000 doses as the smallest vial size, the live vaccines are relatively cheap and easy to use in small flocks.

Mycoplasma Gallisepticum

Mycoplasma gallisepticum (MG) can be spread both horizontally and vertically. These bacteria survive well in the allantoic fluid and yolk. A laying flock infected with MG will show signs of upper respiratory tract disease (especially severe conjunctivitis and sinusitis) with a concurrent drop in egg production. Infected layers will have a caseous exudate in the oviduct. There are no pathognomic lesions, but there are three laboratory test approaches to diagnosis: antibody detection, isolation of MG, and detection of its DNA. With high levels of biosecurity and good screening programmes, eradication of MG has been possible in commercial primary breeding flocks. With a severely affected backyard flock, culling should be considered. If this is not viable, some level of control is possible with metaphylactic antibiosis and vaccination; both live and inactivated vaccines are available.

Mycoplasma Synoviae

Like MG, mycoplasma synoviae (MS) has a short survival time outside the host and similar modes of transmission; some flocks infected with MS remain asymptomatic. Others can show signs of lameness, mild lower respiratory signs, and a drop in egg production with some eggs showing signs of egg apex abnormality. Diagnosis is by similar methods to MG; live vaccines are available for control.

Egg Drop Syndrome

Although commercial hens are vaccinated against the adenovirus infection, egg drop syndrome (EDS-76), most small backyard flocks are not. Eight days postinfection, there is a massive growth in the pouch cell gland region of the oviduct, coincident with the occurrence of egg shell changes. Progeny from these infected eggs can hatch and appear clinically normal but latently infected. When a latently infected individual reaches peak lay, the virus is reactivated. The virus can be transmitted vertically and should an unprotected flock become infected during lay, the egg drop can be profound. Transmission is possible horizontally via the faecal/oral route. Classically an infected flock will initially show a loss of shell pigmentation, followed by thin shelled, soft shelled, and shell-less eggs. There is an apparent drop in egg production, though overall production may be normal, but there will be fewer normal eggs. It has been calculated that the loss equates to about 10 to 16 eggs per hen when a naïve flock is infected (Pattison et al. 2008). Confirmation of a challenge is possible with rising antibody titres on paired serology or PCR testing (assuming isolation of the virus is not required). No treatment is available, but even in small flocks, vaccination should be considered. The only licenced EDS vaccines in the UK and internationally are polyvalent inactivated vaccines. Replacement pullets for an infected site should be injected with this vaccine intramuscularly between 14 and 16 weeks of age.

Notifiable Diseases in the UK and Internationally

Both avian influenza and Newcastle disease are notifiable diseases of poultry, and both can produce a drop in egg production as a clinical sign. With highly pathogenical avian influenza (HPAI), there can be complete cessation of lay in a flock in conjunction with high levels of mortality and morbidity. It must be remembered that low pathogenical avian influenza (LPAI) (H5 or H7) is also notifiable. Clinical signs can be far subtler with much lower levels of mortality and drop in egg production rather than a cessation. Paradoxically this makes LPAI more difficult to diagnose than HPAI and a differential diagnosis for any flock with a drop in egg production. There are no pathognomic lesions for avian influenza on gross postmortem examination, with the carcass merely having lesions suggestive of an acute or peracute viraemia.

Clinical signs for a flock infected with Newcastle disease virus (NDV) are dependent on the pathotype of the NDV. The appearance of shell-less or soft shelled eggs, often laid outside the nest boxes, followed by complete cessation of lay, is a common presentation. With highly virulent forms, high levels of mortality will occur. There can be intestinal, neurological, and respiratory signs, depending on the strain. Like avian influenza, there are no pathognomic lesions. However, haemorrhagic lesions would arouse suspicion especially if the mucosal surface of the proventriculus was affected.

Early detection by veterinary surgeons of these diseases is important for national disease control but can be very difficult for the nonpoultry expert dealing with a small flock. If a suspicion of these diseases persists after an initial investigation, the veterinary surgeon must contact APHA. In cases of avian influenza in which the clinical signs are not profound and after discussions with APHA, the private veterinary surgeon may elect to test in order to exclude

These changes range from the normal brown eggs (N), to the loss of shell pigment (1), thinning of the normal eggshell (2), cracks where the eggs are damaged in the nest box or handling to soft-shelled (4), and shell-less (5) eggs. (From Pattison M, *Poultry diseases*, 6th Ed, Philadelphia, 2008, Saunders.)

• **Fig. 30.20** *Ascaridia galli* having migrated to the yolk of a subsequently shelled egg.

avian influenza, rather than officially notify (Testing for Exclusion of Avian Notifiable Diseases).

Abnormal Eggs/Seconds

Abnormal egg shells are often referred to as 'seconds' as they are downgrades from first class eggs. Numerous abnormalities are recognised (Fig. 30.19), some of which have known aetiologies, whereas others are suggestive of particular conditions. Though egg shell abnormalities are often a result of nutritional or infectious disease in the hen, it should be borne in mind that poor egg handling and storage can lead to damage. Whatever the cause of the egg shell abnormality, invariably there will be a detrimental effect on hatchability.

Double Yolked Eggs

Though this is can be regarded as a bonus in eggs for human consumption, in breeding programmes, they are an important issue, as no double yolked egg has been known to be fertile. Prevalence is higher in young flocks in which up to 20% of eggs can be affected. The condition is exacerbated by prolonged day length and light intensity; excessive intake of methionine can also induce this condition. This phenomenon does put the young hen under additional physical strain, as double yolked eggs are larger than single yolked eggs.

Cracked Eggs

The causes are rough handling by the birds, the equipment, or the flock keeper; it is exacerbated in poorly mineralised, large eggs.

Soft Shelled Eggs

Some viruses can cause soft shelled eggs, notably adenovirus and infectious bronchitis virus. They can also be a manifestation of vitamin A, vitamin D or calcium deficiency.

Shell-Less Eggs

In nest boxes, fully formed eggs minus the shell can be found. Infectious diseases known to damage the oviduct may be implicated, which include infectious bronchitis, egg drop syndrome, and *Mycoplasma gallisepticum.* Nutrient imbalances in calcium, phosphorus, and vitamin D3 may also be responsible.

Discoloured Yolks

Nutrition plays a major part in yolk colour. Feed additives may enhance the richness of the yolk colour (e.g., carotene rich rations) or diminish the yolk colour (e.g., oxidisation of carotenoid feed additives). If blood spots are detected in yolks, it is assumed that the bird has been exposed to some acute stress, such as a thunderstorm or predation. Vitamin K deficiency may also be a factor.

Meat spots in the yolk are due to pieces of ovarian or oviduct tissue becoming embedded in the yolk. There appears to be a genetic component to this condition, as it is more prevalent in brown than white hens.

Albumen Quality

Watery albumen, revealed on cracking an egg, is often indicative of an active viral infection.

Crinkled Eggs

This condition is often associated with an infectious bronchitis challenge.

Vitamin Imbalance Effects on Shell Quality

Inadequate vitamin A and D levels in feed may lead to thin egg shells. A sandpaper texture to eggs may be associated with inadequate levels of vitamin A and/or vitamin D.

Worms in Eggs

Very occasionally, the intestinal nematode *Ascaridia galli* can migrate from the cloaca up the oviduct to become encapsulated in a shelled egg (Fig. 30.20).

VetBooks.ir

Pale Eggs

White hens tend to lay white eggs, and brown hens tend to lay brown eggs. The protoporhyrin-IX pigment that is secreted from the epithelial cells lining the uterus during the 90 minutes just before oviposition is responsible for the brown eggshell colour. Loss of pigment resulting in pale eggs can be seen with certain stressors, such as an infectious bronchitis challenge and the sudden exposure to high levels of UV light.

Small Eggs

Flocks that are 'lit up' with a lighting programme that brings them into lay too early will be afflicted with the production of small eggs.

Blood Stained Eggs

If blood stained eggs are noted, the veterinary surgeon has to ascertain whether the blood is from the distal intestinal, the reproductive tract, or the cloaca/vent.

Egg Apex Abnormality

As previously mentioned, egg apex abnormality (EAA) is highly suggestive of a *Mycoplasma synoviae* infection.

Late Fetal and Chick Pathology

Late fetal deaths and neonatal deaths can be caused by a variety of nutritional, genetic, and infectious issues. Postmortem examination of such cases can reveal oedematous carcasses and is often a result of excessive hatchery humidity. Should the humidity be too low, then the carcasses are seen to be very dehydrated. Bacterial infections are often associated with poor husbandry and cleanliness, which can be traced back to the breeder flock, egg store, hatchery, or brooding hut. Pathogenical *E. coli* infections are the most common cause of lesions to the umbilicus and yolk sac. The umbilicus can be large, swollen, and reddened with the body wall becoming oedematous and discoloured; if this is extensive, the specimens are referred to as mushy chicks. The yolk sac can also be involved, being enlarged, discoloured, and oedematous; this is distinct from retained yolk sacs. In these cases, the chicks will not thrive, but the large yolk sac is a normal colour and not contaminated.

Equine Infertility and Stud Medicine Practice

DALE PACCAMONTI AND JAMES R. CRABTREE

The objective of the veterinarian working in any horse breeding enterprise, regardless of size, should be to produce the maximum number of live, healthy foals from the mares bred during the previous season; we could add to this 'as early as possible' in many breeding programmes. Perhaps the biggest obstacle to achieving this aim is the infertile or problem breeding mare. Very few mares are permanently and completely infertile, but subfertility of varying degrees is a major problem. There are many causes of subfertility that warrant a mare to be categorised as a 'problem breeding mare'. and although it is important to recognise the underlying cause, the implementation of a successful treatment strategy is equally important. Mare owners frequently have problem mares from which they want to produce foals, and the veterinarian must be able to help maximise the chance of this wherever possible. It might take several oestrous cycles to establish a pregnancy, and even then, there is an increased possibility of pregnancy failure. Commitment from both mare owner and veterinarian is needed; the owner should be made aware of this at the outset and be given a realistic expectation as to the chance of success. The aim of this chapter is not only to describe causes of infertility but also to consider the subfertile 'problem mare' and how to provide an effective management policy that can be applied in daily clinical practice.

There are two major ways in which human intervention has negatively influenced breeding success:

1. Reproductive performance is usually not the prime criterion in breeding horses.
2. For many breeds, e.g., Thoroughbred and Quarter Horse, 1 January is the official birthdate for foals in the Northern hemisphere (1 August in the Southern hemisphere) irrespective of their actual date of birth within that year. Because the natural breeding season in the horse centres on the summer solstice (21 June), horse breeders are plagued with problems in attempting to breed mares in the winter and early spring outside their most fertile period. The promotion of yearlings in the autumn sales contributes to this pressure for early breeding because well-grown, older yearlings tend to sell for higher prices. In many breeds, competitive events between 2 year olds are commonplace, and a horse that is 3 or 4 months older than others in the event is at an advantage.

Infertility in the mare can be a herd problem or an individual mare problem and can be very frustrating. From the viewpoint of herd fertility, it is important to review records to understand the degree of infertility or subfertility that actually exists, as opposed to the client's perception. Some grasp of normal expectations of fertility is useful. Assessment of reproductive efficiency is an extensive subject, and for a more detailed review, the reader should refer elsewhere (Hearn 2000, Love 2003, Allen et al. 2007). Possibly the two most important, or at least the two most quoted, parameters in connection with reproductive efficiency are: end-of-season pregnancy rate and live foal rate. From an economic perspective, these may be the most important benchmarks; however from the veterinarian's perspective, pregnancy rate per (oestrous) cycle is a more up-to-date indicator of the efficiency of the breeding operation. A well-managed stud farm should typically achieve pregnancy rates (diagnosed at 15 days of gestation) per cycle of 65%, an end-of-season pregnancy rate of 85%, and a live foal rate in excess of 75%. These figures may be lower than owner's or stud manager's expectations; therefore it is a good idea to discuss what they are at the beginning of the breeding season. The figures may need to be reviewed in the light of the history and past breeding performance of a particular mare (see Box 31.1). Pregnancy rates at the end of the season will depend on the fertility of the stallion, the fertility of mares, and management. This last factor is often related to the value of the horses involved because frequent veterinary attention, in cases in which it is justified by the potential value of the mare and future foal, results in better outcomes. Very expensive stallions tend to attract more fertile mares, or the stud may accept only young fertile mares. Well-managed studs tease mares regularly and individually; this is very time consuming yet hugely advantageous. An experienced stud manager knows, for example, the reasons why some mares fail to exhibit oestrous behaviour. In turn, the length of time that a mare fails to show oestrus before being presented to the veterinarian for examination depends on stud policy and the owner's wishes.

The clinician should be aware of how to investigate the problem breeding mare. A protocol for such an investigation of an infertile or subfertile mare is outlined in Box 31.2.

Causes of Infertility

Failure to Cycle Normally

A frequent history of a mare presented for infertility is that she either does not cycle or does not cycle normally. The first condition that must be ruled out in the former is pregnancy. There are a number

VetBooks.ir

• BOX 31.1 Factors to Include When Obtaining a History During an Infertility Investigation of a Mare

Age
Previous use
Current use
Intended use
Any pertinent health history
Has she ever received any hormones (or vaccines) for training or behavioural modification?
Has she cycled normally in the past?
Has she been bred (natural cover, artificial insemination; fresh, cooled, or frozen semen; fertile stallion)?
Has she ever been pregnant? Outcome?
Has she ever foaled (any problems during delivery, any postpartum complications)?

• BOX 31.2 Outline of Protocol for Clinical Examination of an Infertile Mare

Routine Procedures in All Cases:

1. Obtain previous breeding history.
2. Assess physical condition, general health.
3. Evaluate perineal conformation.
4. Examine reproductive tract by palpation per rectum.
5. Examine reproductive tract by transrectal ultrasound.
6. Obtain culture of clitoral fossa, clitoral sinuses.
7. Examine vagina and cervix visually with speculum.
8. Perform manual examination of vagina and cervix (while performing next step).
9. Obtain culture and cytology of uterine lumen (possibly using low volume lavage technique).
10. Obtain endometrial biopsy.

Procedures Performed in Selected Cases:

1. Perform hysteroscopic examination of uterine lumen.
2. Collect peripheral venous blood sample for hormone analysis.
3. Collect samples (e.g., blood, hair follicle, tissue biopsy) for chromosome analysis.

of situations, such as in a recently purchased mare, or when a mare or a stallion escaped from their living area, or when a mare was housed with a colt that was considered too young to be able to breed, in which mares may be pregnant without the knowledge of their owner. Although normally a pregnant mare does not exhibit oestrous behaviour, a small percentage of mares may exhibit signs of oestrus when pregnant. Obviously, pregnancy must be ruled out before any invasive diagnostic procedures are performed.

Seasonality

Another common cause of mares failing to exhibit regular oestrus is due to seasonal cyclicity. Although mares near the equator do not show a clear seasonal cyclicity, those at higher latitudes typically enter into a period of anoestrus during the winter when the photoperiod is short. Ovaries are small and inactive and the uterus and cervix are typically flaccid. Follicles, if present, are typically less than 15 mm in diameter, and serum progesterone is less than 1 ng/mL. Some, usually older, multiparous mares, may exhibit signs of behavioural oestrus when teased with a stallion. However, examination will reveal reproductive quiescence. The arbitrary birthday of 1 January for horses in the Northern hemisphere and 1 August for those in the Southern hemisphere pressurises breeders and veterinarians to ensure that mares become pregnant in the winter and thus have foals born as close to their arbitrarily imposed 'birthday' as possible. The problem is that mares, being seasonal long-day breeders, would normally be in anoestrus at that time of year. In fact, the average date of the first ovulation of the year for mares in the Northern hemisphere is 7 April (Sharp 1980). Therefore much effort has been made to induce cyclicity earlier than would normally occur. Stud farm managers who do not use such schemes find themselves experiencing subfertility due to a reduced number of breeding opportunities before it becomes 'too late' to breed from the perspective of the mare owners.

This endogenous rhythm cannot be changed in the short term, but with time, it can be modified. By exposing the mare to an artificial long daylight before the winter solstice, cyclic activity can be induced at an earlier date. Exposing mares to a minimum of 10 lux of light for a minimum of 14.5 hours (9.5 hours of darkness) starting from 1 December will stimulate mares to cycle (have their first ovulation) in approximately 70 days. In practice the authors recommend 16 hours daylight and 8 hours darkness. The light should be added at the end of the day rather than in the morning to be effective. Alternatively a 1 hour pulse of light during the night, 9.5 to 10.5 hours after the onset of darkness (Palmer & Driancourt 1981) has the same effect. Practically, 2 hours of light after 9 hours of darkness is recommended. More recently, blue light exposure to one eye via a customised blinker mask (Equilume) has been demonstrated as a practical alternative method of advancing the first ovulation of the year in mares. Photoperiod is not the only determining factor of when a mare begins to cycle. It has been shown that nutrition plays a very important role as well. Mares in good body condition were more likely to cycle all year long, and if they did enter winter anoestrus, they began cycling a month earlier than mares with slightly poorer body condition (Gentry et al. 2002, Waller et al. 2006).

After winter anoestrus, mares go through a period referred to as 'spring transition', characterised by irregular periods of anovulatory follicular waves with or without oestrous behaviour. Spring, or vernal, transition ends when a follicle is induced to ovulate by either a sufficiently large endogenous pulse of luteinising hormone (LH) or an exogenous ovulating agent. In 'late transition', large oestrogenic follicles can develop yet fail to ovulate; these follicles can persist or regress with another follicular wave ultimately ovulating. A somewhat similar period, referred to as the fall (or autumnal) transition, occurs at the end of the breeding season and is similarly characterised by anovulatory follicular waves.

Pharmacological methods to induce earlier cyclicity that have shown promising results involve the use of dopamine antagonists such as sulpiride and domperidone. Results have been variable and appear to be affected by factors such as nutritional status and environmental conditions. Investigations continue with the aim of finding an easy method to induce mares to cycle by the beginning of the breeding season. Even with these methods to induce earlier cyclicity, some mares still undergo a spring transition, a period of variable length that can be frustrating from a breeding management perspective. Mares will develop follicles that reach ovulatory diameter but regress rather than ovulate. On average, 3.7 follicular waves will develop before the first ovulation of the year (Sharp & Davis 1993). A number of ways to shorten spring transition have been suggested, including administration of progestogens, follicular aspiration (Klump et al. 2003), and administration of ovulation inducing agents. Most of the reportedly successful protocols are more effective in late transition than early transition.

VetBooks.ir

Progesterone/progestogen withdrawal therapy is one option. Progesterone exerts a negative feedback on LH secretion; thus when the source of progesterone is withdrawn or its effect wanes because of the withdrawal of the negative feedback effect, there is an increased release of LH, resulting in follicular maturation and ovulation. Progesterone can be administered as an oil-based intramuscular injection, orally as the synthetic progestogen altrenogest, or by using a silastic progesterone-releasing intravaginal device (PRID; see Chapter 8). The preferred drug for many clinicians is a 10-day course of oral altrenogest at 0.044 mg/kg; however, there are many misconceptions about its use, in particular the mechanisms involved in its action. Altrenogest should, in the authors' opinion, not be used 'blind', i.e., without a prior examination of the mare's reproductive tract with reference to the degree of ovarian activity and the presence of luteal structures on the mare's ovaries. It is debatable whether or not altrenogest advances the first ovulation of the season or rather gives a degree of predictability or synchrony to the late transitional phase. As a guide, altrenogest can be effective but only generally when mares are already into the late transitional phase, characterised by the development of multiple oestrogenic follicles with the largest follicle being larger than 25 mm in diameter. Altrenogest is likely ineffective in mares with minimal follicular activity, particularly during deep anoestrus. The desired response is that the mare either ovulates during the period of treatment or she develops an ovulatory follicular wave after cessation of treatment. If the mare has no mature luteal structures on her ovaries, then the routine use of prostaglandin is unnecessary and inappropriate. One cannot determine what treatment or management plan is appropriate for the mare without knowledge of the degree of follicular development in her ovaries.

Many clinicians in broodmare practice use the intravaginal progesterone releasing devices such as the PRID Delta that, when used in a similar fashion to that described for altrenogest, can be utilised in an attempt to hasten the time to first ovulation. These devices inevitably result in a degree of vaginitis with a variable degree of vaginal discharge, which usually spontaneously resolves post device removal. Occasionally mares may show signs of discomfort and possibly colic when the devices are first inserted. Mares are monitored while the device is in place, and once a follicle reaches a size larger than 36 mm in diameter, the device is removed. Work in the author's (JRC) practice has demonstrated that a single PRID Delta contains enough progesterone to be effective for 10 days in the mare.

In the authors' practices, whether oral progestagen or an intravaginal device is being used, the follicular status of every mare should be examined after 7 days. In mares with follicles measuring larger than 35 mm, supplementation is stopped (or the device removed), and the mare is monitored for ovulation. If the follicles are smaller than 35 mm, supplementation is continued for 3 more days, at which time the treatment is stopped or the device removed. The withdrawal of the negative feedback usually results in oestrus within 6 days and ovulation between 7 and 13 days after the last treatment. By examining the mare when under treatment, the possibility of an unexpected ovulation can be minimised. The use of intramuscular injections of progesterone and oestradiol-17β in oil for 10 days produces a similar response to altrenogest, but the interval to oestrus is longer due to the suppression of follicular development by the oestradiol.

Repeated daily injections of equine pituitary gland extract to mares in winter anoestrus lead to follicular development, although others (Hyland et al. 1987) have reported success using a minipump that infused gonadotrophin-releasing hormone (GnRH) intravenously over a period of 28 days. These last two treatments are impractical for routine use. There have also been reports using GnRH or its analogues, administered by injection, infusion, or subcutaneous implant, to hasten ovulation in transitional or even anoestrous mares (Harrison et al. 1990). It is expensive, as treatment is necessary for at least 1 to 2 weeks, with a mean of 15.8 days (Ginther & Bergfelt 1990). It is noteworthy that these authors found high multiple ovulation rates associated with GnRH treatment.

If a follicle is mature enough and is still in the growth phase, as opposed to being in regression, it will likely to ovulate after treatment with an ovulation agent such as human chorionic gonadotropin (hCG) or deslorelin. This treatment is often used alongside other management or treatment strategies but can be used as a single treatment assuming the mare is in late transition and close to cycling spontaneously.

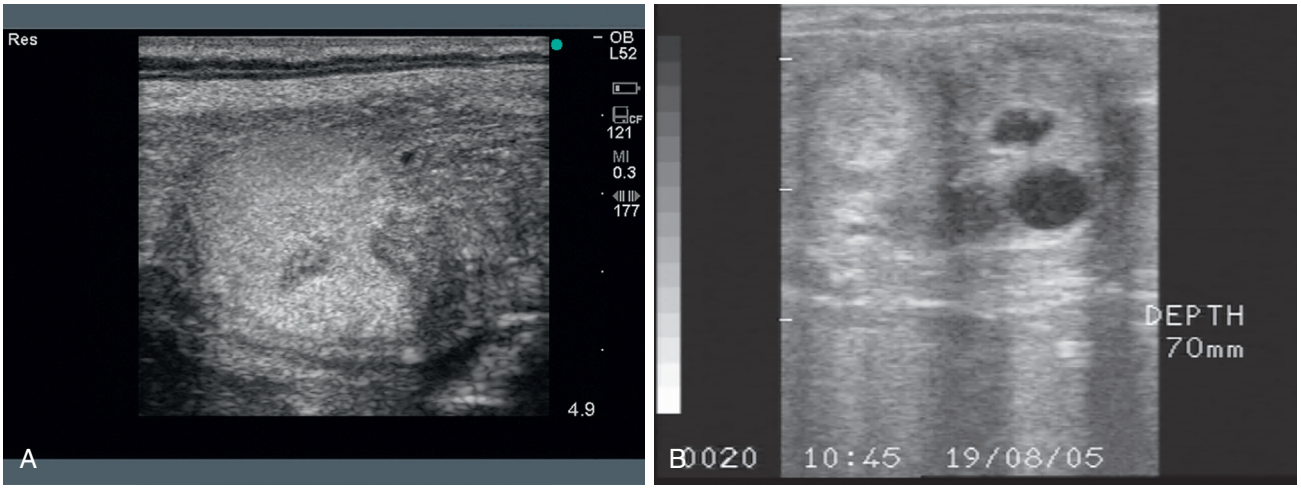
During the transitional period before the first ovulation of the year, mares demonstrate erratic oestrous behaviour of varying intensity. The presence of multiple large follicles, possibly as large as 30 to 40 mm, can make detection of ovulation difficult by palpation alone. Even outside this transitional period, misinterpretation of ovulation, even by experienced clinicians, has been shown to be as high as 50%. It is much easier to visualise the corpus haemorrhagicum/early corpus luteum ultrasonographically when the anechoic follicle is replaced by an intensely echoic area representing the early corpus luteum (Fig. 31.1A and B). It is recommended that the interval between matings should not exceed 2 or 3 days, although there have been no critical studies on the survival time of sperm in the mares' genital tract. The authors have experienced mares which have conceived after a breeding to ovulation interval of 6 or 7 days, but this is not the norm. An early report in the literature reported pregnancy after a breeding to ovulation intervals of 5.25 to 5.75 days in pony mares (Burkhardt 1949). It is important, however, not to begin breeding too early, or this will result in the mare being mated many times. The appearance of uterine oedema (Fig. 31.2) is considered an indication that the follicle should ovulate within a few days, although some transitional follicles can ovulate in the absence of oedema, and follicles can regress in the presence of oedema. A key factor in the emergence from vernal transition is the development of steroidogenic competence by the follicle, leading to an increase in circulating oestrogen concentrations that causes the release of LH from the pituitary due to a positive feedback mechanism. Oestrogen is responsible for the appearance of uterine oedema (in the absence of progesterone), and so this may be why the detection of uterine oedema is important in signalling the emergence of the mare from the transitional period.

Cystic ovarian disease, comparable to the condition described in the cow (see Chapter 22), does not occur in the mare. The persistent follicles that occur during the transitional and other periods are structurally normal; however, their presence may explain why this condition has been diagnosed in the past.

Abnormal Cyclicity During the Breeding Season

Failure to cycle or the occurrence of irregular cycles during what is considered to be the normal breeding season is another matter. Irregular oestrous behaviour may be observed in a mare in which the pregnancy has failed after the endometrial cups have been established. Endometrial cups, derived from fetal tissue that invades the endometrium at approximately 5 weeks gestation (Fig. 31.3), produce equine chorionic gonadotropin (eCG), which has LH-like activity in the mare (see also Chapter 5). Follicular development continues throughout early pregnancy and eCG causes these mature

VetBooks.ir



• **Fig. 31.1** Ultrasonographic images of two equine corpora lutea (CL) with a differing ultrasonographic appearances: (A) an early CL that is large and dense (hyperechoic); (B) mature CL with a central lacuna (hypoechoic).

• **Fig. 31.2** Uterine oedema observed by ultrasonography (crosssection of a uterine horn).

• **Fig. 31.3** Endometrial cups present on the endometrial surface of the uterus at approximately 70 days gestation.

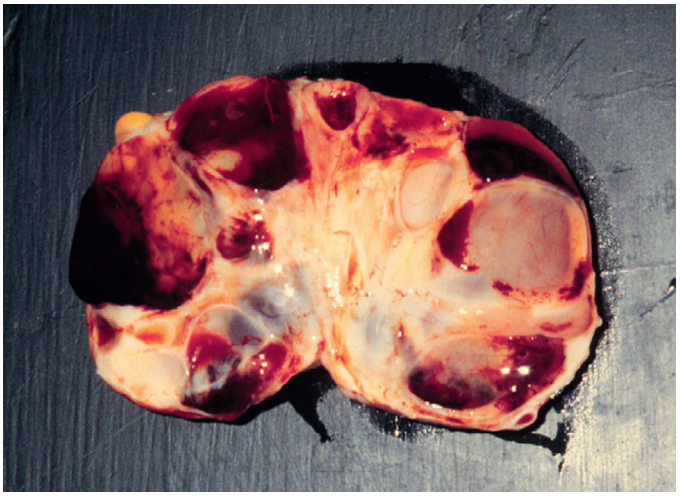
follicles to ovulate or luteinise, forming secondary and accessory corpora lutea, respectively (Fig. 31.4). Because of the presence of these follicles and development of additional luteal structures at various times, mares may show brief periods of oestrus but fail to ovulate or may show a prolonged period of anoestrus. This condition will persist until the demise of the endometrial cups (beginning at approximately 80 days gestation) and the disappearance of eCG from the circulation, usually between 100 and 150 days. Occasionally endometrial cups may persist beyond their normal lifespan, resulting in a persistence of eCG in the maternal circulation with consequent effects on ovarian cyclicity (Crabtree et al. 2011).

Rarely, Cushing's syndrome, caused by adenomatous hyperplasia of the intermediate pituitary, has been associated with anoestrus in aged mares. This is presumably due to destruction of the cells secreting luteinising hormone and follicle-stimulating hormone. Mares with equine metabolic syndrome often experience ovulatory failure, and it has been hypothesised that a contributing factor is glucocorticoid production by abdominal fat which inhibits LH release.

'Silent heat' in which a mare is having a normal oestrus and ovulation but fails to show oestrous behaviour, may cause problems when the breeding programme relies on teasing and natural mating, but with the use of ultrasonography and artificial insemination, this is more easily remedied. The incidence of silent oestrus has been reported to be 6% (Nelson et al. 1985). Silent oestrus is more common in mares with a young foal by their side and in maiden mares early in the breeding season. Other factors affecting oestrous behaviour include being kept with very dominant mares and stallion preferences. Fillies that are in training and have been treated with anabolic steroids may be more likely to suffer from this due to 'androgenisation'.

Ultrasonography and vaginal examinations can confirm that the mare is in oestrus and has follicles of an ovulatory size. It

VetBooks.ir



• **Fig. 31.4** Multiple follicles and luteal structures on the ovaries of a mare 60 days pregnant.

is essential to distinguish the condition from a prolonged luteal phase, in which there is follicular development but a persisting luteal structure secreting progesterone. The use of exogenous PGF is recommended if any doubt exists about the presence of luteal tissue.

Treatment is based on thorough and careful teasing. Frequent and persistent teasing may persuade the mare to show oestrus. Management options include safely restraining the foal within sight of the mare, removing the foal out of auditory range, and tranquilising the mare. Alternatively, placing the mare in a stable next to a stallion may be helpful. If permissible, artificial insemination can be used. In order to breed mares naturally during a silent oestrus, some form of restraint may be necessary; many mares approaching ovulation accept the stallion when twitched and hobbled. An intramuscular injection of oestradiol benzoate (10–20 mg) 6 hours before breeding can be tried as a last resort; however, this drug is no longer available in many parts of the world. The veterinary surgeon must ensure that the mare is physiologically ready to be bred. In some cases when the mare is not psychologically prepared for breeding, treatments are of little value, and although tranquillisation may allow the mare to be covered, pregnancy is unlikely to be achieved. In many cases, it is a failure of oestrous detection rather than a true reproductive disorder of individual mares. However, it has been associated with reduced oestradiol concentrations in the peripheral circulation and a shorter interval from luteolysis to ovulation (Nelson et al. 1985). There is no suggestion that aberrant morphological abnormalities in follicular development are involved.

Prolonged Luteal Activity

Persistence of luteal activity in the nonpregnant mare is a major cause of subfertility. Traditionally, the term 'prolonged dioestrus' has been used to describe a condition in which the corpus luteum (CL) persists beyond its normal cyclical life span of 15 to 16 days, resulting in the maintenance of elevated circulating progesterone concentrations for longer than expected. Ginther (1990) has suggested that the term 'prolonged luteal activity' should be used, as 'persistent dioestrus' implies that the CL persists, whereas it is possible that others are formed sequentially from dioestrous ovulations. In mares, although progesterone inhibits follicular development, it does not inhibit it completely. Therefore mares continue to develop medium to large follicles during dioestrus. Usually, these follicles undergo atresia. However, occasionally, a large follicle will ovulate during dioestrus. These occur in up to 20% of oestrous cycles in Thoroughbred mares (less frequently in some other breeds and ponies) and are not accompanied by oestrus; the cervix will remain pale in colour, dry, and tightly closed. If a dioestrous ovulation occurs late in the luteal phase, when PGF is released from the uterus and lyses the original CL, the more recent CL is at too early a stage in development to respond to the PGF. It then continues to develop, produces progesterone, and prolongs dioestrus.

True persistence of the CL occurs in approximately 20% of ovulations. These mares are a problem for the stud manager, as they can be assumed incorrectly to be pregnant. With stud farm management practices of today, a persistent CL or dioestrous ovulation are easily diagnosed and treated. Plasma progesterone profiles are indistinguishable from those of pregnant animals. The uterus becomes firm and tubular (toned), and the cervix is typical of that of pregnancy; however, transrectal ultrasound imaging fails to detect a conceptus confirming nonpregnancy.

Failure of synthesis and/or release of $PGF_{2\alpha}$ at the end of dioestrus is the most likely cause of persistence of the primary CL. Ginther (1990) has suggested that it might also be due to failure of the CL to respond to PGF, or failure of PGF to reach the CL. Treatment is by the injection of a luteolytic dose of PGF or a synthetic analogue. The interval between treatment and ovulation varies considerably depending on the size of follicles at the time of treatment. Therefore it is advisable always to examine mares using ultrasonography before treatment in order to assess the status of follicular development.

The term 'pseudopregnancy' is often used in the case of a mare that was bred, subsequently has a prolonged luteal period, and is not pregnant when examination is performed. It is then assumed that an embryo was present at the time of maternal recognition of pregnancy but was subsequently lost before the time of pregnancy examination. With the capability to diagnose pregnancy at day 10 to 12, before the time of maternal recognition of pregnancy, using the higher quality ultrasound machines currently available, the true incidence of pseudopregnancy should be readily discernible. True pseudopregnancy occurs if there is early embryonic death after 15 days of gestation, with persistence of the primary CL resulting in a prolonged luteal phase. The cervix remains tightly closed, and the uterus is toned and tubular. It is diagnosed based on an early positive pregnancy examination, followed by a negative pregnancy examination on ultrasound examination during a maintained luteal phase.

Seasonal Anoestrus

Seasonal anoestrus is the term that best describes the mare that has ovarian inactivity (anoestrus) during the normal physiological breeding season. The most commonly encountered form of seasonal anoestrus is that encountered in lactating mares after foaling and is often referred to as 'lactational anoestrus'. Affected mares may have a normal postpartum oestrus (foal heat) after 6 to 12 days but fail to return to oestrus at the end of the first dioestrus. Alternatively, they may not have a normal foal heat at all. This seems to be more common in mares that foal far outside the normal physiological foaling/breeding season. It also appears to be related to nutrition because mares in good bodily condition are less likely to experience seasonal anestrus than those in poor bodily condition. The ovaries resemble those of a mare in deep winter anoestrus, i.e., small and inactive, and the condition can last for several months. Originally it was thought to be due to the presence of high levels

VetBooks.ir

of prolactin suppressing pituitary gonadotrophin release, but this is now in doubt. Affected mares should be teased and examined weekly per rectum to assess their ovarian status. It is expected that most mares will have a 'foal heat' and ovulate at 7 to 14 days post-foaling; mares with little or no ovarian activity at this stage often necessitate treatment to avoid a prolonged period of anoestrus.

In the authors' experience, the preferred treatment for this would be domperidone at 1.1 mg/kg orally once daily; if the mare fails to respond with the development of a follicle of preovulatory size in 7 to 10 days, then additional therapy with progestagen or GnRH should be used. Alternatively, the GnRH analogue buserelin (Veterelin, Receptal), 20 to 40 mcg twice daily by intramuscular injection for up to 10 days or with consideration to the prescribing cascade, a human GnRH analogue Goserelin, available in a 3.6 mg implant (Zoladex), can be used. Half an implant (1.8 mg) is inserted under the skin of the mare, and a response is usually seen within 7 to 10 days. Treatment with GnRH is often expensive and the pregnancy rate at the induced oestrus is perceived to be reduced. In addition, the mare may return to anoestrus after the induced ovulation.

Seasonal anoestrus in young, nonfoaling mares that are in good physical health and condition presents a more difficult challenge. Sexual immaturity and karyotypic abnormalities leading to gonadal dysgenesis are two potential factors to consider; however, severe malnutrition, advanced age, and mares treated with anabolic steroids may also have abnormally small and inactive ovaries. Some presumed 'normal' mares can encounter prolonged periods of acyclicity. Allowing the mare additional time is often the first approach, but if after a period of several weeks during the physiological breeding season the mare has not developed any significant sized follicles or evidence of follicular waves, further investigations or attempts at therapy can be made. The clinician must first determine that the mare is not in a prolonged luteal phase (persistent dioestrus); if there is any doubt, a progesterone assay can be performed to clarify whether there is any active luteal tissue present. Assays for FSH and LH can be performed, along with GnRH challenge to determine whether the hypothalamic–pituitary axis is functional; however, this requires access to a specialist laboratory able to perform them. Treatment with progestagens and/or domperidone is generally used first, but if the mare shows little or no response to these, then GnRH analogues can be used.

A differential cause of a mare or filly with apparent seasonal anoestrus or a failure of follicular development would be previous vaccination against GnRH. Such procedures have become popular in competition horses for the suppression of unwanted sexual behaviours. A GnRH vaccine is commercially available in Australasia (Equity oestrous control vaccine, Zoetis, Australia) for the suppression of oestrus and oestrous-related behaviour in mares not intended for breeding. Such vaccines are also available for other species, such as pigs, and although Equity is only available in Australasia, vaccines for other species are being used 'off-label' in mares in other parts of the world. Mares cease ovarian activity within approximately 4 weeks of the second injection of a primary course and remain suppressed for a variable amount of time (Imboden et al. 2006, Elhay et al. 2007, Schulman et al. 2013). The younger the mare is when vaccinated, the longer the interval to reversibility is likely to be (Schulman et al. 2013). In a study by Imboden and co-workers (2006) of nine mares vaccinated twice, five returned to ovulatory activity in 28 to 100 weeks, three resumed follicular activity without ovulating, and one remained inactive over the 100 week observation period. They concluded that the duration of the inhibitory effect is highly variable, not clearly related to GnRH antibody titres, and resumption of ovulatory activity may require more than 100 weeks. In addition, ovarian suppression did not always prevent the occurrence of sexual behaviour (Imboden et al. 2006), and this would create a very difficult situation if it was not known that the mare had been vaccinated. It is not known for how long mares that receive repeated doses of vaccine (boosters) will remain reproductively inactive.

Genetic Abnormalities

Genetic abnormalities must be considered in a mare that fails to cycle. Although not common, many types of sex chromosome anomalies have been described in the horse. The incidence of chromosomal abnormalities is difficult to assess but must be suspected in maiden mares with very small (< 1 cm), inactive ovaries and an immature tubular genital tract once winter anoestrus has been eliminated as a cause of acyclicity. However, some genetically normal young fillies in training can be acyclic, and thus they must be given more time to mature reproductively. A thorough history and physical examination are necessary. Depending on the particular genetic abnormality, the reproductive tract can be rudimentary, juvenile, or ambiguous. The 63 XO, X chromosome monosomy, often referred to as equine Turner's syndrome (gonadal dysgenesis), is the most common chromosome abnormality in horses with a 'normal' external female phenotype (Blue et al. 1978, Kutzler 2001). This can be confirmed using cytogenetic analysis to determine the karyotype of the individual. Other chromosome abnormalities are rare but include 63 XO/64 XX mosaics, 64 XY sex reversals and 65 XXX trisomy (Blue et al. 1978, Nie et al. 1993, Kutzler 2001, Vallagómez et al. 2011). Most of the XY sex reversal cases are Y chromosome positive but SRY-gene negative. The deletion of the SRY gene causes the fetus to 'default' to the female developmental pathway. Another genotype of 64 XY, SRY positive with female phenotype has been described, which may indicate that other gene mutations are involved (Vallagómez et al. 2011).

Multiple Ovulation and Twinning

Double ovulations occur in up to 30% of oestrous cycles, the frequency depending on the breed and type of the mare (e.g., Thoroughbreds have a higher rate than ponies). Accurate detection of such ovulations is important, as twinning is highly undesirable: first, because it often results in abortion (Fig. 31.5), and second, even if both fetuses survive and are carried to term, many are dysmature, resulting in a high neonatal mortality rate and dystocia with a potentially serious effect on future fertility of the dam, is very likely. A further complication is that if embryonic/fetal death occurs after the formation of the endometrial cups (see Chapters 4 and 5), these latter structures persist until they spontaneously regress as if pregnancy had been maintained, thus resulting in pseudopregnancy.

Not all conceived twins persist as after fixation, unilateral twins will be naturally reduced to a singleton 85% of the time (Ginther 1989a,b). Ginther (1989c) hypothesised that the mechanism for this was via deprivation of adequate embryonal–maternal exchange. Natural reduction via the 'deprivation hypothesis' occurs when a major portion of the vascularised (trilaminar) wall of one member of a twinset is apposed to the wall of the adjacent twin rather than with the endometrium (Ginther 1989c). In physical terms the thick vascularised portion of the small vesicle is forced by the myometrial tone and contractions into the thinner nonvascularised portion of the large vesicle, and therefore the smaller vesicle is unable to obtain adequate nutritional support from the endometrium and fails to survive (Ginther 1998). This explains the reason why, when

VetBooks.ir

• **Fig. 31.5** Aborted twin fetuses.

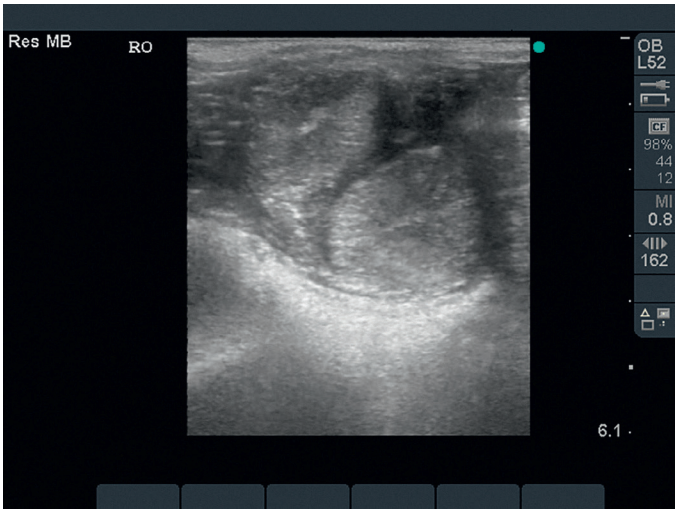
twins of dissimilar size (greater than or equal to 4 mm) fixate unilaterally, the vast majority naturally reduce to a singleton with regression of the smaller vesicle. When each member of the twinset is of similar size (< 3 mm difference), 27% will persist as twins (Ginther 1984, Ginther 1989c). It is the authors' experience that natural reduction is generally complete by day 35 of gestation and is usually preceded by changes in the heart rate or Doppler signal of the dying member of the twinset. Natural twin reduction does not generally occur before day 15 and does not occur when twins fixate bilaterally; therefore twin pregnancies that are detected during the mobility phase or are bilaterally fixated are best managed by the manual transrectal crushing of one embryonic vesicle.

Rectal palpation alone can be misleading in detecting a double ovulation, particularly when the two follicles are on the same ovary. The use of ultrasound examination of the ovaries, which should routinely be performed in conjunction with a thorough transrectal palpation, usually allows detection of a double ovulation. Sometimes the ovulatory area can appear indistinct for the first 24 hours; in these cases the mare should be reexamined 2 days later when it can be seen more easily whether there is more than one CL (Fig. 31.6).

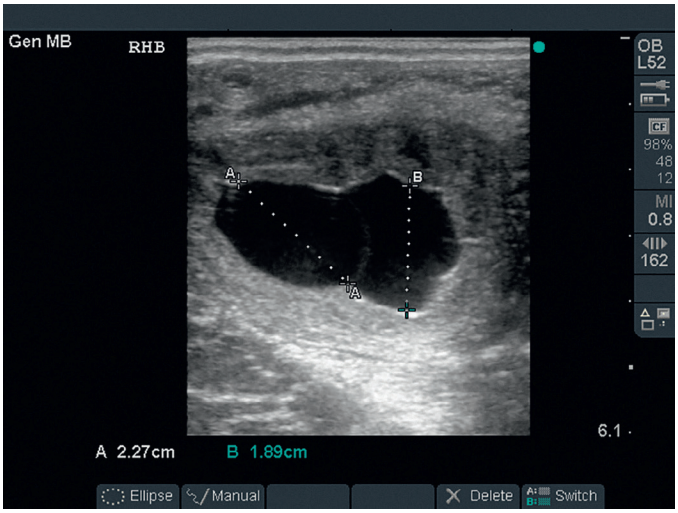
Multiple ovulations in the mare should not be regarded as a reason for withholding breeding. Instead, pregnancy rates are improved after twin ovulation. Although accurate interpretation of the ultrasound images of early pregnancies in the mare and the technique of crushing a conceptus are skills that require experience, the advent of B-mode ultrasound imaging has provided a method of more readily managing a twin pregnancy in the mare (Fig. 31.7).

Approaches to dealing with twins, depends on the stage of gestation at the time of detection:

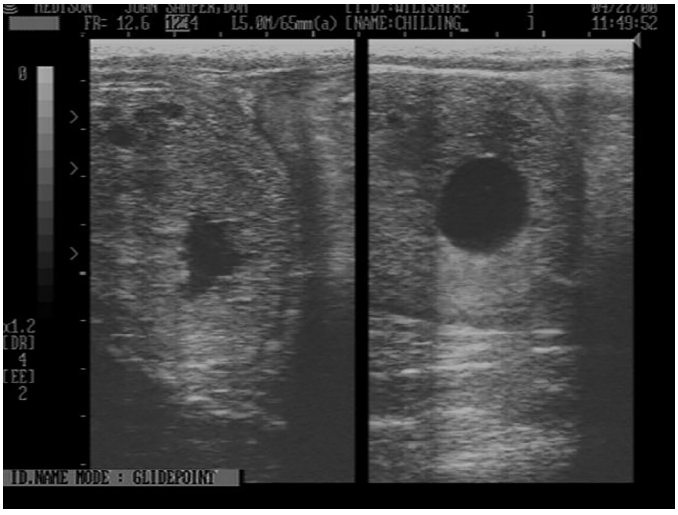
1. If the initial examination of the mare occurs before fixation (day 16–17), the twin embryos are reduced to a singleton by the manual destruction of one, either by pressure with the transducer or by the use of the hand (Fig. 31.8). One of the vesicles is isolated and crushed using the tips of the fingers and thumb, the fingers against the palm of the hand, or with pressure using the transducer.



• **Fig. 31.6** Two mature corpora lutea on the same ovary, leading to twin pregnancy.



• **Fig. 31.7** Unilateral twin conceptuses, 16 days of gestation.



• **Fig. 31.8** Ultrasonographic appearance after crushing one of two twin vesicles.

VetBooks.ir

During the mobility phase, the conceptus vesicles can be separated gently using the transducer to enable the procedure to be imaged. Alternatively, because the vesicles are still in the mobility phase, if the vesicles are situated next to each other, the mare can be reexamined after a short time interval and in many cases the vesicles will have moved apart spontaneously, facilitating isolation of a single vesicle. When the conceptus vesicles are of dissimilar sizes, the smaller one should be ruptured; this is easier at days 14 to 16 when they are 14 to 20 mm in diameter than days 11 to 13 when they are 6 to 11 mm in diameter.

Prefixation manual reduction of twins has the greatest success rate of producing a single normal healthy foal, and does not increase the risk of pregnancy loss higher than those associated with singleton pregnancies (Davies-Morel et al. 2012.) However, mares older than 9 years of age that have a twin reduced are potentially at greater risk of pregnancy failure (Schnobirch et al. 2013). In our veterinary practice (JRC), the subsequent pregnancy failure rate for the remaining member of a twinset is lower than that of singleton pregnancies. Success is dependent on operator experience but is not generally influenced by the position of the twins in the uterus (Sheerin et al. 2010, Schnobirch et al. 2013). Treatment with flunixin meglumine and altrenogest after reduction may reduce pregnancy failure rates by up to 5% (Sheerin et al. 2010) but should be applied on a case by case basis.

The disadvantage of this method is that it is more expensive, in that all mares are scanned before the time of return to oestrus. In addition, if ovulations that occur more than 3 days apart have not been detected, a mistaken diagnosis of a single pregnancy may be made if the second vesicle is too small to detect.

2. If initial examination is done after fixation but before day 30 and if the conceptuses are in opposite horns (bilateral twins), then it is best to manually crush them immediately up to 30 days, as this is usually effective in successfully reducing to a singleton. If both conceptuses are in one horn (unilateral twins), manual reduction can be attempted as long as the vesicles retain their spherical shape and can be separated; as soon as the vesicles coalesce and are separated only by a line on the ultrasound, manual reduction should not be attempted. Another option is to terminate the pregnancy using $PGF_{2\alpha}$. An additional approach is to use transvaginal ultrasound-guided allantocentesis of one vesicle.

Management of twin pregnancies after this period is complicated by the formation of endometrial cups at approximately day 35 of gestation. Endometrial cups remain functional until around days 100 to 150 of gestation in the presence or absence of a viable fetus. Therefore if twin pregnancies are not successfully managed before the cups are formed or if both embryos die after day 35, the mare usually will not return to a fertile oestrus for a prolonged period of time.

3. As twin pregnancy is allowed to progress further in gestation, the management options are reduced and success rates become lower. Dietary restrictions are commonly referred to as a means of reducing a twin pregnancy to a singleton. The evidence for this originates from one study performed by Merkt and co-workers (1982), who reported a 63% chance of success in reducing a twin to a singleton with dietary restriction for 2 to 4 weeks. It must be noted, however, that they also reported a 17% abortion and a 20% pregnancy failure rate; in addition this study was performed postfixation (from 21 days) and in the absence of any ultrasound examinations it is unknown to what extent natural reduction occurred irrespective of the effect of dietary restriction. As a result, such an approach cannot be recommended.

Management options include: manual reduction techniques, transvaginal ultrasound-guided twin puncture, cranio–cervical dislocation, and transcutaneous ultrasound-guided twin reduction. The option for repeated manual traumatisation (membrane slip/pinching/ballottement) still exists; however, there are some novel manipulation techniques available. One technique, described by McKinnon (2011), involves the oscillation of the fetus on its umbilical cord resulting in its dislocation from the umbilical cord. Transvaginal ultrasound-guided needle puncture involves the puncture of the conceptus with aspiration of the yolk sac or allantoic fluid, with or without stabbing the fetus. This is done via a transvaginal approach using a specifically designed transvaginal convex ultrasound probe and needle guide, with a suitably long aspiration needle. This is a technically demanding procedure requiring specialised and inevitably expensive equipment; as such, it is only performed by a limited number of specialists. The technique is successful in 33% of cases (Journée et al. 2013). Two different cranio–cervical dislocation (decapitation) techniques have been described (Wolfsdorf et al. 2005, 2009). The first is cranio–cervical dislocation of one member of a twinset via a transrectal approach between 55 and 90 days of gestation. The second is via a standing flank laparotomy between 58 and 110 days of gestation. Both techniques offer a 63% chance of producing a healthy single foal. Transcutaneous ultrasound-guided twin reduction is best performed between 115 and 130 days of gestation, and it involves the killing of the least developed member of a twinset by transcutaneous intracardiac injection of potassium chloride (Macpherson & Reimer 2000) or injection of the fetal heart, lungs, or abdomen with 10 to 20 mL of procaine penicillin (Ball 2005). After fetal death, the fetus gradually becomes mummified. Success as determined by the overall percentage of live singleton foals born ranges from 38% to 56% (Macpherson & Reimer 2000, Ball 2005, McKinnon 2011).

Failure to Establish and Maintain Pregnancy

Pregnancy failure is a source of major economic loss to the horse industry. Embryonic death occurs before organogenesis is complete, at approximately 40 days of gestation in horses. Abortion is defined as expulsion of the fetus before it is capable of life outside the womb, whereas a stillbirth is expulsion of a dead fetus that would have been capable of life outside the womb.

Embryonic Death

Fertilisation rates are normally high in horses, although differences may exist between normal and subfertile mares. Pregnancy losses are greatest during the embryonic period, estimated to be as high as 24% in mares (as reviewed in Ball (1988)). The period of greatest embryonic death in subfertile mares occurs in the interval before pregnancy can be detected with ultrasound (approximately day 11), particularly at the time when the embryo enters the uterus. Between days 14 and 40, estimates of the rate of embryonic death vary between 8% and 17%. Predicting embryonic loss can be difficult.

VetBooks.ir

Examination by transrectal ultrasonography provides the best means to predict and detect embryonic loss. Because pregnancy is often diagnosed at an early stage, it is important to inform owners that not all pregnancies detected with ultrasound will survive, even when apparently normal. Embryonic vesicles found to be smaller than expected for their age are considered to be at increased risk, whereas oversized vesicles are not (Ginther et al. 1985). Embryonic loss may occur between days 11 to 15 postovulation, without any ultrasonographic indication of its impending occurrence. Later in gestation, however, indications of impending loss may be observed and include a speckled or granular appearance of the conceptus, mobility of the vesicle after the normal time of fixation, fluid surrounding the vesicle, absence of a heartbeat, decreased volume of the conceptus, disruption of conceptus membranes, or oedema of the endometrial folds (Ginther et al. 1985).

In many species, genetic abnormalities play a significant role in pregnancy loss. Chromosomal abnormalities have been identified in normal appearing equine embryos (Rambags et al. 2005), and an increased incidence of embryonic loss has been associated with certain family lines or stallions. Many chromosomal abnormalities may not be inherited but may arise during formation and ageing of gametes and result in an inability of the resulting zygote to develop into a viable embryo. Ageing gametes may be increased when mating is not closely timed to that of ovulation. The incidence of embryonic loss is higher when insemination occurs after ovulation, and increases as the interval from ovulation to insemination lengthens (Koskinen et al. 1990).

A critical period occurs at 14 to 16 days of gestation when the presence of a conceptus inhibits luteolysis. Factors of conceptus origin inhibit the release of PGF from the endometrium and are essential for the maintenance of luteal function (Stout & Allen 2002). Unrestricted conceptus mobility is essential for pregnancy maintenance and prevention of luteolysis (Sharp et al. 1989). Anything that interferes with embryonic mobility, such as transluminal adhesions or endometrial cysts, or with uterine contractions that are the main propulsive force stimulating embryo movement may result in embryonic loss.

Extremes of age, either young or old, negatively affect fertility. The high rate of embryonic loss in yearling mares has been attributed to immaturity, inadequate nutrition, or physical stress (Mitchell & Allen 1975). Older mares have a lower pregnancy rate and a higher loss rate compared with younger mares (Ball et al. 1989). The effect of advanced age, however, is difficult to separate from acquired subfertility and is confounded by the effect of parity as the two are generally correlated.

The effect of age on fertility, at least in part, originates in the oocyte. When embryos were collected from the oviducts of young mares and old mares, significantly fewer cells and poorer morphology were observed in embryos from old mares (Carnevale et al. 1993). In a subsequent study (Carnevale & Ginther 1995), oocyte transfer was used to compare fertility of oocytes from young mares and old mares, and more embryonic vesicles resulted from young than old mares. Significantly fewer oocytes or embryos were recovered from mares 20 years of age or older than from mares 10 years of age or less, suggesting failure of ovulation or oviductal harvesting of the oocyte. Consequently, fewer oocytes had the potential for fertilisation and embryo development in the older mares (Carnevale et al. 1993). Other researchers have similarly found a lower pregnancy rate and an increased incidence of early embryonic death after transfer of embryos from subfertile mares compared with those obtained from maiden mares (Iuliano & Squires 1986, Vogelsang & Vogelsang 1989).

Oviductal pathology may result in either embryonic loss or fertilisation failure. Uterine pathology may affect nutrient transfer to the early embryo via histotrophe production, and result in retarded embryonic development or embryonic death.

Progesterone is essential for the maintenance of pregnancy. The only source of progesterone during the embryonic period is the primary CL (corpus luteum verum). To the authors' knowledge, there is no published evidence that progestagen supplementation will improve conception or 14 day pregnancy rates, yet anecdotally, it is used in cases of repeated conception failure. On the assumption that luteal insufficiency is important in early embryonic death (EED), many mares are given exogenous progesterone or progestogens in an attempt to prevent it from occurring. However, the rationale for this widespread practice is questionable. Although primary luteal insufficiency as a cause of EED has been reported (Bergfelt et al. 1992, Canisso et al. 2013), little evidence exists to indicate that primary luteal insufficiency is a major cause of embryonic loss; in fact, pregnancy loss is rarely caused by a fall in plasma progesterone (Irvine et al. 1990). Progesterone supplementation has been reviewed by Allen (1993), who is sceptical of any benefit. Nevertheless, withdrawal of supplementary progesterone therapy during midgestation may leave the clinician open to criticism if the mare subsequently aborts. Progesterone therapy is appropriate in mares that have uterine oedema and an indistinct corpus luteum at the time of first examination for pregnancy (15 days). These pregnancies are usually lost within a few days, but some can be successfully 'saved' by exogenous progesterone with the pregnancy maintained to term (Canisso et al. 2013).

Secondary luteal insufficiency, resulting from uterine pathology or unrelated inflammatory conditions, is a more likely cause of embryonic loss (Daels et al. 1989, Stabenfeldt & Hughes 1987). Inflammatory conditions with associated PGF release, even soon after ovulation and especially before endometrial cup formation, warrant attention. PGF inhibitors are effective in blocking PGF release but must be administered soon after the inciting cause (Daels et al. 1989). A more likely approach involves administration of progestogens. Exogenous progestogen can maintain pregnancy even after luteal activity is compromised (Daels et al. 1989) and should be continued until placental progestins are capable of maintaining pregnancy by around 100 days of gestation. Supplemental progesterone, however, has not improved pregnancy rates in normal mares receiving embryos (Iuliano & Squires 1986). Many dosage regimens do not effectively elevate or maintain plasma progestogen levels. Progesterone in oil (100 mg, IM), altrenogest **X** (0.044 mg/kg, by mouth) given daily, or a long-acting formulation of progesterone (BioRelease P4, BET Pharm) given weekly have been shown to be able to maintain pregnancy in ovariectomised mares and are therefore considered adequate. A number of synthetic progestogens, including medroxyprogesterone, norgestomet, and megestrol acetate, were unable to maintain pregnancy (McKinnon et al. 2000).

If altrenogest is to be administered to the mare with conception failure the authors would suggest that it is administered from no earlier than day 5 postovulation. If the mare becomes pregnant, therapy should be continued until either it can be demonstrated that endogenous progesterone levels are adequate (> 3 ng/mL; assay dependent) because the mare has secondary ovulation(s) that will boost endogenous progesterone production or until the fetoplacental unit takes over progesterone production at around 100 days of gestation. The authors recommend that mares are weaned off altrenogest by halving the dose for at least 1 week.

VetBooks.ir

There is a general notion that altrenogest therapy will do no harm. However, it should be recognised that altrenogest may suppress endogenous progesterone levels. A study by DeLuca and co-workers (2011) demonstrated that administration of altrenogest to pregnant mares was associated with lower concentrations of endogenous progesterone from days 14 to 18 and on day 21, compared with endogenous progesterone levels in pregnant mares not treated with altrenogest. This effect was presumed by these authors to be mediated by a reduction in pituitary LH release and a decrease in luteotropic support.

To ensure pregnancy maintenance, effective exogenous progestogen therapy should be continued through the first 4 months of gestation, until the placenta can be considered to provide adequate progestogens for pregnancy support. It is noteworthy that if using exogenous altrenogest, plasma progesterone concentrations can still be measured accurately because altrenogest does not cross react with the assay. When plasma progesterone is greater than 3 ng/mL (assay dependent), the altenogest can be discontinued. If the uterine environment is normal, progesterone therapy is probably not needed (Stabenfeldt & Hughes 1987); however, the difficulty lies in determining whether the uterine environment is normal from the viewpoint of the conceptus. Viability of a pregnancy should be reaffirmed when long term progestogen therapy is practised. Retention of a conceptus after fetal death may result from continued treatment.

Field trials conducted by Newcombe and co-workers (2001) on 2346 mares, determined that treatment with 20 to 40 μg buserelin between Days 8 and 12 significantly increased pregnancy rates by approximately 10%. Given the timing of this therapy, the effect is not via improved conception rates, but rather by decreasing pregnancy loss before 14 days of gestation (Pycock & Newcombe 1996b). The mechanism for this remains to be determined; however, increases in circulating LH concentrations have been demonstrated in buserelin treated mares (Kanitz et al. 2007).

Endometritis, which is often the result of a delay in uterine clearance of bacteria, is an important cause of embryonic loss in mares (Woods et al. 1987) and usually causes loss before maternal recognition of pregnancy. Once pregnancy is established, endometritis is a less frequent cause of embryonic loss (Ricketts 2003), provided anatomical defects are corrected. Endometritis is described in more detail elsewhere in this chapter.

Some specific infectious diseases have been associated with embryonic loss. For example, contagious equine metritis (CEM), a transmissible venereal disease caused by *Taylorella equigenitalis,* commonly results in embryonic loss after initial infection (Timoney & Powell 1988). Asymptomatic carriers of both sexes allow persistence within the horse population. Carrier mares, which may or may not have shown signs of previous endometritis, harbour the organisms in the vestibular area, particularly the clitoral fossa and sinuses. To test a mare for CEM, the medial clitoral sinuses (Fig. 31.9) should be swabbed and then seeded on Amies charcoal medium to be transported (kept preferably at 4°C) to a diagnostic laboratory. Information regarding control procedures for CEM and the other venereal pathogens are in national governmental or breed association guidelines and regulations.

Mare reproductive loss syndrome (MRLS), a problem associated with eastern tent caterpillars in Kentucky, is another specific syndrome associated with EED. Although much remains to be learned about the syndrome, it appears that ingestion of the setae of the caterpillars is involved. Reproductive losses occur in the first and last trimester (Riddle 2003). Nonreproductive syndromes associated with the disease include pericarditis and endophthalmitis.

• **Fig. 31.9** Swabbing the medial clitoral sinus for the contagious equine metritis (CEM) organism.

Mares normally resume cyclical ovarian activity very shortly after parturition, so that they are sometimes bred as early as 7 to 10 days postpartum (at the foal heat). There is conflicting evidence about the level of embryonic death if fertilisation occurs at this time, with some studies showing a higher rate and others no effect. An advantage of breeding at the first oestrus postpartum is that the foaling date will be approximately 1 month earlier the next year. Therefore the later a mare foals, the more pressure there is to breed at the foal heat. Pregnancy rates are clearly influenced by the selection criteria for mating at the foal heat. Some studies have found that even though pregnancy rates may be lower, pregnancy losses are no greater after foal heat breeding than after later breedings (Woods et al. 1987, Lowis & Hyland 1991). The presence of intrauterine fluid or ovulation before 9 days postpartum are correlated with lower pregnancy rates and a greater risk of embryonic loss; therefore an ultrasound examination of mares before foal heat breeding will help to differentiate those mares that are good candidates for breeding from those in which breeding should be postponed.

Maternal stress due to severe pain, malnutrition, or transport has been implicated as a cause of EED. Nutritional stress, either from malnutrition (van Niekerk 1965) or poor quality protein in the ration (van Niekerk & van Niekerk 1998), has been associated with an increased incidence of pregnancy loss. A good nutritional programme is clearly advisable for pregnant mares. Other stresses, such as hauling for long periods, are often suggested as causing embryonic loss. However, controlled studies failed to substantiate this belief (Baucus et al. 1990), and recent work failed to demonstrate any difference in pregnancy rates between transported and nontransported mares. The common practice of transporting mares to stud for mating and returning home the same day should not be detrimental to their fertility as long as the transport is safe and comfortable. Far from being avoided, regular exercise is important during pregnancy, although during the latter half, forced exercise

should be decreased. Rectal palpation and ultrasound examinations are safe procedures when performed correctly, and there is no indication that ultrasound examination is detrimental to the embryo (Vogelsang et al. 1989).

Abortion

An overall abortion rate of 10% after 60 days of gestation is usually cited as being normal for the horse; in practice, it is important to distinguish infectious from noninfectious causes. Vaginal discharge, premature lactation, and colic in pregnant mares may indicate an impending or recent abortion.

When abortion occurs, the mare should be isolated, a history obtained, and the fetus sent to an approved laboratory for necropsy. If a veterinary surgeon wishes to perform a postmortem examination, small but representative samples of liver, lung, thymus, spleen, and chorioallantois (ideally multiple sites, one of which is from the cervical star, which is the irregular, star-shaped avillous area of the chorion that lies over the internal os of the cervix (Fig. 31.10) (see also Chapter 4) should be sent fixed in formalin for histological examination. In addition, fresh (unfixed) tissues for equine herpesvirus 1 and 4 detection (EHV 1, 4) by polymerase chain reaction (PCR) should also be submitted. Paired serum samples from the mare and close companions can also be taken for serological investigation. Swabs from fetal heart/pleural fluid or liver/peritoneal fluid and the cervical pole of the chorion are used to screen for bacterial infection.

The fetus and fetal membranes (amnion, chorioallantois, and umbilical cord) must be carefully examined for the presence of abnormalities and areas of discolouration (Fig. 31.11). Placental evaluation in the field has been described (Cottrill et al. 1991, Rossdale & Ricketts 2002, Morresey 2004, Schlafer 2004), and a detailed description of abortion in mares has been described by Acland (1993). Many countries have regulations or codes of practice for the general approach to the management of an aborting mare, and these should always be followed.

Noninfectious Causes of Abortion and Stillbirth

Historically, twins have been the single most important cause of abortion in Thoroughbreds. However, they are now much less common due to the widespread use of ultrasonography. The diagnosis of twin pregnancy abortion can be made even if only one fetus is found, as examination of the placenta reveals an area devoid of villi where the two placentas (Fig. 31.12) were in contact. Twins should still be submitted to a diagnostic laboratory as twin pregnancies are equally susceptible to infectious abortion with EHV 1, 4.

In mares the umbilical cord is twisted, usually in a clockwise spiral. The normal length ranges from 36 to 83 cm (mean 55 cm). Increased cord length (over 80 cm total length) has been associated with excessive cord torsion. This twisting results in increased resistance to blood flow in both directions, and the resulting thrombosis and poor placental perfusion can lead to fetal death and abortion of an autolysed fetus. Decreased cord length can cause premature tearing of fetal membranes, leading to fetal asphyxia. Twisting and vascular compromise reportedly constitute the most common single cause of observed noninfectious abortion in the UK (Smith et al. 2003).

In mares, the interdigitating microvilli are connected by an unidentified electron-dense material. Placental separation involves dissolution of this substance and can occur prematurely. Causes of premature placental separation are largely unknown, although maternal stress and endophyte-contaminated tall fescue have been implicated. When placental separation occurs shortly before parturition, the thickened placenta often does not rupture through the cervical star, and the allantochorion bulges from the vulva as a so-called 'redbag' delivery (Fig. 31.13). As the placenta is

VetBooks.ir

• **Fig. 31.13** Premature separation of the placenta, commonly called 'red bag' delivery.

separating, the foal can become hypoxic, resulting in neonatal maladjustment syndrome.

Normal equine pregnancy is situated primarily at the base of a uterine horn, resulting in the pregnancy being positioned in the body and a pregnant horn. On occasion, the pregnancy fixates and develops in the uterine body. In this condition almost the entire chorionic surface of the placenta contained within the uterine body is without villi, whereas that contained within the horns is covered with an excessive number of villi. The proportion of the placenta corresponding to the two uterine horns is small, and the fetus is situated entirely within the uterine body. The fetus is growth retarded and is frequently aborted completely contained within its placenta. The abortion occurs when the nutritional demands of the fetus exceed the ability of the placenta to meet them at around 8 to 10 months of gestation. A retrospective analysis of breeding records by Jobert and co-workers (2005), reported the outcome of 30 body pregnancies. Nine of the 30 were present in the cranial body, and 21 were present in the caudal body. The pregnancy loss rate by 45 days was 11 and 62% for cranial and caudal body pregnancies respectively. From Day 45 to term the loss rate was 12 and 40% for cranial and caudal body pregnancies respectively, with abortions occurring between 4 and 9 months of gestation. Therefore there is a greater likelihood that body pregnancies will be carried for the full length of gestation if they are in the cranial uterine body (Jobert et al. 2005).

Fetal abnormalities may also result in abortion, although many are carried to term. Severe developmental anomalies involving the central nervous system or development of body cavities have been reported in aborted fetuses (see Chapter 9).

Tall fescue grass is widely used in the United States in pastures. Much of it is infested with an endophyte (*Neotyphodium,* formerly *Acremonium coenophialum*) that has dopamine agonist activity. Fescue infected with this endophyte actually performs better than noninfected fescue in pastures, hence its widespread distribution. However, when mares graze this fescue during gestation, a number of adverse effects have been reported to occur, namely: abortion, stillbirth, prolonged gestation, dystocia, thickened placenta, agalactia, increased mare mortality, and weak foals. In addition abnormal cyclicity, lower conception rates, and increased EED are also seen in mares grazing on infected fescue. Treatment of pregnant mares is aimed at either removing the mares from the fescue at 300 days of gestation, which will prevent problems at parturition, or treating affected mares with a dopamine antagonist such as domperidone.

Infectious Causes of Abortion

Equine Herpesvirus. Equine herpesvirus (EHV) is the single most important infectious cause of equine abortion. Abortion is primarily caused by EHV-1 and, on occasions, EHV-4. EHV-1 is also capable of causing respiratory disease (most noticeable in foals and yearlings), paralysis, neonatal foal disease, and uveitis/hypopyon. EHV-4 normally causes respiratory disease but occasionally has caused abortion in single mares. Transmission is by the respiratory route. Primary replication of the virus is in the mucosal epithelium, followed by a lymphocyte-associated viremia. The virus persists in the pregnant mare for long periods with the majority of abortions (90%) occurring within 60 days postinfection; however, the range from infection to abortion is 14 to 120 days.

Most mares of breeding age are clinically immune to respiratory disease but not to abortigenic infection. Spread of EHV-1 through a herd most commonly occurs without clinical signs. Immunity is short after natural infection (3–4 months), and individuals may be reinfected repeatedly. Additionally, the virus can persist in the trigeminal ganglia and can recrudesce in latent carriers; thus stressing pregnant mares may trigger abortion.

Abortions may occur from the fifth month of gestation to term but most commonly occur from 8 to 9 months to term. Infection of the fetus occurs by migrating leucocytes and/or infection of umbilical blood vessels, with the primary target organs in the fetus being the respiratory tract and liver. Premonitory signs of abortion are few; thus, typically, there is a sudden abortion without milk or udder development. The fetus is delivered in a fresh condition, often still enclosed in its membranes; rarely, some foals survive for up to 7 days, but they are weak, jaundiced, and have a marked leucopenia.

Diagnosis of abortion is by histopathology of the fetus. Fetal lesions include: serous pleural and peritoneal fluid effusions; jaundice of the mucous and placental membranes; enlargement of the spleen; perirenal oedema; haemorrhages of the entire respiratory tract; petechia of the oral mucosa and conjunctiva; focal hepatic necrosis with intranuclear inclusion bodies in liver and lung; and a necrotic and friable thymus. Specimens for submission to the diagnostic laboratory should include lung, liver, and thymus, both fresh/frozen and in formalin. Virus isolation is possible from lung, liver, and thymus samples that have been submitted in viral transport medium; fluorescent antibody tests can be performed on frozen sections of liver and lung. Diagnosis may also be confirmed by virus isolation or PCR, but unfortunately, there is no test to detect latent carriers. Serology of the mare is of no value in the diagnosis of abortion due to EHV because of the time period that has usually lapsed between maternal infection or viremia and abortion. In addition, the mare may have elevated antibody titres due to previous vaccination. Therefore analysis of the fetus and placental membranes remain the samples of choice.

The focus of control measures varies by country. In most countries control is achieved through vaccination programmes, with both modified live and killed vaccines being available. Controlled studies have showed that both are effective and that both have failures with vaccinated mares aborting. The vaccine is best considered as an aid in the prevention of viral abortion rather than absolute protection. Recommendations are to vaccinate pregnant mares with 3 doses, given at 5, 7, and 9 months of gestation.

Even with vaccination programmes, because immunity is not permanent and recrudescence in carriers may occur, management is important in disease control. Groups of mixed ages and reproductive status are most at risk from virus abortion; thus weanlings, yearlings, and other horses should be kept away from pregnant

VetBooks.ir

mares. The pregnant mares should be kept in groups by stage of gestation and maintained in relative isolation. All new arrivals should be isolated for 21 days and allowed to settle into their new environment. First foaling mares should be kept away from older mares. If mares are removed from a group, it is best not to reintroduce them as the whole group will have to reestablish their social 'pecking order' and thus be at risk of stress. All abortions and stillbirths should be investigated and the mare isolated pending the results. If the mare aborts in the paddock, the area where the abortion occurred should be cordoned off and the area disinfected. If other mares have had potential contact with aborted materials the whole group/paddock of mares should be considered at risk and thus isolated as a group and managed accordingly. Newly arrived animals, pregnant or otherwise, should never be mixed with pregnant mares on a farm.

Equine Viral Arteritis. Equine viral arteritis (EVA) is a contagious viral disease of horses first identified in 1953. An EVA outbreak was identified for the first time in the UK in 1993 and is subsequently a notifiable disease in the UK. Some outbreaks of the disease are not associated with abortions, whereas other outbreaks are associated with significant pregnancy losses. Outbreaks have been attributed to the use of fresh cooled semen from a carrier stallion. Although naturally occurring abortion from EVA is not common, it does occur sporadically, sometimes in clusters. Some breeds (e.g., Standardbreds) have a high incidence of seropositive individuals, yet disease is almost never seen. Other breeds are quite naïve and clinical signs (i.e., abortion) are more common; there may be some differences in pathogenicity between strains of the virus.

The two important routes of EVA transmission are: venereal from a stallion with infected semen, and aerosol via the respiratory secretions of an acutely infected horse. Close or direct contact is required for aerosol transmission to occur. After an average incubation period of 7 days, EVA is excreted in all bodily secretions, including respiratory secretions and urine for up to 21 days (possibly longer in urine). After infection, mares clear the infection and develop immunity. However, the virus may persist indefinitely in the accessory sex glands in stallions, which then become inapparent carriers and remain so for years, shedding the virus in the semen. It would appear that carrier status is testosterone dependent and exists in 30% to 60% of stallions that are infected (Little et al. 1991); there is no evidence that mares, geldings, or foals that acquire the infection become carriers. Interestingly, marked changes in semen quality in stallions experimentally infected with EVA have been described (Neu et al. 1992). At present, there is no commercially available treatment for a chronically infected shedder stallion. Surgical castration results in rapid cessation of virus shedding; however, this is not an attractive proposition for a breeding stallion. There has been some work to suggest that semen centrifugation using density gradients may reduce the viral load of semen samples from shedding stallions (Morrell et al. 2013); however, no data is available on the ability of processed samples to infect mares. It has, however, been demonstrated experimentally that reducing testosterone concentrations via GnRH vaccination or by means of GnRH antagonist has resulted in conversion to nonshedder status (Burger et al. 2006, Fortier et al. 2002).

Venereal transmission is believed to be the major cause of widespread dissemination of the virus. In breeds that permit the use of artificial insemination, the virus can be transmitted through the use of fresh, chilled, or frozen semen. In a controlled study (Cole et al. 1986), seronegative mares were bred to carrier stallions. The mares were then transported to another location and housed with seronegative mares that were in the seventh to eleventh month of gestation. All mares became seropositive. Clinical signs would have gone unobserved but for the experimental protocol that included twice daily monitoring of body temperature and weighing of feed remaining at the end of the day. A slight febrile response and mild anorexia was detected. Of the exposed mares, 10 of 14 pregnant mares aborted.

Clinical signs of EVA are very variable, and typically, there are no clinical signs other than abortion in mares. The classic clinical signs are: an influenza-like illness with pyrexia for 1 to 5 days; depression; a nasal discharge; conjunctivitis; anorexia; and a focal dermatitis and oedema of the limbs, ventral abdomen, scrotum, prepuce, and periorbital regions. Abortion may occur during or shortly after an acute illness or subclinical infection. The majority of abortions occur 23 to 57 days after exposure, or 6 to 29 days after the onset of fever in the mare. Foals can be born infected and die within 72 hours, appearing normal when born or born ill, then developing respiratory signs or enteritis.

A definitive diagnosis, based on clinical signs alone, is not possible due to their variable nature. Acute EVA can be confirmed by virus isolation from nasopharyngeal swabs, heparinised blood samples, and urine and semen samples. Serological evidence of EVA exposure can be found by taking an initial serum sample as soon as possible after clinical onset, followed by a convalescent sample 10 to 14 days later to detect a rise in the EVA antibody titre. Diagnosis of abortion due to EVA is largely dependent on virus isolation from the placenta or fetal tissues; there are no pathognomonic gross lesions. After abortion the fetal tissues that should be collected for laboratory diagnosis are: lung, liver, placenta, and fetal fluids. If EVA is the cause of the abortion, it is fairly easy to isolate. Mares infected with EVA will usually abort partially autolysed fetuses in contrast to fresh fetuses aborted by mares infected with EHV.

Because virtually all acutely infected horses recover uneventfully after EVA, any treatment is symptomatic. In the UK, the code of Practice considers control measures for EVA and provides excellent guidance in the event of an outbreak. A modified live-virus vaccine is available in North America, whereas a killed vaccine (Artervac, Zoetis) is available in the UK. In the United States, use of the vaccine, although regulated by the various state governments, is becoming more widely practised due to recent outbreaks. There is some reluctance to vaccinate because once vaccinated, a stallion cannot be distinguished from a naturally infected animal by serology alone. Virus isolation from the semen can distinguish seropositive carriers from vaccinates. It must be remembered that certain countries will not accept the importation of seropositive animals or their semen. If an animal is to be vaccinated, a blood sample for serology should be taken before vaccination, followed by a second blood sample taken 10 days after the second vaccination to ensure an adequate serological response to vaccination. Many studs in the UK are requiring confirmation that mares are seronegative to EVA before arrival at stud and exposure to the stallions. Vaccination of stallions has been widely adopted in the UK in Thoroughbred and sportshorse stallions, yet issues with vaccine supply and cost of the vaccine has resulted in less uptake in recent years. The UK is EVA free, yet other areas of mainland Europe are not.

Other measures of control include keeping a distance of about 90 yards between a shedding stallion and other horses or between a mare bred to a shedding stallion and other mares. Mares can be bred to a shedding stallion as long as they are vaccinated at least 21 days before breeding or are kept isolated from other seronegative horses for a month after breeding.

VetBooks.ir

Leptospirosis. Leptospirosis is a zoonotic disease with worldwide distribution. The predominant serovar affecting horses varies by country and region. *Leptospira interrogans* serogroup *Pomona* serovar *kennewicki* has been reported to be most often implicated in equine abortion in Kentucky. *L. kirschneri* serogroup *Grippotyphosa* serovar *grippotyphosa* has also been reported. The raccoon is the maintenance host for grippotyphosa, but the maintenance host for Pomona serovar *kennewicki* has not been identified.

Favourable conditions are moist, warm environments, and invasion occurs through mucous membranes and soft moist skin. A bactaeremia occurs after an incubation period of 4 to 10 days, with pathogenical serovars localising in the kidneys or genital tract; clinical signs in the mare are often unobserved, with abortions occurring from 6 months to term. Gross lesions of the fetus vary and may include icterus and a swollen liver and/or kidneys, whereas placental lesions are common. Diagnosis is by identification of the organisms by real-time PCR and/or fluorescent antibody test (FAT) and by serology of the mare by microscopical agglutination test (MAT) (Erol et al. 2014); control is achieved by good sanitation, hygiene, and control of wildlife. Some reports indicate potassium penicillin may be useful in pregnant mares with rising titres, whereas human studies indicate that intravenous penicillin in high doses may be a reasonable treatment. A vaccine (Lepto EQ Innovator) is available in the United States to protect against infection by Leptospira interrogans serovar Pomona.

Bacterial/Fungal Abortion. Bacterial/fungal abortion (placentitis) is a leading cause of abortion and neonatal disease in horses. A large number of bacterial species that gain access to the placenta can cause abortion in the mare, with the ascending pathway via the cervix being the primary route of infection. Rarely, bacteria may be in the uterus at the time of conception or arrive haematogenously afterwards. Bacteria that spread rapidly through the allantochorion often infect the fetus, causing acute bacterial septicaemia. More chronic ascending infections are often localised around the cervical star and cause a focal or local placentitis (Fig. 31.14), which often leads to placental insufficiency with abortion of a growth-retarded fetus or the birth of a dysmature foal. The placenta is often thickened and covered with exudates, and the fetus is septicaemic. Bacteria that cause placentitis are similar to the organisms that cause endometritis (see later in this chapter); they are often opportunist pathogens that can be isolated from the caudal genital tract of normal mares. Normally, there are premonitory signs of an impending abortion, such as premature mammary gland enlargement, premature lactation, and relaxation of the vulva.

• **Fig. 31.14** Ascending placentitis; note the discoloured, thickened area at the cervical pole.

Early diagnosis is critical to be able to begin effective treatment that can result in the survival of a healthy foal. The ability to diagnose placentitis early, before clinical signs of premature lactation or vaginal discharge are observed, will improve the chances of successful treatment. Although it cannot be recommended to examine all mares routinely at intervals for placental abnormalities, mares with a history of problems or at high risk may be periodically examined for signs of placental disease.

Reef and co-workers (Reef et al. 1996) have described the assessment of fetal well-being in utero using a transcutaneous approach. The uterus is examined at multiple sites, attempting to cover all four quadrants. Fetal heart rate, the diameter of the fetal aorta, fetal activity, maximum depth of fetal fluids, utero placental contact, and utero placental thickness have been found to be related to the pregnancy outcome. Significant utero placental thickening is consistent with placentitis, whereas anechoic spaces between the uterus and placenta suggest placental separation. Although observed abnormalities are good indicators of placental disease, the lack of abnormal signs on transcutaneous examination does not mean that placental disease does not exist; focal areas of placentitis may go undetected.

Most cases of placentitis stem from the spread of bacteria through the cervix, infecting the chorioallantois in the region of the cervical star, and spreading from there. Renaudin and others (1999) have examined using transrectal ultrasonography the utero placental unit near the cervical os, near the area where most cases of placentitis would be expected to originate. Measurements of the combined thickness of the uterus and placenta (CTUP) at the ventral portion of the uterus, rostral to the internal cervical os, are obtained. The normal thickness of the utero placental unit is dependent on gestational age (8 mm at 270–300 days gestation, 10 mm at 300–330 days, 12 mm > 330 days). Normal values for the CTUP have been established in a variety of breeds; the authors generally use those determined in Quarter Horses (Renaudin et. al. 1997) as a guide. Multiple measurements should be taken and the mean value obtained because a single value may be misleading, especially if the image is taken at an oblique angle. Placentitis has been demonstrated to cause a marked increase in CTUP, and thicknesses higher than the normal ranges have been associated with pending abortion and placental pathology. Although an elevated CTUP may suggest pathological changes, mild increases may require confirmation by the presence of other clinical signs. Conversely, not all mares suffering from an ascending placentitis show ultrasonographically detectable placental thickening.

Other features of ascending placentitis are placental separation with accumulation of purulent material/fluid between the uterus and placenta. Measurements in these cases are overruled by the presence of separation, which is strongly indicative of an ascending placental infection (Fig. 31.15).

Speculum examination of mares with a purulent discharge usually reveals an exudate originating from the cervix; this will also enable swabbing of the cervix in order to determine the aetiological agent(s) and their sensitivity pattern. In addition, progestagen and total oestrogen concentrations can be measured to assess the health of the fetoplacental unit. Mammary electrolytes are unreliable for predicting readiness for birth in cases of placentitis. Serial hormone measurements have been suggested as a means of diagnosing pathological changes, with mares with acute placentitis often demonstrating a rapid decline in plasma progestagen concentrations, whereas mares that develop chronic placentitis often have increased plasma

VetBooks.ir

• **Fig. 31.15** Ultrasonographic image of the combined uterus and placenta, near the internal cervical os. The placenta and uterus are separated by a hyperechoic exudate.

progestin concentrations. Ball and co-workers (2013b) demonstrated that concentrations of oestradiol-17β sulphate declined precipitously after experimentally induced bacterial placentitis, suggesting that maternal oestrogen concentrations may be useful as an early marker of a placental insult. Recent work by Canisso and co-workers (2014) demonstrated that concentrations of the acute phase proteins serum amyloid A (SAA) and haptoglobin (Hp) rapidly increased subsequent to experimental induction of placentitis and remained elevated until abortion. Neither fibrinogen nor white blood cell concentrations appeared to be useful markers for placentitis in this study. Parturition did not trigger an increase in either SAA or Hp in normal foaling mares. SAA, however, is also a very nonspecific indicator as many other acute inflammatory conditions (i.e., vaccination) may result in an elevation of SAA.

If placentitis is diagnosed via clinical signs or detection of an increased CTUP, treatment should be initiated immediately to ensure the best case outcome; parturition should not be induced. The longer the fetus is carried in utero, the better chance it has to reach a level of maturity that will allow it to survive after birth. If a vaginal discharge is present, culture and sensitivity may be beneficial in choosing an appropriate antibiotic. The treatment strategy is aimed at controlling the infection, reducing the associated inflammation and promoting myometrial quiescence. Antibiotic choice should be determined by culture and sensitivity results. If these are not available, broad spectrum antibiosis should be instigated. Trimethoprim sulfadiazine (30 mg/kg, bid) or a combination of potassium penicillin G (22,000 IU/kg, qid) and gentamicin (6.6 mg/kg, sid) have been demonstrated to penetrate placental and fetal tissues and are therefore the antibiotics of choice. Despite ceftiofur sodium being found to penetrate endometrial tissues, it has not been found to cross to the fetal membranes, and thus it is not recommended for cases of placentitis (Macpherson et al. 2014).

Many treatment regimens have been suggested – many extrapolated from other species – and have been largely anecdotal. Progestins are advocated to promote uterine quiescence in mares with high risk pregnancies and have been demonstrated to prevent prostaglandin induced myometrial activity; they are effective in preventing prostaglandin induced abortion. Tocolytics, such as isoxsuprine and clenbuterol, have been shown to cause short-term uterine relaxation; however, they may not be of practical use in cases of placentitis. Nonsteroidal antiinflammatories, such as flunixin meglumine and phenylbutazone, are obvious choices to reduce inflammation and prevent prostaglandin-mediated abortion. Other agents have been investigated, including pentoxifylline, which is used clinically in humans as a peripheral vasodilator and has been demonstrated to down regulate proinflammatory cytokines and reduce the mortality rate in premature human infants with sepsis. Recent data from Bailey and co-workers (2012), however, suggests that short term therapy with pentoxifylline does not affect uterine blood flow in the mare. Acetylsalicylic acid (aspirin) has been demonstrated to reduce the incidence of preeclampsia in women with abnormal placentation and has been demonstrated to improve uterine blood flow in the mare.

Recent research with experimental models of placentitis would suggest that aggressive antibiotic therapy with trimethoprim sulfadiazine alone can substantially improve pregnancy outcome (Christiansen et al. 2010). The addition of aspirin (50 mg/kg, PO, bid) resulted in a marginal increase in the percentage of viable foals born in this study. A combination of trimethoprim sulfadiazine (30 mg/kg, PO, bid), altrenogest (0.088 mg/kg, PO, sid), and pentoxyfylline (8.5 mg/kg, PO, bid), however, would appear to be the recommended therapy at this time (Bailey et al. 2007). A specific cause of placentitis, found primarily in Kentucky and the surrounding area, has been identified as a nocardioform organism, *Crossiella equi.* This disease is characterised by an area of placentitis with a tan mucoid exudate located at the base of a uterine horn near the body of the placenta.

Aspergillus spp. is the most common cause of mycotic placentitis and abortion in the mare. Other fungi such as *Mucor sp.* have been reported; much less common is placentitis due to *Candida spp.* infection. Fungal disease can have a similar pathogenesis to bacterial abortion with inflammation of the chorion beginning at the cervical pole. Infection may also originate from the respiratory tract, through the circulatory system, to the uterus and placenta. Typical gross lesions of the placenta include necrotic areas that are difficult to distinguish from bacterial lesions. The chorionic surface may be dry, thick, and leathery. There may be lesions on the fetus, especially the skin. Fungal elements are easily demonstrable in smears and cultures if they are responsible for the abortion. Before term, these cases are very difficult to manage due to the difficulty in administering antifungal medications, and cases often result in abortion.

Endometritis

Endometritis, an acute or chronic inflammatory process involving the endometrium, has been recognised for many years as a major cause of infertility in brood mares. This subfertility is due to a hostile environment for the developing conceptus, and in some cases, the endometritis causes early regression of the CL through inflammation and endogenous prostaglandin release. Endometritis frequently occurs as a result of microbial infection but can also be due to noninfectious causes.

VetBooks.ir

The underlying aetiology of the specific cause of endometritis determines the type of treatment to be used, and the following classification system for equine endometritis is useful:

- Venereal infection
- Chronic infectious endometritis
- Persistent breeding-induced endometritis (PBIE) caused by delayed uterine clearance (DUC)

In the past it was generally assumed that the uterine lumen of the normal fertile mare is bacteriologically sterile or may have a temporary, nonresident microflora. This is despite the fact that the mare's reproductive tract is often contaminated with bacteria from the act of coitus, foaling, and veterinary procedures. In addition, mares with a defective vulvar conformation can also aspirate air, bacteria, and debris into the vagina that can develop into endometritis.

The bacterial species that cause bacterial endometritis are numerous and can be classified as follows: (1) contaminants and commensals; (2) opportunists, causing an acute endometritis; and (3) venereally transmitted. Normally, the vestibular and clitoral area has a harmless and constantly fluctuating bacterial population. In association with benign saprophytic organisms, opportunistic organisms such as *Streptococcus zooepidemicus, E. coli,* and *Staphyloccocus spp.* can be found. The stallion's penis is colonised by similar organisms. *S. zooepidemicus* is the most commonly isolated bacterial species from acute endometritis, particularly in the initial stages. *E. coli* is the next most common isolate. The uterus responds to these bacteria with a rapid influx of neutrophils (Pycock & Allen 1990). Normally, these neutrophils phagocytose and kill the bacteria rapidly (<24 hours). The inflammatory byproducts are then mechanically evacuated, and the endometritis resolves itself except when the mare suffers from pneumovagina or is a 'susceptible' mare. Susceptible mares have a delay in uterine clearance and fail to resolve the inevitable postbreeding endometritis, with inflammatory byproducts accumulating as intrauterine fluid. Such mares have a reduced pregnancy rate due to a hostile environment for the early developing conceptus.

Venereal Endometritis

In addition to opportunist pathogens, some bacteria may be venereally transmitted – e.g., *Taylorella equigenitalis* (contagious equine metritis organism, CEM), *Klebsiella pneumoniae* (capsular types 1, 2 and 5), and *Pseudomonas aeruginosa* (some strains) – by asymptomatic carriers of either sex. Mating or gynaecological examination may result in their transfer into the uterus. Stallions may harbour the organisms over the entire surface of the penis and in the distal urethra. Control is by routine screening of swabs taken before mating by laboratories experienced in the isolation and identification of these specific organisms. Anaerobic bacteria have been isolated from the mare's uterus, with *Bacteroides fragilis* the most frequent (Ricketts & Mackintosh 1987). Further work is needed to assess the importance of anaerobes in endometritis.

Diagnosis. Before the breeding season, swabs should be taken from the clitoral fossa, clitoral sinuses (only the medial sinus may be obvious), and the vestibule. The perineal area of the mare should not be cleaned except for the removal of gross contamination of the vulva with faeces using a dry paper towel. A protective disposable glove should be worn by the veterinary surgeon on the hand used to evert the ventral commissure of the vulva and expose the clitoris. The swabs should be placed in transport medium, clearly labelled with the mare's name, and sent to an approved laboratory. It is important to penetrate the clitoral sinus, and therefore a large swab tip should not be used. Swabs are cultured aerobically on blood and MacConkey's agar to screen for the presence of *K. pneumoniae* and *P. aeruginosa.* Microaerophilic culture on chocolate blood agar (with and without streptomycin) must also be done for the detection of CEM if not in a CEM-free country. In addition, in stallions, multiple swabs must be taken from the urethral orifice, ideally before and after ejaculation, with the former sample being of preejaculatory fluid, urethral fossa, and/or sinus, penile sheath, and semen. In the UK, this screening has been successful in virtually eradicating CEM and vastly reducing the incidence of venereal disease.

Treatment. Any mare that is suspected of having a venereal infection must not be bred. In the case of clitoral or vestibular infections, topical treatment is used. This involves thorough cleaning with chlorhexidine surgical scrub followed by the application of 0.2% nitrofurazone ointment for *T. equigenitalis,* 0.3% gentamicin cream for *K. Pneumoniae,* or silver nitrate and gentamicin cream for *P. aeruginosa.* These pathogens, particularly *P. aeruginosa,* are difficult to eliminate from the clitoris; hence clitoral sinusectomy or clitorectomy may have to be used in refractory cases. A broth culture containing a mixture of growing organisms prepared from the normal clitoral flora can suppress venereal pathogens in some cases. Evidence for the successful elimination of infection is based on three negative sets of clitoral and endometrial swabs, taken at weekly intervals.

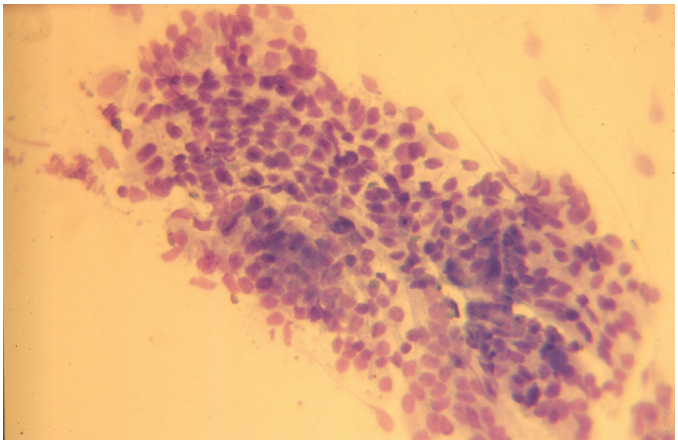
Chronic Infectious Endometritis

Chronic infectious endometritis is found most frequently in older mares that have had several foals. Such mares have compromised uterine defence mechanisms that allow the normal vestibular and vaginal flora to colonise the uterus, thus inducing a chronic endometritis. A diagnosis of endometritis can be made by collection of samples during oestrus for bacteriological culture and cytological examination. The veterinarian must verify that the mare is not pregnant before passing a swab through the cervix. The ideal technique should ensure that the samples are obtained from the uterine lumen only. It is important to ensure that the method of swabbing does not introduce bacteria into a previously normal uterus. A guarded swab is passed into the uterine lumen, and the swab tip is exposed only when it is in the uterine lumen. A swab for cytological examination should also be taken. A flaw with this technique is that the swab only samples a small area of the uterus, usually in the more caudal regions of the uterine horn or body. It has been suggested that the type of bacteria influences the exudate produced by the endometrium, which in turn affects the ability to obtain a representative cytology sample by swabbing (LeBlanc et al. 2007). A low volume lavage (LeBlanc et al. 2007) is a preferable method in many cases, especially in cases of negative culture results even when associated with infertility. To utilise this technique, a small volume (100 mL) of saline or lactated Ringers is introduced into the uterus in an aseptic manner with a large bore catheter. The lavage fluid is then massaged in the uterus per rectum in order to cover a greater percentage of the endometrial surface and then retrieved into a sterile vessel such as a 50 mL centrifuge tube. If the retrieved fluid is not clear it should be centrifuged, and the pellet used for culture and cytological examination. More recently, a double-guarded low volume lavage technique using 250 mL of fluid has been described (Christoffersen et al. 2015). Another option for the collection of cytology samples is to use a cytobrush. The low volume lavage and cytobrush are both superior to the use of the cotton swab (Overbeck et al. 2011, Cocchia et al. 2012), yet due to the fact that they are more sensitive, more studies

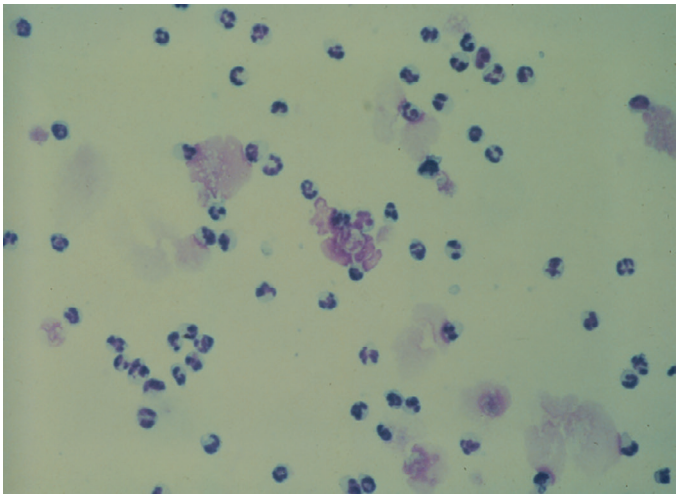
VetBooks.ir

are needed to establish criteria for interpretation of inflammation (Cocchia et al. 2012).

Although *Strep. zooepidemicus* typically incites a strong inflammatory response, resulting in the identification of intraluminal fluid on transrectal ultrasound examination and a positive cytology (and culture), it has been shown that other pathogens such as *E. coli* may not incite the inflammatory response to the same degree, and cytology (and culture) may be negative (LeBlanc et al. 2007). Swabs for culture should be plated on blood and MacConkey's agar and incubated at 37°C for 48 hours. Chromogenic agar plates are used by some practitioners in addition to blood and MacConkey's to aid in the identification of the bacteria isolated (Beehan & McKinnon 2009); cultures should be examined at 24 and 48 hours. An air-dried smear for cytology is made by gently rolling the other swab on a microscope slide. The smear is then stained with a rapid modified Wright's stain such as Diff-Kwik (American Hospital Supplies); the stained smear should be examined for the presence of inflammatory and endometrial cells (Fig. 31.16), the latter confirming that a satisfactory sample was obtained. Uterine cytology provides critical information that assists in interpretation of culture results, and diagnosis of endometritis is based on the presence of significant numbers of neutrophils in the smear (Fig. 31.17). Mares that have more than 5 neutrophils/high power field (X400) present in a cytology smear should be considered to have active endometritis.



• **Fig. 31.16** 'Negative' endometrial cytology: numerous endometrial cells, no neutrophils.



• **Fig. 31.17** 'Positive' endometrial cytology: numerous neutrophils.

If certain pathogens (e.g., *Strep. zooepidemicus*) are present in the uterus, the mare's immune system will mount a response, and neutrophils will usually be observed in a cytology sample. If the cytology sample is 'negative', it means that there are sufficient endometrial cells present to make a diagnosis, and if there are no or rare neutrophils, then bacteria that result from the culture taken may be contaminants inadvertently picked up during the procedure. However, in some cases a positive culture with a negative cytology warrants treatment (LeBlanc et al. 2007).

In Table 31.1, the possible outcomes are outlined. First, if the cytology is 'positive', then the culture should be submitted to the laboratory to identify the pathogen and determine its antibiotic sensitivity. If a pathogen is not identified (i.e., 'no growth'), yet the cytology is positive, various explanations exist. The mare may be recovering from a previous infection, and although residual inflammation is evident, the pathogen has been eliminated. Alternatively, some other cause of noninfectious inflammation may be present. Then again, the mare may have a uterine infection, but a sample handling or laboratory error killed the pathogen, resulting in a negative culture result. It has also been suggested that anaerobic bacteria will result in a positive cytology but fail to yield results with standard aerobic culture techniques (Ricketts & Mackintosh 1987). In the case of a positive cytology and negative culture, a decision must be made, based on history and other findings, whether to repeat the culture and cytology procedure or treat the mare. If treatment is considered, modalities such as uterine lavage rather than antibiotic infusion may be preferable.

In some cases, an endometrial biopsy may be a useful diagnostic aid. It has been suggested that culture and cytology (via histopathology) from an endometrial biopsy may be the gold standard as it is more sensitive with a greater positive predictive value compared with cotton swabs (Nielsen 2005). This topic is covered in more detail later in this chapter, under "Uterus". For detailed reviews of the clinical application and pathological findings, readers should consult Kenney and Doig (1986).

Ultrasonography is indispensable in the diagnosis of endometritis. Since the first description of the identification of the collection of small volumes of intrauterine fluid using ultrasound, which could not be palpated per rectum (Ginther & Pierson 1984), general awareness of the frequency of this abnormality has increased. Endometrial secretions and the formation of the small volume of free fluid may be associated with the same mechanism that causes normal oestral oedema (Fig. 31.18). In many cases, the uterine luminal fluid that accumulates before mating is sterile and contains no neutrophils (Pycock & Newcombe 1996a). However, free fluid in the lumen is a warning sign that the mare may have problems

TABLE 31.1 Possible outcomes of endometrial culture and cytology examination

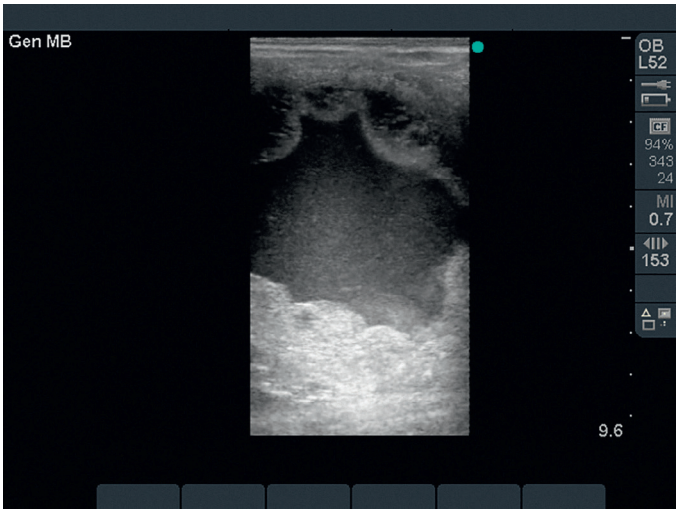
• **Fig. 31.18** Uterine oedema and a small amount of fluid in the lumen of the uterine horn, typical of early oestrus to midoestrus.



• **Fig. 31.19** Excessive uterine fluid in the lumen of the uterine body, indicative of severe endometritis.

with delayed uterine clearance (see persistent breeding-induced endometritis (PBIE) later in this chapter). The amount of fluid that should be considered significant is not clear. The significance depends to some extent on when during oestrus the fluid is observed; fluid detected early in oestrus may have disappeared when the mare is further advanced in oestrus and the cervix relaxes more. Small volumes of intrauterine fluid during oestrus do not affect pregnancy rates, in contrast to mares with larger (> 2 cm depth) collections of fluid (Pycock & Newcombe 1996a, Brinsko et al. 2003). In mares that are susceptible to endometritis, there is an accumulation of more fluid than in nonsusceptible mares.

Generally, if there is more than 1 cm of fluid during oestrus, some attempt should be made to remove this before breedin g using oxytocin treatment. If the volume is more than 2 cm (Fig. 31.19), the fluid should be investigated for the presence of inflammatory cells and bacteria. Intrauterine fluid during dioestrus is indicative of inflammation and associated with subfertility due to early embryonic death and a shortened luteal phase (Newcombe 1997).

Transrectal ultrasonography provides a rapid, noninvasive method of assessment of the uterus. In a study involving ultrasonographic examination, cytological, and bacteriological sampling of the uterus in 380 brood mares before mating (Pycock & Newcombe 1996a), it was concluded that if no free fluid is detected during oestrus, then acute endometritis as detected in cytology is absent in 99% of cases.

The most favoured approach to treatment has been the infusion of various antibiotics into the uterine lumen during oestrus. The intrauterine route is usually preferable to systemic therapy, as most acute endometritis cases are localised. Systemic treatment alone, or in combination with local application, is suitable in a few circumstances. Ideally, the choice of antibiotic for local treatment should be based on *in vitro* antibiotic sensitivity tests. However, in many cases this is not possible and a broad spectrum antibiotic or combination of antibiotics should be used that is effective against the mixed aerobic and anaerobic infections that commonly occur. Although 35 to 40 mL is a sufficient volume to cover the entire endometrial surface in most mares, a larger volume (up to 100 mL) may be better in older, pluriparous mares to ensure distribution throughout the uterus. Larger volumes will flow back out through the cervix and be lost. The number of treatments required depends on individual circumstances and the inciting pathogen, but a single treatment may be effective or daily infusions for 3 to 5 days during oestrus are effective in most cases, especially if combined with oxytocin. The success of treatment can be monitored using ultrasonography to identify the presence of intrauterine fluid. Repeated endometrial swab/smear or biopsy examinations may be used to monitor the response to therapy; however, every time the cervix is breached there is the risk of introducing more bacteria.

Immunomodulators have been used as treatment adjuncts for endometritis. Available products use a mycobacterium cell wall extract or propionobacter preparations. Although it is not yet clear the exact mechanism by which fertility is improved, there is some evidence that, in some mares, treatment is helpful (Rogan et al. 2007).

In addition to the antibiotic therapy, repeated treatment with PGF increases the frequency of the follicular phases, thus allowing intrauterine therapy to be used more readily. It also reduces the duration of the luteal phase in which progesterone increases the susceptibility to infection. Predisposing causes to the chronic endometritis, such as defective vulvar or cervical conformation, should also be treated.

Recurrent infections with the same bacterial or fungal agent are frustrating to deal with, and it is not uncommon for the clinician to treat one infection only to culture a different one at the next cycle. Of particular interest are agents which colonise in an extracellular matrix known as a biofilm. Biofilm formation is a highly complex process involving the switch from a free floating existence to a sessile (attached) mode of growth. The latter enables the biofilm community to be protected from adverse environmental conditions, such as desiccation, as well as antimicrobial agents. Approximately 80% of the Gram-negative bacteria, e.g., *E. coli, Klebsiella pneumoniae, Pseudomonas aeruginosa,* cultured from the equine uterus are able to produce biofilm *in vitro* (Ferris et al. 2014), and although *Candida* spp. are usually referred to as fluid living, they are known biofilm producers. Beehan and co-workers (2015) demonstrated that approximately 30% of *E. coli* cultured from the reproductive tracts of mares had biofilm-forming potential and subsequently demonstrated for clarity by scanning electron microscopy that these isolates were capable of forming a biofilm colony. In addition, Ferris and co-workers (2016) demonstrated that *P. aeruginosa* was capable of producing biofilm-like material *in vivo*.

VetBooks.ir

Solutions of acetylcysteine (ACE), hydrogen peroxide, ethylenediaminetetraacetic acid (EDTA)-Tris, and dimethyl sulfoxide (DMSO) have been used clinically to treat uterine infections suspected to be complicated by biofilm presence, but only limited evidence from controlled studies is available. *In vitro* studies (Ferris et al. 2014, Ferris et al. 2016, Loncar et al. 2017) have assessed the effectiveness of ACE, EDTA-Tris, gallium nitrate, hydrogen peroxide, DMSO, and antimicrobial peptide mimic (APM; Ceragyn) as antibiofilm treatments. They have cumulatively demonstrated that no one treatment consistently prevents biofilm biomass in all bacterial isolates. These bacterial species-specific results stress the importance of acquiring organism identification when developing a treatment plan for bacterial endometritis because not all treatments are effective against every bacterial species (Loncar et al. 2017). It is the author's preference to use a 10% to 20% solution of DMSO in 1 L lactated Ringer's as an antibiofilm agent; it also seems to be particularly useful in mares with a significant amount of mucus (Causey et al. 2000). It is the author's (JRC) preference to use a 10% to 20% solution of DMSO in lactated Ringer's as an antibiofilm agent; it also seems to be particularly useful in mares with a significant amount of mucus.

Recent work has indicated that *Streptococcus equi* subspecies *zooepidemicus* may reside deep in the endometrium in a dormant state (Petersen et al. 2009). Petersen and co-workers (2015) suggested that some strains of *S. zooepidemicus* were able to form 'persister cells' and acquired a tolerance to penicillin by means of their dormancy. They subsequently demonstrated, in a population of subfertile mares, that it was possible to activate the dormant persister cells by means of an infusion of a proprietary product (bActivate).

Fungal Infections. Mycotic endometritis is not as common as that of bacteriological origin, but recognition of a fungus as the causal agent is important because commonly used intrauterine antibiotic therapy is ineffective. In cases of fungal endometritis, mares may have a history of normal or abnormal oestrous cycles, they may be anoestrus or barren, they may have had a recent abortion or fetal membrane retention, or there may be a history of repeated intrauterine antibiotic therapy. Yeasts more frequently cause endometritis than moulds, with *Candida albicans* being the most common isolate.

The diagnosis is based upon the presence of fungal elements and inflammatory cells in endometrial smears. Yeasts can often be identified after staining with Diff-Kwik using a magnification of X400. Fungal elements are more readily identified in endometrial biopsies after staining with Gomori's methenamine silver or periodic acid–Schiff (PAS). Successful culture of endometrial smears for fungi can be difficult because the organisms may be present in low numbers, and furthermore, they require a long incubation period.

Fungal infections are very difficult to treat, particularly if they are chronic or deep-seated; uterine biopsy may be useful to determine how deep the infection is within the endometrium. Ideally fungal culture and sensitivity to antimycotics would be performed in all cases; however, such diagnostic facilities are not always accessible or economic. A study by Beltaire and co-workers (2012) reported on 102 fungal isolates and demonstrated, within their referral population of samples in North America, a 95% to 100% susceptibility of isolates to the polyenes and a 47% to 81% susceptibility of isolates to the azoles. Uterine lavage with 2 to 3 litres of saline or dilute povidone-iodine (1%–2% solution daily for 5 days), followed by intrauterine antimycotic preparations such as nystatin (5 g or 500,000 units daily for 5 days) or clotrimazole (400–600 mg daily for 6 days) have been used with limited success. Lufeneron, an insect growth inhibitor, has been reportedly used with some success (Hess et al. 2002); however, these results have not been repeated in practice. Uterine irrigation with acetic acid or vinegar has also reportedly been successful in conjunction with antifungal agents, perhaps enhancing efficacy of therapy by altering the uterine pH. However, treatment failure rates are high, and may be in the region of 40% to 70%. Some clinicians have suggested that the addition of a systemic antifungal agent, such as fluconazole for 2 to 3 weeks, reduces treatment failure rates. As discussed previously, if fungal biofilms are present, other 'antibiofilm' therapies may be indicated in the treatment of fungal endometritis.

The prognosis for the subsequent fertility of mares with mycotic endometritis is poor. If there is no success in eliminating the yeast or fungal infection after three attempts, the owner must be advised of the unlikely chance of success. It is suggested that a normal healthy uterus can eliminate mycotic infection; this means that, even if the mycotic infection is successfully treated, the mare must be treated as a susceptible mare.

Persistent Breeding-Induced Endometritis

Persistent breeding-induced endometritis (PBIE) associated with delayed uterine clearance has been shown to be a significant cause of reproductive failure in mares. At coitus, semen, along with microorganisms and debris, is deposited directly into the mare's uterus. Spermatozoa induce an inflammatory response in the uterine lumen (Kotilainen et al. 1994), (Troedsson et al. 2001), which is the same for both live and dead spermatozoa (Katila 2001). In most mares, this transient endometritis resolves spontaneously within 24 to 72 hours so that the environment of the uterine lumen is compatible with the establishment of pregnancy. It is important not to regard this endometritis as a pathological condition but rather a physiological reaction that aids in removing excess sperm and debris from the uterus before the embryo descends from the uterine tube into the uterine lumen 5.5 days after fertilisation.

Classically mares are described as being susceptible or resistant to PBIE, the classification of which is dependent on the mare's response to breeding. If the physiological endometritis persists, in addition to being incompatible with embryonic survival, the premature release of PGF may result in luteolysis and an early return to oestrus. These mares are referred to as susceptible, and they develop a persistent endometritis (Allen & Pycock 1988). Resistant mares can eliminate induced infection without treatment, whereas susceptible mares cannot (Hughes & Loy 1969). Older mares with chronic inflammatory changes within the endometrium (Troedsson et al. 1993) or intrauterine fluid in dioestrus (Troedsson 1995) are likely to be susceptible, although it has been reported that some maiden mares may also be 'susceptible' (Malschitzky et al. 2006). Susceptibility to endometritis is not an absolute state because failure of uterine defence mechanisms need only slow the process of eliminating infection. There is a wide range of susceptibility to endometritis, and mares cannot be neatly categorised into 'resistant' or 'susceptible' (Pycock et al. 1997). Studies on immunoglobulins, opsonins, and the functional ability of neutrophils in the uterus of susceptible mares have not confirmed the presence of an impaired immune response (see the review by Allen & Pycock 1989).

Reduced physical drainage may contribute to an increased susceptibility to uterine infection (Evans et al. 1986). The physical ability of the uterus to eliminate bacteria, inflammatory debris, and fluid is now known to be the critical factor in uterine defence. Experimentally, a failure to clear an intrauterine bacterial challenge (Troedsson et al. 1993b) or the ability to clear intrauterine

VetBooks.ir

radiocolloid within 2 hours defines susceptibility (Troedsson et al. 1991, LeBlanc et al. 1994). Delayed uterine clearance is primarily due to impaired uterine contractility (Troedsson et al. 1993b) and impaired lymphatic drainage (LeBlanc et al. 1995); however, this is compounded by anatomical deficiencies that lead to a more pendulous uterus or a breakdown in the vulvovestibular or cervical seals. Conversely, a cervix that fails to relax during oestrus, such as that encountered in older maiden mares, will likely inhibit fluid clearance. Retention of fluid, inflammatory cells, and inflammatory by-products, with or without bacterial colonisation, is understandably not conducive to the establishment of pregnancy.

The reason susceptible mares have this defective contractility is not known. Regulation of muscle contraction by the system may be impaired (Liu et al. 1997).

Identification of susceptible mares can be difficult as there may be only subtle changes in the uterine environment not readily detected by current diagnostic procedures. Often in a clinical setting, diagnosis is made postbreeding, when the optimum window for therapeutic intervention may have passed. Many mares show no signs of inflammation before mating, but the inevitable endometritis that follows mating persists. Although the response to bacterial or semen challenge has been used in research studies, history is perhaps the most useful indicator of a susceptible mare in practice. Transrectal ultrasonography to detect uterine luminal fluid after breeding has proved useful in identifying mares with a clearance problem and is the most useful technique available in practice. The presence of free intraluminal fluid before breeding strongly suggests susceptibility to persistent endometritis (Pycock & Newcombe 1996a, Brinsko et al. 2003).

Various treatments are available to enhance uterine clearance and reduce the effects of persistent mating-induced endometritis, including uterine ecbolics, uterine lavage, and intrauterine antibiotics. The success of such treatments can be influenced by a number of factors, such as time of treatment in relation to ovulation and mating and other medications that may be administered concurrently.

Uterine activity is greater during oestrus when the concentration of progesterone is low than when progesterone concentrations are elevated (Cross & Ginther 1987). Myometrial activity and the increase in intrauterine pressure after exogenous oxytocin are inversely related to the concentration of progesterone (Gutjahr et al. 2000). Moreover, reduced uterine clearance is observed under the influence of progesterone (Evans et al. 1986, Evans et al. 1987). The inhibition of myometrial activity by elevated progesterone may necessitate modifications to treatment protocols in the postovulatory period. It is preferable to treat mares with uterine clearance problems before ovulation rather than after. When comparing the effects of 10 or 25 IU oxytocin on intrauterine pressure, although both were effective preovulation, only the high dose increased pressure postovulation (Gutjahr et al. 2000). Consequently, when using oxytocin after ovulation, the dose should be increased to enhance uterine clearance. Assuming good quality semen is used, mating a problem mare earlier, for example 48 hours rather than 24 hours before ovulation, may be beneficial, thus allowing a longer period for treatment to improve uterine clearance before progesterone concentrations begin to rise.

Oxytocin has been shown to be more effective than PGF or its analogues in the short term for enhancing uterine clearance (LeBlanc 1997). Yet, because of the relatively short half-life of oxytocin (Paccamonti et al. 1999), drugs with a longer course of action have been sought. Although the increase in uterine activity after administration of PGF analogues, e.g., cloprostenol, does not begin as early as after oxytocin, the increase in activity persists much longer.

An important factor to consider when using prostaglandin analogues for treatment of delayed uterine clearance is the time of administration in relation to ovulation. Although it is widely accepted that the equine CL is refractory to the luteolytic effect of prostaglandin until five or 6 days postovulation, this is not absolute. In early reports examining the timing of prostaglandin administration, two of five mares treated with PGF 3 days after ovulation responded by returning to oestrus within 2 days (Oxender et al. 1975). Furthermore, more recent work has shown repeated small doses of prostaglandin to be more effective than a single larger dose in inducing luteolysis and a return to oestrus (Irvine et al. 2002).

An additional concern is evidence that even when luteolysis does not occur, luteal function may be affected, at least temporarily, by the use of cloprostenol, a prostaglandin analogue, in the early postovulatory period. Numerous studies have shown that mares treated in the postovulatory period had lower concentrations of progesterone during the ensuing early to middioestrus; however, luteal function seems to be able to recover by the end of dioestrus (Mocklin et al. 2006, Nie et al. 2003, Troedsson et al. 2001). The eventual effect on the establishment of pregnancy is not clear but warrants consideration when prescribing treatment. Further work is needed to clarify the effect of prostaglandins or analogues administered in the early postovulatory period on the establishment of pregnancy. Nevertheless, reports to date indicate that the time of treatment in relation to ovulation as well as the dose and number of treatments should be considered when using prostaglandin or analogues for improving uterine clearance. Although either oxytocin or prostaglandin analogues are effective and safe in the preovulatory period, prostaglandin analogues are best avoided after ovulation.

A long-acting analogue of oxytocin, carbetocin (Reprocine, Vetoquinol), is available and may be useful in situations in which a more prolonged uterine contraction is desired. It has been shown to be safe and effective at inducing uterine clearance. Two intramuscular injections of 0.14 mg carbetocin are given 12 and 24 hours after breeding in mares with marked uterine oedema or free fluid before breeding, or in mares with more than 2 cm uterine fluid 12 hours after breeding.

Another factor to consider in the pharmacological treatment of delayed uterine clearance is the concurrent use of other pharmaceuticals, such as tranquilisers or nonsteroidal antiinflammatory agents. The uterotonic effect seen after oxytocin administration is due to both a direct effect on the myometrium and also indirectly via a release of prostaglandin (Paccamonti et al. 1999). Nonsteroidal antiinflammatory drugs, such as phenylbutazone, can decrease uterine clearance by interfering with endogenous prostaglandin release. Phenylbutazone was found to inhibit uterine clearance, but when mares were pretreated with phenylbutazone before being treated with oxytocin, clearance of radiocolloid from the uterus was restored to that which occurred in control mares treated with only oxytocin (Cadario et al. 1995). Therefore, when antiinflammatory drugs are used around the time of mating, extra attention should be paid to uterine clearance and appropriate therapy instituted when needed.

The use of sedatives or tranquilisers may also affect uterine clearance; acepromazine decreases uterine activity (Gibbs & Troedsson 1995). Consequently, a mare being treated with acepromazine for laminitis, for example, should be monitored closely after breeding for delayed uterine clearance. Conversely, xylazine and detomidine increase uterine activity (De Lille et al. 2000, Gibbs & Troedsson

VetBooks.ir

1995); the actions of these substances may affect the response to oxytocin treatment. Some studies indicate that mares with delayed uterine clearance have different patterns of uterine activity and respond to exogenous drugs in a different manner than normal mares (vonReitzenstein et al. 2002, De Lille et al. 2000). When sedation is required in a mare in which uterine clearance is a concern, xylazine or detomidine are preferred over acepromazine because of their enhancement rather than inhibition of uterine motility and clearance.

The successful management of susceptible mares may also include uterine lavage and/or intrauterine antibiotic infusion. Regardless, the emphasis should be on treatment in relation to breeding and not ovulation. Too often in the past, veterinarians have waited until ovulation before treating these mares. By then, there has usually been a large accumulation of fluid, and the bacteria are in a logarithmic phase of growth.

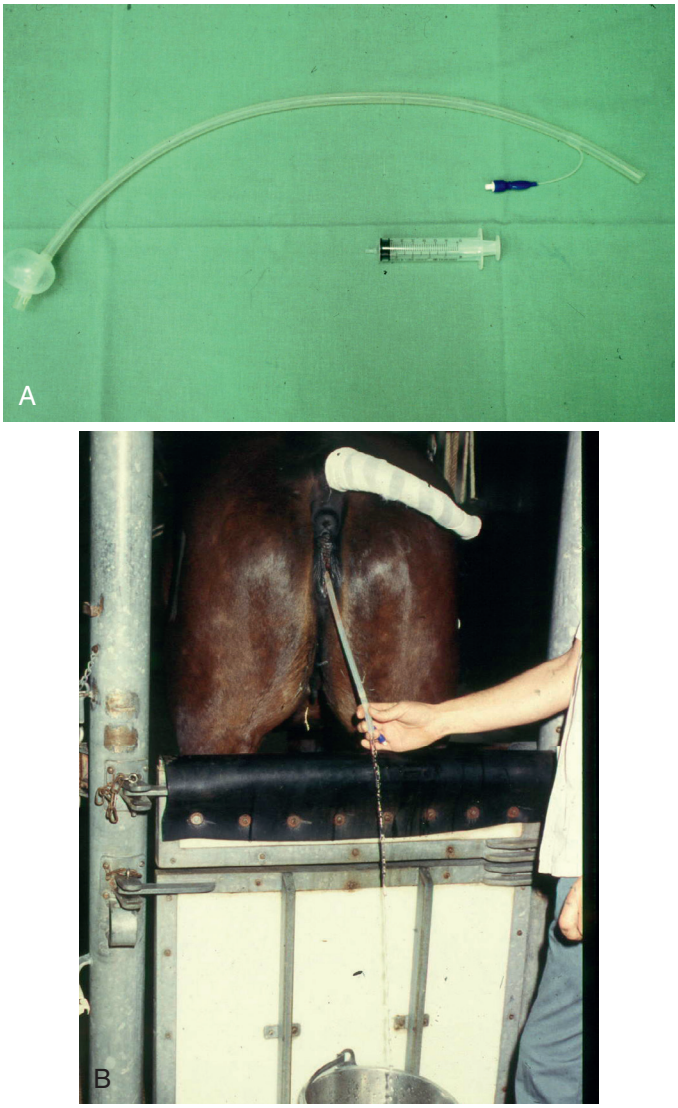
Recognition of the importance of the mechanical evacuation of uterine contents accounted for the introduction of large volume uterine lavage. The technique involves the infusion and retrieval of multiples of 1 L of warm, sterile, physiological (buffered) saline or lactated Ringer's solution into the uterus via a catheter that has been retained within the cervix via an inflatable cuff. The most convenient is a large bore (30 French) (80 cm) autoclavable equine embryo flushing catheter (Fig. 31.20A and B). The cuff is useful as it effectively seals the internal cervical os. The catheter should only be inserted after thorough cleansing of the perineum. The rationale for such an approach is:

- The removal of accumulated uterine fluid and inflammatory debris that may interfere with neutrophil function and the efficacy of antibiotics;
- Stimulation of uterine contractility; and
- Recruitment of fresh neutrophils through mechanical irritation of the endometrium.

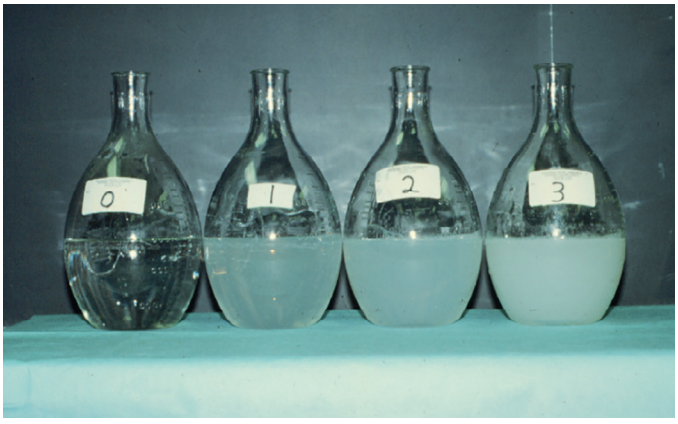
The saline is infused by gravity flow 1 litre at a time, and the washings are inspected to provide immediate information concerning the nature of the uterine contents (Fig. 31.21). The lavage should be repeated until the fluid that is recovered is clear. In most cases, the fluid is evenly distributed in both horns, making transrectal massage of the uterus unnecessary. If a rectal examination is performed while the catheter is in the uterus, care must be taken to avoid contaminating the catheter. The fluid can be recovered in the same container from which it was infused, thereby preventing air being aspirated into the uterus via the catheter. Measurement of the recovered fluid and ultrasonographic examination of the uterus should be performed after flushing to ensure that all the fluid has been recovered. This is necessary because the mare under treatment has an impaired ability to drain its uterus spontaneously. For this reason, the process is usually combined with oxytocin treatment. Ideally, these mares will be bred only once, but if repeated matings are necessary, uterine lavage should be performed after each mating. Although in many cases uterine lavage is performed at 24 hours postmating, there is some evidence that early lavage at 6 to 8 hours postmating is beneficial in problem mares (Knutti et al. 2000).

Large volume lavage is beneficial in many cases, particularly in a mare with a relatively large (more than 2 cm depth) accumulation of fluid after breeding. The process is time consuming, and there is the possibility of further contamination of the uterus by passage of a drainage tube. Nonetheless, when there is more than 2 cm of uterine fluid or a mare is known to be highly susceptible, the risks are outweighed by the benefit of treatment (Knutti et al. 1997).

It has been shown that saline lavage and uterotonic drugs are as effective as antibiotics in eliminating bacteria from the uterus



• **Fig. 31.20** (A) A large bore catheter with an inflatable cuff, used for uterine lavage. (B) Fluid drainage from the mare.



• **Fig. 31.21** Increasing grades of opacity of fluid recovered after uterine lavage.

VetBooks.ir

(Troedsson et al. 1995). However, this was an experimental study in which a single bacterial species was infused into the uterus and lavaged within 12 hours of mating. Clinically, there is often a mixed bacterial flora, and lavage cannot always be performed within 12, or even 24, hours. This is why many practitioners continue to use intrauterine antibiotics as part of the treatment protocol.

It is particularly important to recognise and manage appropriately the older maiden mare, as in many cases these mares are susceptible to postbreeding endometritis even though they have never been bred before. Often sport or Warmblood mares are not considered for breeding until they are in their teens, and these older maiden mares can be very difficult to get in foal. Many of these mares have some common characteristics. Endometrial biopsy samples reveal glandular degenerative changes and stromal fibrosis (endometriosis) as an inevitable consequence of ageing, despite the fact that they have not been bred (Ricketts & Alonso 1991a). In fact, some feel that endometriosis is worse in a mare that has never been pregnant than in a mare of similar age that has been pregnant nearly every season. Another common characteristic of these mares is uterine fluid accumulation. Often, an older maiden mare has an abnormally tight cervix that fails to relax properly during oestrus so that fluid is unable to drain and accumulates in the uterine lumen (Pycock 1993). In many cases, this fluid is negative for bacterial growth and presence of neutrophils. Once the mare is bred, the fluid accumulation will be aggravated due to poor lymphatic drainage and impaired myometrial contraction compounded by the tight cervix. The amount of intrauterine fluid will vary in individual mares, ranging from a few millilitres to over a litre in extreme cases. All too often, owners assume that the fertility of these mares is comparable to that of young maiden mares. One of the most important aspects of breeding the old maiden mare is to make the owner aware that there is a high possibility that she will be a problem. These mares must be considered highly susceptible and managed accordingly.

From 4 hours postbreeding, uterine lavage can be performed in mares with a significant fluid load. If a tight cervix is encountered, then manual cervical dilation is performed. Bader (1982) demonstrated that sperm arrived at the oviduct by 2 hours postinsemination, significantly more than after 4 hours. Brinsko and co-workers (1991) demonstrated that uterine lavage performed 4 hours after insemination did not adversely affect pregnancy rates, whereas the pregnancy rate was reduced when the lavage was performed 0.5 or 2 hours after insemination (Brinsko et al. 1990). The authors have lavaged mares within 2 hours postinsemination and achieved pregnancies, as did Brinsko and co-workers (1990); however, in view of Bader's work (1982), lower sperm numbers are likely to be present in the oviduct. It is also important to note that this work was not performed in a group of susceptible mares, and it is possible that these mares also have delayed sperm migration.

Given that breeding is not necessarily a sterile process and the ejaculate itself will likely to have a bacterial load, we need to ask the question: are antibiotics indicated in the management of the susceptible mare? The evidence in support of routine prophylactic antibiotic use is weak (Cooke 2014), despite Pycock and Newcombe (1996c) demonstrating a beneficial effect of intrauterine antibiotics and oxytocin on pregnancy rates. The authors acknowledge that a single dose of antibiotics given in this manner needs further consideration given the current state of bacterial antibiotic resistance.

The use of corticosteroids has been advocated in mares with excessive inflammation. Buccal and co-workers (2008) studied the use of 50 mg dexamethasone at the time of breeding and demonstrated an improved postbreeding uterine environment with decreased endometrial oedema and reduced fluid accumulation. Another study using a lower dose, 10 or 20 mg dexamethasone, did not show a beneficial effect on pregnancy rates (Vandaele et al. 2010). The authors have had success using 40 mg dexamethasone administered at the postbreeding examination, especially in cases in which excess uterine oedema has been identified; however, the authors' preferred choice of steroids for preemptive treatment is 0.5 mg/kg prednisolone administered twice daily, starting 24 to 36 hours before breeding, and finishing postovulation (adapted from Dell'Aqua et al. 2006).

Management Protocol Useful in the Highly Susceptible Mare. A mare that from past experience/history is known to produce a large amount (several centimetres depth) of luminal fluid after mating should be managed using the following protocol. Overall management of such mares must be of the highest quality before breeding. Good hygiene at foaling is essential, and all mares should be thoroughly examined postpartum for the presence of trauma that might compromise the physical barriers that prevent uterine contamination. Gynaecological examinations, particularly of the vagina, should be performed as aseptically as possible. Thorough digital examination of the cervix can identify fibrosis, lacerations, or adhesions that may need treatment before breeding. Because air in the vagina can cause irritation of the mucosa, it should be expelled by applying downward pressure with the hand through the rectal wall. Attention should be paid to hygiene at mating by using a tail bandage and washing the mare's vulva and perineal area with clean water (ideally from a spray nozzle which avoids the need for buckets). Breeding should occur at the optimal time, and the number of breedings should be minimised. This means that these mares need very close monitoring of the oestrous period by rectal palpation and ultrasonography. The use of hCG or other ovulation inducing agents is strongly recommended in an attempt to ensure they are bred only once. Prediction of ovulation can also be made easier by not breeding these mares too early in the year, i.e., before they have begun to cycle regularly. If feasible, the use of artificial insemination can be helpful to reduce (but not eliminate) the inevitable postbreeding endometritis.

The management protocol is as follows:

- A single breeding must be arranged 1 to 2 (or even 3) days before the anticipated time of ovulation.
- Ultrasound examination of the uterus 4 to 12 hours after mating is performed to assess the amount and echogenicity of any intrauterine fluid.
- Uterine lavage is performed 4 to 8 hours postmating.
- Oxytocin (10 IU before ovulation, but increased to 20–25 IU postovulation) should be given after lavage and approximately every 4 hours after until evening and repeated the next morning by either the intravenous or intramuscular route. In mares with lymphatic stasis the slower release prostaglandin (cloprostenol 500 mg IM) may be useful in addition to oxytocin. Cloprostenol should be given some 2 to 4 hours after the oxytocin injection but should not be used after ovulation.
- The mare is reexamined the next day, and oxytocin treatment is repeated if fluid is still present. If fluid accumulation persists, an infusion of antibiotics or another lavage procedure followed by antibiotic infusion may be performed. Evaluation of the uterus postbreeding is a crucial time to assess all mares, and too many clinicians fail to do this.

• **Fig. 31.22** Equine herpes virus 3 lesions in the perineal area of a mare.

Viral Infectious Disease

Equine coital exanthema (ECE) is a relatively benign venereal disease of both sexes caused by equine herpesvirus type 3 (Studdert 1974). It is spread by direct contact, and there have been reports of its transfer during gynaecological examinations. Once infected, horses remain carriers for life. The virus can remain dormant until conditions favour its recrudescence and proliferation with the development of the characteristic clinical signs. Normally, after coitus, signs develop after an incubation period of 4 to 7 days. Multiple vesicles appear on the vulvar mucosa and perineum, resulting in a short period of local irritation. These rupture, leaving small ulcers 3 to 10 mm in diameter that are painful to the touch (Fig. 31.22). In the absence of infection with opportunist pathogens, healing occurs in 10 to 14 days, when it ceases to be contagious; there is permanent loss of pigmentation at the site of the healed lesions. Pregnancy rates are not reduced; however, there is often reluctance to allow mating due to pain associated with the lesions. In the stallion, the vesicles develop on the shaft of the penis and the prepuce; if severe, he may be reluctant to breed.

As with other herpesvirus-induced diseases, lifelong infection is the rule. Recrudescence after stimuli such as stress, systemic disease, or trauma to the genital area can occur. No specific treatment other than disinfection of pustules and ulcers to prevent secondary bacterial infections during the acute phase is recommended. Natural service should be avoided while active lesions are present to prevent transmission of the disease. Affected mares can be artificially inseminated during the symptomatic stage of the disease or wait for 6 weeks after complete healing of ECE-associated lesions before natural service.

Protozoal Infections

Trypanosoma equiperdum causes a venereal disease called dourine, which is currently prevalent in Africa, the Middle East, and Central and South America; it has been eradicated from Europe and North America. The incubation period is 1 to 4 weeks, and the disease has an extremely protracted course that can extend over a period of weeks or months. It affects horses, mules, and donkeys of either sex. The initial sign is a nonpainful swelling of the external genitalia of both stallions and mares; mares show a vaginal discharge and stallions develop a paraphimosis. Some weeks later, depigmented areas and urticaria-like raised plaques 2 to 10 cm in diameter appear over the body surface. The disease is characterised by a low morbidity but a high mortality of 50% to 75%.

Diagnosis of dourine is based on the clinical signs, particularly the skin plaques, together with demonstration of the trypanosome in the discharges and in the skin lesions. A complement fixation test is also available. Treatment using quinapyramine sulphate has been attempted, but stallions that recover may become carriers. Therefore strict screening using a complement fixation test, with slaughter of positive and affected animals, as well as the institution of quarantine programmes, should be used to control this disease.

Infertility Classified by Anatomical Location

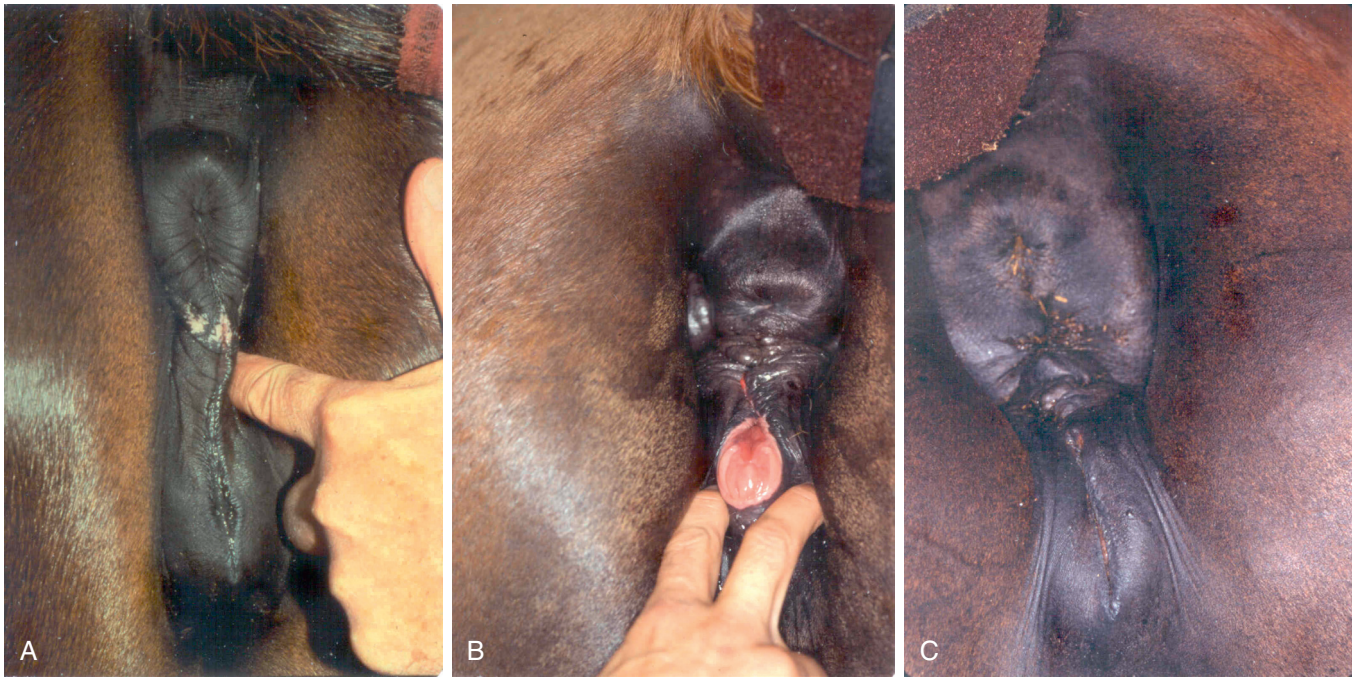
To maintain fertility, the uterus must be protected from the external environment. Three physical barriers exist to protect the uterine lumen. The first and most external are the vulvar labia. The second, and arguably most important, is the vaginal/vestibular sphincter; the third and last is the cervix. Poor perineal conformation is a common cause of infertility and should not be ignored in the examination of a mare with chronic endometritis, failure to conceive, or abortion due to placentitis. If a deficiency is noted, surgical correction is usually necessary to restore normal function.

Vulva and Perineum

The integrity of the vulvar labia and their anatomical relationship with the perineal area and anus are an essential component of a mare's fertility because they provide the first barrier to contamination between the external environment and the uterus. The endocrine patterns associated with each stage of the oestrous cycle and pregnancy can influence the disposition of the vulva, affecting vulvar length and tone. At least 75% of the length of the vulva should be ventral to the brim of the pelvis (the brim of the pelvis is easily palpated using the index and second fingers placed on either side of the vulva to locate the pubic bones – ¾ of the vulva should be below the fingers) (Fig. 31.23). The vulva's longitudinal axis should be perpendicular to the ground (estimate the slope of the vulva in relation to the vertical axis, it should not be greater than 10°; the greater the divergence, the poorer the conformation), and the vulvar labia should form a tight seal (perform a 'windsucker' test – gently part the labia and listen for an inrush of air) (Fig. 31.24). Absence (natural or acquired) of a normal perineal conformation can facilitate the entry of air (pneumovagina, also called 'windsucking'), faeces, and potential pathogens into the reproductive tract, which will jeopardise the mare's fertility. The initial vaginitis may lead to cervicitis and acute endometritis resulting in subfertility. In addition, pneumovagina, by creating an air filled void, disrupts the normal positioning of the tissues relative to one another with the vestibule and urethral opening, being displaced cranially. In some instances this may result in urine pooling in the vagina (urovagina). The more severe conformational abnormalities are more likely to result in failure of the vulvar seal and increased faecal contamination because the vulva forms a shelf on to which faeces may collect.

Severe loss of body condition, as experienced by some pregnant mares inadequately fed especially in winter, results in a sunken

VetBooks.ir



• **Fig. 31.23** (A) Location of the brim of the pelvis in a mare with good conformation; (B) location of brim of pelvis in mare with poor conformation; and (C) mare with severely sloping vulva.

• **Fig. 31.24** Parting the vulvar labia ('windsucker' test) to test the integrity of vaginal–vestibular sphincter.

anus and an increased slope of the vulva. An apparently normal perineal conformation noted in mares in good body condition may become less than adequate if body weight loss is extreme, especially in late gestation as the heavy uterus pulls the caudal reproductive tract cranially and ventrally. Contamination of the vagina with faeces during mid to late gestation may lead to an ascending bacterial placentitis, one of the leading causes of abortion and neonatal septicemia.

Ageing of the mare, associated with repeated foaling, can cause stretching and loss of tone of the perineal muscles that enable the vulva to form a barrier to external contamination and entry of air into the vagina. This condition is additionally aggravated when a mare is injured during foaling, resulting in loss of vulvar tone and apposition of the labia. Mares undergoing episiotomy may also have permanent damage to vulvar structures.

Caslick (1937) first pointed out the importance of this defect in relation to genital infection. Some breeds may be more predisposed than others. Rarely, defective vulvar conformation can be congenital or acquired due to: (1) vulvar stretching after repeated foaling; (2) injury to perineal tissue; or (3) poor body condition (old, thin mares).

Older multiparous mares are more commonly affected with pneumovagina. However, young mares that are in work and have little body fat and/or poor vulvar conformation can develop pneumovagina. In some mares, pneumovagina may only occur during oestrus when the perineal tissues are more relaxed. A 'Caslick index' has been described in an attempt to determine which mares require treatment (Pascoe 1979), but its use is not widespread. Rectal palpation of a ballooned vagina or uterus from which air can be expelled confirms the diagnosis. Cytological and histological examination of the endometrium may demonstrate significant numbers of neutrophils indicative of an endometritis. Eosinophils may also be found in association with pneumovagina.

Caslick's Vulvoplasty

This is the most common surgical procedure performed in stud farm practice. Surgical closure of the dorsal part of the vulvar labia is intended to correct poor perineal conformation. By decreasing the length of the vulvar cleft, the likelihood of the entry of air and potential pathogens into the vagina is decreased in a mare otherwise susceptible to pneumovagina, faecal contamination, and associated complications. This procedure, however, is overutilised in mares in which such intervention is not warranted. A mare with successive Caslick's surgeries can experience considerable loss of vulvar tissue, thus, paradoxically, resulting in an abnormal perineal conformation. The operation should be reserved for mares with a true vulvar defect rather than just because the mare has ovulated after mating or has failed to become pregnant.

VetBooks.ir

Another indirect complication associated with the Caslick's vulvoplasty is the increased incidence of vulvar lacerations and dystocia in which the vulva was not 'opened' by a surgical incision before foaling. Regardless of the originating cause, the Caslick's operation is used to correct first degree perineal lacerations in which only the perineal skin and vulvar mucosa are affected. For repair of second degree lacerations (laceration of deeper tissues of the perineal body) and third degree (a defect resulting in communication of the ventral rectum with the dorsal vagina) lacerations, more elaborate reconstructive surgery is required (Trotter & McKinnon 1988). This is described in the mare and cow in Chapter 20. As a rule, any postpartum corrective surgery of the perineal body and vulva should be delayed until inflammation and oedema of the involved tissues is no longer present. Mares with third degree rectovestibular lacerations invariably develop endometritis, but endometrial biopsy of mares affected with third degree lacerations have shown a rapid endometrial response after surgical repair of the laceration; mares can be then artificially inseminated as early as 2 weeks after surgery (Schumacher et al. 1992); natural breeding however needs to be avoided for several months until the tissue has healed.

Caslick's procedure is: The mare should be suitably restrained, and her vulva thoroughly cleaned and dried. The level of the floor of the pelvis is determined, which enables the surgeon to ascertain the level to which the dorsal commissure of the vulva must be sutured. Beginning at this level, the mucocutaneous junction of the vulva is infiltrated with local anaesthetic through a 21-gauge, 1-inch needle. It is important to use sufficient local anaesthetic, and in many cases at least 20 ml will be needed. The distension induced by the volume of local anaesthetic helps to evert the mucocutaneous junction. Both sides of the vulva are infiltrated in a stepwise fashion proceeding dorsally up to the dorsal commissure, being sure that local anaesthetic is placed right at the dorsal extent of the vulva. For mares operated on previously, it is important to infiltrate deeply. Using rat-toothed forceps and scissors, a *very thin* (no more than 4 mm) strip of mucosa should be removed from the anaesthetised area. For older mares that have had the operation performed several times, more radical dissection may be necessary before healthy (bleeding) tissue is reached. In some cases in which there is not much vulvar mucosa remaining, it is best just to debride the junction with a scalpel blade to induce slight haemorrhage and not actually remove any further tissue. An alternative method, that avoids removal of tissue, is to incise with a scalpel, to a depth of a few millimetres, the vulvar labia at the mucocutaneous junction in a plane parallel to the labia. The exposed submucosal tissues are sutured together using simple interrupted or continuous sutures or a locking pattern. The gauge of the suture material should not be too thick as this encourages faecal material to attach to the sutures. Skin staplers can be used, but the authors have not found it quicker compared with conventional suture techniques, and it is harder to obtain a good seal. Antibiotics are not given, but tetanus prophylaxis is needed if the mare is not adequately vaccinated.

The aim of the operation is to reduce the vulvar aperture and so prevent pneumovagina and faecal contamination of the vestibule. The time of suture removal is not crucial, and is normally done approximately 2 weeks after surgery. However, the vulva must be reopened by performing an episiotomy before the next foaling; otherwise, major injury can result. Mares that require natural mating subsequently may also need to have the Caslick's opened if the size of the vulva has been greatly reduced. If not, the vulva may tear and/or injury to the stallion's penis may occur. The episiotomy wound should be repaired soon after foaling or mating to prevent pneumovagina. If there has been severe trauma to the vulva at foaling, it may be necessary to wait for the tissue swelling to subside before attempting repair.

If repeated episiotomy followed by closure is not done very carefully, there can be considerable loss of vulvar tissue, poor healing, and major problems for the mare.

Neoplasia

Melanoma is the most common disease affecting the vulva. It occurs in 80% to 100 % of adult grey horses and, less frequently, in ageing horses of other colours. Common sites for melanoma include the anus, perineum, and vulva; there is no effective systemic treatment available for treating melanomas. For solitary benign lesions, excision may be curative. The evidence for a positive benefit for the use of cimetidine in managing melanocytic tumours is weak (Goetz et al. 1990); however, developments in the use of molecular vaccines are promising. Oncept (Merial Limited, Duluth, USA) is a canine vaccine that targets tyrosinase, a catalyst in the synthesis of melanin that is overexpressed in equine melanocytic tumours. Lembcke and co-workers (2012) demonstrated its safety and a significant positive humoural and cell-mediated immune response subsequent to vaccination with Oncept. Large scale studies to evaluate the usefulness of this approach in the clinical management of equine melanocytic tumours are ongoing.

Occurrence of squamous cell carcinoma is less common than melanomas. Squamous cell carcinoma of the vulva is observed more commonly in the lower latitudes where solar radiation is more intense. Genital tumours are at risk of metastatic spread to local lymph nodes. Lesions may be removed by standard surgical techniques, laser surgery, or cryosurgery; however, regrowth is likely to occur if surgical margins are not adequate.

Clitoris

The clitoris is enclosed in the clitoral fossa in the ventral part of the vulva but is rhythmically exposed after urination or teasing (winking) as a result of contractions of the vulvar constrictor muscle. The clitoris has several sinuses in which is found a natural smegma. Whereas the lateral sinuses are shallow, the median sinuses are deep enough to allow the growth of bacteria. Understanding the anatomy of the clitoris of the mare has become particularly important because it is an important reservoir for bacteria that may have infected the reproductive tract; of particular note is *Taylorella equigenitalis,* which causes contagious equine metritis (CEM). The disease is highly contagious, and the organism can be harboured in the clitoral fossa and sinuses (especially the median sinuses) for prolonged periods. The same applies to pathogenical strains of *Pseudomonas aeruginosa* and *Klebsiella pneumoniae.*

Even in CEM-free areas, it is important to keep in mind that the clitoral sinuses may function as a nidus for uterine infections, especially those iatrogenically induced during diagnostic procedures of the reproductive tract or artificial insemination. Careful cleaning of the perineal and vulvar areas, including the clitoral fossa, with a mild disinfectant before any invasive procedures are performed minimises the risk of introducing potential pathogens into the uterus.

Congenital anomalies of the external genitalia are seen in intersex animals, which may have underdeveloped vulvar labia associated with an abnormally enlarged clitoris. Treating prepubertal mares with anabolic steroids may lead to enlargement of the clitoris, resulting in a partially and permanently exteriorised clitoris.

VetBooks.ir

Vagina

The vestibule is the area of the genital tract that separates the vulva and clitoris from the vagina. At the cranial border of the vestibule, where it meets the vagina, lies the vaginovestibular fold or sphincter. This folded mucous membrane acts as the second and most important (Hinrichs et al. 1988) physical barrier between the uterus and the external environment. In young horses the hymen is usually a weak membranous extension of the vaginovestibular fold; occasionally, a persistent hymen may be present in a maiden mare. Usually, a manual examination of the vagina will be enough to rupture the persistent hymen; some mares with a persistent hymen may accumulate fluid in the vagina proper and uterus (mucometra). Sometimes the hymen may be so tough that it can only be ruptured using a guarded scalpel blade or scissors. The small incision can then be enlarged using the fingers and hand; once the persistent hymen is disrupted, evacuation of the fluid is uneventful. Rarely, failure of proper fusion of the Müllerian ducts may result in the presence of dorsoventral bands of fibrous tissue in the anterior vagina and fornix. They do not necessarily interfere with fertility and are often easily broken down manually.

Listening for an inrush of air into the vagina when the vulvar labia are gently parted can test the adequacy of the vaginovestibular fold as a physical barrier to external contaminants. A positive test (noticeable the sound of air rushing into the vagina) indicates that the vestibular fold is not adequately protecting the vagina proper from the outside environment.

Improper functioning of the first barrier (vulva) and second barrier (vaginovestibular fold) may lead to the constant or frequent entry of air into the vagina. The condition can be exacerbated during oestrus, when the perineal body is more relaxed than in other stages of the oestrous cycle. Accumulation of small amounts of a frothy fluid in the cranial vagina are indicative of pneumovagina, as well as the presence of air in the uterus (pneumouterus) and can be identified as hyperechoic particles present between the endometrial folds during ultrasonographic examination.

In mares with severe alterations of the perineal conformation, vulvar closure using Caslick's vulvoplasty may not correct the defect and surgical reconstruction of the perineal body (perineoplasty) may be required.

Urovagina

This is also known as vesicovaginal reflux or urine pooling and refers to the presence of urine in the cranial vagina and possibly in the uterus. As with pneumovagina, mares with marginally normal perineal conformation may be predisposed to the accumulation of urine in the vagina during oestrus when reproductive organs and the perineal body are relaxed. Transient urine pooling, which is sometimes found in postpartum mares, usually resolves after uterine involution has occurred. In older mares with splanchnoptosis (the abnormal downward displacement of one or more internal organs), the reflux of urine into the genital tract may be permanent. Clinical signs can include urine dripping from the vulva, urine scalding, and a history of failure to conceive. Diagnosis is easiest using a speculum examination during oestrus to detect urine in the cranial vagina. Urovagina can cause vaginitis, cervicitis, and endometritis, which ultimately result in infertility. The condition is surgically corrected by vaginoplasty (perhaps more correctly termed caudal relocation of the transverse fold, as surgical intervention is in the vestibule) (Monin 1972), urethral extension (Hughes & Loy 1969), or perineal resection (Pouret 1982).

Varicose Veins

During oestrus and especially during pregnancy, varicose veins may develop in older mares. Varicose veins can be present in any part of the vagina; however, they are often found in the vestibular/vaginal area. Bleeding may occur after natural service, or spontaneously during mid to late gestation. Occasionally, a persistent haemorrhage will result in considerable blood loss; however, the condition usually subsides with the end of pregnancy. Cautery or ligation of varicose veins is warranted if haemorrhage is persistent or frequent.

Neoplasia

Vaginal neoplasias are uncommon in mares. Leiomyomas and squamous cell carcinomas have been reported.

Rectovaginal Fistulas

During parturition the foal's foot may be directed towards the dorsal vagina/ventral rectum, and if unattended, a third degree perineal laceration will follow. However, if the dystocia is corrected in time, the damage may be limited to a first or second degree rectovaginal laceration or fistula. The condition is most often seen in young, primiparous mares, although the overall occurrence is less than 0.1% of all foalings. Immediately after it has occurred, it is usually difficult to estimate the amount of damaged and devitalised tissue present, even though the edges of the wound may look fresh and clean. This is why immediate repair is not normally performed unless it is possible to attempt repair within 2 hours of the injury; however, most clinicians advise delaying surgery (see Chapter 20).

First aid treatment should include:

- Debridement of nonviable tissue;
- Provision of haemostasis and general cleaning of the area;
- Parenteral broad spectrum antibiotics for 5 days;
- NSAIDs and tetanus prophylaxis;
- Daily cleaning; and
- Monitoring of uterine involution.

Originally, it was thought that these lesions should be corrected after surgical conversion to a third degree perineal laceration, In addition, it was recommended that this was delayed by a minimum of 6 to 10 weeks postfoaling; often they were left until after weaning, and the mare was left barren that season. More recently, Jalim and McKinnon (2010) described a predominantly transrectal repair technique, performed immediately postbreeding; the results compared favourably to previous techniques and allowed breeding within the same breeding season in which the injury occurred. Surgical correction of the anatomical defect (described in Chapter 20) is necessary to restore fertility.

Breeding Trauma

Vaginal lacerations may occur during natural service when the stallion is disproportionately large compared with the mare. It is important to consider the location of a vaginal laceration regarding treatment and prognosis. Based on the location of the tear in relation to the peritoneal reflection, a vaginal tear may communicate with the peritoneal cavity, likely resulting in peritonitis, or it may be retroperitoneal. Treatment includes broad spectrum antibiotics, antiinflammatories, and tetanus prophylaxis. Peritoneal lavage may be beneficial if the tear communicates with the peritoneal cavity. A breeding roll positioned under the mare's tail and dorsal to the stallion's penis will prevent the stallion from introducing its penis's full length into the vagina and, consequently, help to preventing mating-induced trauma.

VetBooks.ir

Cervix

The cervical injuries and abnormalities are often overlooked as a possible cause of infertility. The cervix is the last of the three physical barriers protecting the uterus from the external environment; cyclic hormonal changes determine the tonicity of the cervix. Anatomically, the cervix is a thick-walled sphincter, with dilation and contraction occurring as a consequence of the action of the longitudinal and circular smooth muscle, which is also rich in elastic fibres. Distinctive features of the equine cervix are its dilatability and the absence of rigid, annular constricting rings as seen in ruminants. During anoestrus, the cervix is flaccid and dry and may be partially open. Higher concentrations of progesterone during dioestrus or pregnancy cause the cervix to become tubular, firm, and tightly closed. These changes are readily palpable per rectum. Moreover, a vaginal examination during oestrus will reveal the cervix positioned low upon the ventral floor of the cranial vagina, relaxed, and easily dilated or open, thus allowing access to the uterus. The cervix must relax during oestrus to allow intrauterine ejaculation and drainage of uterine fluid. During dioestrus or pregnancy, a vaginal examination will reveal a tightly closed cervical os, which is pale in colour and positioned dorsal to the floor of the vagina. In older mares or those with fibrotic changes due to cervical trauma, failure of cervical relaxation can result in delayed uterine clearance or persistent mating-induced endometritis. Artificial insemination has been used successfully in mares with an abnormally narrow cervix. Failure to relax can be treated with local application of PGE and/or manual dilation. Interestingly, mares with a fibrous cervix that become pregnant do not normally have any difficulties at foaling. Failure of the cervix to close during dioestrus can lead to persistent endometritis and failure to conceive or early embryonic death; failure to maintain closure during pregnancy can lead to gestational failure. Both surgery and exogenous progesterone have been used in an attempt to encourage closure of the cervix.

Assessment of the cervix must form a part of the routine prebreeding examination of a mare, either directly using a speculum per vagina and/or by digital exploration, preferably during dioestrus when it is more tightly closed under the influence of progesterone.

Cervicitis

Inflammation of the cervix often accompanies vaginitis or endometritis. Cervicitis is most commonly seen in the postpartum period, especially when there has been dystocia. Severe cervicitis associated with metritis may be also seen in mares infected with organisms such as *Taylorella equigenitalis* that cause a copious purulent discharge (Katz et al. 2000). Infusion of certain chemicals, such as chlorhexidine or strong iodine solutions, into the uterus to treat endometritis may irritate not only the endometrium but also the cervix and vaginal mucosa. If potentially irritant solutions are used, vaginal speculum examinations between treatments to assess the condition of the cervix are warranted.

Trauma

Although cervical lacerations may occur during natural service, they are usually small and resolve without major consequences. Occasionally, maiden mares in oestrus have a tightly closed cervix, which may suffer laceration during natural service, especially if the stallion is disproportionately larger than the mare or the mare was not in full physiological and behavioural oestrus. However, these tears are usually small and heal without further treatment. Most serious lacerations occur during parturition and may occur during normal parturition or can be iatrogenic during intervention to correct a dystocia by mutation or fetotomy (see Chapter 20). Although the cervix should be examined digitally after dystocia, especially if a fetotomy is involved, the extent and severity of a cervical laceration is best evaluated once the cervical lesion is healed. The competency of the cervix should be evaluated during dioestrus or when the mare is under the influence of exogenous progestogens, thus verifying its ability to close tightly. The cervix can also be permanently damaged by irritant chemicals such as povidone iodine. Adhesions of the cervix can be broken down manually, but this must be done daily to prevent recurrence. If severe, adhesions may contribute to the development of pyometra; older, multiparous mares may be predisposed to cervical lacerations (Miller et al. 1996).

Transluminal adhesions and anatomical defects are often more easily diagnosed by digital examination of the cervix rather than by vaginoscopy. There are differences of opinion on which cervical lacerations require repair. If severe, cervical lacerations may need surgical repair to restore normal cervical shape and function, but because surgical correction is difficult and not always rewarding, a biopsy of the uterus should be taken to assess the mare's potential to maintain a pregnancy before surgical correction is attempted. Repairs can be performed in the standing patient or in the Trendelenburg position for ventral tears (O'Leary et al. 2013).

Postbreeding repair of cervical lacerations has been described by Foss and others, (1994). Because many cases of cervical lacerations are only detected at the prebreeding examination or at the time of AI, postbreeding repair is preferable because it avoids a 4- to 6-week healing period, resulting in a reasonable chance of pregnancy occurring. Developmental abnormalities of the cervix have been described; these include aplasia and a double cervix.

Cervical Polyps or Cysts

Occasionally, pedunculated, cyst-like structures are found on visual or manual examination of the cervix. They are attached to either the cervical os or emanate from the cervical lumen and protrude into the vagina or uterine body. Although the cause is unknown, they do appear to be associated with infertility, and removal either by laser or ligation is recommended.

Uterus

Ventral Sacculations

Aside from changes associated with pregnancy, other pathological conditions may cause focal enlargements in the ventral portion of the uterus. These uterine changes are usually associated with increased age and parity and are invariably found at the base of either or both uterine horns where pregnancies are usually established. These enlargements may be mistaken for a pregnancy, especially if inexperienced palpators do not use ultrasonography to confirm their palpation findings. Mechanisms contributing to formation of ventral uterine enlargements have been identified, including but not limited to: endometrial atrophy, focal myometrial atonia, and lymphatic lacunae (Kenney & Ganjam 1975). Furthermore, in older and multiparous mares, the uterus may tilt ventrally in relation to the pelvic brim (uterine splanchnoptosis). Mares with ventral sacculations and uterine splanchnoptosis have a higher incidence of delayed uterine clearance than normal mares (LeBlanc et al. 1998).

Endometrial Cysts

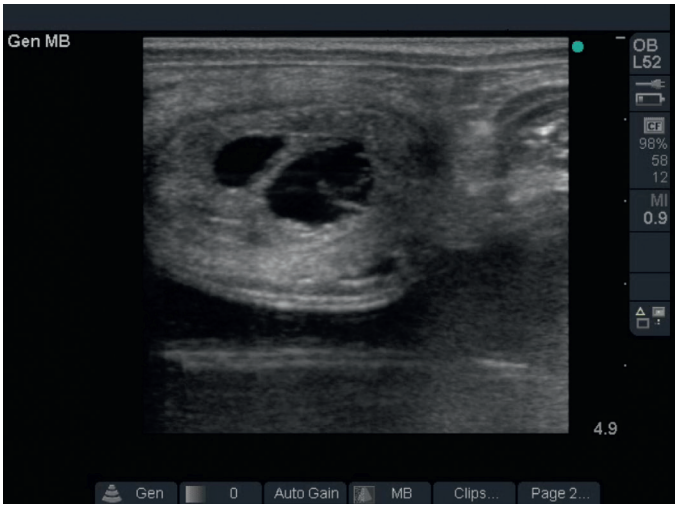
Endometrial cysts (Fig. 31.25) are often cited as a cause of infertility; however, a cause and effect relationship has not been clearly

VetBooks.ir

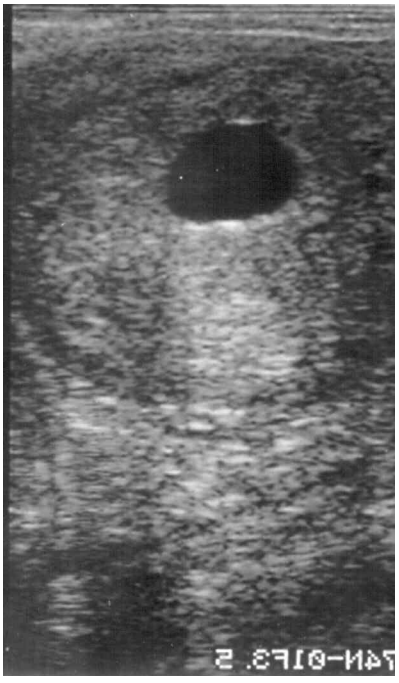
• **Fig. 31.25** Endometrial cyst, removed by stalk transection.

established. Rather than being viewed as a cause of infertility, endometrial cysts should be considered as an indication of underlying pathological changes in the uterus. Endometrial cysts are of lymphatic origin, and their occurrence may be associated with disruption of normal lymphatic function. The proportion of mares with endometrial cysts increases with age. Mares over 11 years of age are more than four times as likely to have endometrial cysts as younger mares, and a majority of mares over 17 years of age will have endometrial cysts (Eilts et al. 1995). Reports that associate endometrial cysts with a lower pregnancy rate or increased embryonic loss fail to account for the effect of advancing age and degenerative changes in the endometrium. When the effects of, for example, such factors as parity and age are considered, the assumption that cysts cause infertility is not supported (Eilts et al. 1995). Another report by a different group of researchers, which did control the time of pregnancy diagnosis, similarly found no difference in pregnancy loss between mares with cysts compared with those without, although mares with endometrial cysts had a lower day 14 and day 40 pregnancy rate (Tannus & Thun 1995). There appeared to be a quantitative effect of cysts on fertility because an effect was not evident until a mare had numerous cysts or the cysts were very large. However, even then, the effect of endometrial cysts on fertility was much less than that seen with delayed uterine clearance or intrauterine fluid accumulation. A quantitative effect of endometrial cysts could be due to interference with embryonic mobility. It is well known that the equine embryo undergoes a period of mobility after entering the uterus, finally becoming fixed at approximately 16 or 17 days gestation. If mobility is restricted during this period and the embryo is not permitted to come in contact with a sufficient portion of the endometrium, maternal recognition of pregnancy may not occur, resulting in luteolysis and embryonic loss. Additionally, if cysts are numerous and/or large at the site of embryonic fixation (at the base of the uterine horns), the presence of the cyst(s) may interfere with nutrient exchange between the endometrium and the developing conceptus, much in the same way as two opposing twins (Ginther 1989c).

Endometrial cysts are best diagnosed with ultrasonography. Cysts can be identified as hypoechoic, immovable structures with a clear border in the lumen of the uterus (Fig. 31.26), as opposed to intraluminal fluid, which is movable and has a less distinct shape or border. Endometrial cysts are usually multiple and are most commonly found located at the base of the uterine horns. Cysts may change in size and number during the estrous cycle and pregnancy.



• **Fig. 31.26** Endometrial cysts, observed on ultrasonographic examination.



• **Fig. 31.27** Endometrial cysts can appear much like a conceptus during ultrasonographic examination.

Endometrial cysts can complicate early pregnancy diagnosis because, often, an endometrial cyst can be similar in size and appearance to an early conceptus. Cysts that appear spherical can often be shown to have a more irregular shape if the ultrasound probe can be reoriented in relation to the cyst. To make early pregnancy diagnosis easier and more reliable, the size and location of endometrial cysts should be recorded either using a diagram or by storing ultrasonographic images during a prebreeding examination. Differentiation is based not only on previous cyst mapping but also the early mobility of the conceptus, the presence of specular reflections, the conceptus's spherical appearance, and growth rate. Some cysts can be very difficult to distinguish from pregnancies (Fig. 31.27), and pregnancy examination may need to be repeated or confirmation delayed in some mares with endometrial cysts.

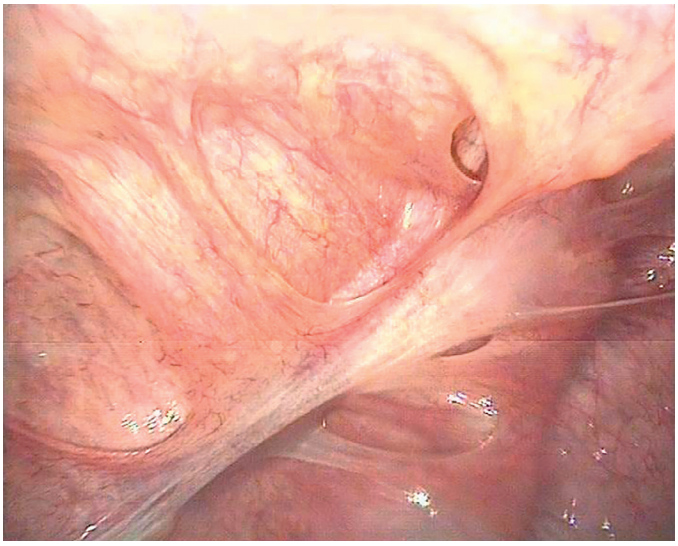
• **Fig. 31.28** Showing an endometrial cyst (small and round) and a larger 18-day conceptus.



• **Fig. 31.29** Uterine adhesions that are formed as a result of intrauterine iodine infusion.

Often, there is an opportunity to scan the mare before or immediately after breeding, but this is not always possible. In that case, it may be impossible to be certain whether there are: twin unilateral vesicles of approximately 20 and 16 days; a single pregnancy and a 19 mm cyst; a cyst with adjacent free fluid; or a 19 mm conceptus with adjacent free fluid. In these cases, it is vital to study the ultrasonographic image carefully. When one looks closely at the wall between the two structures in Fig. 31.28, it is relatively thick and hyperechoic compared with the twin vesicle shown in Fig. 31.7. This would confirm that at least one structure is a cyst. Reassessment of the irregular structure will confirm that the fluid is contained and does not extend up or down the horn as would be found with free fluid. The appearance of an embryo in the conceptus around 20 to 22 days of gestation or of a heartbeat at approximately 24 days provides a definitive diagnosis. Thorough identification of cysts at the beginning of the breeding season minimises the chance of false positive pregnancy diagnosis.

In most cases of endometrial cysts, no treatment is necessary other than recording their size and location for future reference during pregnancy examination. However, if the cysts are sufficient in size or number that they pose a potential threat to embryonic migration, treatment can be aimed at facilitating establishment of pregnancy by providing exogenous progestogen. If a mare is diagnosed at the beginning of the breeding season with a large number of cysts, it is generally best to continue to attempt to get the mare in foal that season. Progestogen, usually in the form of altrenogest (0.044 mg/kg, PO, daily), can maintain pregnancy even when the signal for maternal recognition of pregnancy is lacking and can be used in an attempt to circumvent the interference with embryonic mobility caused by the cysts. If she fails to become pregnant, some form of treatment should be attempted, and an endometrial biopsy should be taken to help determine the likelihood of her carrying a foal to term. The cysts may be removed surgically, usually transendoscopically, utilising a laser or electrocautery loop to ablate it, or in the case of the latter, snare and subsequently remove cyst tissue. Wounds after cautery appear to heal very quickly, usually within 4 to 6 weeks. Because endoscopy should be done while the mare is in dioestrus when the cervix is relatively closed, PGF should be given after cauterization, and the uterus should be lavaged with saline. Ligation and transection of the stalk of pedunculated cysts is an alternative. Merely puncturing and draining the cyst or incising its wall will not provide long-term remission.

Most uterine cysts involve the endometrium, but occasionally, an extraluminal uterine cyst lying external to the endometrium can be identified on ultrasound examination. Its location should be verified by identification of the uterine lumen; extraluminal cysts usually have no adverse effects on fertility.

Uterine Adhesions

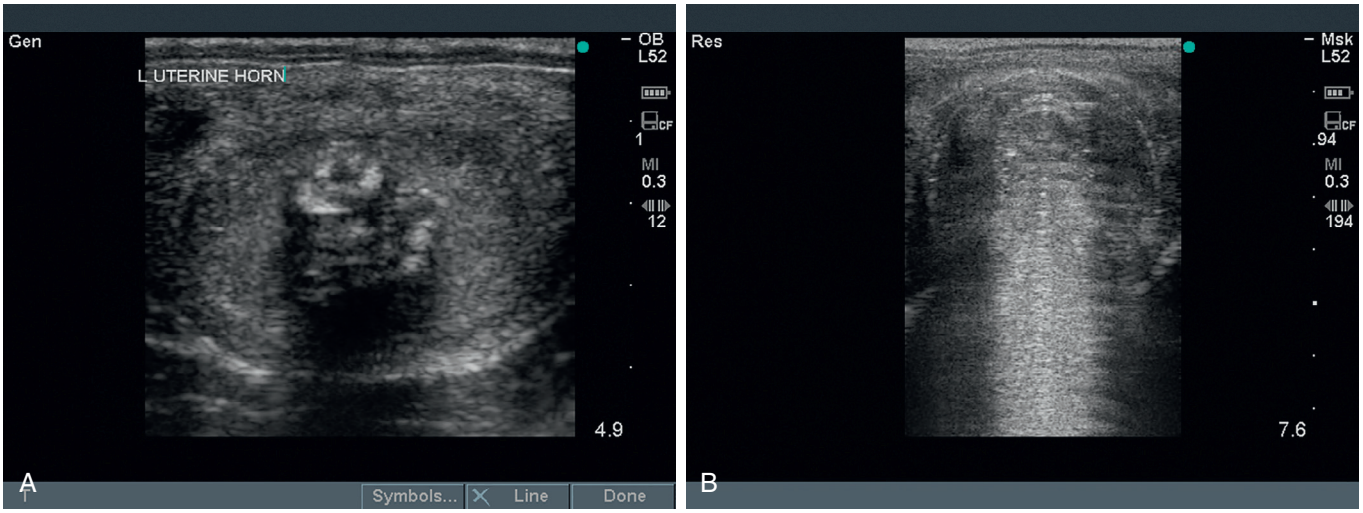
Severe infectious or chemically-induced (after intrauterine infusion of irritating chemicals) endometritis may cause the formation of transluminal adhesions in the uterus. Uterine adhesions are most frequently diagnosed on endoscopic examination. It has been suggested that the incidence may be greater than was previously thought (Stone et al. 1991). Multiple adhesions adversely affect fertility by causing fluid accumulation resulting in mucometra or pyometra or by affecting the mobility of the conceptus. Severe adhesions can completely obstruct one or both of the uterine horns. It is possible to remove the obstruction endoscopically by either cautery or laser techniques, starting at the thin membranous parts of the obstruction (Fig. 31.29). It is important not to 'burn' too deeply the uterine wall as in these cases more severe damage can occur. After removing the obstruction the uterus should be flushed to remove any debris, and the mare treated with PGF. In addition to an assessment of an endometrial biopsy, the prognosis for future breeding also depends on the severity of the obstruction and to what extent the obstruction could be removed.

Adhesions involving the serosal surface of the uterus may occur after Caesarean section or uterine tears. No effective treatment other than attempted surgical excision exists once they are formed. Therefore steps should be taken to minimise the likelihood of their formation, including daily palpation of the uterus after Caesarean section.

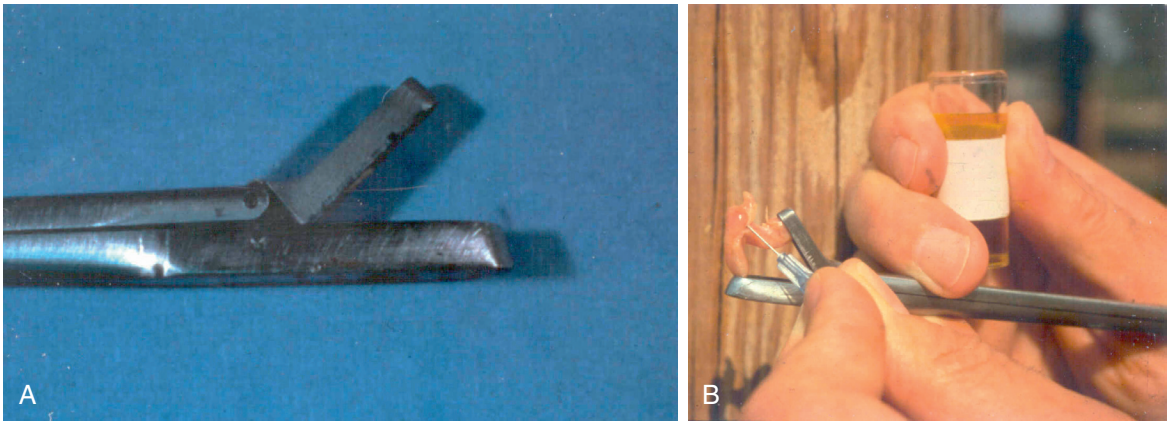
Uterine Foreign Bodies

Uterine foreign bodies (e.g., fetal remnants), which may act as a nidus for the establishment of chronic endometritis, have been documented (Ginther & Pierson 1984) but are uncommon. In one case the mare had a history of failure to conceive, with short interoestrous intervals after a dystocia. Ultrasound examination

VetBooks.ir



• **Fig. 31.30** (A) Hyperechoic fetal bone visible on ultrasonographic examination of the uterine body. (B) Ultrasound appearance of an intrauterine glass marble.



• **Fig. 31.31** (A) Uterine biopsy instrument. (B) Biopsy tissue being removed after procurement and then placed in Bouin's solution for fixation.

revealed hyperechoic fetal bone, part of the scapula, (Fig. 31.30A) which was removed manually via the cervix. The mare conceived after appropriate intrauterine lavage and antibiotic treatment for the endometritis. Other foreign bodies that have been reported include straws after AI and the tips of uterine swabs. More recently, the use of intrauterine glass balls (see Fig. 31.30B) for the management of oestrous behaviour in fillies and mares has led to cases of whole or fractured glass balls acting as foreign bodies with or without associated uterine infection (Turner et al. 2015, Morris et al. 2017). As a result, glass balls (marbles) are not recommended for this purpose, but rather sterile water filled or solid plastic spheres are recommended. However, it should be noted that there are no studies into the long-term presence of these devices in the uterus of mares, and therefore, if they are to be used, they should be removed at the end of the physiological breeding season.

Biopsy

Before committing to the expense of laser surgery for removal of cysts or other reconstructive urogenital surgery, an endometrial biopsy is usually recommended. An endometrial biopsy is also usually considered to be a routine part of a complete breeding soundness or end of season barren mare examination. Because an endometrial biopsy can aid in predicting a mare's chances of carrying a foal to term, the information provided by a biopsy should be considered before purchase or undertaking reproductive surgery such as repair of a cervical tear. Biopsies in some cases provide information that is useful in the diagnosis of infertility and may provide a basis for treatment. It must be realised, however, that an endometrial biopsy alone is not the only, nor usually the most important, piece of information and must be taken in context with other information obtained from the history and reproductive examination.

The procedure is as follows: The perineal area should be thoroughly cleaned for an aseptic procedure. The biopsy instrument is held in a closed position and passed manually through the cervix. Once the instrument is placed into the uterus, the hand is withdrawn from the vagina and placed in the rectum and the tip of the instrument identified. The instrument is then opened and the uterus is pressed through the jaws of the biopsy instrument and a small portion of an endometrial fold is obtained by closing the biopsy forceps (Fig. 31.31A and B).

Generally, a biopsy specimen is taken from a site at the base of one of the uterine horns. When procuring a biopsy, care should be taken that the tissue is not obtained from a site near the internal cervical os. Glands are less dense near the cervix, making a biopsy obtained from that area less representative of the uterus as

VetBooks.ir

a whole and more difficult to interpret. Moreover, if the cervix is accidentally biopsied, adhesions can result.

It has long been considered that a single biopsy is representative of the entire uterus; however, studies have shown that variation by as much as an entire category may exist between sites (Dybdal et al. 1991). Therefore a thorough examination by palpation and ultrasonography should be performed first to determine whether any areas of the uterus appear to be 'abnormal'. If an abnormal area is detected, biopsies should be obtained from both the 'abnormal' and the 'normal' areas. Repeated or multiple biopsies do not significantly affect subsequent fertility because a mare may become pregnant when bred just a few days after a biopsy specimen is taken (Watson & Sertich 1992).

Biopsies may be taken at any time during the year or during any stage of the oestrous cycle because the mare's cervix is easily dilated. Some recommend taking a biopsy during dioestrus for diagnostic purposes because the endometrium is under the influence of progesterone and the glands have achieved maximum tortuosity. Others recommend taking a biopsy during oestrus when the cervix is relaxed and the biopsy instrument is most easily passed into the uterus. Either way, it is important to relay all pertinent history, including the stage during which the biopsy was taken, to the pathologist reading the biopsy. Periglandular fibrosis may appear worse in biopsies taken during anoestrus because of the sparseness of glands. In addition, biopsies taken during anoestrus or the transition phase may have evidence of increased inflammation because the cervix has been in a relaxed state for a prolonged period due to the absence of progesterone. A recent study by Killisch and co-workers (2017) demonstrated that 22% to 30% of biopsies taken during the spring or autumn transition demonstrated 'irregular' endometrial differentiation, and they concluded that diagnostic biopsy sampling should therefore be performed between late April and before September. Thorough descriptions of the pathological changes have been published and can be reviewed, but in most cases, a pathologist associated with the service that processes the sample will read the biopsy. Even so, if the practitioner can review the biopsy slide, it can be helpful in developing recommendations for the future management of the mare.

Endometrial biopsies are classified into four categories (I, IIA, IIB, III) based on scheme published by Kenney and Doig (1986). A mare with a Category I biopsy has an essentially normal endometrium. The likelihood of her becoming pregnant and carrying a foal to term, estimated at 80% to 90%, depends more on broodmare management than on the mare's inherent fertility. Mares with a Category III biopsy have severe pathological changes in the endometrium and an estimated 10% chance of carrying a foal to term, even with good breeding management. Most mares will be classified as a Category IIA or IIB, with an estimated 50% to 80% and 10% to 50% chance, respectively, of carrying a foal to term; it is reflective of a combination of management practices and the mare's inherent fertility.

A complete histopathological description is usually provided by the pathologist. However, of primary concern to the practitioner is the severity and distribution of inflammation and degenerative changes, including periglandular fibrosis, angiosis, and lymphatic lacunae. Degenerative changes carry a worse prognosis than inflammatory changes because they are considered to be permanent and progressive. Attempts have been made to improve the 'quality' of the endometrium and improve breeding prognosis by physical (Ricketts 1985) or chemical curettage (Bracher et al. 1991). Ricketts (1985) demonstrated that mechanical endometrial curettage resulted in an overall improvement in the extent and degree of chronic degenerative endometritis in 82% of cases; 58% of the mares produced live foals after curettage. Bracher and co-workers (1991) reported on the use of kerosene as a chemical agent for endometrial curettage. An infusion of 50 ml of commercial kerosene during dioestrus induced a severe acute inflammation of the endometrium of short duration with mild to severe necrosis of the luminal epithelium. Pregnancy was established in 65% of treated mares, half of which had grade 3 histological changes; no adhesions developed in any mares treated. Although these studies suggest an improvement in biopsy grade and pregnancy outcome, the techniques have not been widely adopted. The use of kerosene remains particularly controversial, and there is a lack of information from controlled, randomised clinical trials. The cause of such degenerative conditions is not known, although it is presumed by many to be due to repeated insults to the uterus. They are more commonly seen in older mares (Ricketts & Alonso 1991a). Dilated lymphatics are often an indication of a uterine clearance problem; however, delayed clearance is more reliably diagnosed by ultrasonographic examination in the postmating period.

Although biopsy can reveal the presence of an inflammatory condition, other methods (such as examination of perineal conformation) must be employed to reveal why it is present, and a culture is needed to identify the particular pathogen. A repeat biopsy after appropriate therapy may reveal the degree of success of treatment and allow an assessment of breeding prognosis (Ricketts & Alonso 1991b).

Endometriosis

Endometriosis has been referred to in the past as chronic infiltrative endometritis, and currently refers to the presence of fibrosis in the stromal and periglandular compartments. The degree of endometriosis is closely associated with the ability of a mare to establish and maintain a healthy pregnancy until term. Parity and age contribute to degenerative changes occurring in the endometria of mares (Ricketts & Alonso 1991a).

Fibrotic changes may be seen around the endometrial glands and in association with the basement membrane in the stratum compactum. The amount and pattern of the distribution of the fibrotic tissue has been descriptively classified as: slight, 1 to 3 layers of periglandular fibrosis; moderate, 4 to 10 layers; severe, greater than 10 layers of periglandular fibrosis (Kenney 1978). Cystic glandular dilatation is another manifestation of endometriosis. Periglandular fibrosis, glandular epithelial hypertrophy, or inadequate lymphatic drainage may lead to dilatation of the endometrial glands.

Other degenerative alterations in the endometrium that lead to endometriosis include lymphatic lacunae and angiosis (Gruninger et al. 1998, Ricketts & Alonso 1991a). Lymphatic lacunae are histopathological indications of lymphangiectasia. Angiosis (vascular pathologies) is associated with ageing and parity, especially in uteri with ventral sacculations and associated venous congestion, which are pathogenical factors for angiosis (Gruninger et al. 1998). There are no treatments for these anatomical and vascular degenerative changes in the uterus. Mares with lymphatic lacunae and disseminated uterine angiosis are at risk of infertility caused by delayed uterine clearance and persistent mating-induced endometritis (Gruninger et al. 1998, Ricketts & Alonso 1991a).

Pregnancy loss attributed to endometrial fibrosis is more commonly manifested during the embryonic period, postulated as due to a decreased ability to produce histotrophe, required by the embryo for nutritional sustenance. If uterine fibrosis interferes with implantation of the placenta, then pregnancy failure will occur later in gestation. Microcotyledonary attachments begin to

VetBooks.ir

develop between 80 and 120 days of gestation (Bracher et al. 1990). Ultrastructural evaluation of the placenta in mares with chronic degenerative endometritis (endometriosis) has shown a delay in microcotyledon development and a reduction in the number of microcotyledons and villi per surface area (Bracher et al. 1991). Endometrial atrophy may not result in abortion but can influence fetal growth. Fetal weights in mares with degenerative endometritis were lower than in normal mares (Bracher et al. 1991). Evidence of endometrial atrophy may be evident upon inspection of the placenta after the birth of the foal (Asbury 1988).

Pyometra

Pyometra is an accumulation of large quantities of purulent exudate in the uterus causing its distention (Hughes et al. 1979). It must be distinguished from the smaller, intermittent accumulations of fluid that can be detected by ultrasonography in acute endometritis. Pyometra occurs because of interference with natural drainage of fluid from the uterus, which may be due to cervical adhesions or an abnormally constricted, tortuous, or irregular cervix. In some cases, the fluid accumulates in the absence of cervical lesions, presumably due to an impaired ability to eliminate the exudate.

Unlike cows, mares with pyometra do not necessarily have a persistent CL, and many may cycle normally. When the endometrium is severely damaged, resulting in extensive loss of surface epithelium, severe endometrial fibrosis, and glandular atrophy, a prolonged luteal phase, presumably due to interference with the synthesis or release of PGF, may be observed.

A mare with pyometra seldom shows overt signs of systemic disease even when there is up to 60 litres of exudate in the uterine lumen; very occasionally, there is weight loss, depression, anorexia, or recurrent colic. Pyometra has been classified into two categories in mares: open and closed (Hughes et al. 1979). In a case of closed pyometra, the fluid accumulates due to a closed cervix, whereas in open pyometra, the cervix remains partially dilated but purulent material accumulates because of impaired uterine clearance. A vulvar discharge is often observed in open pyometra, especially at oestrus, which may vary in consistency from watery to cream-like.

In a mare with an enlarged uterus, pyometra is readily diagnosed by transrectal ultrasonography when a large volume of intraluminal fluid with moderate echogenicity is seen in the uterus. Due to the lack of systemic illness, most mares with pyometra are brought to the veterinarian's attention at an advanced stage. Degenerative changes such as endometrial atrophy may preclude mares from returning to normal fertility after treatment. A biopsy of the uterus should be examined to determine the prognosis for potential fertility before treatment of pyometra.

The aim of treating pyometra is to expel the purulent material from the uterus. In the absence of systemic illness or an unsightly vulvar discharge, treatment of chronic pyometra may not be indicated, although some mares can show signs of discomfort during exercise. Many cases can be significantly improved by repeated large volume lavage with several litres of warm saline via a wide-bore tube such as a nasogastric tube. Initially, PGF can be used to induce luteolysis of the CL if present, which should allow the cervix to relax sufficiently for digital exploration for the presence of any adhesions. PGE may also help relax the cervix. After repeated large volume lavage and oxytocin to achieve drainage of exudate, appropriate antibiotics, based on culture and sensitivity, should be infused. If a cervical lesion is identified, it must be corrected to reduce the chance of recurrence of the pyometra. Monitoring the uterus, by a combination of rectal palpation and ultrasound, provides information on the response to treatment. Even if successfully treated and if the mare is to be bred, she must be considered a susceptible mare and managed accordingly.

In nonresponsive cases, hysterectomy can be performed after drainage of the exudate from the uterus, although great care has to be taken to prevent contamination of the peritoneal cavity.

Neoplasia

Uterine neoplasms are uncommon in mares. Leiomyomas, often referred to as fibroids, are benign mesenchymal neoplasms derived from smooth muscle and are often associated with the presence of fibrous tissue; leiomyoma is the most common neoplasm affecting the uterus of mares and, if small, does not necessarily cause reproductive failure. Leiomyosarcoma, lymphosarcomas, and adenocarcinoma are rare malignant neoplasms affecting mares.

Neoplasia affecting the equine uterus is usually discovered when palpation per rectum and transrectal ultrasonography are performed in broodmares during the breeding season. If the presence of a uterine neoplasm is suspected, uterine endoscopy should be performed and a biopsy of the tissue taken for final diagnosis. Surgical excision of a neoplasm is indicated when extensive haemorrhage and endometritis are present or when the presence of the neoplasm would be incompatible with establishing a pregnancy. Prognosis for future fertility is reduced, but pregnancy has been reported in mares with partial hysterectomy (Santschi & Slone 1994).

Uterine Tubes

The function of the uterine tubes and the tubal environment are essential for normal fertility. Mares are unique in that unfertilised oocytes are retained in the uterine tubes and not transported to the uterus. The mechanism(s) accounting for this phenomenon (selective transport of fertilised vs unfertilised oocytes) has not yet been fully elucidated but appears to involve secretion of PGE_2. A healthy uterine tube is responsive to embryonic signals, resulting in proper timing of tubal transport. Diagnosis of pathologies in the uterine tubes is difficult and often found only in postmortem examinations.

Postmortem examination of reproductive tracts found that salpingitis was not uncommon in mares; 37% had infundibulitis, 21% had ampullitis, and 9% had isthmitis (Vandeplassche & Henry 1977). In that study, 50% of mares were older than 15 years and 85 % were 11 years old or older. The infundibulum was generally found adhered to the uterus, mesovarium, or ovary. The incidence of adhesions on the right side was significantly higher than on the left side (Vandeplassche & Henry 1977). Although evidence of salpingitis could be detected in problem breeding mares, the incidence was no different from that noted in normal, fertile mares (Ball et al. 1997).

Uterotubal obstructions are less common in the mare than in the cow, although masses of collagen have been found in the oviducts of young maiden mares and pregnant mares and were observed more often in mares more than 7 years old (Liu et al. 1990). Historically, postmortem analysis of uterine tubes suggested that reduced tubal patency is not a major problem in mares. An examination of 700 postmortem specimens, primarily from mares over 11 years old, found that almost all oviducts were patent, although over 40% had adhesions involving the infundibula (Vandeplassche & Henry 1977). Only one uterine tube was found to be occluded when 1248 pairs of uterine tubes were flushed postmortem (David 1975, Vandeplassche & Henry 1977). Contrary to this, in a more recent report, Bennett and co-workers (2002) investigated 31 mares with histories of prolonged infertility for two to four breeding seasons.

VetBooks.ir

Evaluation of the reproductive tract using transrectal palpation, ultrasound, culture, cytology, biopsy, and hysteroscopy was performed and failed to provide a definitive diagnosis for the cause of infertility. The uterine tubes of these mares were assessed under general anaesthesia and demonstrated that 42% were bilaterally occluded and 19% were unilaterally occluded. Twelve mares that were bilaterally occluded had their uterine tubes flushed in an orthograde direction and were subsequently bred; a 67% conception rate was achieved. Recent work by Köllmann and co-workers (2011) demonstrated that the uterine tubes can be successfully observed and flushed using a laparoscopic flank approach.

In one author's practice (JRC), PGE gel is applied under laparoscopic guidance to the uterine tubes in mares suspected of having uterine tubal blockage. Allen et al (2006) demonstrated that laparoscopically guided administration of PGE_2 gel (dinoprostone) directly onto the surface of the uterine tubes was successful at restoring fertility in mares assumed to have occlusion, based on their reproductive histories. Fifteen mares that had failed to conceive over 1 to 4 years were treated, of which 93% conceived within the same or subsequent breeding season; 60% of mares conceived to their first mating (Allen et al. 2006). Application of PGE_2 to the uterine tubes is best performed during the breeding season (Martynski et al. 2015). More recently, uterine tube catheterisation has been described by Inoue (2013) via hysteroscopy and demonstrated that the technique was applicable to retrograde flushing of suspect blocked oviducts (Inoue 2017).

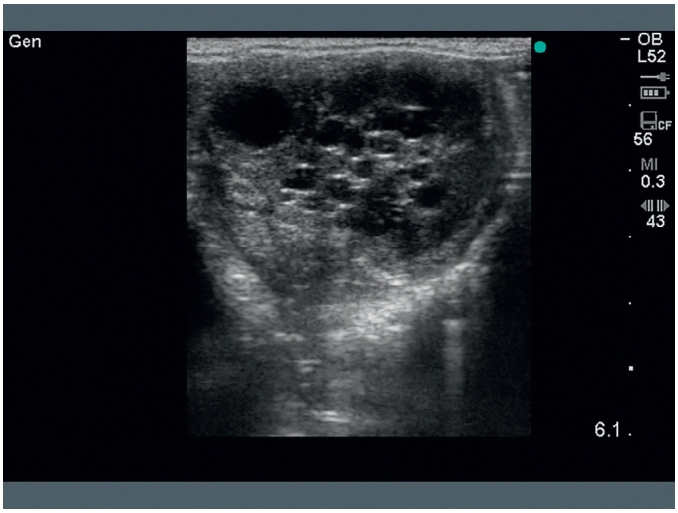
Most uterine tube abnormalities and periovarian structures diagnosed antemortem are remnants of embryological structures. Periovarian cysts, which are fairly common, are not endocrinologically active, do not usually interfere with the process of ovulation, and do not generally affect fertility. Occasionally, large cysts may be palpated or imaged with ultrasonography and may be confused with follicles. However, the lack of change in size or appearance of these structures is usually diagnostic.

Ovaries

The presence of an enlarged ovary in a mare may be normal or may be an indication of ovarian pathology. Consideration of the various reasons and careful diagnostic procedures are necessary to avoid surgical removal of normal ovaries. A thorough history, including changes in behaviour, oestrous cycle characteristics, sexual behaviour, and last observed oestrus, are important to consider. Ultrasonography, palpation, and hormonal assays are all helpful in arriving at an accurate diagnosis. In some mares, sequential examinations are beneficial in determining changes in the size of ovaries or various structures on an ovary. Various factors, such as season and pregnancy status, must be considered when interpreting a finding of ovarian enlargement. Large ovaries may be normal during the transitional periods in the spring and fall and are expected during early gestation.

Discovery of an enlarged ovary may be an incidental finding during a normal reproductive examination or may be stimulated by specific clinical signs. Behavioural changes or signs of colic in a mare warrant examination of the reproductive tract, with special attention given to the ovaries. Mares with a history of infertility or behavioural abnormalities are often suspected of having abnormalities of the ovaries and deserve a thorough examination before surgical removal of an enlarged ovary.

Cysts lying within the ovarian stroma near the ovulation fossa of the ovary arise from the surface epithelium and are often seen in older mares during examination of the ovary. They are known as 'retention', 'inclusion', or 'fossa' cysts and generally have no adverse effect upon fertility (Fig. 31.32). They are termed ovarian cysts by some authors, which may account for the diagnosis of 'cystic ovaries' in the mare. Sometimes 'cystic ovaries' are falsely diagnosed during the vernal transition, when a single follicle or multiple large ones persist without ovulating. Fossa cysts are normally only a few millimetres in diameter. Care must be taken not to confuse them with a normal ovary with several small follicles or even conceptuses. Careful examination allows accurate identification of their position. It is possible that sometimes, particularly if they are large and numerous as can occur in older mares, they could impede the release of the oocyte from the ovulation fossa. Small nodules, located within the loose connective tissue covering of the ovary (adrenocortical nodules), have also been identified.



• **Fig. 31.32** Ultrasound image of an old mare's ovary with numerous inclusion cysts.

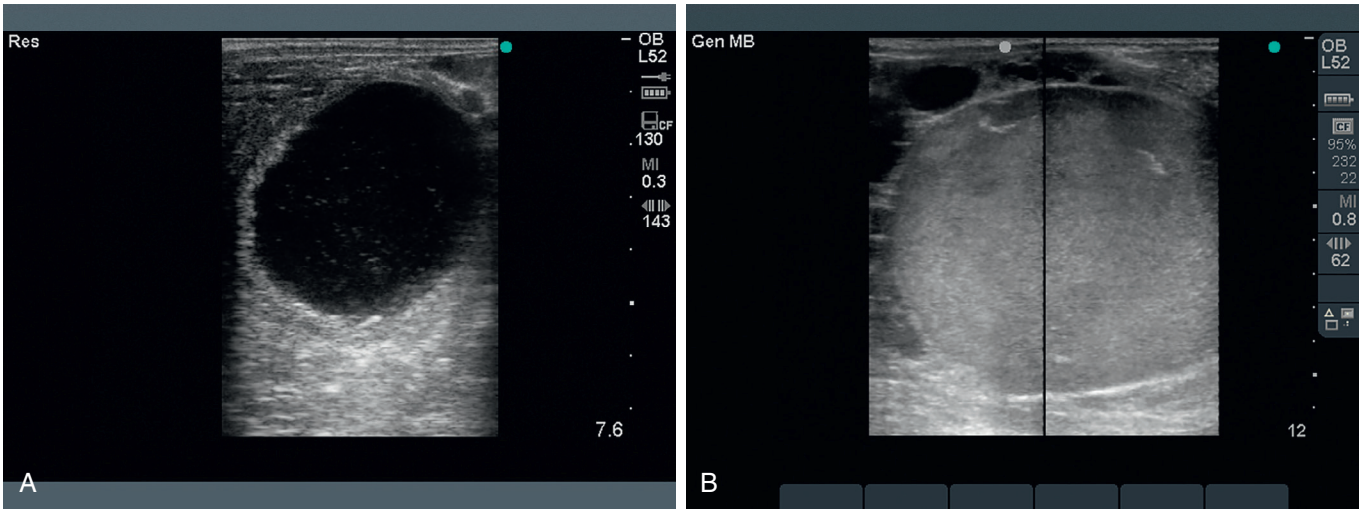
Nonneoplastic Ovarian Enlargement

Anovulatory Follicles

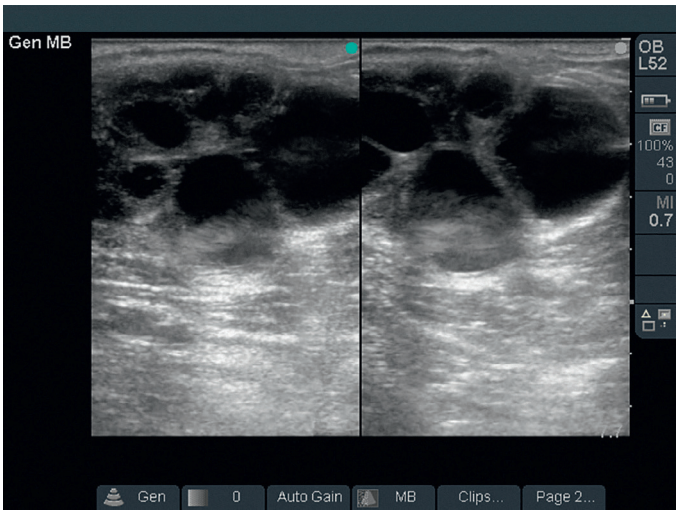
During early gestation, ovarian enlargement is normal and should be expected. Ovarian enlargement is associated with increased follicular activity and subsequent ovulation (secondary corpora lutea) or anovulatory luteinisation (accessory corpora lutea) in response to the presence of eCG from the endometrial cups. An increase in follicular growth begins before day 20 of gestation. New CLs form around day 40 of gestation. Multiple CLs and haemorrhagic anovulatory follicles are commonly found from day 40 to 60 of gestation. Mares bred early in the season have greater follicular activity during the first 4 months of gestation than mares bred after July.

Anovulatory follicles are most commonly observed in mares near the end of the breeding season as they go into the autumn transition. Their significance is that the oocyte is not released but remains within the large unruptured haemorrhagic follicle. These follicles may grow to an unusually large size (70–100 mm) yet fail to ovulate. Instead, they fill with blood and develop a 'gelatinous consistency'. A thick wall (compared with a normal follicle) commonly forms. Ultrasonographically, free floating echogenic spots in the antrum of the follicle are observed, which increase in number as the follicle grows (Fig. 31.33). When the follicle stops growing, the contents become organised with an echogenic appearance and fibrin strands. They become firmer and then regress over time, usually disappearing within a month. Formation of luteal

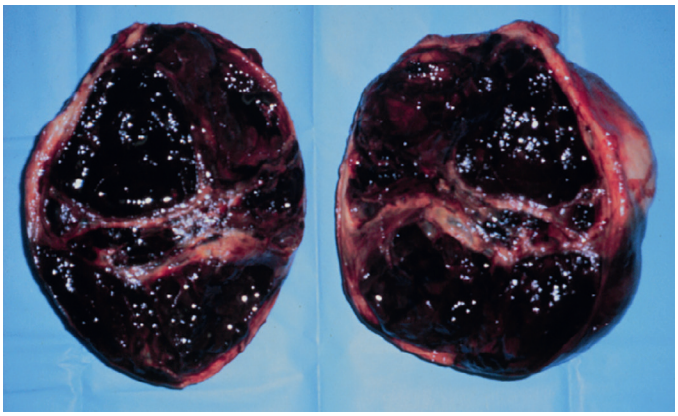
VetBooks.ir



• **Fig. 31.33** (A) An early anovulatory follicle and (B) a large, more developed haemorrhagic anovulatory follicle.



• **Fig. 31.34** Transitional ovaries; note numerous follicles.



• **Fig. 31.35** Ovarian haematoma.

tissue around the periphery of the anovulatory follicle is usually minimal in a true 'autumnal follicle' that occurs at the end of the season. The cause of autumnal follicles is hypothesised to be due to changes in the hormonal status of the mare that occur with autumn transition.

During the spring, as mares undergo transition from winter anestrus to the normal ovulatory season, they undergo periods of prolonged anovulatory follicular development. These periods are characterised by the development of numerous follicles, at times quite large, on either or usually both ovaries. The follicles may persist for varying lengths of time and then regress and new follicles develop. This period lasts for a variable time depending on the individual mare, photoperiod, and other undetermined factors. The ovaries can be quite large during this time and may mistakenly be called cystic (Fig. 31.34). No treatment is necessary, although a combination of progesterone and oestrogen, as previously discussed, is often used to suppress follicular activity in an attempt to hasten the onset of ovulation and normal cyclicity. The transition period ends with the first ovulation of the season, after which follicular activity and ovarian size return to within normal limits.

Although there is no true menopause in mares, an age-related ovulation failure has been documented (Vanderwall et al. 1993). Some aged mares, particularly over 20 years, fail to ovulate despite showing oestrous behaviour.

An ovarian hematoma forms as haemorrhage occurs into the previous follicular lumen after ovulation. On occasion, this haemorrhage can be excessive, possibly due to an anticoagulant in follicular fluid. Hematomas can be very large, up to 20 cm in diameter or more (Fig. 31.35). Because this structure is a postovulatory phenomenon, the oocyte will have been released, and the mare may become pregnant if mated. They are able to produce progesterone, and there is no effect on the oestrous cycle. Although the ovulation fossa is still present, palpating it can be difficult if the hematoma is very large. The ultrasonographic appearance can vary, causing confusion with a granulosa cell tumour. Large fluid filled cavities may be observed, or it may have a more solid appearance, sometimes with fibrin strands. A trait that is at times useful in differentiating a hematoma from a granulosa cell tumour is the responsiveness to prostaglandin. Hematomas that are at least 5 or 6 days old usually respond to prostaglandin by decreasing in size because of the luteolytic effect, and the mare will return to oestrus. Granulosa cell tumours do not respond to prostaglandin treatment with any change in size, shape, or ultrasonographic appearance. With hematomas, because the follicle wall still undergoes luteinisation

VetBooks.ir

despite the presence of the hematoma, cyclicity remains unaltered; thus normal fertility is not compromised. However, the enlargement of the ovary due to the presence of a haematoma may persist for several oestrous cycles, even though the lifespan of the luteal tissue is normal.

The definition of an anovulatory follicle is one that fails to ovulate and thus fails to release its follicular fluid and oocyte. Two forms of anovulatory follicles exist. Approximately 15% appear to become 'cystic' and do not luteinise; these are sometimes referred to as persistent anovulatory follicles (PAFs). The other 85% consist of the follicles that luteinise without releasing the oocyte (McCue & Squires 2002). The most common form of luteinised anovulatory follicles is the haemorrhagic anovulatory follicle (HAF); far fewer show no evidence of bleeding and are defined as luteinised unruptured follicles (LUF). Anovulatory follicles can have a variety of morphological forms, and these can be functionally different. The haemorrhagic anovulatory follicle (HAF) is the most well recognised form because of its striking ultrasound characteristics.

The incidence of anovulatory follicles varies from 4.5% to 8.2% of oestrous cycles (Chopin et al. 2001, McCue & Squires 2002). The incidence of anovulatory follicles increases with age (4.4% incidence with mares 6–10 yrs, 13.1% incidence with mares 16–20 yrs; McCue & Squires 2002), and they are more likely to occur late in the season (Ginther et al. 2007, Cuervo-Arango & Newcombe 2010); some individuals appear to be more prone to the condition (McCue & Squires 2002, Ginther et al. 2006, Ginther et al. 2007, Cuervo-Arango & Newcombe 2010). In six mares that had a history of HAF in the previous season, the occurrence was 54% of all oestrous cycles (Ginther et al. 2006, Ginther et al. 2007). Cuervo-Arango and Newcombe (2010) estimated that the likelihood of mares having consecutive HAF was 31.5%; some mares may have a much higher incidence of HAF (25%) than other mares (Cuervo-Arango & Newcombe 2010). It should be noted that repeated HAF formation has been associated with persistent endometrial cups in mares with low levels of circulating eCG (Crabtree et al. 2011). As the definition of an anovulatory follicle is one that fails to ovulate, pregnancy rate is zero (McCue & Squires 2002).

The indicators of impending ovulation (decreased turgidity, loss of spherical shape, echoic specks in antrum, serration of granulosa, and an apical area) do not differentiate ovulatory from anovulatory follicles up until the day of expected ovulation (Ginther et al. 2006, Ginther et al. 2007). Follicles become haemorrhagic when blood appears to enter. However, in HAF, when ovulation would be expected if it was a normal follicle, it does not. Instead, the wall of the follicle becomes excessively serrated, and there is an increase in the echogenic particles in the follicle (see Fig. 31.33); sometimes they are so great that contents of the follicle appear like a swirling 'snow storm'. Often, there is an increase in size of the follicle at the same time (31.33b). Ginther et al (2006) and Ginther et al (2007) determined the Doppler blood flow characteristics of ovulatory and anovulatory follicles and demonstrated in anovulatory follicles an increase in the blood flow signal in the apical area (where the follicle ruptures via the ovulation fossa) in the 24 hours before expected ovulation; conversely, ovulatory follicles demonstrated minimal apical blood flow preceding ovulation. In the days afterwards, as the blood clot begins to organise, echoic bands or strands develop in the follicle, and these tend to 'quiver' when the follicle is ballotted (see Fig. 31.33B). This is due to the fact that follicular fluid contains a heparin-like substance slowing the clotting process (Stangroom & Weevers 1962). HAF appear to reach maximum diameter by approximately 3 days postovulation failure, increasing to as much as 70 to 100 mm, and become firmer. At the same time as this organisation of the HAF, the wall tends to become thicker as it becomes luteinised. The PAF physically mimics a dominant follicle and may persist for several weeks or months and then spontaneously regress. The LUF will demonstrate wall thickening as it undergoes luteinisation.

McCue and Squires (2002) reported that in over 151 HAF cycles, the average interovulatory interval was prolonged to 38.5 +/− 15 days. However Ginther and co-workers (2006) reported a normal interovulatory interval in seven HAF cycles, so it would appear that the response of the HAF to endogenous $PGF_{2\alpha}$ is variable, or that the normal luteolytic mechanism is not activated. In general terms the HAF and luteinised follicles will regress after treatment with $PGF_{2\alpha}$ but probably not at the same stage as a normal CL. This is because the vast majority of HAFs do luteinise, and thus a single injection of $PGF_{2\alpha}$ can be used to induce luteolysis once the HAF is functional with plasma P4 concentrations greater than 1 ng/mL or there is physical evidence of luteinisation (absence of floating echoic specks, thickened follicle wall). Typically, this occurs 5 to 7 days after initial signs of HAF formation. Another approach to prevent luteinisation and hasten structural regression of the HAF with return to oestrus is to administer serial injections of $PGF_{2\alpha}$ as soon as the formation of HAF is being suspected or diagnosed. This protocol was originally reported to prevent luteal formation in ovulating, cyclic mares, and it seems to be useful in promoting a fast resolution of HAFs. Daily or twice daily injections of dinoprost tromethamine (10 mg; IM) for 5 consecutive days are typically sufficient to prevent functional luteinisation and promote structural regression of the haemorrhagic/luteinising anovulatory follicle (Coffman et al. 2014). Nonluteinised anovulatory follicles do not appear to influence the oestrus and can be viewed as atretic structures with limited clinical significance.

The exact cause of HAFs is unknown; however, there have been some interesting developments in recent years. Cuervo-Arango and Domingo-Ortiz (2011) demonstrated that systemic treatment with a high dose of flunixin meglumine is able to induce HAF formation. In addition, Martínez-Bova and Cuervo-Arango (2016) demonstrated that intrafollicular treatment with $PGF_{2\alpha}$ inhibited this formation and restored normal ovulation, whereas systemic cloprostenol administration did not (Cuervo-Arango 2012). Studies of HAFs have demonstrated higher oestradiol concentrations a few days before HAF formation but no alterations in progesterone, LH, or FSH (Chopin et al. 2001, Ginther et al. 2006). Lower concentrations of inhibin and androstenedione have been demonstrated in the late follicular stage (Chopin et al. 2001).

The use of cloprostenol to 'short cycle' mares may induce some individuals to produce HAFs, and it appears to be dose dependent (Cuervo-Arango & Newcombe 2010). The premature stimulation of a young follicle with LH/hCG could also induce premature luteinisation (Coulam et al. 1982) without follicle rupture, as seen in pregnant mares under constant stimulation with eCG (Cuervo-Arango & Newcombe 2010). The use of prostaglandin can cause LH release (Jöchle et al. 1987), and this might be the mechanism for the effect of cloprostenol on HAF formation (Cuervo-Arango & Newcombe 2010). The general guidance in a mare prone to HAF formation is to use the lowest luteolytic dose of prostaglandin possible, such as 25 to 125 mcg cloprostenol (Cuervo-Arango & Newcombe 2010).

Ovarian Abscessation

Ovarian abscesses are often attributed to procedures involving puncture of the ovary, such as biopsy or follicle aspiration. As assisted

VetBooks.ir

reproductive techniques became more successful and therefore more popular, the incidence of ovarian abscesses was thought likely to increase. However, this has not proven to be the case. Moreover, not all ovarian abscesses can be attributed to iatrogenic causes. Ovarian abscesses have been reported in mares that have had no such procedures performed on them (Ramirez et al. 1998). In these cases, they are likely to be due to the hematogenous spread of bacteria, perhaps into a haemorrhagic structure, or may be associated with strongyle migration.

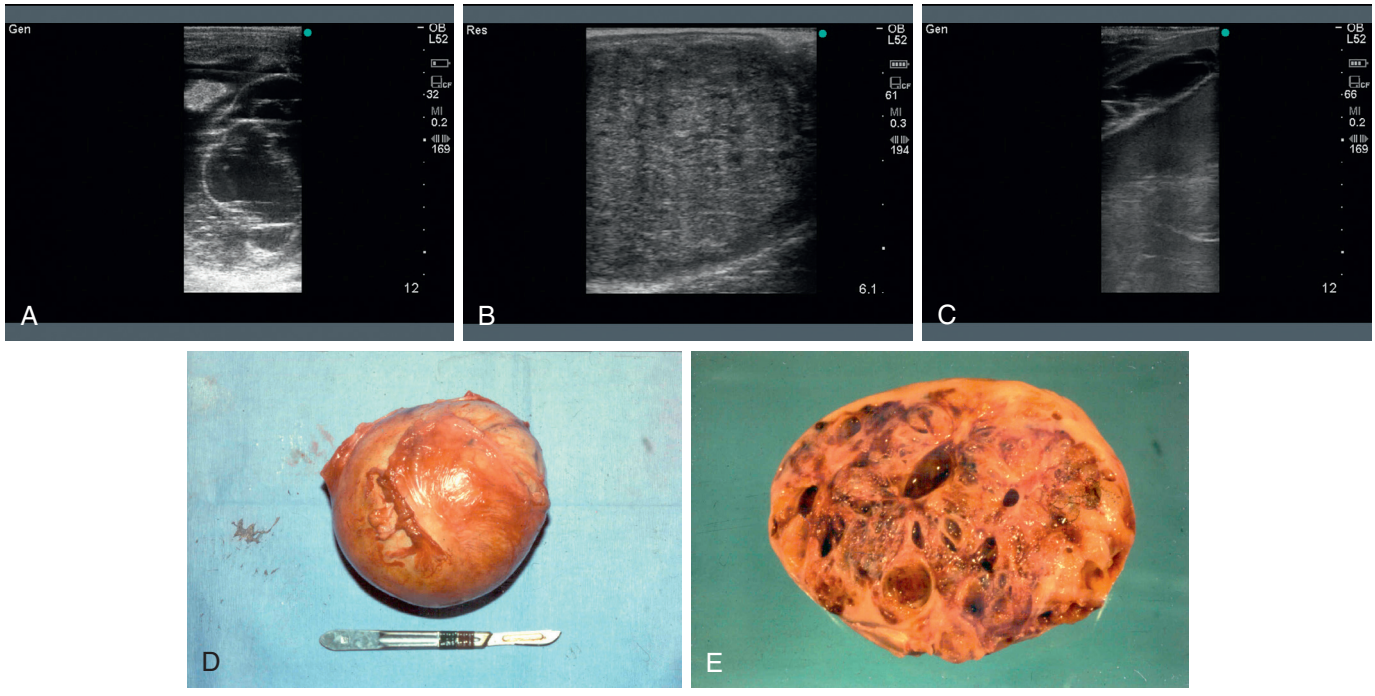
Affected mares may be febrile and anorexic with an elevated WBC. On ultrasonographic examination, the enlarged ovary typically has a thick-walled, fluid-filled structure; the fluid is usually hyperechoic. Medical management with long-term antibiotic therapy has been successful in treating these cases. Surgical removal of the affected ovary is an alternative treatment, but care must be taken that the abscess does not rupture in the abdominal cavity.

Ovarian Neoplasia

The granulosa cell tumour (GCT) is the most common ovarian tumour in the mare (McCue et al. 1998). They are either comprised primarily of granulosa cells or granulosa and theca cells, the latter being termed 'granulosa theca cell tumours' (GtCT) (Kennedy & Miller 1993). The tumour is predominantly slow growing and benign (Kennedy & Miller 1993). The mean age of affected mares is 10.6 years and ranges from 2 to 20 years (Meagher et al. 1977); rarely juvenile GCTs have been reported (Hultgren et al. 1987, Green et al. 1988, Charman & McKinnon 2007). GCTs have been detected in maiden, barren, pregnant and foaling mares (Stickle et al. 1975, Meagher et al. 1977, Crabtree et al. 2013).

Ultrasound examination of the affected ovary usually reveals an enlarged multicystic structure but can be in the form of a solid mass or single large fluid filled cyst (Crabtree 2011; Fig. 31.36A–C). They are usually unilateral and present with a small and inactive contralateral ovary (Meagher et al. 1977, Stabenfeldt et al. 1979). GCTs are hormonally active producing variable amounts of testosterone, oestradiol, and inhibin (Stabenfeldt et al. 1979, McCue et al. 2006). Mares demonstrate abnormal behaviour in the form of prolonged anoestrus, stallion-like behaviour, or persistent oestrus (Meagher et al. 1977, Stabenfeldt et al. 1979), depending on the predominant steroid hormone produced. Testosterone concentrations are elevated in approximately 50% to 60% of cases (McCue et al. 2006), and progesterone concentrations are almost invariably low, consistent with the absence of active luteal tissue (Stabenfeldt et al. 1979). Measurement of oestrogens is generally regarded to be of limited value as concentrations are variable and not always clearly related to the predominant behaviour expressed (Stabenfeldt et al. 1979). Inhibin is elevated in approximately 90% of cases (McCue 1992, Bailey et al. 2002), and it is hypothesised that inhibin produced by the GCT is responsible for the inactivity of the contralateral ovary through the suppression of pituitary FSH release (McCue 1992). GCT has, however, been described in mares that continued to cycle despite the presence of a GCT (Hinrichs et al. 1990, McCue et al. 1991, Nie & Momont 1992, Crabtree et al. 2013). It is assumed that these situations represent incipient tumours, which have not been present for long enough to inhibit activity in the contralateral ovary.

Due to the variabilities in the described hormones in cases of GCT, the normal variation in levels of inhibin during the oestrous cycle, and the difficulties encountered in interpreting GCTs in pregnant mares, serum anti-Müllerian hormone (AMH) has become the 'gold standard' in the diagnosis of GCT. Serum AMH concentrations are not different between normal cyclic mares and pregnant mares, and there are no significant variations in serum AMH concentrations during either the oestrous cycle or pregnancy (Almeida et al. 2011, Ball et al. 2013a). Elevations in serum concentrations of AMH appear to have a greater sensitivity than inhibin,



• **Fig. 31.36** Granulosa cell tumours with (A) a typical multiloculated appearance, (B) where there is a more solid state, and (C) associated with a large fluid filled structure. (D) Granulosa cell tumour after removal. (E) The tumour has been incised to show its multiloculated structure.

VetBooks.ir

testosterone, or the combination of inhibin and testosterone for the diagnosis of GCTs in mares, and elevations in serum AMH concentrations greater than 4 ng/mL seem to be diagnostic for equine GCTs (Ball et al. 2013a, Ball et al. 2014).

The differential diagnoses for ovarian enlargement in the mare include neoplasia, GCT, teratoma, serous cystadenoma, dysgerminoma, and thecoma (Crabtree 2011). Other tumours of the ovary are considered hormonally inactive, although cystadenomas with elevated testosterone levels have been reported (Hinrichs et al. 1989). Nonneoplastic differentials are a persistent anovulatory follicle, a haemorrhagic anovulatory follicle, ovarian haematoma, ovarian abscess, and ovarian enlargement during pregnancy (Crabtree 2011).

Medical complications due to or associated with the presence of GCT are uncommon; however, GCTs have been associated with colic, intraabdominal haemorrhage, adhesions to adjacent abdominal structures, and lameness (Meagher et al. 1977, Green et al. 1988, Crabtree 2011). Cases of malignant and metastasising GCTs have been reported (Meagher et al. 1977, Crabtree 2011), and this must be considered when advising mare owners regarding treatment. Single case reports also exist of cases of GCT associated with hypertrophic osteopathy, cutaneous lymphoma, granulomatous dermatitis, and secondary diabetes mellitus (Crabtree 2011).

Surgical removal of the affected ovary is recommended. Surgical approaches for tumour removal include colpotomy, flank and ventral midline laparotomy, and laparoscopy (Crabtree 2011). The selected surgical approach for ovariectomy is based on the size of the tumour, availability of surgical expertise, and economics. Standing laparoscopic ovariectomy is becoming the method of choice because it provides excellent observation of the surgical field ensuring haemostasis and reduced morbidity and hospitalisation time (Hubert et al. 2006). Larger ovaries can be drained or incised in order for them to be removed via a flank incision.

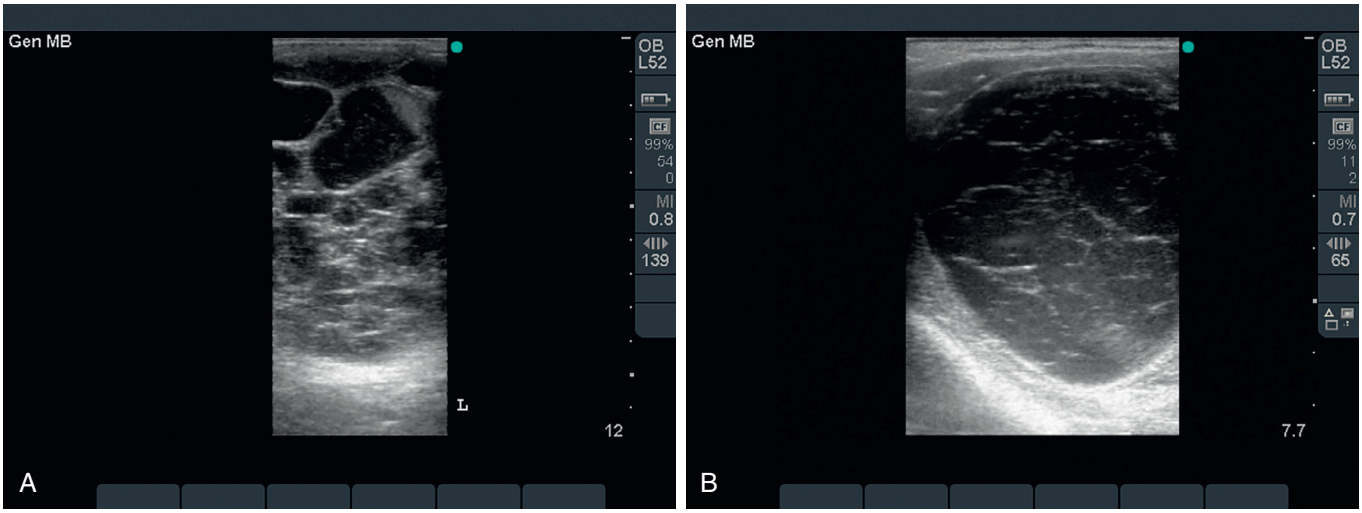
Testosterone and inhibin concentrations decline rapidly after surgical removal of the affected ovary (Stabenfeldt et al. 1979, McCue 1992, Bailey et al. 2002). Meagher and others (1977) reported that 74% of mares returned to oestrus, and 77% of mares known to have been bred postsurgery produced live foals. The time taken to return to cyclic activity is inevitably under seasonal influence, and even if the mare cycles within the same breeding season, she will most likely be bred the next season. The contralateral ovary returns to normal function on average 8.5 months after surgery in most mares (Meagher et al. 1977).

Behavioural changes alone can be misleading because many affected mares do not show any behavioural changes. Occasionally, owners express the opinion that their mare is difficult to handle or unmanageable when in oestrus and request veterinary treatment. Frequently, such mares are required to perform to a high level, and in the authors' opinion, most behavioural problems are not related to the reproductive system. If examination during a reported period of abnormal behaviour reveals marked follicular development, it is tempting to diagnose 'cystic ovaries' as the cause of the behavioural changes. On other occasions, the mare may even be in dioestrus when examined. In any case, owner pressure to perform an ovariectomy on suspicion of a GTCT should be resisted, at least until the mare has been monitored throughout several cycles to determine whether her behavioural problems are related to oestrus.

When it is thought that the behavioural problems are truly linked to oestrus, daily treatment with progesterone or a synthetic progestogen should prevent cyclical ovarian activity and oestrus. Although rare in an unbred mare, there is a possibility of an increased risk for endometritis in a mare on long-term progesterone supplementation, and she should be monitored for this. In addition, the problems may well recur after cessation of treatment. Another possibility is to breed the mare and establish pregnancy. Possible disadvantages of this approach are that she cannot be shown or compete in the later stages of pregnancy, and the problems may recur after birth of the foal. There may be some permanent conformational changes due to the pregnancy that could detract from the mare's showing potential.

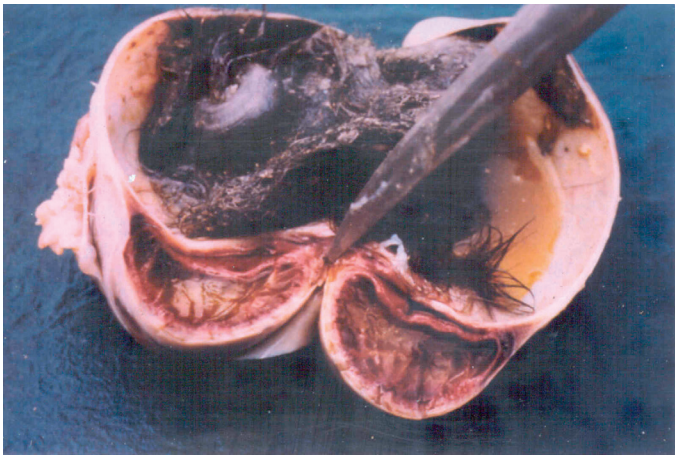
The enlarged ovary may be smooth or 'knobbly', hard or soft, and may feel like there are multiple follicles present. Typically, the ovulation fossa on the enlarged ovary cannot be palpated, although with any greatly enlarged ovary, the fossa may be very difficult to palpate (see Fig. 31.36D and E).

Although ultrasonography is a useful adjunct, it may not yield a definitive diagnosis in many cases. The ultrasonographic image of granulosa cell tumours can be very similar to other ovarian abnormalities, especially haemorrhagic anovulatory follicles and haematomas (Fig. 31.37A and B). A variety of reported appearances



• **Fig. 31.37** Ultrasound image of (A) a granuloma cell tumour and (B) a haemorrhagic anovulatory follicle.

VetBooks.ir



• **Fig. 31.38** Ovarian teratoma.

• **Fig. 31.39** Granulosa thecal cell tumour, which subsequently resulted in ovarian torsion.

makes diagnosis based solely on ultrasonography impossible in many instances.

Teratomas, although uncommon, are the second most common ovarian tumours; they contain at least two, if not all three, germinal layers. Most teratomas found in mares are benign. They usually contain hair and may also contain bone, teeth, and neural tissue (Fig. 31.38). Teratomas are usually an incidental finding because most are small and do not often cause significant ovarian enlargement. However, on occasion, large teratomas develop that result in ovarian enlargement. Teratomas do not affect the oestrous cycle and therefore lack obvious outward clinical signs.

Serous cystadenomas are neoplasms of epithelial origin usually found in an older mare; they do not metastasise. Although they have been found in mares with high plasma testosterone (Hinrichs et al. 1989), behavioural changes are not characteristic. The contralateral ovary is not affected, and it continues to have normal activity and does not atrophy; affected mares continue to cycle. On the affected ovary, the ovulation fossa is not obliterated and can be palpated.

Dysgerminomas are highly malignant tumours also of germ cell origin. They metastasise rapidly to the abdominal and thoracic cavity; they are considered to be the counterpart of the testicular seminoma. Because of their nature, they can affect other organ systems, and cases have been reported of associated hypertrophic, pulmonary osteoarthropathy (Vanderkolk et al. 1998). Clinical signs on presentation are therefore often unrelated to the reproductive system. These tumours carry a poor prognosis.

Ovarian Torsion

Ovarian torsion, a condition not uncommon in women, has been reported in a mare with a large granulosa–theca cell neoplasm showing signs of abdominal discomfort (Fig. 31.39) (Sedrish et al. 1997). Ovarian torsion may be suspected in mares with known ovarian enlargement if sudden signs of abdominal pain develop.

Infertility in the Pig and the Control of Pig Herd Fertility

OLLI AARNO PELTONIEMI AND BAS KEMP

It is generally accepted that a sow should have expressed standing oestrus before 7 days after weaning her litter. If she fails to achieve this level of reproductive performance, then she can be classified as being subfertile or possibly infertile. In fact, sows that show oestrus early after weaning are known to be more fertile than those that show oestrus after a more prolonged interval (Fig. 32.1).

The owner or manager of a pig breeding unit will normally have set specific target values for the required reproductive performance of the herd. Together with the veterinarian responsible for the herd, there will be a policy on how to respond to a situation in which such a target is not being met. The remedy for the previous example, in which an individual sow has not expressed standing oestrus by 7 days after weaning or in which the average value for the herd is greater than the 7 days situation, may involve active intervention. The intervention may involve hormonal treatment, or increasing the time to allow for the individual(s) to recover from the 'metabolic burden' caused by the preceding lactation, or as a last result, culling of the animal. The choice of the remedy should be based, when possible, on the cause for the delay in expressing oestrus, its likely success, and the cost effectiveness. Advisors such as the herd veterinarian should provide the herd manager with agreed target values for reproductive performance, the measures that are needed to ensure that they are achieved, and the actions required to correct them. The most important targets for reproductive performance are defined in Table 32.1.

Methods for Examining the Reproductive System of the Subfertile/Infertile Gilt/Sow

Transrectal Palpation

The method is easy and fairly quick to perform and requires no equipment, although it is not applicable to gilts due to the small size of the pelvic canal which does not allow for insertion of the hand. In sows that have farrowed at least once, the method can be used with caution. After removal of faeces from the rectum, abundant amounts of lubricants should be used. If blood is observed on the operator's gloved hand at any time during the procedure due to damage of the rectal mucosa, then palpation should be stopped and the sow examined by alternative methods.

In diagnosing ovarian abnormalities, rectal palpation may be used to obtain an overall appreciation of the functional status of the ovary. It is possible to differentiate cystic ovaries from normal physiological ovaries based on their overall size as well as determination of the approximate the size of individual cysts. In most cases it is difficult to differentiate between normal size follicles close to ovulation and corpora lutea (CL) due to their similarity in size, their numbers, and texture. However, it may be possible to differentiate between small size follicles and normal physiological CLs, as the size of the former may be less than half of that of CLs. The obvious disadvantage of rectal palpation is that it can only be used in a proportion of breeding units because in most cases the feeding stall design does not allow for sows to be approached safely from behind.

Rectal palpation also needs substantial experience because the chances of false diagnosis, particularly discriminating between preovulatory follicles from CLs, is a risk.

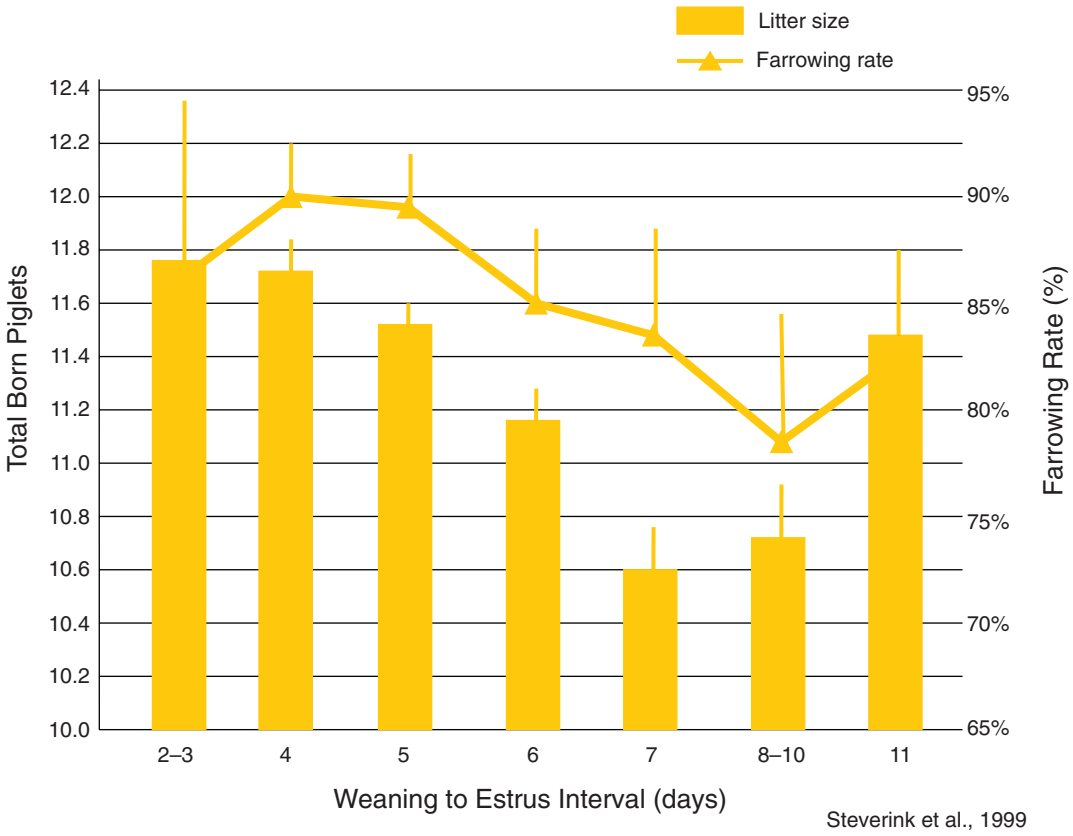
Real Time Ultrasound

Real time B mode ultrasonography appears to be the most effective and accurate tool in diagnosing ovarian and uterine abnormalities in the gilt and sow (Kauffold et al. 2004a, Kauffold et al. 2004b, Kauffold & Althouse 2007). In transcutaneous examination of the ovary and the uterus, a 3,5 MHz sector probe is the optimal frequency; however, the widely used 5 MHz linear transducer probe will provide satisfactory images for clinical purposes. In rectal examination, the 5 MHz linear probe is very effective for diagnosis of ovarian disorders.

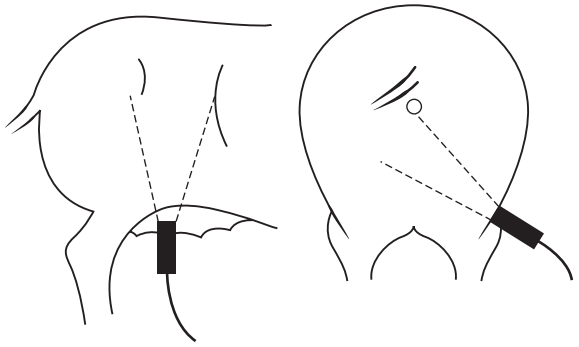
For transcutaneous examination, the probe is placed on the ventral abdominal wall just above the stifle joint and lateral to the mammary glands (Fig. 32.2). The probe is then directed towards the opposite tuber coxa and then redirected cranially until the urinary bladder is imaged. The ovaries and the uterus are located cranial and adjacent to the urinary bladder. Multiple sections of a single uterine horn may be seen in the same image due to the folding of the uterine horn that can be more than 1 m in length.

Ovarian function was examined in a study involving the use of transcutaneous ultrasonography of gilts and sows that had not conceived after breeding (Kauffold et al. 2004a, Kauffold et al. 2004b). The following is the frequency of ovarian structures identified: CL, 46%; follicles of 2 to 6 mm in diameter, 28%; periovulatory findings (follicles of 7–8 mm in diameter and corpora haemorrhagica), 19%; polycystic ovarian degeneration, 6%. These findings

VetBooks.ir



• **Fig. 32.1** Relationship between weaning to oestrus interval and fertility in the sow. (Data from Steverink et al. 1999.)



• **Fig. 32.2** Positioning of the transducer probe of the ultrasound scanner on the flank of the sow for transcutaneous scanning.

TABLE 32.1 The most important parameters regarding reproductive performance in a sow herd and their present target values

Parameter	Definition	Target
Weaning to oestrus interval	Days from weaning to oestrus	5 d
Farrowing rate	Proportion of mated sows that farrow	95%
Piglets weaned/ sow/year	Number of live piglets upon weaning the herd produces a year divided by the number of sows	30

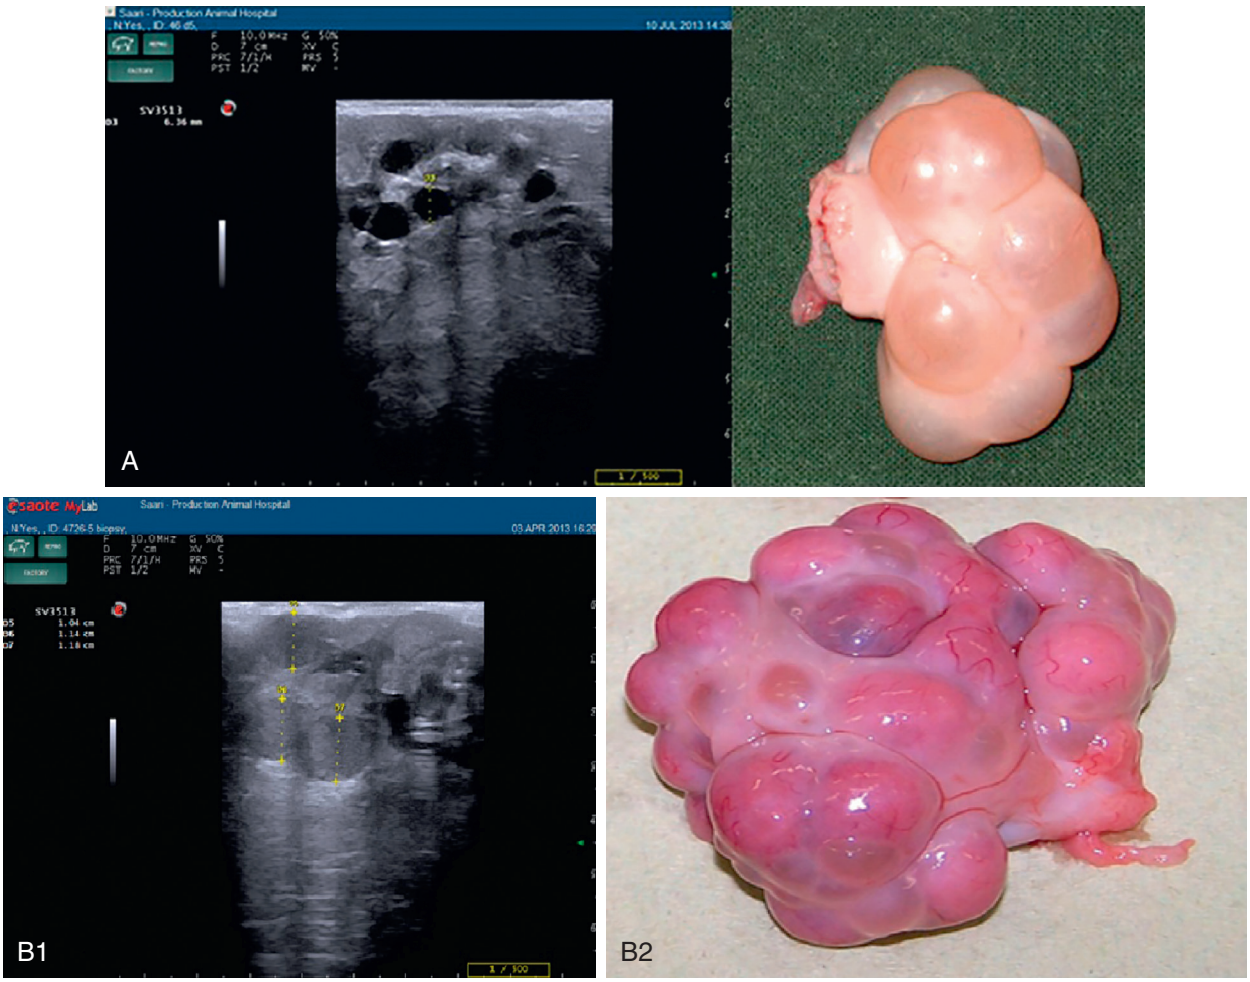
indicate that, although the individuals had failed to conceive, the majority was undergoing normal cyclical ovarian activity, and as far as ovarian function is concerned, they have the reproductive potential to become pregnant if bred correctly.

The relative frequencies of ultrasound findings can vary from one farm to another, and assessing these frequencies may help to identify the problem on the farm and help in the employment of successful strategies. As an example, if ultrasound is used on Day 3 after weaning, it is very likely that an ovary with preovulatory follicles will be identified, as shown in Fig. 32.3A. However, if a high proportion of sows are found to have CL (see Fig. 32.2B) on their ovaries, then it indicates occurrence of oestrus during lactation in these sows. This would require the use of a different treatment than in sows in which ultrasound findings indicated the absence of CL sows on Day 3, but many present at Day 8 if they have not shown oestrus after weaning. In the latter, silent oestrus seems to have been the problem, and remedies should be to optimise oestrous detection strategies. Thus ultrasound examination after weaning may help to identify the problem and with advice given on the appropriate action.

Real time ultrasonography may also be used to determine the timing of the onset of puberty in gilts. The uterine horns increase in size and become readily identifiable with well-defined sections of uterine horns a few days before the onset of puberty (Martinat-Botté et al. 2003). This method was described as having over 90% sensitivity and specificity and is a useful diagnostic tool in herds with a problem of apparent delayed puberty or whether puberty has occurred but oestrus has not been identified.

The presence of embryos or fetuses can be reliably be determined from Day 25 after mating and onwards; before this stage, accuracy

VetBooks.ir



• **Fig. 32.3** (A) Ultrasound image *(left)* and photograph of an ovary with preovulatory follicles 6.3 mm in size. (B) Ultrasound image *(left)* and photograph of an ovary with functional corpora luteae 10.4 to 11.8 mm in size.

may not be good (Maes et al. 2006). A photograph and ultrasound image of a 35-day-old fetus are shown in Fig. 32.4A and B.

Vaginoscopy

The vaginoscope used for the examination of the vagina and cervix of the sow is usually 400 mm in length and 35 mm in diameter, which is considerably narrower than that used in the dairy cow. Vaginoscopy in the sow can be quite difficult to perform; it can be a very valuable tool to determine the source of a vulval discharge, which has been previously identified on the vulvar lips. The sources of discharge can be the urinary bladder, vagina, cervix, or uterus.

The sow or gilt should be adequately restrained, and the vulva are washed thoroughly and disinfected with an iodine-based disinfectant. The vaginoscope is inserted carefully using adequate amounts of lubricant; excessive quantities may compromise the evaluation of secretions. After assessing the volume and type of secretions, colour and appearance of the mucus membrane are evaluated. Furthermore, it is valuable to examine the caudal part of the cervix for the degree of patency of the opening (closed/half closed/dilated). Vaginoscopy is therefore helpful in determining the stage of oestrous cycle and differentiating between physiological and pathological.

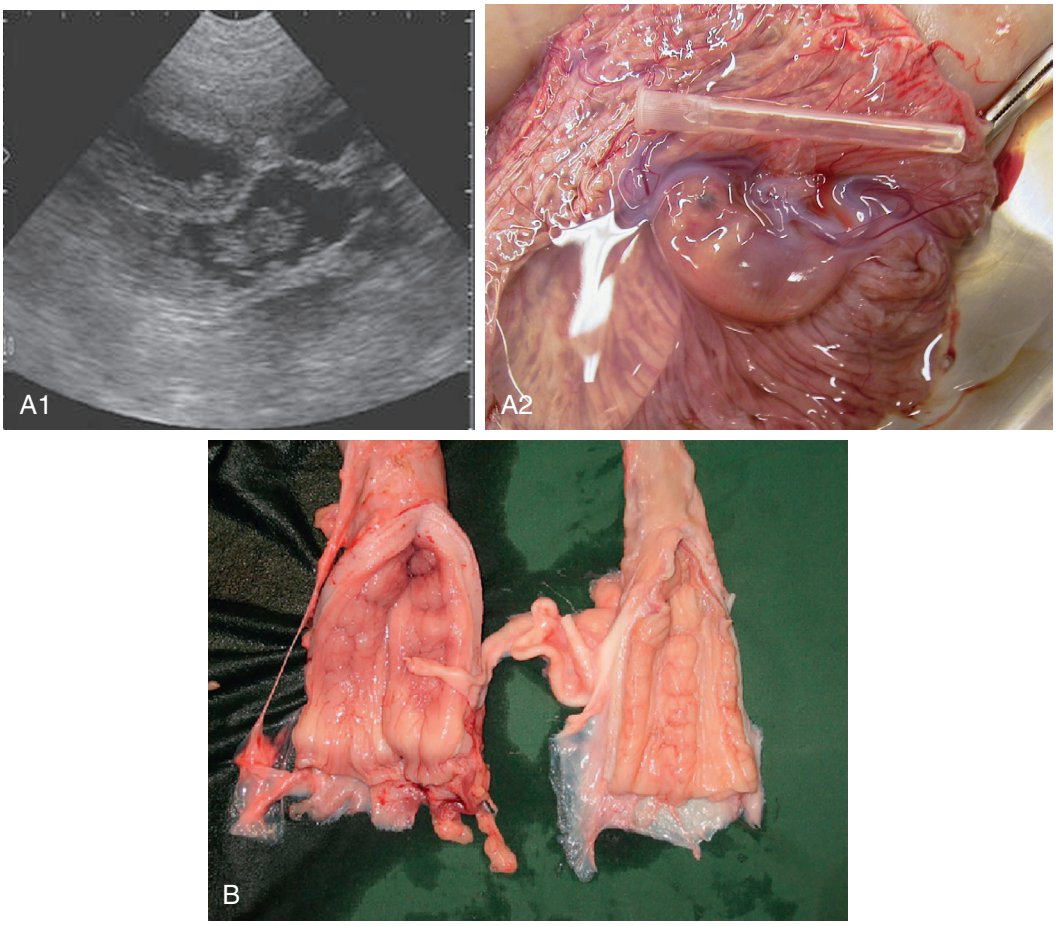
Using Herd Management Programmes to Detect Reproductive Problems

Analysis of the records from herd management programmes is a very useful tool in diagnosing herd subfertility and problems associated with poor reproductive performance. However, basic epidemiological and statistical skills are needed when interpreting these data in order to find appropriate advice for their remedy and correction.

If there is a high proportion of older parity sows, which were inseminated at Days 14 to 18 after weaning, then it would indicate that an undetected lactation oestrus has occurred, and they are actually in the second heat. Furthermore, if the proportion of sows with weaning-to-oestrous intervals of between 25 and 28 days is high, then it may indicate that the first oestrus after weaning was actually missed.

Long intervals from weaning to oestrus in primiparous sows, and poor performance in their second litter may indicate problems in lactation management. However, herd management data needs to be interpreted with caution because the number of data available is often limited, and its quality is dependent on the accuracy of data collection and inserting into the database.

VetBooks.ir



• **Fig. 32.4** (A) Real time ultrasonogram *(left)* and photographic image *(right)* of a 35 day old fetus. Organogenesis has begun as illustrated by the developing ribs and eyes. (B) Postmortem appearances of the cervix from two sows: the one on the left was in midoestrus and the one on the right was in the middioestrus at the time of euthanasia.

Postslaughter Examination of Female Genitals

A highly valuable tool for the accurate diagnosis of reproductive disease and disorders is postslaughter gross pathological examination. The genital organs, together with the urinary tract and bladder, are collected from specified sows on the slaughter line at the abattoir and submitted for pathological examination. To obtain representative samples, it is preferably to collect and examine as much of the material from as many of the problem sows as possible. In addition to a gross pathological examination, further analyses based on histological examination and bacteriological culture may be appropriate. However, the slaughter process may compromise the bacteriological findings, and the results should therefore be interpreted with caution. It is important that postslaughter examination is performed soon after sows are diagnosed as having reproductive problems. Long intervals between diagnosis and slaughter may mask the problems.

Microbiological Examination

Although considered by some to be of little value, the authors consider microbiological examination of swabs of a vulvar discharge to be a valuable method in determining the origin of the discharge, as well as providing useful information in relation to successful treatment of such cases (Oravainen et al. 2008). In order to collect samples, the vulvar lips are first washed three times with a polyvidone-iodine solution, rinsed with water, and wiped five times with gauzes saturated with chlorhexidine. The vaginoscope is then introduced into the vagina and a guarded swab inserted into the anterior vagina through the scope, and a sample can be collected. The swab is then placed in transport medium and submitted to the microbiological laboratory for culture.

Blood Sampling

In the search for pathogens and the measurement of reproductive hormone concentrations, blood sampling of gilts and sows is a basic clinical requirement. In modern housing environments (feeding stalls and a lying area), it often easier to approach a sow from behind when sows are closed into the feeding stalls. Therefore the tail vein (*vena coccygea)* or the saphenous vein (*vena saphena)* of the hind leg is often the first choice as a site for sampling. The tail vein runs longitudinally on the ventral midline of the tail, whereas the saphenous vein can be found on the caudomedial aspect of the hind leg and above the hock joint (Fig. 32.5). The tail vein is easier to access; however, it is a

VetBooks.ir

• **Fig. 32.5** Blood sampling of the sow using the saphenous vein of the hind leg.

more sensitive site and the sow will react to the insertion of the needle. The skin covering the saphenous vein is less sensitive, and blood sampling can often be performed without any reaction from the sow. However, a disadvantage of this site is that the vein may be difficult to find in fat individuals. Ear vein, jugular vein, and *vena cava caudalis* may also be used for blood sampling. However, using these sampling sites would involve restraining the sows, for example, by fastening them around the upper jaw with a rope snare and tying them up to a fence. In addition to the previously mentioned blood sampling methods, the saphenous vein of the front leg may be used in the gilt.

Causes of Subfertility/Infertility

Vulva Discharge Syndrome

Although the prevalence of vulvar discharge syndrome is generally considered to be quite low in the whole overall population of domestic sows, it may cause a serious problem in some individual herds (Oravainen et al. 2006b). The most important predisposing factor is thought to be the production environment in which the activity of sows is discouraged due to a too restricted activity area (< 2.5 m^2/sow space), inadequate bedding material, and restraining the sow in the feeding stall. In such circumstances, sows tend to drink less, resulting in reduced urine output. In addition, they also tend to lie down for prolonged period on dirty slats, resulting in heavy faecal contamination of the vulva and perivulvar area of the integument, so that there is an increased risk of environmental bacteria such as the E. coli entering the genital tract (Oravainen et al. 2006b).

The origin of the discharge may be: the uterus (metritis/endometritis); the cervix (cervicitis); the vagina (vaginitis); or the urinary tract. In the evaluation of the discharge, the normal physiology of the oestrous cycle should be kept in mind. During the luteal phase or pregnancy, the mucus membrane in the cranial vagina and caudal cervix should appear pale and dry, whereas during the follicular phase and oestrus, it should be more reddish in colour and moist. The cervix should be more or less closed during the luteal phase and pregnancy. During the follicular phase, the cervix may appear partially dilated which becomes more obvious during the oestrus. Physiological postweaning secretions associated with oestrus are usually clear, whereas the viscosity varies depending on the phase of the oestrous cycle. Secretions that are white, grey, or other coloured may be considered as pathological, especially if the volume is less than 5 mL and has an abnormal (unpleasant) odour.

It is useful to note the volume of the discharge. In urinary tract infections and metritis, the volume of the discharge is substantial (> 100 mL), whereas it is usually less in cases of vaginitis, cervicitis, or endometritis. In the interpretation of vaginoscopical findings, it is also useful to consider the association of discharge with the phase of the oestrous cycle. In endometritis, the discharge usually appears at the time of oestrus, whereas if there is a urinary tract infection, the discharge appears at the time of urination; blood and protein may be demonstrated, as well as a high pH value of 8 to 9 instead of the normal range of 4 to 5.

Mycotoxins

Mycotoxins, which contaminate pig food, can impair fertility as well as causing abnormal development of pig fetuses. They have been suspected as being the cause, not infrequently, of reproductive disorders in pigs. However, often it is quite difficult to link the actual mycotoxin contents found in a particular feed or bedding sample to the clinical signs observed because there are no guidelines for interpreting the significance of quantitative laboratory results.

Zearalenone is a classical oestrogenic mycotoxin that has been associated with clinical reproductive symptoms in pigs. Zearalenone has been reported to cause repeat breeding, signs of oestrus due to vulvovaginitis in prepubertal growing pigs, vaginal and rectal prolapses, pseudopregnancy, and signs of oestrus during pregnancy (Osweiler 2006). In field studies of clinical cases, although some of these symptoms were present, the authors have been unable to demonstrate significant zearalenone contamination of feed samples because the observed values were only slightly beyond the detection limit (Table 32.2). In a study by Zwierzchowski et al (2005) in which zearalenone was given orally at a dose of 200 microg/kg body weight, it caused disturbances in the process of development and maturation of ovarian follicles. Furthermore, although zearalenone contamination at levels of 1500 to 2000 µg/kg feed (1.5–2 ppm) has caused some signs of vulvovaginitis in prepubertal gilts, higher concentrations of 20 to 60 ppm are usually required for clinical signs to appear. Female pigs are more susceptible to zearalenone than adult males, who are relatively tolerant to the toxin in terms of reproductive function. However, young boars may experience reduced libido, preputial enlargement, and decreased testicular size if exposed (Osweiler 2006). Normal long-term reproductive function should return after removal of the toxin from the feed.

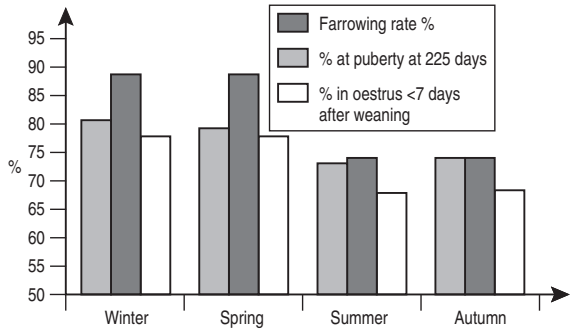
Beside zearalenone, the authors have observed significant deoksynivanole (DON) and nivalenole contamination in clinical samples. These Fusarium toxins may be of clinical significance (Table 32.2) because they have been reported to cause loss of appetite

VetBooks.ir

TABLE 32.2 Clinical feed samples from eight pig herds experiencing subfertility

Mycotoxin[a]	Range Found in Clinical Samples (μg/kg)	Detection Sensitivity (μg/kg)	Method Used
Zearalenone	2–3	2	fluid chromatography
Deoksynivanole (DON)	27–2256	10	gas chromatography – mass spectrometry
Nivalenole (NIV)	85–181	30	gas chromatography – mass spectrometry
HT-2-toxin	20–45	20	gas chromatography – mass spectrometry

[a]Analysis for the following toxins was also carried out, but they were not identified (detection sensitivity in brackets): ocratoxin A (OA, 1 μg/kg); 3-asetyldeoksi-nevalenole (3-AcDON, 10 μg/kg); Fusarenon-X (F-X, 10 μg/kg); diasetoksiskirpenole (DAS, 10 μg/kg); and T-toxin (20 μg/kg).
From: Production Animal Clinic of the University of Helsinki in 1999–2005.



• **Fig. 32.6** Major manifestations of seasonal infertility in the pig presented as percentages for each reproductive parameter. (Data from Peltoniemi & Virolainen 2006.)

and vomiting in pigs and thus may indirectly cause reproductive disorders because sows may lose body condition, thus impairing follicular growth. HT 2 toxins may be present in food prepared from Fusarium species–infected grain. Wet weather during the growing season and increased moisture during storage are risk factors for the presence of these mycotoxins in grain. Trichothecene contamination of grain, as an example, may therefore increase before harvesting.

Ergot alkaloids produced by the parasitical fungus *Claviceps purpurae* may affect rye, oats, and wheat. They are most commonly associated with agalactia in gilts and sows but may also cause low birth weight of piglets, low piglet survival, and low weight gain in neonatal piglets (Osweiler 2006). Abortion has not been associated with ergot toxins.

Seasonal Infertility

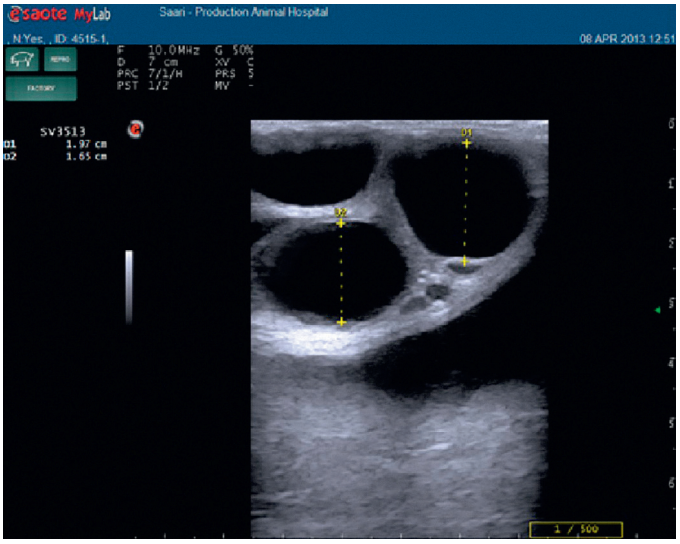
Seasonal infertility is defined as decreased fertility of the gilt and sow in summer and autumn. The signs of subfertility include: reduced farrowing rate, prolonged weaning-to-oestrous interval, and delayed puberty of gilts (Fig. 32.6). In feral wild pigs, decreasing day length in late summer and autumn would provide a physiological cue to indicate that it is not an optimum time for breeding because the piglets would be born in the midwinter. Thus in nature, that would most likely mean death of the newborn piglets and loss of the whole litter. The feral wild pigs are seasonally anoestrous, with the onset of the anoestrous period being under the control of the photoperiod (Tast et al. 2001). However, the end of the anoestrus period and return to cyclical ovarian activity are dependent on other environmental cues such as the increased availability of food (Mauget 1982). In the domesticated environment, cues such as increased availability of food and, in housed animals, a comfortable microclimate are absent, and these cues for seasonal breeding are removed. Therefore variable responses to decreasing daylight in the breeding activities of the female domestic pig population are frequently observed in late summer and autumn.

Seasonal infertility may be avoided by improving the reproductive management of the herd. This includes the use of a relevant light programme in which 16 hours of light and 8 hours of dark is provided in the breeding unit (see 'Light Programmes' later in this chapter). This recommendation is combined with advice to explore and, if needed, increase the light intensity to a level of at least 200 lux at the level of the eyes of the sow. Feeding of pregnant, group-housed females during late summer and early autumn is an issue of interest. Increasing feed availability in this time is an effective method of decreasing the stress of sows around the time of implantation of embryos and thereby reducing early embryonic loss and resultant return to oestrus. Moreover, stress of gilts and sows before insemination and during pregnancy is reduced by grouping them correctly according to size and age. Furthermore, other actions – such as genetic selection, reduced stocking density in summer to autumn, cooling systems applied especially during lactation in a hot production environment, and gonadotrophin treatments – may also be found useful in attempts to reduce seasonal effects on fertility (Peltoniemi & Virolainen 2006).

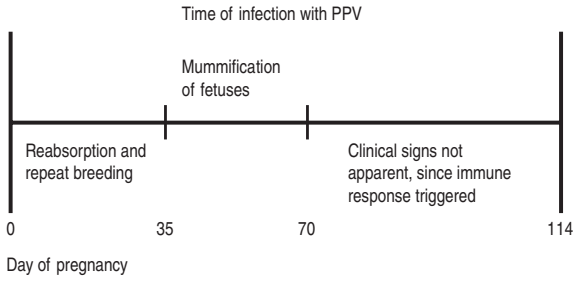
Cystic Ovarian Disease

Ovarian cysts are defined as persistent pathological fluid filled-structures (larger than 10 mm in diameter) present in the ovaries that prevent normal cyclical ovarian activity. Typically, ovarian cysts are multiple, each of which is 20 to 30 mm in diameter, so that the overall diameter of the ovary can be up to 100 mm, as shown in the real time ultrasound image in Fig. 32.7. B mode, real time ultrasound scanning, either transcutaneously or transrectally, enables the diagnosis of the disorder (Kauffold et al. 2004a). Recent findings in our laboratory indicate that the LH surge that triggers ovulation may not occur, and the follicles continue to grow beyond the normal size for ovulation of 7 to 9 mm in diameter. The impaired LH surge may be due to stress, zearalenone toxicity, hormonal (gonadotrophin) treatment administered at an inappropriate phase of the oestrous cycle (early dioestrus), or early induction of ovulation after parturition (e.g., early weaning protocols). The incidence of ovarian cysts has been reported to vary between 5% and 10%. Multiple ovarian cysts may contain some luteal tissue, which, if it persists, will inhibit subsequent

VetBooks.ir



• **Fig. 32.7** A real time transcutaneous ultrasound image showing multiple ovarian cysts in a sow; the distance between the marks (+—-+) represents 10 mm.



• **Fig. 32.8** Temporal relationship between the development of immune competence of porcine conceptuses and the consequences of PPV infection throughout pregnancy in the gilt and sow.

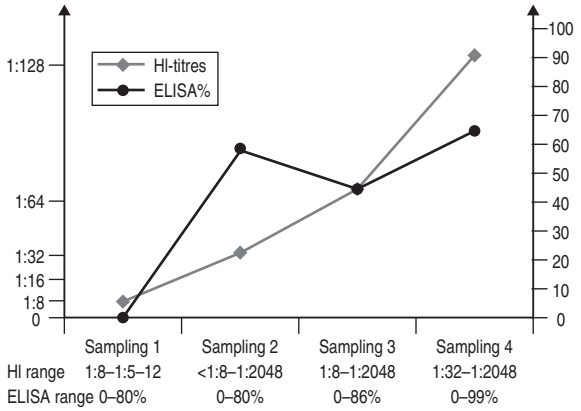
LH secretion and thus cyclical ovarian activity. Large multiple ovarian cysts generally severely compromise fertility; single and smaller ovarian cysts may increase the rate of repeat breeding and result in reduced litter size (Almond et al. 2006, Castagna et al. 2004). Early segregated weaning (weaning < 14 day of lactation) and a short weaning to oestrous interval (< 3 days) are known to increase the risk of ovarian cysts (Castagna et al. 2004). Prognosis and response to any treatment are generally poor, and culling of the sow is therefore often warranted.

Infectious Causes for Infertility

Viral Infections

Porcine Parvovirus

Porcine parvovirus (PPV) is a classical example of a viral disease that affects mainly the reproductive system. It has also been used as an example of the temporal relationship between the acquisition of immunocompetence and the development of the embryos and fetuses (Fig. 32.8). During the embryonic period of development, infection is likely to cause death and resorption of the embryos. In the fetal period, if the infection occurs before day 70 of pregnancy, the fetuses become mummified. However, if infected after immunocompetence has been acquired, the consequences are not serious, resulting in either slight weakness of the newborn piglets or the complete absence of clinical signs.



• **Fig. 32.9** HI titres and ELISA percentages of 39 gilts before and after vaccinations against porcine parvovirus. Sampling 1: before the first vaccination at the age of 6 months with the booster 3 weeks later (N = 39). Sampling 2: 2 to 3 weeks after the booster (N = 39). Sampling 3: in midpregnancy (N = 35). Sampling 4: after farrowing but before weaning (N = 13). (Oravainen et al. 2006a.)

PPV disease is widespread, with the herd prevalence in most countries exceeding 60 %. Thus for most producers, it is a disease with which they have to cope because eradication may not be a feasible exercise. The control programme involves vaccination of all breeding animals in the herd: gilts, sows, and boars. As PPV is known as the 'gilt disease', it is essential that gilts are vaccinated twice before they are inseminated for the first time. Vaccine-induced immunity is boosted in a stepwise manner, so that sows that have farrowed at least once clearly have higher antibody titres than unbred gilts (Fig. 32.9). Therefore in practice, signs of PPV may be seen in cases in which vaccination of replacement gilts has not been carried out or in which there is vaccination failure. Common vaccination failures can be due to the use of out of date vaccines, inappropriate injection site (neck instead of the base of the ear), storage problems (frozen/heated vaccine), and poor vaccination technique. It may also be that some animals do not have the required immune response because of a compromised physiological or immune status or a nutrient deficiency.

Circo Virus

Circo virus (PCV 2) infections are known to cause reproductive problems in sow herds in a number of countries, including South Korea and Spain (Chae 2005, Maldonado et al. 2005). The virus infects the conceptuses after transplacental transmission. Embryonic or fetal death, with the loss of the whole litter, may occur at any stage of pregnancy (Chae 2005). After embryo transfer, the majority of experimentally PCV 2–infected embryos did not survive for the 14-day period when there was observation of their development (Mateusen et al. 2007). However, in addition to abortion, an increased number of mummified fetuses, stillbirths, and weak but live-born piglets, may be observed. The oronasal route of transmission is considered to be the most common route of infection; horizontal transmission between pen mates and from one pen to another may be very efficient. However, transmission through semen may also occur, although it has not yet been proven to be a significant route (see review by Maes et al. 2008). Herds suffering from the epizootic phase of infection associated with reduced farrowing rates and increased stillborn rate may benefit from vaccination programmes that have recently been developed (Segales et al. 2007).

VetBooks.ir

Porcine Reproductive Respiratory Syndrome

Porcine reproductive respiratory syndrome (PRRS) is known to affect female pigs and cause respiratory disease in nursery and growing–finishing pigs, late term abortion, mummified fetuses, and weak but live-born piglets. However, transplacental infection may occasionally also occur earlier during pregnancy. Routes of shedding include saliva, nasal secretions, urine, and faeces. In semen the virus may be shed for a variable period of time ranging from 2 to 92 days after exposure (Christopher-Hennings et al. 2001). Sperm head defects, such as acrosome abnormalities and other morphological sperm abnormalities, may occur as a result of the infection (Feitsma et al. 1992). As a consequence of infection, there may be acute illness and infection of fetuses, resulting in abortion. It has also been reported that fetuses may die of hypoxia due to arteritis of the umbilical vessels (Lager & Halbur 1996). Exposure of PRRS-naïve replacement gilts to positively confirmed virus-infected tissues resulted in prebreeding infection of gilts, followed by the development of sufficient immunity to protect the subsequent pregnancy (Menard et al. 2007).

Aujzesky's Disease

A herpesviral disease of pigs, which mainly affects the reproductive system is Aujeszky's disease (pseudorabies). Herd prevalence of pseudorabies in Western countries is usually low, but once infected, a herd with continuous pig production may suffer from it for a long time. The route of transmission of the virus is usually by inhalation or ingestion. Replication usually occurs in the nasal and pharyngeal mucosa as well as in the genital tract. The virus may also be transmitted at coitus, and it has been detected in the urine, semen, and on the preputial lining after natural, as well as experimental, infection (Maes et al. 2008). Aujeszky's disease is characterised by nervous and respiratory clinical signs, together with pyrexia and often death of young piglets. Infection in adults may result in stillbirths and abortion. In adult boars and sows the clinical signs of the disease are seldom severe and usually consist of pyrexia, general depression, and anorexia, which last for up to a week. Of great significance to the breeding herd is the fact that the virus causes embryonic death, fetal mummification, and stillbirths.

Other Viral Agents

A variety of other viral infections have been associated with reproductive disorders in the pig (Almond et al. 2006, Maes et al. 2008). However, they are more likely to cause general symptoms such as high fever. These general symptoms have an indirect effect on reproductive function rather than a specific effect on the reproductive system.

Bacterial Infections

Leptospirosis

Leptospirosis is known to be a widespread disease compromising reproduction in the pig population all over the world. *Leptospira pomona* is the best known pig pathogen, but serovars *tarassovi, bratislava,* and *icterohaemorrhagiae* may also be pathogenical in pigs. Leptospires have a predilection for the kidneys where they persist and reproduce; they are then secreted via the urine into the environment intermittently for a period of up to 2 years. Adult, nonpregnant sows may act as asymptomatic carriers, and they may shed the bacteria in their urine to the environment for extended periods up to a year. Rodents are often thought to be the most significant reservoir species, maintaining the infection in the production environment. During the acute phase of the disease, mild general symptoms such as fever and anorexia may be seen; however, this phase often passes unrecognised. During the chronic phase of the infection, abortion rates of both gilts and sows increases considerably, especially during the second half of gestation. In the endemic the stillbirth rate may increase and newborn piglets may lack viability. Diagnosis is based on serological testing (microscopical agglutination test (MAT) and demonstrating the presence of leptospires in tissues and body fluids. Prevention is based on rodent control, good general hygiene management, and good urine drainage. High titres may indicate the presence of systemic disease, whereas low titres are evidence of venereal infection (Ellis 2015). Furthermore, antimicrobials (tetracycline and streptomycin) and vaccines are available for treatment and prevention.

Brucellosis

Brucellosis has been recognised as a disease associated with abortion in the pig since early 1900s; it is widespread in South America, Africa, and Asia. Although the bacteria may not be highly pathogenical for the pig, the zoonotic nature of the disease does present a risk to farm staff involved in the handling of pigs as well as interspecies transmission. The most frequently identified *Brucella* species found in the pig is *B. suis;* however, other species, such as *B. neotomae, B. ovis, B. canis, B. abortus,* and *B. Melitensis,* have also been identified. The most significant route of transmission is by direct contact between animals; infection is usually acquired through the oronasal or genital route. Sows may be infected when mated with infected boars (Lord et al. 1997). Adult pigs that are infected usually lack any general symptoms such as fever and loss of appetite. Abortion may occur at any stage of pregnancy. As sows usually eliminate the bacteria within 30 days after infection, a resting period lasting up to the length of two oestrous cycles may be enough, and subsequent AI may be warranted. Other signs of the disease include infertility, orchitis, posterior paralysis, and lameness. Boars may be unable to eliminate the bacteria and may act as carriers within a herd. Antimicrobial therapy is often ineffective, and eradication programmes may offer the best outcome.

Other Bacterial Diseases

Bacteria that trigger an acute phase response in the pig usually present a risk for reproductive health. For instance, endotoxemia caused by Gram-negative bacteria or general symptoms caused by *Erysipelothrix rhusiopathiae* can cause abortion at any stage of pregnancy. The better the immunity of the herd against these pathogens, the lower the risk to reproductive health.

Reproductive Management to Ensure Optimum Fertility

Management of Lactation

An important way to ensure optimum fertility and thus reduce the level of subfertility is by preventing excessive weight loss during lactation. Generally, some weight loss is both inevitable and acceptable, but weight losses during lactation (measured from after birth of the piglets to weaning) should be less than 12.5%. Optimising feeding and nutrition during lactation can achieve this outcome, as will be discussed in this chapter in the section 'Feeding the Sow'.

Another method of relieving the sow from the 'metabolic burden' of lactation is by reducing the effects of the suckling stimulus. Reducing the number of piglets during the whole or part of lactation may reduce milk production and may also reduce the inhibition of the suckling- induced suppression of LH release

VetBooks.ir

by endogenous opioids. Low numbers of piglets during lactation have been shown to improve reproductive performance of sows, but the reduction in the number of piglets has to be substantial to have any effect, partly because piglets in smaller litters will consume more milk per piglet.

Effects of interrupted suckling (a daily temporary removal of the whole litter) or split weaning (a permanent removal of part of the litter a few days before completing weaning) on subsequent reproduction have been reviewed by Matte et al (1992). In general, effects of such techniques on the weaning-to-oestrous interval are variable, and relatively small. Recent studies from our laboratory and in Australia (see Kemp & Soede 2012, for review) show that intermitted suckling can induce lactation oestrus, especially when intermitted sucking starts around the normal weaning age and is combined with boar stimulation. Oestrus can be induced during lactation in about 70% to 90% of the sows within 6 days after start of induction; farrowing rates and litter size are comparable to controls. Success is dependent on parity (primiparous sows do not respond very well) and breed. Lactation oestrus has the potential advantage that the lactation period can be extended while sows are pregnant to allow piglets to be better developed when they are eventually weaned. However, lactational oestrus may also be considered disadvantageous because the signs are often poorly expressed by the sow when there is inadequate boar stimulus; it is also laborious, and not all sows will respond to intermitted suckling and boar contact, which results in reduced synchrony in planning process.

Generally, sows that lose more than 12.5 % of body weight during lactation have an increased risk of lower subsequent farrowing rates and litter size; first litter sows are at greater risk. An approach that allows the first litter sow to recover from the effects of the previous lactation is to inseminate or serve her at the second oestrus after weaning instead of the first one ('skip a heat'). Missing the first oestrus can improve pregnancy rates by 15% and subsequent litter sizes by 1.3 to 2.5 piglets (Clowes et al. 1994, Werlang et al. 2011). When using this approach, an intense oestrous detection regime is important to ensure that the second oestrus is observed.

Whether or not these techniques should be used is a matter of economic calculations. The costs of an extended weaning-to-service interval should be balanced against the benefits of improved pregnancy rates and litter sizes.

Gilt Management and Feeding

Gilt development has been an important aspect of optimising litter size. Generally speaking, mating gilts at a young age or at a relatively low body weight has no negative effect on first litter size. However, second litter size can be compromised because young sows still have the impetus to grow while feed intake is limited during the first lactation. Sows with low weaning weights after the first lactation may have a second litter that is smaller in number than the first litter. This phenomenon is known as the 'second litter syndrome'. This has persuaded many veterinarians in practice to recommend inseminating gilts when they are older and are more mature. First breeding ages of 250 to 260 days are nowadays common in Europe, and this may be too old from an economical perspective.

Sows that become fat during pregnancy have a lower voluntary feed intake during lactation. In addition, insufficient feed intake during pregnancy results in thin sows, which cannot be compensated for by increased voluntary feed intake during the subsequent lactation. Thus these thin sows may have a prolonged weaning-to-oestrous interval, lower subsequent pregnancy rates, and smaller litter sizes. Therefore gilts should be fed according to their requirements for maintenance, reproduction, and growth but not be overfed. In practical terms, gilts may have an energy intake of 24.8 and 36.1 MJ metabolisable energy (ME) per day at the beginning and end of pregnancy, respectively (Everts et al. 1994).

Feeding the Sow

During lactation, energy requirements of sows are estimated to be 12.6 MJ ME per 100 kg of sow weight for maintenance, plus 6.2 ME per suckling piglet for milk production. For a 200 kg sow nursing 12 piglets, this means a daily ME intake of 99.5 MJ ME per day. In most commercial sow diets, this represents a daily feed intake of 7.7 kg/day. Due to low parity or high farrowing house temperatures, this daily requirement is sometimes not met. Thus many sows should be fed to appetite during lactation. Only in breeds with an innate high appetite is it advisable not to exceed recommendations because lactational oestrus may occur.

It has also been shown that the last week of lactation is a critical period as gonadotrophins begin to stimulate follicular growth sometime before weaning. As far as follicular growth is concerned, energy balance and feed intake of the sow during early lactation is secondary to that in late lactation. If feed is restricted during the last week before weaning, the weaning-to-oestrous interval is extended, the ovulation rate is decreased, and embryonic survival is reduced (Table 32.3) (Zak et al. 1997a). Sows that were deprived of food during the last week of lactation also had a lower number of large follicles, and the *in vitro* maturation capacity of ova from these follicles proved to be reduced (Zak et al. 1997b). In addition, the quality of the fluid in these follicles was poorer because slaughterhouse-derived ova matured *in vitro* in the follicular fluid from these sows showed impaired maturation.

These data suggest that poor nutrition during lactation impaired follicular development during and after lactation, resulting in a lower ovulation rate and an impaired quality of ova and follicular fluid. This may also explain increased embryonic mortality during the subsequent pregnancy. A lower ovulation rate and increased embryonic mortality may both result in a lower litter size at farrowing. When the ovulation rate is low or embryonic mortality is high, the number of viable embryos may be below the minimum of two per uterine horn.

TABLE 32.3 Weaning-to-oestrus interval (WEI), ovulation rate (OR), and embryo survival rate (ESR) at day 28 of pregnancy of sows with different pattern of feed intake during a 28 day lactation period

	Feeding Pattern		
	AA	AR	RA
WEI (h)	88.7[a]	122.3[a]	134.7[a]
OR	19.9[a]	15.4[a]	15.4[a]
ESR	87.5[a]	64.4[a]	86.5[a]

AA = sows receiving ad lib feeding; AR = Ad lib the first 21 days, 50% of ad lib the last 7 days; RA = 50% of ad lib the first 21 days, ad lib the last 7 days.
[a]Significant difference.
From: Zak et al. 1997a.

VetBooks.ir

In that case, sows will not remain pregnant and will return to oestrus after 21 days.

Some reports show that feeding lactating sows more than twice a day will improve overall feed intake compared with ad lib feeding systems. A 10% higher feed intake has been observed when using self-feeders instead of feeding twice a day. Generally, it is advisable to remove feed from the trough once daily to prevent it from becoming mouldy and sour.

A gradual increase in feed intake during the first week of lactation and a good appetite thereafter, without periods of loss of appetite, have been found to be a superior pattern of feed intake (Koketsu et al. 1996b, Koketsu et al. 1996a). The sows in this study had the best reproductive performance in the 'follow-up' period. If sows are overfed at the onset of lactation, sometimes there is a drop in feed intake during the remainder of the lactation. In these sows, reproductive performance is lower. Therefore it is advisable to increase feed intake gradually from the first days of lactation. Two kg of diet at farrowing and a stepwise increase of feed intake of 0.5 kg per day until the recommended feed intake is reached has been recommended as a feeding strategy during the puerperium.

Use of the Boar

The use of the boar for oestrous stimulation and detection of standing oestrus is essential in the modern reproductive management of the sow. Proper expression of oestrus signs and therefore adequate detection of oestrus require a direct nose-to-nose contact between sows and the boar. The best management routine is to allow a direct nose-to -nose contact with the boar at least twice a day while applying the back pressure test on the sow. This contact should be allowed daily after weaning until AI has been performed and standing oestrus has ceased in the sow. Introducing the boar to the sow in order to detect oestrus is better than the continuous housing of the boar and sows adjacent to each other. Daily nose-to-nose contact between gilts younger than 5 months of age and the boar has been shown to enhance puberty, and this daily routine should be carried out until the gilts have been successfully bred.

Timing of AI

Timing of AI is an important factor in ensuring good fertility. Inseminating too early may be unsuccessful, whereas if the sow is bred too late after ovulation, endometritis, resulting in decreased litter size, may occur. In the sow, standing oestrus lasts for about 48 hours on average, and ovulation takes place when two-thirds of the duration of standing oestrus has passed. The duration of ovulation (from the first ovulation to the last) is about 2 to 4 hours. Sperm may remain viable in the female genital tract for 20 to 24 hours, and ova may be fertilised for up to 2 to 4 hours after ovulation. Therefore an optimal time for AI has been found to be 0 to 24 hours before ovulation. In practice, timing of ovulation is not usually monitored, and a second insemination 12 to 24 hours after the first AI is warranted. Artificial insemination after ovulation and at the end of standing oestrus should be avoided in the event that endometritis has been caused by the late AI. Reduced fertility may be caused by inadequate oestrous detection routines or because first inseminations are timed too late in oestrus. The latter can be a problem in sows with slightly prolonged weaning-to-oestrous intervals and those that have a short duration of oestrus, in which case they should be inseminated early after the onset of heat. In some farms the sow population as a whole has an average short duration of standing oestrus. To verify this, the farmer should be advised to have the ovulation time of his sows verified by the herd veterinarian or a specialist veterinarian. Insemination routines can be adopted to improve the timing of the first insemination.

Light Programmes

The light intensity in the breeding area should be at least 200 lux, and light cycles provided for the sows should be consistent. Continuous light for 16 hours, followed by 8 hours of darkness, is a good rotational regimen to optimise fertility. In the rotational regimen, 8 hours of light and 16 hours of darkness should be used in the lactation unit, followed by 16 hours of light and 8 hours of darkness in the breeding unit. The most important point regarding the use of lighting regimens is that they should be consistent, with a clear difference between night and day, so that the sow can adapt her physiological functions accordingly (Tast et al. 2005).

Hormonal Treatment Protocols

Synchronising Oestrus in Gilts

A group of gilts may be synchronised for oestrus using physiological and pharmacological approaches. The physiological approach involves regrouping of gilts and placing them adjacent to a boar (Pearce 1992).

If a larger scale, a more precise synchronisation is required, so a pharmacological approach may be useful. A synthetic progestagen given daily by mouth for 14 to 18 days may synchronise oestrus and hence the time of breeding of gilts; standing oestrus is likely to occur 4 to 6 days after the last day of progestagen administration. Furthermore, gonadotrophins given parentally, 1 to 2 days after the last day of progestagen treatment, enhanced follicular development and ovulation. Results from Soede et al (2007) showed that gilts synchronised with progestagens had improved follicular development when under the influence of the progestagen, resulting in higher ovulation rates after their withdrawal.

After Weaning

Use of Gonadotropins

The use of hCG + eCG directly after weaning may result in an improvement of the weaning-to-oestrous interval, but it may also result in lower pregnancy rates or lower litter size. The latter may be related to differences in follicle development at the time of hCG + eCG injection, but no data are available to substantiate this.

Use of Progestagens

Epidemiological studies have shown that a short weaning-to-oestrous interval is a risk factor for the 'second litter syndrome'. Sows with a long weaning-to-oestrous interval are more likely to produce a larger second litter (Morrow et al. 1992). This may provide an explanation as to why ovulation rates or embryo survival may be improved by allowing the sow to recover for a longer period after lactation. For such a recovery, sows may be given resting period for the duration of a whole oestrous cycle ('skip a heat'). Alternatively, sows may be treated with a progesterone analogue, such as altrenogest, after weaning to artificially extend the weaning-to-oestrous interval. Treatment periods between 3 and 7 days after weaning have been used but have resulted both with positive and negative effects on the subsequent farrowing rate and litter size. However, daily treatment 14 days after weaning has resulted in sustained reproductive benefits (Van Leeuwen et al. 2011). The positive effects on ovulation rate, embryo development,

VetBooks.ir

and embryo mortality can be explained by restoration of follicular development under progestagen treatment after lactation.

Control Programmes for Oestrus and Ovulation

Traditionally, good fertility at a herd level is based upon the weaning of sows after 4 weeks of lactation, after which oestrus is detected, and is followed by double artificial insemination on the first and second day of standing oestrus. Therefore the timing of AI is based on the time of beginning of observation of standing oestrus. The optimal time for AI is within the last 24 hours before ovulation. Real time ultrasonography can be used to assess if sows are correctly inseminated relative to ovulation because follicle development is even measurable on the ultrasound image (see Fig. 32.4A). At ovulation, the follicles become filled with blood, and the hypoechogenic follicles cannot be seen any more. Insemination after ovulation is to be avoided.

The use of exogenous hormones provides the farmer with further possibilities for the timing of insemination close to the time of ovulations, so that less time is spent on oestrous detection. Progestogens, such as altrenogest, are used to time the onset of the follicular phase. eCG is used to stimulate and synchronise follicular development during the follicular phase, and GnRH analogues, hCG, and porcine luteinising hormone may be used to induce ovulation. Use of one or more of these hormones may help to reduce the time and effort spent on oestrous detection. The sequential use of these hormones may be used to induce ovulation, so that and AI may be performed at a fixed time after the administration of the hormones (fixed-timed artificial insemination, FTAI) without the need to observe behavioural oestrus. In gilts, results of timing of AI based on oestrous behaviour after synchronisation as described previously result in pregnancy rates of about 70%. In sows, in addition to the protocols described previously, successful results have been reported by eCG treatment at weaning, followed by GnRH or pLH at the time of the onset of oestrus, and either single or double AI thereafter.

In addition, single or double FTAI may be applied after a protocol based on altrenogest as described previously, followed by eCG and then GnRH or pLH a few hours later. Furthermore, FTAI may be carried out after the use of a protocol of eCG at weaning, followed by hCG, GnRH or pLH, and then FTAI. Studies of the results from these FTAI programmes have reported similar results to the traditional use of AI, based on the time of detection of standing oestrus (De Rensis & Kirkwood 2016). A relatively new approach is the use of a single dose of a GnRH analogue, some 90 to 110 hours after weaning, to induce and synchronise ovulation.

Veterinary Herd Fertility Control Programmes

The implementation of herd fertility control programmes based on the advice and support of the herd veterinarian may prove to be very useful for the pig farmer. This can be combined with other herd health work during regular herd visits. The programme can be based on the creation of specific targets for fertility related to the particular herd. For example, the targets may include: frequency and success of farrowing assistance and piglet mortality; proportion of sows in oestrus after weaning; accuracy of AI in relation to behavioural oestrus and the time of ovulation; pregnancy rates; abortion rates; number of piglets born and weaned; and number of stillborn piglets.

Regarding oestrous detection, the timing of AI in relation to ovulations can be assessed as previously described, and thus the arrangement of AI in relation to oestrous detection can be organised more precisely. Sows not 'coming into oestrus' within the week after weaning may be subjected to a gynaecological examination approximately 1 week after the expected oestrus; this will include palpation of the cervix and ultrasound scanning of the ovaries.

Sows returning to oestrus after AI (repeat breeders) can be examined during the visit as well. Pregnancy detection at 4 weeks, followed by a subsequent detection at 7 weeks to account for early pregnancy loss, is generally recommended and frequently done by the farmer or herdsperson on a routine basis. However, when there are fertility issues, the use of advanced ultrasound technology provides opportunities for early pregnancy detection at 17 days after insemination and may be utilised by the herd veterinarian in such situations. Cases where routine pregnancy checking results in an inconclusive outcome, can be further examined by the herd veterinarian during the following visit.

The frequency of veterinary fertility control visits will depend on the schedule of events in the batch farrowing system of the herd. In large herds in which large groups of sows are weaned every week, weekly visits will be warranted. In smaller herds in which the weaning groups of sows occur every second week, third week, or after more weeks, the frequency of scheduled visits can be reduced and may be set accordingly.

Antimicrobial Treatments

In uterine infections, the causative bacteria may originate from the environment, or they can be transmitted between animals – for example, via natural mating or AI. In postpartum dysgalactia syndrome (PDS) and in postmating endometritis, the bacteria causing the disease are usually of environmental origin; coliforms have been reported as the most common contaminant isolated at culture (Klopfenstein et al. 2006, Oravainen et al. 2006b). In the vaginal discharge syndrome, between-animal transmission may be important, and *Actinobaculum suis* has been reported to be a likely pathogen. For coliforms, in addition to supportive therapy (fluids, NSAIDs, and oxytoxin), antimicrobials such as ampicillin and trimethoprim-sulfa may be indicated. For *Actinobaculum suis,* procaine penicillin G may be the antimicrobial agent of first choice (Friendship 2006, Peltoniemi et al. 2003). In the treatment and prevention of leptospirosis, tetracycline and streptomycin may be indicated (Friendship 2006).

Genetics

It appears that various physiological changes may have occurred in the reproductive function of sows over recent decades (1954–2006). Although ovulation rates have nearly doubled from 13 to 16 to 20 to 26, embryo survival rate has decreased from 75% to 79% to 60%, and fetal survival has decreased from 69% to 74% to 50%. The increased ovulation rate is apparently due to selection for larger litter size, and good fertility is generally expected if the sow is correctly inseminated; the fertilisation rate is generally good (85%–95%) in the sow. Uterine capacity may be the most significant factor that has reduced the rate of embryonic survival because experiments simulating uterine crowding have shown that reduced uterine space increased embryonic and fetal mortality and reduced fetal growth (Pere et al. 1997). In the future, as litter size may continue to rise due to increasing ovulation rates, negative effects on birth weights of piglets resulting in a compromised start to neonatal life is anticipated. Gilts that show good oestrous signs at puberty may show better signs of oestrus after weaning, and thus

VetBooks.ir

the intensity of oestrous signs may be used as a selection criterion for replacement females in the future (Sterning et al. 1990).

Another aspect that has changed in the contemporary sow is their reactivity to low feeding levels during lactation. In the literature published during the 1970s and early 1980s, feed restriction resulted in quite dramatic effects on the weaning-to-oestrous interval (about 10 days) but with hardly any effects on ovulation rate and embryo survival. In more recent papers, the effects of feed restriction during lactation on weaning-to-oestrous interval are quite small (less than a day), whereas effects on ovulation rates and especially on embryo survival are far more pronounced. Feed restriction seems to decrease ovulation rates by about 2 to 4, and embryo survival by about 10% to 20% in modern sows. This change in responsiveness of sows due to feed restriction during lactation is a result of a strong selection against weaning-to-oestrous interval in the past 20 years. This implies that, in the modern sow, effects of low feed intake during lactation on weaning-to-oestrous intervals is less pronounced but that effects on litter size are more pronounced. The first litter sow is most vulnerable due to a restricted feed intake capacity. Based on the analyses of 135 United States farms, Morrow et al (1992) showed that, in about 40% of the farms, the second litter size of their sows was lower than or equal to the first litter produced. Since then, this phenomenon has been known as the 'second litter syndrome' (Morrow et al. 1992).

Infertility in the Bitch and Queen

GARY C. W. ENGLAND

The dog and cat are among the most common species kept as pets. There have been considerable advances in our knowledge of canine and feline reproduction, and over the last few years, there has been increased awareness of infertility in these species. In the dog in particular, this has been the result of attempts at selective breeding for working and show purposes, for assistance animals for disabled people, and as models for endangered species. Much attention has also been paid to the control of reproduction, principally as a result of the considerable problem worldwide of pet overpopulation (Stavisky et al. 2012). However, there is no doubt that reproductive failure is common, and this may be attributed in part to the high degree of inbreeding (Leroy et al. 2015).

In normal circumstances the fertilisation/implantation rate is high – between 80% and 90% (Reynaud et al. 2006). The extent of infertility is, however, unknown. In the bitch, reduced fertility may not be fully appreciated because mating is relatively infrequent compared with other domestic species and because the majority of breeding animals are housed singly or in small groups. The situation is further complicated because 'fertility' often represents an owner's personal expectation of the reproductive performance of their own bitch or queen; this expectation may differ between a commercial breeding establishment and the owner of an individual pet. In addition, there are wide breed variations, particularly in litter size, which make it difficult to compare animals of different breeds.

It is with increasing frequency that both individual breeders and the managers of breeding colonies approach the veterinarian for help with breeding problems. Ultimately, this approach is because of the value of an individual animal that fails to reproduce or because of a concern for the decline in the productivity of a breeding colony. In the former case, continuation of a breeding line is the ultimate aim, whereas for the latter, greater productivity allows smaller numbers of breeding animals to be maintained. The breeding of large numbers of dogs and cats is common for pharmaceutical and biological laboratories and also for the production of working and assistance animals such as guide dogs for visually impaired people. Colony management usually requires not only a high output but also consistent production throughout the year.

The normal expectation of fertility in the bitch is a whelping rate in the region of 70% to 80% (England 1992), whereas the queen may rear between one and three litters per year (Stabenfeldt & Shille 1977). There are considerable variations from this, depending on age and breed. For the bitch the peak in reproductive efficiency occurs at approximately 3 years of age, with a decrease in the pregnancy rate from age 8 (Fig. 33.1), and a significant decline in the number of pups born in bitches aged 7 years and older (Blythe & England 1993). Blythe and England (1993) also demonstrated a variation in prolificacy between different breeds of dog. Similarly, in the cat, an age-related reduction in the number of litters per year and average litter size has been noted, which is most marked after 6 years of age (Lawler & Bebiak 1986). A study of 2400 pregnancies demonstrated that in older bitches, although fewer pups were born within each litter, there was also a lower incidence of stillbirth, such that overall the rate of decline in weaned pups was slower than the decline in the number of pups born (Phillips & England, unpublished observations). It should be remembered, however, that there are marked breed variations for normal litter size in both the dog and cat (Robinson 1973); these should be considered when an animal is presented because of alleged subfertility.

The investigation of infertility in the bitch is complicated by the fact that failure to conceive does not result in an immediate return to oestrus as occurs in polyoestrous species. However, the early diagnosis of pregnancy is now possible, using real-time ultrasonography and the measurement of plasma concentrations of relaxin. These methods allow improved investigations into why an individual animal fails to produce live offspring. Furthermore, studies have demonstrated the value of real-time ultrasound in documenting early pregnancy failure (England & Russo 2006).

As with other species, infertility in the bitch and queen may be categorised according to whether the cause is: (1) structural (including congenital, acquired, and neoplastic diseases); (2) functional (including endocrinological abnormalities); (3) infectious; or (4) managemental. The influence of the male should always be investigated; collection and evaluation of a semen sample provide a basic assessment of the male's fertility. In addition, attention should also be given to the mating routine because owners who are unfamiliar with normal mating behaviour may inadvertently be hindering conception. Examples of this are: the belief that ovulation shows a set number of days after the onset of prooestrus in the bitch and that only a single mating is necessary to induce ovulation in the queen.

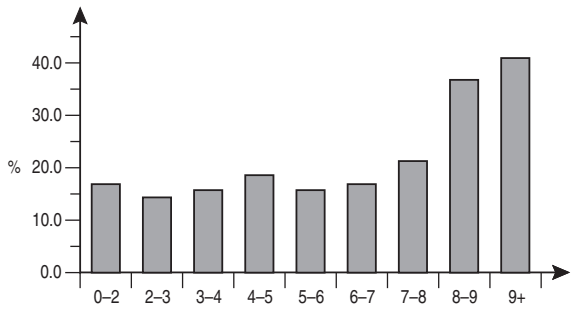
The Bitch

Structural Abnormalities of the Bitch's Reproductive Tract

Congenital Abnormalities

Ovarian agenesis is rare, and does not cause infertility unless both ovaries are affected. In some cases, there may also be agenesis of the ipsilateral uterine tube and/or uterine horn, although the latter may occur with a normal ovary. Ovarian dysplasia has also been

VetBooks.ir



• **Fig. 33.1** The percentage of bitches not pregnant after mating to a fertile stud dog according to maternal age.

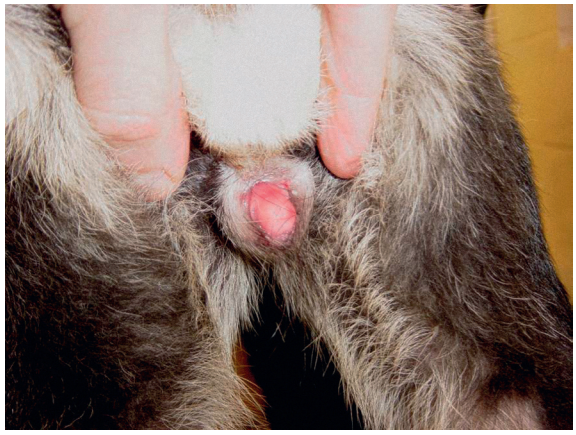
reported in a bitch with an abnormal number of chromosomes (Johnston et al. 1985), and evaluation of the karyotype may be useful when investigating the cause in these cases.

Bitches with uterine tube and/or uterine horn agenesis and normal ovaries usually exhibit typical oestrous behaviour but either fail to become pregnant (if there are bilateral lesions) or have small numbers of offspring (if there is a unilateral lesion). Diagnosis usually relies upon direct inspection of the reproductive tract via laparotomy or laparoscopy; the use of radiography after the injection of radiopaque contrast media into the uterus (Lagerstedt 1993) is not as useful in the bitch as for other species, particularly for demonstrating lesions of the uterine tube, which in this species is very small and rarely fills with contrast medium.

Other congenital anomalies of the tubular genital tract include segmental aplasia of the Müllerian duct system. These anomalies may be: (1) a failure of the paramesonephric ducts to form, which results in segmental uterine horn aplasia or absence of a uterine horn; (2) a failure of fusion of the caudal paramesonephric ducts so that a single lumen does not form, resulting in duplication of the uterus (didelphus) or cranial vaginal septation; or (3) a failure of the caudal paramesonephric ducts to fuse properly with the urogenital sinus, resulting in imperforate hymen. The aetiology of the condition is uncertain; however, administration of exogenous hormones during pregnancy may result in this type of abnormality. Complete aplasia of the vagina results in infertility and allows the accumulation of uterine fluid.

Anatomical abnormalities of the caudal reproductive tract are perhaps most common in bitches. Such congenital abnormalities may be considered to have five aetiologies: (1) they are the result of hypoplasia of the genital canal, which causes vestibulovaginal hypoplasia and a vaginal stricture of some length; (2) they are the result of poor or inadequate fusion of the Müllerian ducts to the urogenital sinus, causing annular fibrous strictures at this site; (3) they relate to tissue vestiges remaining at the vestibulovaginal junction, resulting in hymenal remnants or a complete hymen; (4) the incomplete fusion of the two Müllerian ducts may result in a double vagina or a vertical fibrous division within the vagina; or (5) they have imperfect joining of the genital folds and genital swellings resulting in vestibulovulvar hypoplasia.

Congenital abnormalities of the external genitalia are rare. Vulvar hypoplasia associated with perivulvar dermatitis has been described; the relationship between this condition and early neutering has not been fully established. The condition may be worsened if the bitch becomes obese because the perivulvar skin folds may then develop and cover the vulva. Masculinised female pups that have an abnormally shaped vulva may be produced after androgen or progestogen administration to the dam during pregnancy (see 'Habitual Abortion' later in this chapter).



• **Fig. 33.2** A 4-month-old intersex German Shepherd with clitoral hyperplasia and the presence of an os clitoris.

Intersex

Intersex animals have ambiguous genitalia. In the bitch, this is usually recognised because of an abnormal phenotypic sex appearance; externally, the animal appears female, but when it reaches puberty, the clitoris enlarges and male-like behaviour may develop (Fig. 33.2). Intersex animals may be classified as those with abnormalities of: (1) chromosomes, (2) gonads, or (3) phenotype; these conditions have been reviewed by Meyers-Wallen (1993).

Fetal mammals develop female genitalia unless there is the presence of a Y chromosome. The SRY gene (the sex-determining region on the Y chromosome) encodes the testis-determining factor. It is thought that SRY activates genes in the testis pathway and/or suppresses genes in the ovarian pathway (Meyers-Wallen 2006). The normal diploid number in the bitch is 78XX.

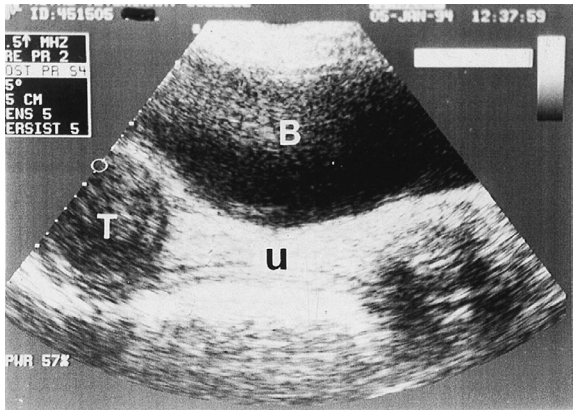
Abnormalities of chromosomal number include phenotypic females (XO or XXX), which have underdeveloped genitalia, and chimeras and mosaics that arise from two cell populations with different chromosome constituents. In chimeras and mosaics, there may be both ovarian and testicular tissue (true hermaphrodite); the phenotype of the animal depends on the amount of functional testicular tissue.

Animals with abnormalities of gonadal sex are those in which chromosomal and gonadal sex are dissimilar; such individuals are called 'sex-reversed'. XX sex reversal is inherited as an autosomal recessive trait in the American Cocker Spaniel and appears to be familial in other breeds. Affected animals may conform to one of three categories: (1) true hermaphrodites with one ovotestis, bilateral uterine tubes, and normal external female genitalia; (2) true hermaphrodites with ovotestes and/or epididymides and masculinised external male genitalia; and (3) XX males.

Animals with abnormalities of phenotypic sex are those in which chromosomal and gonadal sex is the same; the internal or external genitalia are ambiguous. Animals may be either female or male pseudohermaphrodites. Female pseudohermaphrodites generally occur as the result of androgen or progestogen administration during pregnancy; they have masculinisation of the external or internal genitalia but with two ovaries. The clinical appearance may vary from simple clitoral enlargement to almost male-like external genitalia. Progestogens administered during pregnancy have been most frequently implicated because these agents are used by some veterinarians to prevent alleged luteal deficiency (a presumed low progesterone output from the corpora lutea (CL) during pregnancy that results in pregnancy failure; often

VetBooks.ir

• **Fig. 33.3** Bitch with hyperplasia of the vagina during oestrus. The entire circumference of the vaginal mucosa is hyperplastic and protrudes from the vulva. Top is the dorsal commissure.



• **Fig. 33.4** Ultrasound image of the uterus of a bitch demonstrating a hypoechoic uterine tumour *(T)*. The uterus *(U)* lies dorsal to the bladder *(B)*.

also called habitual abortion). Male pseudohermaphrodites have testes, but the internal or external genitalia are feminised. This may be the result of failure of Müllerian duct regression or the failure of androgen-dependent masculinisation. In many cases the exact aetiology remains unknown. However, removal of the reproductive tract, including gonads, is usually necessary. After a gonadectomy, an enlarged clitoris may reduce in size, although clitoridectomy may be necessary if it continues to protrude from the vulva and be traumatised by the bitch.

Acquired Abnormalities

Acquired atrophy of the genitalia has been seen with neoplasia of the hypothalamus or pituitary; this is termed Fröhlich's syndrome but is very rare.

Other acquired abnormalities of the reproductive tract include endometrial hyperplasia (often cystic endometrial hyperplasia), pyometra (which are discussed later), and vaginal hyperplasia (Fig. 33.3). The latter condition may cause infertility by preventing mating. The aetiology is not clear; however, in some bitches the vaginal mucosa cranial to the urethral orifice becomes hyperplastic during an otherwise normal prooestrus and oestrus and may protrude from the vulva. In some cases, only the ventral mucosa protrudes as a simple tongue-shaped piece of tissue, whereas in other cases, it may involve the entire circumference of the vagina, resulting in the protrusion of a cylindrical-shaped mass through the vulvar lips. The hyperplasia appears to be an accentuated response to normal circulating oestrogen concentrations, which regresses at the beginning of the luteal phase (metoestrus/dioestrus). The hyperplasia commonly returns at the subsequent oestrus and, in many cases, appears to worsen at each subsequent cycle. Conservative therapy using emollient creams and topical antimicrobial agents is often sufficient, and recurrence may be prevented by performing an ovariectomy or ovariohysterectomy during the subsequent anoestrus. If the bitch is required for breeding, a submucosal resection may be performed during early oestrus. However, breeding from these bitches should be questioned because a familial tendency has been reported (Jones & Joshua 1982).

True vaginal prolapse is very rare in bitches but has been reported during oestrus (Schutte 1967), and chronic prolapse requiring hysteropexy has been observed during pregnancy (Memon et al. 1993).

Neoplasia

Ovarian tumours are uncommon in the bitch, accounting for approximately 1% of all neoplasms. There is an increased incidence of ovarian neoplasia in older dogs; the mean age of occurrence is 8 years (Withrow & Susaneck 1986). Ovarian tumours may be germ cell, epithelial, or sex cord stromal in origin. The most important are granulosa cell tumours, which may become very large and produce clinical signs related to the mass effect or ascites. They do not frequently metastasise, and are usually endocrinologically inactive; however, they may secrete: (1) progesterone, resulting in the absence of cyclicity, cystic endometrial hyperplasia, and pyometra; or (2) oestrogen, resulting in signs of persistent oestrus or possibly bone marrow suppression. Rarely, alopecia is a presenting clinical sign.

A less common tumour is the papillary cystadenocarcinoma, which may occur bilaterally. They commonly metastasise to the peritoneal lymphatics, producing obstruction and ascites, and have been found to be a consequence of prolonged administration of exogenous oestrogen.

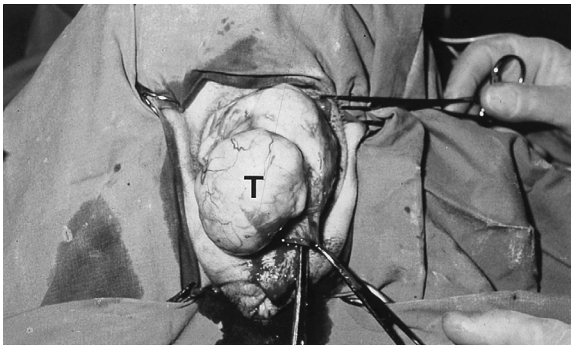
The diagnosis of ovarian tumours is usually made on the basis of clinical signs, abdominal palpation, radiography, and ultrasonography. Ovariectomy or ovariohysterectomy may be curative if performed early. It is possible to induce seeding of a tumour at the time of surgery, but this is not common because of the presence of a well-defined ovarian bursa.

Uterine tumours are uncommon. The most frequently reported are fibroleiomyoma. These are discrete and nonmalignant, but haemorrhage may occur, resulting in a sanguineous vulvar discharge. These tumours seem only to develop in entire bitches and are very rarely diagnosed in ovariectomised animals. Uterine tumours may be diagnosed using real-time B-mode ultrasound (Fig. 33.4).

Tumours of the cervix are rare, but benign tumours of the vagina and vestibule are more common and include fibromata, fibroleiomyoma, and lipomata (Fig. 33.5). These often originate from the ventral vaginal floor cranial to the urethral orifice and may cause a local vaginitis and haemorrhage. Usually, they can be removed via an episiotomy; concurrent ovariectomy or ovariohysterectomy reduces the risk of recurrence.

The transmissible venereal tumour (TVT) (Fig. 33.6) affects the vagina and external genitalia of the bitch and the penis of the dog. Transmission of the tumour occurs at coitus when infected cells 'seed' the genital mucosa of the recipient. Autotransmission

VetBooks.ir



• **Fig. 33.5** Surgical removal of a large vaginal tumour *(T)* via an episiotomy.

• **Fig. 33.6** Transmissible venereal tumour within the vestibule of a bitch.

to the nasal and oral mucosa may occur by licking of the tumour. The lesions, which are often friable and multilobulated and may be single or multiple, generally reach their maximum size after 5 to 7 weeks; many then regress spontaneously within 6 months. The use of surgical debulking and various chemotherapeutic regimes has been described, including cyclophosphamide and vincristine, and radiation therapy. Intratumoural injection with vincristine and interleukin-2 appears to have a dramatic therapeutic effect (Den Otter et al. 2015). Such tumours are more common in tropical countries and in the UK and Europe generally only occur in imported animals.

Function Abnormalities of the Bitch's Reproductive Tract

Delayed Puberty and Prolonged Anoestrus

The age of puberty in the bitch ranges between 5 and 24 months, although this is influenced by breed, body weight, and environmental conditions. Bitches that do not reach puberty by 2.5 years of age are therefore considered to have delayed puberty. Because it is not uncommon for there to be few signs associated with the first oestrus, bitches that are thought to have delayed puberty may simply have had an unobserved oestrus. Failure to identify oestrus should also be considered in bitches that have prolonged interoestrous intervals. A high peripheral plasma progesterone concentration (> 2.0 ng/mL/ 6.5 nmol/l) demonstrates that ovulation has occurred within the last 60 days (i.e., a recent oestrus has been missed).

The normal interoestrous interval is between 26 and 36 weeks, and this is variable both within and between breeds and cannot be used to predict the next oestrus in an individual bitch. Therefore it is difficult to define prolonged anoestrus except that it is an interoestrous interval greater than that which was anticipated for a particular individual (normally > 8 months). The Basenji dog frequently exhibits its pubertal oestrus at approximately 300 days of age and thereafter cycles annually (Concannon 1993).

To investigate both delayed puberty and prolonged anoestrus, it is necessary to ensure that an oestrus has not been missed and that the animal's body weight and nutritional status are normal. Debilitating disease may result in a failure to cycle, as may the use of certain drugs, including progestogens, androgens, and anabolic steroids.

Some bitches with delayed puberty have an underlying chromosomal abnormality. Of these, many are phenotypically abnormal with a small, cranially positioned vulva and developing clitoral enlargement at puberty. A smaller proportion is phenotypically normal, but the abnormal complement of sex chromosomes results in ovarian hypoplasia or ovarian dysgenesis. Establishing a karyotype usually demonstrates chromosomal abnormalities such as 77XO, 79XXX, 79XXY, and 78XX/78XY.

Progesterone-producing ovarian cysts that prevent a return to oestrus have been described in the bitch, although these are very rare. In these cases the animal fails to return to oestrus and has persistently elevated plasma progesterone concentrations. Ovarian cystic structures may be found within the ovaries at ultrasound examination. Some bitches present with pyometra rather than an absence of cyclicity.

There has been considerable interest in the role of hypothyroidism as a cause of acyclicity in the bitch. The mechanism for this is not fully understood, although the administration of thyrotrophin-releasing hormone (TRH) causes the release of prolactin; therefore factors that affect TRH are likely to affect both thyroid function and prolactin secretion (Concannon 1986). It is rare for only reproductive signs to be present in dogs with hypothyroidism (there is more likely to be coat changes, weight gain, and lethargy); interestingly, the condition was shown not to be related to poor reproductive performance (Segalini et al. 2009), and so this must remain a dubious diagnosis in infertile dogs.

Induction of Oestrus

It is possible to induce cyclicity in bitches provided that there is no underlying disease. Unlike other domestic species, it is not possible to induce oestrus by shortening the luteal phase using prostaglandins because the luteal phase is followed by a variable, but prolonged, period of anoestrus. The most successful regime is to use the prolactin inhibitor (cabergoline); the precise mechanism is uncertain. A return to oestrus can be induced by daily administration of cabergoline starting in either the luteal phase or anoestrus, but fertility is best when treatment commences in anoestrus (Kutzler 2005). Exogenous gonadotrophin-releasing hormone (GnRH) may also be used to induce oestrus, using short acting implants or implants that are placed subcutaneously and then removed after a few days (Kutzler 2005).

For bitches with delayed puberty, it may be necessary to attempt oestrus induction using gonadotrophins should administration of prolactin inhibitors fail. Many protocols have used exogenous gonadotrophins for the induction of oestrus; commonly, low doses of equine chorionic gonadotrophin (20 IU/kg for 5 days) with a single administration of human chorionic gonadotrophin (500 IU on the fifth day) are recommended. Exogenous gonadotrophins should be used with care because Arnold et al (1989) showed that high doses and long treatment times could induce hyperoestrogenism,

VetBooks.ir

which prevents implantation and induces bone marrow suppression and death.

Silent Oestrus

Normal cyclical endocrine changes may occur in some bitches without obvious external signs of prooestrus or oestrus. It is possible that oestrous events are not observed by the owner because there is only slight vulvar swelling and minimal serosanguineous discharge or because the bitch is particularly fastidious. On some occasions, overt pseudopregnancy occurs in the absence of a preceding observed oestrus. However, ovulation can be confirmed by the measurement of peripheral plasma progesterone concentrations. If suspected, oestrus can be detected by the weekly examination of exfoliative vaginal cytology.

Split Oestrus

Occasionally, and most commonly at their first oestrus, bitches develop vulvar swelling and a serosanguineous vulvar discharge of a short duration. However, ovulation does not occur; follicles presumably regress and the signs of prooestrus disappear. A normal oestrus follows several weeks later. If the split oestrus (false oestrus) syndrome is recognised, it is important to ensure that mating occurs at the correct time in relation to ovulation. In some cases, the initial or subsequent oestrus is prolonged, and here induction of ovulation may be attempted using human chorionic gonadotrophin (hCG), although it can be difficult to be certain when to administer this preparation. This is most successful when administered at the peak of vaginal epithelial cell cornification. Occasionally, a split oestrus is not recognised, and the return to oestrus is mistaken for pyometra because of the development of a vulvar discharge.

Unpredictable Ovulation Time

Most bitches ovulate between 10 and 14 days after the onset of prooestrus. However, ovulation in normal bitches may occur as early as day 5, or as late as day 30, after the first signs of prooestrus (Fig. 33.7). In addition to this, there are large variations in the pattern of cyclical activity, thus bitches are not necessarily consistent between cycles (England et al. 1989). Infertility may therefore result because of attempted matings at inappropriate times in relation to ovulation (see 'Management Factors Affecting Fertility' later in this chapter).

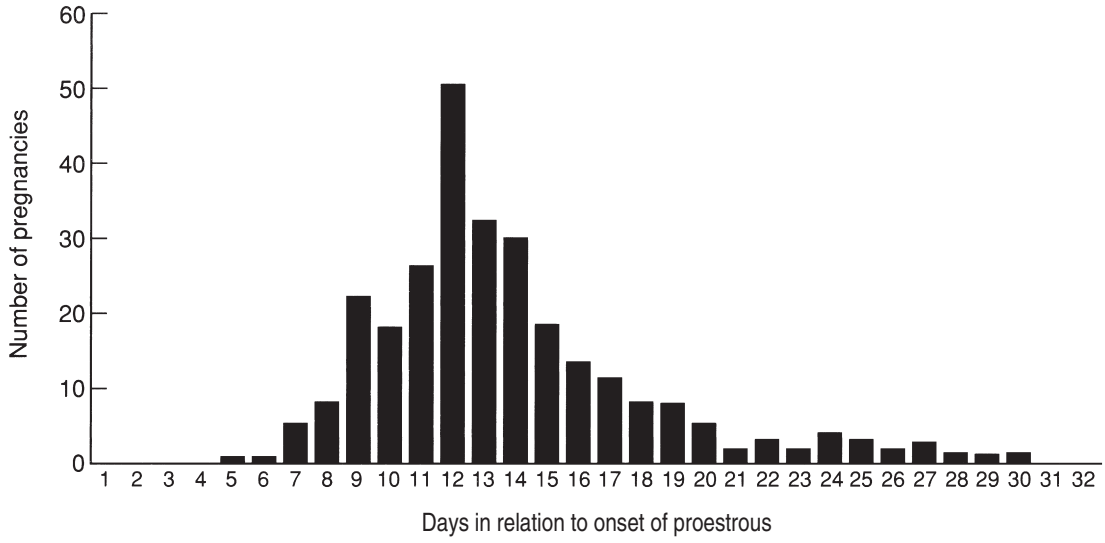
Prolonged Prooestrus/Oestrus

The normal interval between the onset of prooestrus and ovulation varies from 5 to 30 days. However, most bitches ovulate by Day 14 after the onset of prooestrus, and those that ovulate later than this are often considered to have prolonged oestrus. In fact, the majority of these animals are normal and do not require treatment but require careful assessment of the optimal mating time. Bitches in whom prooestrus or oestrus persists longer than 30 days (Wright 1990) may require treatment. The induction of ovulation may be attempted by the administration of hCG (20 IU/kg). It can be difficult to predict the correct time to administer hCG because its early use may result in either failure of response or possibly luteinisation without ovulation. Commonly, hCG is administered when more than 80% of exfoliated vaginal epithelial cells are anucleated.

Oestrogen-secreting follicular cysts are very rare in the bitch, but these may produce persistent oestrus. Similar clinical signs may be seen with oestrogen-secreting ovarian tumours, in which high concentrations of oestrogen may lead to bone marrow suppression, resulting in anaemia and thrombocytopenia. In such cases, treatment is by unilateral ovariectomy, although consideration should be given to the fact that the bitch may be normal or have a split oestrus syndrome.

Ovulation Failure

Until recently, the diagnosis of ovulation failure was most commonly made on the basis of a shortened interoestrous interval. However, after the introduction of routine monitoring of plasma progesterone concentrations, bitches that fail to ovulate have been detected. The incidence of ovulation failure has not been established, but it seems particularly common in German Shepherd



• **Fig. 33.7** The relationship between the calculated day of ovulation and the number of days from the onset of proestrous behaviour in 278 bitches (England, unpublished observations).

VetBooks.ir

and related breeds, sometimes manifesting as ovulation with a short luteal phase. Attempts at treatment may be made by the administration of hCG as described previously.

Ovarian Cysts

Cystic follicles (Fig. 33.8) and CL are very rare in the bitch; most ovarian cystic structures are of parabursal origin (Fig. 33.9), and although they may be detected by ultrasound and misinterpreted by the inexperienced clinician, they have no clinical significance because they are endocrinologically inactive.

• **Fig. 33.8** An ovary of a Labrador bitch demonstrating multiple follicular cysts.

• **Fig. 33.9** The reproductive tract of a bitch demonstrating multiple parabursal cysts adjacent to the ovary and proximal uterine horn.

True oestrogen-secreting follicular cysts produce persistent oestrus with vulvar discharge, and after several months, there may be flank alopecia and hyperkeratosis. Ultrasonographically, large fluid-filled follicles may be identified but must be carefully differentiated from normal follicles and early CL, both of which have central fluid-filled cavities. Some follicular cysts can be induced to luteinise by alternate day administration of hCG on three occasions. In others, such treatment does not succeed, but the cysts may respond to progestogen administration using hormones such as megestrol acetate. With the latter, there is an increased risk of pyometra because the progestogen is administered after a prolonged period of oestrogen priming. Ovariectomy may be necessary in cases that do not respond to exogenous hormone therapy.

Luteal cysts have been identified in postmortem studies; however, their significance is unknown. Burke (1986) suggested that they may secrete progesterone and produce prolonged anoestrus (sic) and cystic endometrial hyperplasia; in some cases, this may progress to pyometra.

Follicular and luteal cysts appear more commonly in older bitches. Some of these (often both types occur simultaneously) have been noted in the ovaries of aged bitches, which have a mucohaemorrhagic vulvar discharge, a condition referred to as metrorragie (Lesbouyries & Lagneau 1950). These bitches are often attractive to male dogs, but they will not allow coitus; a study of exfoliative vaginal cells demonstrates neutrophils, erythrocytes, and parabasal epithelial cells. This condition is often persistent and unresponsive to medical therapy such that ovariohysterectomy is usually the treatment of choice.

Premature Ovarian Failure

Premature ovarian failure has been suggested as a rare, but permanent, cause of anoestrus in previously normal bitches (Feldman & Nelson 1987). For an accurate diagnosis, investigation of the karyotype and measurement of plasma concentrations of gonadotrophins and thyroid hormone should be undertaken (Johnston 1989). In valuable breeding animals, oestrous-induction regimens may be contemplated; however, there is no information on the aetiology of the condition or on the efficacy of these treatments.

Habitual Abortion

There is little, other than anecdotal, evidence to suggest that habitual abortion is a clinical problem in the majority of breeds of dog, with the exception of the German Shepherd, in whom inadequate luteal function has been documented (Gunzel-Apel et al. 2006). Cases of abortion and resorption with normal progesterone concentrations are commonly documented using real-time B-mode ultrasound, although England (1992) suggested that there was no increased incidence in those bitches that had previously had reproductive disease. Most cases of abortion are probably related to an abnormal uterine environment (cystic endometrial hyperplasia), fetal defects, and/or the result of infectious agents.

The role of poor luteal function as a cause is less certain and appears unlikely. Although implicated by some workers, the minimum concentration of progesterone required to support the pregnancy is only 2 ng/mL (Concannon & Hansel 1977); i.e., it is very low. There is no doubt that the CL remain the principal source of progesterone production throughout gestation and that

VetBooks.ir

pregnancy may be terminated by ovariectomy or the induction of luteolysis at any stage. However, clinical problems appear only to occur in the German Shepherd (Gunzel-Apel et al. 2006) and related breeds or after oestrus-induction regimens and in one case of oophoritis (Nickel et al. 1991). In the author's experience, plasma progesterone concentrations of bitches with habitual abortion are not dissimilar to those of normal pregnant bitches (except for the German Shepherd dogs). Progesterone or progestogen supplementation during pregnancy may produce masculinised female pups and cryptorchid male pups and may possibly impair or delay parturition, resulting in fetal death. Progestogen therapy should be restricted to those cases in which a true luteal insufficiency has been diagnosed; this requires serial monitoring of progesterone concentrations.

Infectious Agents of the Bitch's Reproductive Tract

There are three categories of organism that may exert an influence upon fertility: (1) those that are known to have a specific pathogenical effect upon the reproductive tract; (2) those that are present in the normal environment and, under certain circumstances, can become opportunistic pathogens; and (3) those that cause systemic disease and exert their effect upon reproduction indirectly.

Normal Vaginal Bacterial Flora

There is a widespread belief among breeders and veterinarians that infertility, vaginitis, and fading puppy syndrome are caused by bacteria that inhabit the reproductive tract of the dog and bitch. This arose from the work of Stafseth et al (1937) and Hare and Fry (1938), who concluded that streptococci, especially beta-haemolytic types G and L, were responsible for infertility, abortion, anoestrus, and weak pups. With the advent of virus isolation techniques, several specific viruses have been identified, and it seems likely that the earlier work overemphasised the importance of the streptococci. These bacteria are now considered to be part of the normal commensal flora and probably invade subsequent to viral damage or are contaminants.

Many aerobic and anaerobic bacteria normally inhabit the vestibule and vagina of the healthy bitch, and the bacterial flora is normally mixed. The aerobic bacteria isolated from normal bitches include *Escherichia coli,* staphylococci, and streptococci; the anaerobic bacteria include *Prevotella* spp. and *Peptostreptococcus* spp. Mycoplasmas have been isolated from between 30% and 88% of normal bitches (Baba et al. 1983). Greater numbers of bacteria are found within the vestibule compared with the vagina; the uterus is normally sterile. The stage of the oestrous cycle may influence the bacterial flora because there is a significant increase in vaginal bacterial numbers when oestrogen concentrations are elevated (van Duijkeren 1992). Several authors have examined the vaginal bacterial flora of normal bitches and compared them with those of infertile bitches. These studies, which were reviewed by van Duijkeren (1992), showed that the bacterial species cultured from infertile bitches did not differ significantly from healthy bitches. Similarly, Hirsch and Wiger (1977) found that the organisms recovered from bitches with vaginal discharge were qualitatively the same as the normal bacterial flora, although the bacterial numbers were higher.

Therefore the results of microbiological examination of the reproductive tract of the bitch must be treated with caution because the simple isolation of bacteria from the vagina does not constitute a diagnosis of reproductive disease.

Opportunistic Pathogens

The bacterial species found in bitches with reproductive disease do not differ significantly from those found in healthy bitches. However, disease may result if the uterine or vaginal defence mechanisms are depressed, thereby allowing overgrowth of the normal commensals (Olson et al. 1986). Many of the normal vaginal inhabitants may become pathogens if a breakdown in local immunity occurs (van Duijkeren 1992). Some species of *E. coli* are more likely to be pathogenical because they possess particular adhesive capacity; these are called the uropathogenic *E. coli.*

Bacteria may enter the uterus during oestrus when the cervix is relaxed and could then cause infertility either directly by interfering with the zygote or by producing spermicidal factors. Bacteria may persist within the uterus after mating, particularly if the uterus is abnormal. It is clear that cystic endometrial hyperplasia can lead to mating-induced endometritis and reduced fertility, which can be improved by postmating antibiotic administration (England et al. 2012). Persistence of opportunistic pathogens, in the presence of endometrial hyperplasia, may lead to the later development of pyometra during the progesterone-dominant phase of the cycle.

If vaginal microbiological sampling reveals bacteria present in a pure growth or in very large numbers, then they may be considered significant, although pure growths of bacteria may also be isolated from normal dogs (Bjurstrom & Linde-Forsberg 1992). Those bacteria most commonly thought to be significant by some workers, but not this author, include *Pseudomonas* spp., *Proteus* spp., and some streptococci. Repeated culture after 1 week should be performed to confirm the diagnosis before attempting treatment. Appropriate antimicrobial therapy, based upon sensitivity tests, should only be administered after investigation of possible predisposing causes such as anatomical, neoplastic, or mechanical abnormalities of the vagina. In the author's experience, the presence of these organisms in pure growth is nearly always secondary to some other cause. Parenteral and topical administration has been advocated. It is noteworthy, though, that prolonged antibiotic treatment can lead to selection of pure growth of some bacteria, and so inappropriate antibiotic use may be the primary cause of this problem.

Mycoplasmas and ureaplasmas have been implicated in causing reproductive disease in the bitch (Lein 1986), although they are also frequently isolated in clinically normal animals with no evidence of reproductive tract disease. Mycoplasmal colonisation of the vagina has been demonstrated after prolonged treatment of bitches with oral ampicillin and potentiated sulphonamides (Strom & Linde-Forsberg 1993); this suggests that the widespread use of antimicrobial agents in healthy bitches should be avoided.

Specific Infections

Brucella Canis

Brucella canis is a Gram-positive bacterium that can produce abortion and infertility and result in significant economic losses for dog breeders. It is the only bacterium known to be a specific cause of infertility in the bitch. *Brucella* infertility was first reported in the United States but has subsequently been found in several countries worldwide. Barton (1977) found that between 1.5% and 6.6% of dogs in the United States had antibodies diagnostic

VetBooks.ir

of infection. Current rates may now be higher, and certainly they are in other countries; Keid et al (2017) found 42% of commercial breeding kennels in Brazil had at least one positive dog. *B. canis* is not present, except sporadically, in imported animals in the UK. *B. canis* can be transmitted in several ways, including contact with aborted fetal or placental tissue, contact with the vaginal discharge of infected bitches, venereal transmission, and congenital infection. The most common method of infection is venereal. Abortion occurs most commonly between days 45 and 55 of pregnancy; however, there may be early fetal resorption or the birth of stillborn or, more rarely, weak pups.

The isolation of the bacterium from blood or aborted tissue is diagnostic of the disease; however, there may be prolonged periods when the bitch is not bacteraemic, so that a negative blood culture does not rule out infection. Treatment can be difficult because of the intracellular nature of bacterial replication; prolonged infection and shedding is common (Reynes et al. 2012). Because a carrier state can occur and these animals may be potential sources of infection, they are best neutered to remove them from the breeding programme.

Toxoplasma Gondii

Toxoplasma gondii infection causes abortion, premature birth, stillbirth, and neonatal death. Surviving infected pups may carry the infection. The public health consequences of *Toxoplasma* infection should be considered whenever it is diagnosed. The condition is best diagnosed by examination of impression smears from dead neonates. Although clindamycin is often used to treat the condition in dogs and cats, most regimes appear to have little effect on the bradyzoite stage.

Canine Herpesvirus

Canine herpesvirus in adult male dogs generally produces mild clinical signs, limited to the respiratory or genital tract. However, the virus may cause resorption, abortion, and stillbirths. Viral recrudescence may occur at subsequent pregnancies such that the clinical problem may persist for some considerable time in a breeding programme.

Infection of the pregnant bitch results in placental lesions and the infection of fetuses. The infected placentae are macroscopically underdeveloped and possess small, greyish white foci characterised by focal degeneration, necrosis, and the presence of eosinophilic intranuclear inclusion bodies. Experimental infection during early pregnancy causes fetal death and mummification, whereas infection during midpregnancy results in abortion; infection during late pregnancy results in premature birth. The virus has also been recovered from vesicular lesions on the external genitalia of bitches. Variable-sized vesicles are commonly observed in the vestibule, and frequently these lesions are evident at the onset of prooestrus, suggesting that venereal transmission is probably important in adult dogs.

Pups may become infected at birth during passage through the vagina and subsequently die with characteristic widespread histological necrotising lesions. Pups that survive the illness may show persistent neurological disorders. Pups are only at risk while in utero and during the first 3 weeks of life; experimental attempts to produce the generalised disease in older pups have failed. In the pups, the disease is rapidly fatal and treatment is often unrewarding; symptomatic therapy is all that is available because specific antiviral agents are not efficacious. Recrudescent viral shedding from the vesicular lesions may be stimulated by the stress of pregnancy and parturition.

With respect to diagnosis, serology demonstrates exposure, not infection, and virus isolation of pathological examination of fetuses is required. Infection is becoming increasingly prevalent within Europe, and as a result, a vaccine has been licensed for use (Chabchoub et al. 2006). The vaccine contains canine herpesvirus glycoprotein subunits and is administered 1 to 2 weeks after mating and again 6 weeks later (i.e., 1–2 weeks before the expected date of whelping). Revaccination is recommended at each pregnancy. A high level of efficacy has been demonstrated, although protective levels of antibody appear to be present for only 3 months.

Canine Parvovirus

Canine parvovirus infection has been implicated by some breeders as a cause of infertility in their kennels. However, Meunier et al (1981) found that after the introduction of canine parvovirus to a kennel of 2000 brood bitches, the conception rate, incidence of stillbirths, average litter size, and average number of pups weaned per litter did not change. However, canine parvovirus may cause an acute generalised infection in pups and death after the time that maternally derived antibody wanes, often after weaning. More rarely, there is infection in neonates less than 2 weeks of age, which can occur as a consequence of uterine infection or as a result of exposure to the virus soon after birth. Certain premises may have significant problems with canine parvovirus as a result of subclinical infection maintaining a viral output that infects neonates shortly after birth. In these cases, it may be necessary to cease breeding to remove susceptible animals from the equation and to ensure thorough cleansing and vaccination of any other animals before introduction.

Canine Adenovirus

It is well established that infection with canine adenovirus during pregnancy may result in the birth of dead or weak pups that die within a few days of parturition. The disease is uncommon except in unvaccinated bitches. In most cases the virus is ingested by neonates and causes mortality from 3 weeks of age onwards. Virus shedding can persist for some considerable time, and the virus may persist in the environment for up to 10 days. Carrier bitches may act as a source of infection for pups. Bitches should be vaccinated before mating, and when this is undertaken, there is reasonable maternally derived antibody for up to 10 days after birth.

Canine Distemper Virus

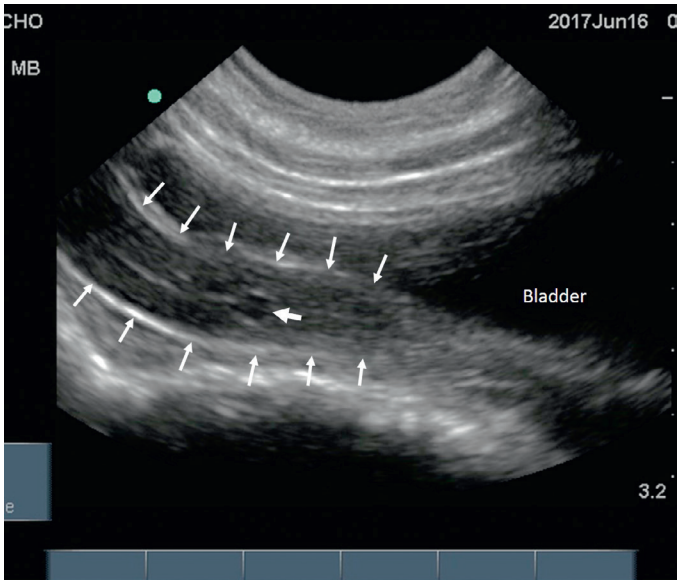
Experimental exposure of pregnant bitches to canine distemper virus was found to produce either clinical illness in the bitch with subsequent abortion or subclinical infection of the bitch and the birth of clinically affected pups. This provides evidence for transplacental transmission, although the frequency of this under natural conditions is unknown but appears to be rare.

Cystic Endometrial Hyperplasia

Aetiology

Although the exact aetiology of cystic endometrial hyperplasia (CEH) and pyometra is uncertain, this syndrome is probably best categorised as an infectious cause of infertility, even though the role of the endocrine environment is significant. It has been suggested that cystic endometrial hyperplasia, which precedes pyometra as a clinical disease, may cause infertility by allowing the development of a mating-induced endometritis (Freeman et al. 2013), resulting in conception failure and embryonic resorption. The condition may be recognised by ultrasound examination of the uterus during

VetBooks.ir



• **Fig. 33.10** Ultrasound image of the uterus of a bitch with cystic endometrial hyperplasia. The uterine body is seen in longitudinal plane *(arrows)* and a single central endometrial cyst is obvious *(large arrow)*.

the luteal phase. The detection of multiple small, focal, fluid-filled cystic regions within the endometrium is diagnostic (Fig. 33.10); endometrial biopsy is unnecessary. In many cases, cystic endometrial hyperplasia leads ultimately to pyometra, the incidence of which is high. In fact, pyometra is recognised as one of the common causes of illness and death in this species.

There has been considerable debate over the predisposing factors and the exact aetiology of CEH/pyometra. Most observers are of the opinion that CEH is a spontaneously occurring disease of middle aged or old bitches (Moxon et al. 2016). Continuing glandular hyperplasia occurs under the influence of progesterone and regresses at the end of the luteal phase. However, during the animal's life, there is progressive hyperplasia, which ultimately results in the development of pathological lesions termed cystic endometrial hyperplasia. The mean age of clinical pyometra is approximately 8 years, but it is not clear whether there is any association with parity or characteristics of the oestrous cycle. Pyometra is, however, very clearly a disease of the luteal phase, with most bitches showing clinical signs between 5 and 80 days after the end of oestrus; progesterone is the main hormone concerned with inducing uterine glandular hyperplasia.

Organisms isolated from the uterine fluid in cases of pyometra are those found as part of the normal vaginal and vulvar microflora. It is generally agreed that the predominant bacterium isolated is *Escherichia coli,* but has especial virulence factors. Sandholm et al (1975) found that the progesterone-sensitised endometrium and myometrium had an affinity for *E. coli.* These workers postulated that urinary tract infection was associated with pyometra, the uterus becoming infected during the early luteal phase when receptors for *E. coli* develop within the endometrium, thus enhancing the colonisation of the uterus with bacteria. It is likely that the long luteal phase of the bitch is an important contributory factor in the development of the condition because it has been shown that, in the cow, progesterone increases the susceptibility of the genital tract to infection. Brodey (1968) hypothesised that anogenital bacteria entered the uterus during oestrus and were able to proliferate during the luteal phase. This suggestion offers a plausible explanation of the aetiology because the condition is more likely to develop when there is cystic endometrial hyperplasia. A further factor that must be considered in the aetiology of pyometra is the use of exogenous reproductive hormones. Pyometra may be induced by the administration of exogenous progesterone or progestogens. The experimental use of oestrogens in the bitch does not usually result in the development of pyometra. However, oestrogens enhance the stimulatory effects of progesterone on the uterus. For this reason, when oestrogens are administered postmating to prevent conception, pyometra may be induced.

Clinical Signs

There is a wide range of clinical signs associated with pyometra in the bitch. When a complete history is available, it is usually found that the bitch was in oestrus a few weeks before the illness. In some cases, when there is a vulvar discharge, the owner may consider this to be a continuation of oestrus (Table 33.1).

If presented early, the general history is that the animal has been lethargic with a reduced appetite; increased thirst and vomiting are variable findings. Some bitches may be presented later when there is a vulvar discharge, which in some cases is associated with improvement in the general health. In other cases, the bitch remains unwell, and there is no discharge of pus. The bitch's abdomen may become distended, and she may be thought to be pregnant, although systemic illness is common. These cases generally end fatally, often within 14 to 21 days from the onset of clinical signs; the cervix remains closed throughout. Death may be due to toxaemia alone, or it may be associated with peritonitis due to rupture of the uterus. Occasionally, the cervix relaxes, and there is an outpouring of pus just before death.

In a further category, there may be intermittent opening of the cervix, with relative good health after the discharge of pus and malaise during the intervening periods.

Some cases of open cervix pyometra may persist for months, with a more or less continuous vulvar discharge. Body temperature may be normal or slightly elevated in cases of open cervix pyometra, whereas there is commonly an elevated body temperature in cases of closed cervix pyometra. In toxaemic patients the temperature may be subnormal.

The character of the vulvar discharge may vary considerably. Most often, it is of thin consistency and light chocolate brown in colour and has a characteristic odour. In other cases, it is yellow in colour, often blood-tinged, and varying from a watery to a creamy consistency. The vulva is generally enlarged, and there may be discoloration or scalding of the perivulvar tissues and perineum.

An increased thirst is commonly observed in advanced cases, which is due to reduced permeability for water in the distal convoluted tubule of the kidney. Renal dysfunction is probably caused by the formation of immune complexes. A small proportion of cases develop neurological signs, particularly ear twitching.

Diagnostic Features

Abdominal Palpation

Before examination, the animal should be given the opportunity to urinate and defecate. In cases of open cervix pyometra the uterine horns may be detected as thickened, often irregular, and slightly turgid structures from 1 to 3 cm in diameter. Their location within the abdomen is not generally altered from normal. Occasionally, some areas of the uterine horns are turgid and solid on palpation whereas others, which are distended by pus, may be indistinguishable from the surrounding bowel. Care must be taken not to confuse the colon with thickened uterine horns. In cases

VetBooks.ir

TABLE 33.1 Differential diagnosis of vulvar discharge in the bitch

Nature of the Discharge	Condition	History	Condition of the Vulva	Cytological Findings	Comments
Clear or straw-coloured	Oestrus	Expected in 'heat'	Swollen or slightly soft	LIEC, AEC, RBC, no WBC	Attractive to male
Mucoid	Metoestrus	Recent oestrus	Large but soft	PBC, SIEC, VSIEC, WBC	No malaise
Mucoid	Normal pregnancy	Pregnant/recent oestrus	Large but soft	PBC, SIEC, WBC	No malaise, does not threaten pregnancy
Purulent	Juvenile vaginitis	Before first 'heat'	Normal	PBC, SIEC, WBC	May respond to antibiotics but recurs Recovery after puberty
Purulent	Vaginitis	Variable but often excessive licking, attractive to male	Depends on the stage of the cycle	Depends on the stage of the cycle	Specific causes include: certain bacterial or viral infections, chemical irritation (urine), mechanical irritation (foreign body), neoplasia and anatomical abnormalities
Purulent/ haemorrhagic	Pyometra	Oestrus 2–8 weeks previously	Slightly swollen	WBC, SIEC, LIEC, RBC, bacteria, cell debris	Diagnosis using ultrasonography Often malaise
Purulent/ haemorrhagic	Metritis	Recent parturition	Large	Multinucleated cells, LIEC, uterine cells	Severe malaise
Haemorrhagic	Proestrus	Expected in 'heat'	Swollen	SIEC, LIEC, RBC, WBC	Attractive to male
Haemorrhagic	Oestrus	Expected in 'heat'	Swollen or slightly soft	LIEC, AEC, RBC, no WBC	Attractive to male
Haemorrhagic	Follicular cysts	Persistent discharge	Swollen	LIEC, RBC, ± WBC	No malaise, attractive to male, may develop bone marrow suppression
Haemorrhagic	Vaginal ulceration	Recent trauma or mating	Depends on the stage of the cycle	RBC, depends on the stage of the cycle	Rare, may start up to 2 weeks after mating
Haemorrhagic	Placental separation	Pregnant	Normal or slightly swollen	RBC, mucus	Ultrasound, radiography, etc., will confirm pregnancy
Haemorrhagic	Subinvolution of placental sites	Persistent discharge after whelping	Normal or slightly swollen	RBC, large polynucleated vacuolated cells	No malaise, refractory to treatment
Haemorrhagic	Transmissible venereal tumour	Not all countries of the world	Depends on the stage of the cycle	RBC, tumour cells?	Identification of tumour on vulva or in vagina confirms diagnosis
Haemorrhagic Cystitis	Cystitis	Frequent urination	Depends on the stage of the cycle	RBC, mucus	Small volumes of urine, dysuria
Haemorrhagic	Urinary tract neoplasia	Dysuria	Depends on the stage of the cycle	RBC, tumour cells?	Endoscopy may show origin of haemorrhage, positive contrast cystourethrography may be diagnostic
Haemorrhagic/ brown-coloured	Abortion	Pregnant	Slightly enlarged	RBC, mucus	Ultrasound shows uterus with similar appearance to postpartum
Green/brown-coloured	Parturition	Pregnant	Slightly swollen	RBC, SIEC, uterine cells	Painting, nest making, milk production
Green/brown-coloured	Dystocia, placental separation	Nonproductive straining	Slightly swollen	RBC, SIEC, uterine cells	Ultrasound will confirm pregnancy and fetal viability

PBC, parabasal cells; *SIEC,* small intermediate epithelial cells; *LIEC,* large intermediate epithelial cells; *AEC,* anuclear epithelial cells; *RBC,* erythrocytes; *WBC,* polymorphonuclear leucocytes; *VSIEC,* vacuolated small intermediate epithelial cells ('metoestrus cells').

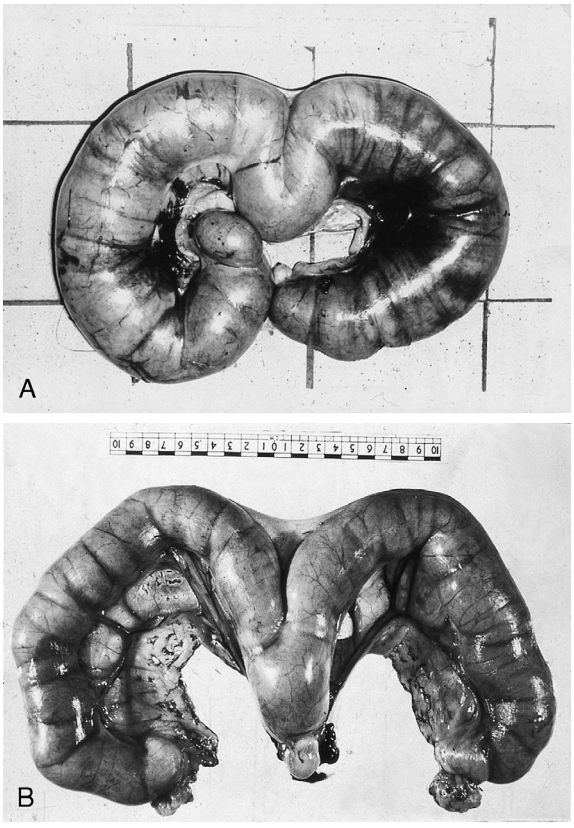
• **Fig. 33.11** Ultrasound image of the reproductive tract of a bitch with pyometra. The uterine horns *(U)* are distended with anechoic fluid and can be seen in three crosssectional planes dorsal to the bladder *(B)*.



• **Fig. 33.12** The reproductive tracts from two bitches with pyometra. Note the different degrees of distension.

of closed cervix pyometra, the degree of uterine distension may be greater, and there may be visible abdominal enlargement. In large or obese patients, abdominal palpation may not be possible.

Ultrasonography

Ultrasound is particularly valuable for detecting the uterus that is filled with fluid. The uterus has an increased diameter and may be folded upon itself so that several sections of each horn may be imaged in a single plane (Fig. 33.11). The diameter of the uterus may vary, depending on whether the cervix is open or closed. The uterine wall is usually relatively hypoechoic and is increased in thickness. The uterine lumen is usually grossly dilated with anechoic fluid, although small echogenic particles and mass lesions may be identified. The diagnosis is most simple when the diameter of the uterus increases to larger than that of the small intestine. Ultrasonography may be used to monitor cases of pyometra during treatment (England et al. 2007).

Radiography

The detection of a soft-tissue–opacity mass lesion within the caudal abdomen, causing cranial displacement of the small intestine and dorsal displacement of the colon, has been used for some time to indicate enlargement of the uterus. It should be remembered, however, that these findings are not specific for pyometra because early pregnancy has a similar radiographic appearance.

Haematology

The total number of leucocytes is frequently elevated in cases of pyometra, although the degree is much less marked in cases of open cervix pyometra compared with closed cervix pyometra. However, an elevated white cell count is not always present.

Rectal Examination

It may be possible to palpate the distended uterus per rectum using a finger, especially if slight backward pressure is applied to the abdominal wall.

Treatment

Ovariohysterectomy to remove the pus-distended uterus (Fig. 33.12) is the treatment of choice for pyometra. Bitches that are presented early in the course of the disease are usually a low surgical risk, and very high success rates have been reported. Lower success rates may occur when bitches are toxaemic. Intravenous fluid therapy is essential in all cases to ensure minimum renal toxic effects. Attention should also be paid to plasma electrolytes and acid–base status because complications associated with septicaemia, bacteraemia, and uraemia are common. Although the ideal situation is to administer intravenous, broad spectrum, antimicrobial agents and fluid therapy, it is not always possible to stabilise the patient before surgery.

If the condition is not life threatening and the animal is particularly valuable or when the clinical situation precludes surgery, medical treatment may be considered. Although repeated administration of prostaglandin will cause lysis of the CL and uterine contraction, it produces adverse effects (restlessness, pacing, hypersalivation, tachypnoea, vomiting, and diarrhoea) and is contraindicated if the cervix is closed. A better option is treatment with cabergoline (the prolactin inhibitor) with prostaglandin. Inhibition of prolactin removes endocrine support for the CL, so that progesterone concentrations decline (and closed cervix cases are converted to open cervix cases) before the administration of prostaglandin, which also cause luteolysis and uterine contractions. Treatment for 10 days, combined with fluid and antimicrobial therapy, is highly effective (England et al. 2007). Other medical regimes include the progesterone receptor antagonist (aglepristone), which blocks the action of progesterone. It is likely that, in the future, more complex treatment regimes, involving combinations of these three drugs (prolactin inhibitors, prostaglandins, progesterone receptor antagonists), will prove to be even more efficacious. Regardless of whether there is underlying endometrial hyperplasia, although the acute disease can be treated nonsurgically, there is a high rate of recurrence after the subsequent oestrus.

• **Fig. 33.13** Schematic representation of the changes in peripheral plasma hormones during proestrus, oestrus, and early metoestrus (dioestrus) and the relationship to the fertile period and the fertilisation period in the bitch.

Management Factors Affecting Fertility of the Bitch

The majority of bitches presented for fertility investigation are normal healthy fertile animals**,** whose apparent infertility is related to a misunderstanding of proper breeding management. In modern breeding protocols, the dog and bitch are often not allowed to display normal courtship behaviour because they are introduced when the owner considers that the time for mating is correct. This is usually based simply upon counting the number of days from the onset of vulvar swelling and the appearance of a serosanguineous vulvar discharge.

Although the majority of bitches ovulate between 10 and 14 days after the onset of prooestrus, this event may occur as early as Day 5 or as late as Day 30. In addition, bitches are not necessarily consistent between cycles (England et al. 1989). Therefore should a bitch be mated on Days 12 to 16 after the onset of prooestrus (which is common breeding practice), this may be inappropriate and result in a failure of conception.

The Fertile and Fertilisation Period

A surge in plasma LH concentration is the trigger for ovulation, which occurs 40 to 50 hours later. Ovulation is spontaneous, and eggs are ovulated as primary oocytes. The oocytes are immature at ovulation and must reach the metaphase of the second meiotic division after extrusion of the first polar body before fertilisation; this further stage of maturation takes 48 to 60 hours. Eggs remain fertilisable for a further 2 to 3 days; therefore, the time span over which fertilisation may occur, termed the 'fertilisation period', is between 4 and 7 days after the LH surge (i.e., between 2 and 5 days after ovulation) (Fig. 33.13).

Dog sperm can remain viable and fertile within the uterus and uterine tubes for at least 6 days or more (Doak et al. 1967). Therefore it is possible for matings that take place before the fertilisation period to result in conception. A second term may therefore be used, the 'fertile period', which differs from the 'fertilisation period' in that it encompasses the period of sperm survival within the female reproductive tract before ovulation and oocyte maturation. The fertile period extends from 3 days before until 7 days after the preovulatory LH surge and may be even longer for dogs with exceptional semen quality. Determination of the time to mate can therefore be assessed on the basis of the time of the LH surge or methods that may reliably indicate the 'fertilisation period' or the 'fertile period'.

Although it was initially thought that the LH surge occurred synchronously with the onset of standing oestrus, it was subsequently shown that this may occur between 3 days before and 9 days after the onset of oestrus. Therefore teasing the bitch has little value in determining the fertile period. Clinical assessment of the volume and colour of the vaginal discharge is similarly unreliable for determining the fertile period.

The Optimal Mating Time

The optimal time for mating is likely to be during or immediately before the fertilisation period, and the period of peak fertility for natural matings ranges from 1 day before to 5 to 6 days after the LH surge (see Fig. 33.13). Determination of the time to breed could therefore be based upon methods for estimating the time of the LH surge.

VetBooks.ir

TABLE 33.2 Plasma (serum) progesterone concentration in relation to stage of the bitch's cycle for the purposes of breeding management

Phase of the Cycle	Progesterone Concentration	Range
LH surge	≈ 2.5 ng/mL (8 nmol/l)	2.0–3.0 ng/mL
Ovulation	≈ 7 ng/mL (21 nmol/l)	5–9 ng/mL
Beginning of the fertilisation period	≈ 10 ng/mL (32 nmol/l)	8–15 ng/mL
Middle of the fertilisation period	≈ 15 ng/mL (45 nmol/l)	10–30 ng/mL
End of the fertilisation period	≈ 28 ng/mL (85 nmol/l)	25–40 ng/mL

Hormone Measurement

Measurement of plasma concentrations of LH is a reliable and accurate method of determining the optimum time to mate. However, there is no readily available commercial assay for canine LH. A further key challenge in measuring LH is the fact that concentrations peak and return to basal values within a short period of time, necessitating daily sampling.

Plasma progesterone concentrations begin to increase towards the end of prooestrus at the time of the LH surge. Progesterone is produced by luteinising follicles, and therefore, serial monitoring of plasma progesterone concentrations allows anticipation of ovulation. Because progesterone concentrations rise slowly before ovulation, daily sampling is not necessary. Commercial test kits designed to measure the concentration of plasma progesterone by ELISA are available. Plasma progesterone concentrations in relation to the different phases of the cycle are shown in Table 33.2.

Vaginal Cytology

Examination of exfoliative vaginal cells is commonly used to monitor the oestrous cycle. During prooestrus, increased plasma oestrogen concentrations cause thickening of the vaginal mucosa, which becomes a keratinised squamous epithelium. Vaginal epithelial cells may be collected either using a moistened swab or by aspiration. The relative proportions of different types of epithelial cells can be used as a marker of the endocrine environment. Several methods for staining of the cells and various indices of cornification and keratinisation have been suggested as markers for the stage of the cycle. In general, the fertile period can be predicted by calculating the percentage of epithelial cells that appear cornified using a modified Wright–Giemsa stain, although staining with a modified trichrome stain, allowing an assessment of the percentage of keratinised cells, has been suggested as being most useful. A schematic representation of the changes of exfoliative vaginal cells is given in Chapter 1.

Polymorphonuclear leucocytes are absent from the vaginal smear during oestrus because the keratinised epithelium is impervious to these cells. Their reappearance during late oestrus reflects the breakdown of this epithelium. The return of polymorphonuclear leucocytes to the vaginal smear has been used by some workers as an indicator of the time of optimum fertility; also, it is easy to document.

Many workers suggest that breeding should be attempted throughout the period when more than 80% of epithelial cells are cornified (Fig. 33.14). Although this is a good guide, some bitches reach peak values of only 60% cornification, whereas in others, there may be two peaks of cornification (van der Holst & Best 1976). Some bitches demonstrate poor cellular changes in the vaginal smear, and typical metoestrous cells may be found during prooestrus. Allen (1985) noted that polymorphonuclear leucocytes may be found throughout the entire period of oestrus; the extent of these variations has not been quantified. Planning of mating, based on evaluation of the anuclear cell index of cells aspirated from the cranial vagina, was found to increase the pregnancy rate and litter size of a group of bitches compared with a similar group mated only on the basis of the onset of prooestrus (England 1992). The technique is particularly useful for bitches with irregular oestrous cycles and those with a prolonged prooestrus or oestrus.

Vaginal Endoscopy

Vaginoscopy is the technique of examination of the vaginal mucosa using a rigid endoscope. Vaginoscopic assessment is based upon observation of the mucosal fold contours and profiles and the mucosal colour (Lindsay 1983). Enlarged oedematous pink or pinky/white mucosal folds are present during prooestrus and oestrus. Progressive shrinking of these folds is accompanied by pallor; such effects are probably the result of an abrupt withdrawal of the water-retaining effect of oestrogen during its preovulatory decline. Subsequently, mucosal shrinkage is accompanied by wrinkling of the mucosal folds, which become distinctly angulated and dense cream to white in colour. These gross changes have been used to assess the fertile period (Moxon et al. 2012).

Vaginoscopic evaluation is based upon assessment of the appearance of the vaginal wall (the mucosal fold contours and profiles, the colour of the mucosa, and the presence of any fluid) and the changes in this appearance at specific times of the oestrous cycle. A specific scoring system was devised by Lindsay and others (1988) and Jeffcoate and Lindsay (1989) and has been modified by this author as follows (Fig. 33.15):

- **Inactive phase (I)**: This phase is characterised by a thin, red, dry mucosa with low and flattened mucosal folds.
- **Oedematous phase (O)**: This phase is characterised by a thickened and oedematous mucosa, that appears turgidly swollen, rounded, and grey/white in colour.
- **Shrinkage phase (S)**: This phase is characterised by a thickened mucosa, which is normally white in colour but in which there is reduced turgidity with progressive furrowing, wrinkling, and indentations. The mucosal fold profile is, however, still rounded rather than angular. The progressive nature of this phase means that the early changes are designated 'S1' and the later changes 'S2'.
- **Angulated phase (A)**: This phase is characterised by a thickened mucosa, which is normally white in colour, but in which there is significant reduced turgidity to the extent that, in profile, the mucosal folds have progressive shrinkage and angulation, such that the peaks are sharp-tipped and irregular in appearance. The mucosa is wrinkled and shrunken in appearance. The progressive nature of this phase means that the early changes are designated 'A1' and the later changes 'A2' and 'A3'.
- **Declining phase (D)**: This phase is characterised by a progressive decline in the size of the mucosal fold profile. Early in the phase (designated 'D1'), there is a flaccid appearance to the mucosal fold profile. Subsequently, the folds become more rounded ('D2'), and there is sloughing of the cornified layers of

the epithelium ('D2' and 'D3'), resulting in a thin mucosa of variegated colour with flattened folds and a rosette-appearance to the mucosa ('D4').

- **Inactive phase (I)**: The decline phase is followed by a return to a phase characterised by a thin, red and dry mucosa**,** with low and flattened mucosal folds. This appearance is also designated 'I'. There may be more debris present at this stage than found in phase I before the onset of prooestrus.

A clear relationship is present between the appearance of the vaginal wall and the underlying endocrinology (see Fig. 33.15). The specific timing of some events is variable**,** but a good correlation has been demonstrated between the onset of ovulation and phase A1 and a good relation between the fertilisation period and phases A1 through A3. Generally, the onset of the fertile period can be detected by observing the onset of mucosal shrinkage without excessive angulations, although gross shrinkage of entire mucosal folds with obvious angulation (phase A2 and A3) is characteristic of the fertilisation period (see Fig. 33.15). Breeding is best planned approximately 4 days after the first detected mucosal shrinkage or at the onset of the period of obvious angulation of mucosal folds. The end of the fertilisation period can be detected by observing sloughing of the vaginal epithelium (see previous mention) and development of a variegated appearance to the colour of the mucosal surface.

Ultrasound Examination

Real-time B-mode ultrasound imaging has been used in several species to monitor follicular growth and to identify the time of ovulation. Imaging of the bitch's ovaries and the detection of ovulation have now been reported in some detail (England et al. 2009). Detection of follicles with ultrasound can be difficult in obese animals when there is significant fat in the ovarian bursa. Even in thin females ovulation is quite difficult to detect because follicles do not collapse and because CL have central, fluid-filled cavities unoccupied by luteal tissue (Fig. 33.16). Regular (probably daily) examination is required to detect ovulation, and for this reason, ultrasound is not a technique that has found widespread clinical application.

Study of the Cervicovaginal Secretion

Variations in the electrical resistance of the vaginal secretion during the oestrous cycle have been described. In dogs, however,

VetBooks.ir

the technique appears to have limited value and, in the author's experience, is not clinically useful. It is, however, used commercially for the detection of the insemination time of the fox (Fougner 1989).

Van der Holst and Best (1976) suggested that the amount of glucose within the vaginal discharge was a useful indicator of the optimum time of breeding. The principle of this technique is related to a change in the pH of vaginal secretion because glucose is liberated from carboglutelin, which is then converted into lactic acid (Vogel & van der Holst 1973). Although initial results were promising, this technique has not found clinical acceptance, presumably because of individual bitch variations.

Crystallisation of mucus collected from the anterior vagina has been described in the bitch (Fig. 33.17), occurring after the peak in plasma oestrogen concentrations (England & Allen 1989). Assessment of the mucus may be useful when combined with vaginal cytology for determining the optimal mating time.

Vulvar Softening

During prooestrus, the vulva becomes enlarged and turgid. There is often a distinct softening and decrease in swelling after the decline in plasma oestrogen, which occurs at approximately the day of the preovulatory LH surge. This method is imprecise but is probably the single clinical event that has proved to be useful for assessing the optimal mating time.

Cat

Structural Abnormalities of the Queen's Reproductive Tract

Congenital Abnormalities

The range of congenital abnormalities of the reproductive tract of the queen is similar to that of the bitch. Ovarian agenesis is rare and results in permanent anoestrus and infertility. Small ovarian remnants containing fibrous tissue may be identified at laparotomy or laparoscopy. Similar to the bitch, the establishment of a karyotype may be useful in the investigation of these cases.

Ovarian hypoplasia is also rare in the queen, although phenotypically normal queens may have nonfunctional ovaries secondary to chromosomal abnormalities.

There are a small number of reports of aplasia of the tubular genital tract and unilateral and/or bilateral agenesis of the uterine tube and uterine horn. It is not uncommon for these lesions to be associated with absence of the ipsilateral kidney and ureter. The queen may be fertile when the abnormality is unilateral, although litter size is often reduced. In many cases, these lesions are only diagnosed at exploratory laparotomy.

Vaginal aplasia may result in the retention of uterine fluid and cause endometrial changes and infertility. The uterus may be so large that it can be detected by palpation; otherwise, ultrasonography will demonstrate a tubular fluid-filled uterus present within the caudal abdomen. In rare cases, simple vaginal bands or strictures may be identified and can be manually broken down, allowing normal coitus.

Disease of the caudal reproductive tract is rare. Vulvar and vaginal atresia may occur separately or simultaneously. Small labia**,** with or without stenosis of the vestibule, are observed in the former, whereas stenosis of the vagina is observed in the latter.

Intersex

Female cats with ambiguous genitalia may be seen in clinical practice. In many cases, the external genitalia are underdeveloped until puberty, when the animal may demonstrate male-like behaviour. Clitoral enlargement has not been reported. An exact diagnosis may not always be reached; however, removal of the reproductive tract, including gonads, is necessary in most cases. Animals may be classified as having abnormalities of chromosomal, gonadal, or phenotypic sex; a full description of this is described earlier in the chapter for the bitch.

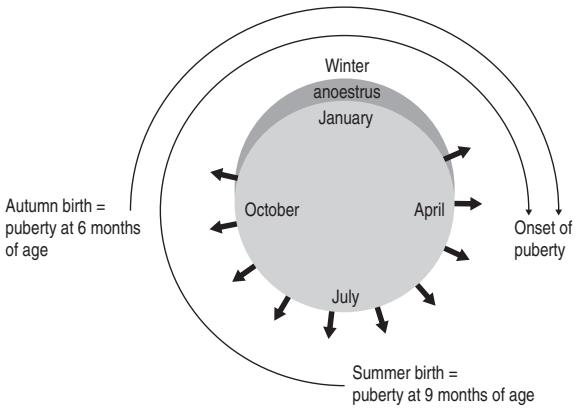
Acquired Abnormalities

Acquired abnormalities of the reproductive tract of the queen are rare. Occasionally, ovariobursal adhesions of unknown aetiology are identified, but these are usually unilateral and cause reduced fertility rather than infertility. The most common acquired abnormality is pyometra (see later in this chapter), although hydrometra has also been reported.

Neoplasia

Ovarian tumours are uncommon in the queen. They generally reach a large size before diagnosis and are not frequently metastatic, often being granulosa–theca cell tumours. These may be endocrinologically active and result in clinical signs of persistent oestrus, cystic endometrial hyperplasia, and bilaterally symmetrical alopecia, depending on whether they produce oestrogen or progesterone, respectively. The treatment of choice is ovariectomy. Malignant

VetBooks.ir



• **Fig. 33.18** Schematic representation of seasonal polyoestrous cyclicity in the queen *(large arrows represent oestrus)*, which show the variation of age at puberty depending on time of birth.

endometrial adenocarcinoma is the most common uterine neoplasm, although benign tumours have also been reported. These tumours may be associated with a persistent haemorrhagic vulvar discharge and straining. In all cases, ovariohysterectomy is curative, provided that metastases have not developed. Tumours of the vagina include pedunculated leiomyomata and fibromata. These are rare and generally produce clinical signs of vaginitis and straining to defecate because they may impinge upon the colon and rectum. Local excision is usually curative, and ovariohysterectomy may reduce the risk of recurrence.

Functional Abnormalities of the Queen's Reproductive Tract

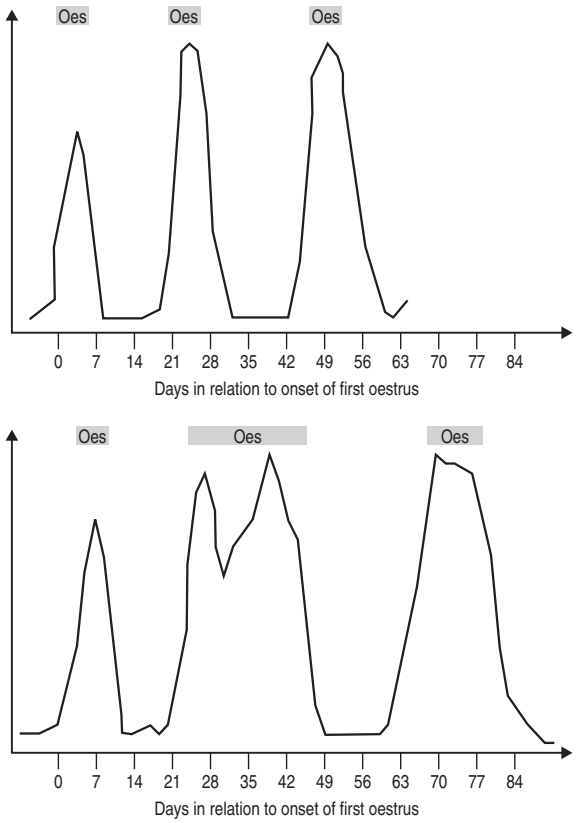
Delayed Puberty and Prolonged Anoestrus

The onset of puberty in the queen is influenced by both body weight and the season of birth because, normally, the queen is a seasonally polyoestrous breeder. In most cases, puberty occurs in the spring; as a consequence those animals born in autumn may exhibit their first oestrus at 6 months of age, and those born in the summer reach puberty at 9 months of age (Fig. 33.18). However, queens born in winter or spring may not exhibit puberty until 12 months of age (Goodrowe et al. 1989).

Queens that do not reach puberty by their second spring are considered to have delayed puberty. In the northern hemisphere, queens generally commence oestrous behaviour in January or February, an event that is dependent on photoperiod. Prolonged anoestrus may be associated with systemic disease, poor nutrition, or a high parasite burden. If these factors are eliminated, 14 hours of daylight should abolish anoestrus in the healthy normal queen. Attention should also be given to whether progestogens have been used for the control of dermatological or behavioural problems because their use will prevent oestrus.

Induction of Oestrus

When it is necessary to breed the anoestrous queen, it may be possible to induce cyclicity provided that there is no underlying disease by ensuring an appropriate day length (14 hours of light per day). When this fails, induction of oestrus can be attempted by the use of a depot GnRH preparation (deslorelin), followed by hCG (which is LH-like in activity) given when there is maximum cornification of vaginal epithelial cells; this is done for the purpose of ensuring ovulation (Zambelli et al. 2015).



• **Fig. 33.19** Plasma oestrogen in normal cycling queen *(top)* and queen with prolonged oestrus *(bottom)*; the period of standing oestrus (Oes) in these unmated queens is shown by the grey bar.

Silent Oestrus

Cases of silent oestrus are usually identified in queens that are low in the hierarchy of a cat colony. The incidence of silent oestrus is unknown, and the diagnosis is made because of the absence of behavioural oestrus when endocrinological events are normal. Cases are best evaluated by the study of vaginal cytology to demonstrate oestrus (see later), or removal of the queen to a new environment, or the induction of oestrus. Occasionally, the condition occurs in queens that are lactating, although more commonly cats are anoestrus at this time.

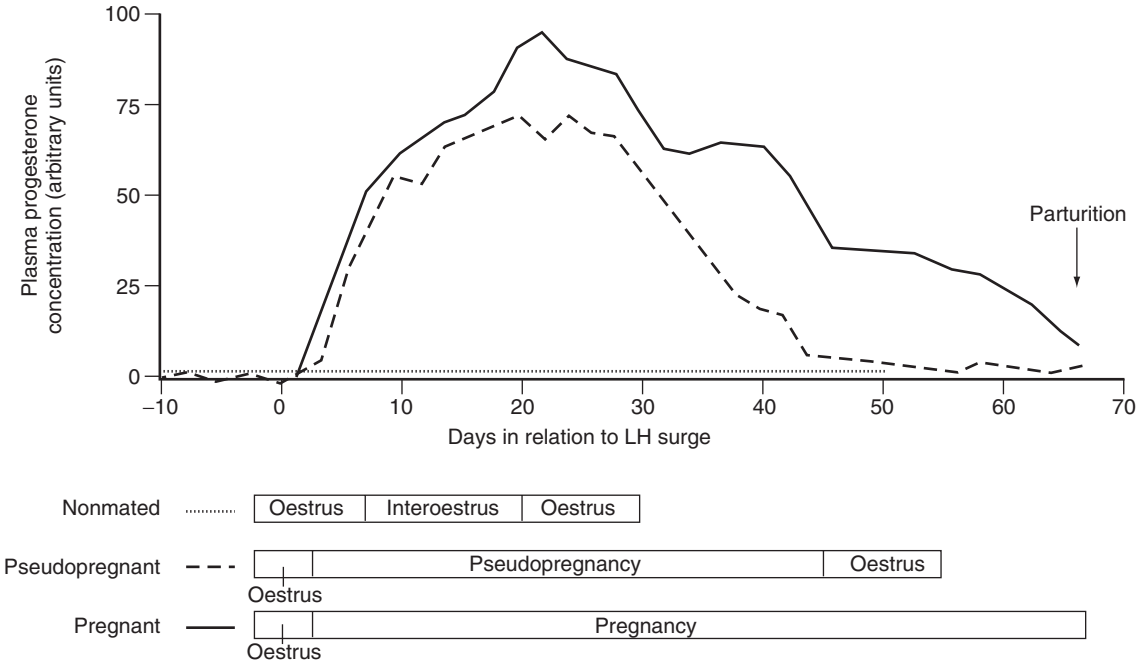
Prolonged Oestrus

Some queens appear to have a behavioural oestrus that persists for the duration of up to two follicular cycles (Fig. 33.19). In these cases, oestrogen concentrations remain high, presumably the result of overlapping follicular waves in the absence of ovulation. The condition is more common in oriental-type breeds. The fertility of these cycles is uncertain, although it is likely that fertility may be reduced because of inappropriate mating time and resultant failure of ovulation. In most cases, treatment is not warranted because prolonged oestrus is generally a sporadic occurrence.

Ovulatory Failure

Cats are induced ovulators, with oocytes being fertilisable at ovulation after mating or artificial stimulation of the genitalia. Copulation produces a rapid pituitary-mediated release of LH, and multiple

VetBooks.ir



• **Fig. 33.20** Schematic representation of the changes in peripheral plasma progesterone concentrations in the nonmated, pseudopregnant, and pregnant queen. The hormone profiles are plotted in relation to the time of the LH surge for the mated animals and the onset of oestrus in the unmated animals.

copulations usually are required to ensure that ovulation occurs. Failure of ovulation may occur if the queen is not mated a sufficient number of times. However, approximately 90% of queens ovulate if mated three times at 4-hour intervals within the first 3 days of oestrus (Schmidt 1986). There is a reduced magnitude of LH release after matings that occur later into oestrus. Therefore breeding on the first few days of oestrous behaviour ensures the greatest success. Ovulatory failure may be diagnosed by a return to oestrus after 3 weeks (cats that ovulate but fail to become pregnant enter pseudopregnancy and have a delayed return to oestrus) and by measurement of plasma progesterone concentrations that remain basal after cessation of behavioural oestrus. Ovulation may be facilitated by ensuring that sufficient matings occur at the beginning of oestrus or by the administration of a single dose of hCG (500 IU) on the first day of oestrus; the hCG mimics the mating-induced LH surge.

Pseudopregnancy

Although, in the bitch, pseudopregnancy is not a cause of infertility, in the queen, pseudopregnancy does cause a delay to the return to oestrus. Nonfertile matings or occasional spontaneous ovulations (Lawler et al. 1993) result in the formation of CL, which secrete progesterone. During the life span of the CL, the queen does not demonstrate oestrous activity, resulting in interoestrous intervals of between 35 and 70 days, with an average of 45 days. Diagnosis of the condition is based upon the demonstration of elevated concentrations of plasma progesterone (Fig. 33.20). Late in the breeding season, pseudopregnancy may be followed by anoestrus rather than a return to oestrus.

Ovarian Cysts

In the queen, cystic structures can be associated with the ovaries. However, the majority of these are not of ovarian origin, being remnants of mesonephric and rete tubules. These cysts are endocrinologically inactive and do not produce clinical signs. True follicular cysts, associated with hyperoestrogenism, have been reported and may be associated with prolonged oestrus. Diagnosis may be made on the basis of clinical signs, on measurement of plasma oestrogen concentrations, or by the demonstration of persistent cornification of vaginal epithelial cells. hCG may be administered in an attempt to induce ovulation; however, in most cases, either ovariectomy or the use of progestogens to suppress the clinical signs is necessary.

Premature Ovarian Failure

Premature ovarian failure has been suggested as a cause of permanent anoestrus in previously fertile queens, which results in a shortening of their reproductive life. The condition is difficult to confirm, and diagnosis relies upon elimination of other causes of anoestrus. In valuable breeding animals, oestrus-induction regimes may be contemplated; however, there is no information on the efficacy of these treatments.

Habitual Abortion

There is little nonanecdotal evidence to show that habitual abortion occurs in the queen; however, the condition is occasionally diagnosed and treated. In many cases, it is suggested that habitual abortion is the result of progesterone deficiency, although evidence for this is lacking. As in the bitch, the minimum plasma concentration of progesterone required to maintain pregnancy is approximately 1 to 2 ng/mL, with ovarian-derived progesterone being the major source throughout pregnancy (Verstegen et al. 1993). The administration of progesterone or progestogens has been advocated to prevent habitual abortion; however, this therapy is empirical and suffers the risk of prolonging gestation and producing masculinised female kittens and cryptorchid male kittens.

VetBooks.ir

Progestogen administration should be limited to those cases in which a true luteal insufficiency has been diagnosed.

Infectious Agents Affecting the Queen's Reproductive Tract

There are no reported venereal-transmitted bacterial infections or specific genital infections that are recognised as causes of infertility in cats. However, there are several opportunistic pathogens and specific infectious agents that may have a direct effect upon fertility.

Opportunistic Pathogens

Many aerobic and anaerobic bacteria normally inhabit the vestibule and vagina of queens. It has been suggested that they may enter the uterus at mating and subsequently cause abortion because the progesterone-dominant uterine environment allows them to proliferate. It is not clear, however, whether bacteria isolated from aborted fetuses have caused the abortion or whether they have invaded the uterus after dilatation of the cervix at the time of the abortion. Bacteria commonly isolated include *E. coli,* staphylococci, streptococci, salmonellae, and mycobacteria. Immediately before an abortion, the queen may become pyrexic and lethargic. Treatment includes the administration of broad spectrum antimicrobial agents, fluid therapy, and drugs to stimulate uterine evacuation. Hysterotomy to remove fetal tissue is rarely necessary, although ovariohysterectomy may be required should a severe metritis develop.

Specific Infection

Feline Leukaemia Virus

Feline leukaemia virus (FeLV) has been implicated in a variety of clinical syndromes including infertility, embryonic resorption, and abortion. FeLV is believed to be the single most common cause of infertility in the queen (Jarrett 1985). Fetal resorption is seen frequently, although abortion and the birth of permanently infected kittens also occur. The aetiology of the reproductive disease is uncertain and, although it is known that the virus may cross the placenta, one possibility is that secondary bacterial infections occur because of FeLV-induced immunosuppression (Jarrett 1985). Diagnosis of FeLV infection may be achieved by virus isolation, immunofluorescence, or an ELISA method. Owners should be discouraged from breeding from FeLV-positive queens because all offspring are born persistently infected. These kittens usually develop a FeLV-related disease soon after birth. Vaccines are now available that provide protection against FeLV and its related diseases.

Feline Herpesvirus

Feline herpesvirus I may result in abortion during the fifth or sixth week of gestation. Lesions may be found within the uterus; however, placental lesions have only been demonstrated after experimental infection. Classically, the organism causes feline viral rhinotracheitis, and in the naturally occurring disease, abortions are thought to be the result of a nonspecific reaction to the infection. Transmission of the virus occurs via the respiratory tract, with up to 80% of cats remaining as chronic carriers. The diagnosis of herpesvirus infection is based upon the clinical signs and the isolation of the virus. Vaccination of queens provides good immunity and should be recommended for all breeding animals; however, vaccination does not prevent development of the carrier state, in which stress may result in a return of viral shedding.

Feline Panleukopenia Virus

Feline panleukopenia virus is transmitted by direct contact with saliva, faeces, and urine. Infection of pregnant queens may result in abortion, stillbirths, neonatal deaths, and fetal cerebellar hypoplasia. These effects are the result of transplacental infection, leading to fetal death and resorption in early pregnancy, and cerebellar hypoplasia**,** when infection occurs from the middle third of pregnancy onwards. Diagnosis may be made on the basis of the clinical signs, histopathological findings, virus isolation, and paired serum samples that demonstrate a rising antibody titre. There is no treatment for kittens with cerebellar hypoplasia.

Feline Infectious Peritonitis Virus

Feline infectious peritonitis virus has been implicated as a cause of infertility, stillbirths, endometritis, resorption and abortion, chronic upper respiratory tract disease, and fading kitten syndrome. Queens are not always ill and may suffer resorption, which is unnoticed. Abortion generally occurs during the last 2 weeks of pregnancy. Diagnosis is made by serological and pathological investigation.

Toxoplasma Gondii

Toxoplasma gondii infection has been incriminated as a rare cause of abortion and congenital infection of cats. It is thought that pregnancy loss is caused by systemic illness in the dam rather than induction of uterine or fetal lesions. Transplacental infection, or transmission by suckling, presumably explains how *T. gondii* cysts have been identified in very young animals before the likely time for establishing cysts via ingestion of the organism after birth. Serological screening is necessary to demonstrate the role of this protozoon in cases of abortion. Raw or undercooked meat should not be fed to seronegative pregnant queens.

Chlamydophila Felis

There is limited evidence that *Chlamydophila felis* causes abortion in the queen. The mode of transmission has not been elucidated, although the organism has been isolated from the genital tract of infected cats, and there is circumstantial evidence associating infection with reproductive disease. As well as direct isolation of the organism, diagnosis is possible by demonstrating high antibody titres. It is difficult to confirm whether the isolation of this organism indicates its role in an abortion because it may simply be an opportunistic bacterium. Vaccination is highly protective and, in most cases, results in maternally derived antibodies that persist until approximately 2 months of age.

Cystic Endometrial Hyperplasia and Pyometra

Aetiology

Both naturally occurring and experimentally induced cystic endometrial hyperplasia and pyometra have been described in the queen. The syndrome is more common in older animals and is uncommon during winter when queens are generally acyclic. In naturally occurring cases, CL are present within the ovaries, suggesting that progesterone is involved in the pathogenesis in a similar manner to the bitch. Interestingly, approximately half of the cases are seen in unmated queens, in which there should be no luteal phase. This may be explained by the observation of Lawler et al (1993),

VetBooks.ir

which showed that 35% of queens ovulated spontaneously without copulation or mechanical stimulation of the cervix.

The bacteria isolated from cases of pyometra are similar to those found in the bitch, frequently being opportunistic organisms that are normal inhabitants of the genital tract of cats, including *E. coli.* Culture of vaginal swabs is therefore of limited value.

Clinical Signs and Diagnostic Features

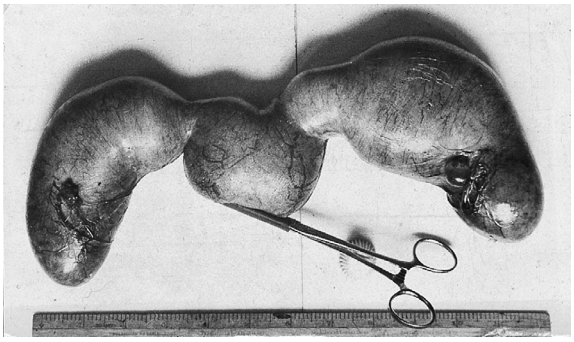
The severity and clinical signs of the cystic endometrial hyperplasia/pyometra complex vary considerably. In early cases, there may simply be mild endometrial hyperplasia with glandular dilatation. This leads to a hostile uterine environment, which may lead to fetal resorption. Queens with endometrial hyperplasia are often clinically normal, although occasionally the uterus may be enlarged and can be palpated. Ultrasound examination of these cases can reveal the presence of anechoic regions within the uterine mucosa, representing cystic glandular tissue; occasionally, free uterine fluid may be detected.

Cases of pyometra are not often difficult to diagnose because many queens have a malodorous vulvar discharge, although some queens may be particularly fastidious and regularly clean their perineum. Often, oestrus will have been observed within 2 months of the onset of the discharge. The range of diagnostic methods described in the bitch may be helpful to confirm the diagnosis. The use of real-time diagnostic ultrasound provides the most accurate method, although radiography, haematology, and clinical examination are also rewarding. Care must be exercised in palpating the abdomen because of the risk of causing rupture of the uterus.

Treatment

As in the bitch, ovariohysterectomy is the treatment of choice for pyometra. Attention should always be paid to the electrolyte and acid–base status of the animal before surgery; intravenous fluid therapy is always warranted. The complete reproductive tract from a queen with pyometra after ovariohysterectomy is shown in Fig. 33.21.

Medical therapy may be useful and has been shown to have a good success rates using either cabergoline (a prolactin inhibitor), prostaglandins, or aglepristone (a progesterone receptor antagonist) or combinations of these preparations (Hollinshead & Krekeler 2016); these are used together with appropriate fluid and antimicrobial therapy.



• **Fig. 33.21** Reproductive tract of a queen with pyometra.

Management Factors Affecting Fertility of the Queen

In the queen, modern breeding protocols may hamper reproductive performance because of a misunderstanding of the normal reproductive physiology.

Ovulation is induced by an adequate surge of plasma LH released after coitus. In one study, single copulations induced an LH surge sufficient to cause ovulations in only 50% of queens (Concannon et al. 1980). When 4 to 12 unrestricted matings were allowed in a 4-hour period, the mean concentrations of LH were three to six times higher than for single matings, and all queens ovulated (Concannon et al. 1980). Matings at limited, predetermined intervals on single or sequential days of oestrus can result in LH release of variable incidence, magnitude, and duration. It can be seen, therefore, that restricted mating regimens, which are common breeding practice, may result in failure of ovulation in a high proportion of queens. Multiple matings should result in ovulation, although Glover et al (1985) suggested that repeated matings very early in oestrus may not result in adequate LH release, whereas similar matings in midoestrus are likely to be successful at inducing ovulation. Therefore it is important that not only multiple matings but also normal courtship be allowed to ensure that matings occur throughout oestrus and not simply at the time the breeder considers to be correct.

It is difficult to identify accurately the stages of prooestrus or oestrus in the queen; however, unlike in the bitch, the behavioural events are more repeatable. During the 1 to 2 days of prooestrus, the queen refuses copulation but is more active and may show interest in the male; this period can only truly be identified in the presence of a male. Oestrus may last between 3 and 20 days, with an average of 8 days. During this time the queen displays a crouching and lordotic stance, which facilitates mounting by the male. This response can be elicited by firmly grasping the queen by the skin on the back of the neck. Mating should be attempted commencing at midoestrus, 3 to 4 days after the initial signs of prooestrus.

Vulvar swelling during oestrus does not occur; therefore clinical assessments of the queen are of little value for determining the optimum breeding time. A small amount of white vulvar discharge may occasionally be noticed during oestrus. The examination of exfoliative vaginal cytology is useful in the queen for determining the stage of the cycle; however, the technique does not enable the prediction of the onset of oestrus because up to one-third of queens may show signs of oestrus before the vaginal smear contains evidence of cornified cells. The technique is therefore most useful for verifying oestrus. The smear may be collected either using a moistened cotton swab or by irrigation with an eyedropper containing sterile saline. Staining of the epithelial cells can be achieved using a variety of stains, including a modified Wright–Giemsa stain. Erythrocytes are not found within the vaginal smear because uterine diapedesis is not a feature of oestrus in the queen. The changes in the vaginal smear are therefore limited to changes in morphology of epithelial cells because polymorphonuclear leucocytes are also usually absent except during early metoestrus and pregnancy. The percentage of epithelial cells that are cornified in appearance changes in a similar manner to that seen in the bitch. During oestrus, more than 80% of cells are cornified, although many remain nucleated, unlike the situation in the bitch. If the queen does not ovulate, the exfoliative cells return to a state similar to that observed during anoestrus or early prooestrus. Early metoestrus is characterised by

VetBooks.ir

increasing numbers of parabasal and small intermediate epithelial cells, although debris, mucus, and polymorphonuclear leucocytes also become evident.

Care should always be taken when collecting vaginal epithelial cells because the technique may induce ovulation.

Pharmacological Control of Reproduction in the Dog and Cat

GARY C. W. ENGLAND

Knowledge of reproductive function and disease in dogs and cats has increased over recent years. The wider availability of pharmacological preparations has improved management of reproduction in both females and males (see Chapter 8).

This chapter details common methods of prevention of breeding, describes the use of pharmacological preparations for the management and treatment of common reproductive diseases, and outlines methods for the testing of reproductive function. The reader is directed to other texts that describe adverse effects of exogenous drugs by pharmacological category (England 1998a, Verstegen 1998).

Female

Prevention of Breeding

Prevention of Oestrus

Until recently, the most common method for control of breeding has been the administration of progestogens to bitches or queens when in anoestrus. This appears to alter gonadotrophin secretion and therefore prevents a return to cyclical activity (Beijerink et al. 2008). Progestogens are given either orally daily at low doses for up to 2 years or are depot preparations given by subcutaneous administration that may be repeated at 4 to 6 monthly intervals. Generally, most females will cycle normally when therapy stops, although the return to oestrus is not immediate after withdrawal of the progestogen; at least in the bitch, it appears that there is a period of inactivity similar to that which occurs physiologically, namely anoestrus, after a normal luteal phase. Progestogens are not recommended in breeding animals because of a potential effect on fertility, probably mediated by uterine changes (progestogens may induce cystic endometrial hyperplasia and pyometra). A similar effect of prevention of oestrus can be achieved by the administration of androgens (e.g., depot or daily testosterone esters), but such use is not widespread.

More recently, a long acting gonadotrophin releasing hormone (GnRH) agonist implant, deslorelin, has been used to prevent oestrus in both bitches and queens (see Lucas 2014). Insertion of the implant produces an initial release of FSH and LH which is commonly associated with signs of oestrus and can be fertile (in fact removal of the implant at this time can be used as a method for oestrous induction; see later), but there is then receptor downregulation and induction of sexual inactivity. The duration of effect relates to the dose of drug present in the implant but can be 12 months or greater. Fertility after the return to cyclical activity is good.

Although not available in all countries, there has been recent interest in the GnRH antagonist acycline (see Gobello 2012). This drug causes a decrease in FSH and LH concentrations and appears promising for future development to prevent oestrus in dogs and cats.

Queens are seasonal, long day breeders, in which hypothalamic function is downregulated by melatonin produced when days are short. Melatonin implants are commercially available for stimulation of hypothalamic function in ewes (which are short day breeders in which melatonin stimulates a return to oestrus), and administration of these melatonin implants to anoestrus cats will prevent the return to oestrus potentially for several months (Faya et al. 2011). They may also be useful within the breeding season, although the duration of effect is shorter.

Suppression of Oestrus

When prooestrus or oestrus has already begun, it is possible to inhibit the progression of the cycle by administration of progestogens similar to when used for prevention of oestrus, although higher doses are commonly used. Anecdotally, there is greater risk of inducing pyometra with this regime because progestogens are given to the oestrogen-primed tract. For this reason, some progestogens that are more potent stimulants of endometrial development are not licensed for suppression of oestrus (e.g., medroxyprogesterone acetate). Androgens tend not to be efficacious for suppression of oestrus that has already begun. Although the gonadotrophin releasing hormone agonist deslorelin is efficacious, the downregulation takes some time, and it is possible that the bitch may be mated and become pregnant at that oestrus. (In effect, the drug does not cause suppression of oestrus, but as long as the bitch is not mated, the treatment can be administered during oestrus and will prevent the return to a subsequent oestrus.)

Treatment of Unwanted Mating

Historically, the most common method for treatment of an unwanted mating in the bitch was the administration of oestrogens during a short window after mating, whereas in the queen, a similar regime using a high dose, short-acting progestogen was recommended. These regimes appear to interfere with the functioning of the uterine tube and are relatively efficacious at creating

VetBooks.ir

a hostile environment that prevented the establishment of pregnancy. Both regimes, however, risked induction of pyometra (see Chapter 33). More recently, a progesterone receptor antagonist, aglepristone, has become available, which has a mean residence time of approximately 6 days, when given at two doses 24 hours apart (see Gogny & Fieni 2016). Aglepristone can be used around the time of mating (including from shortly before ovulation) to prevent the establishment of pregnancy. This preparation can also be used at any time after ovulation to induce embryonic resorption or fetal abortion (see next section).

Termination of Pregnancy

As noted previously, progesterone-receptor antagonists such as aglepristone can be administered in the first one-third of pregnancy to induce embryonic resorption. If used early, there may be no signs of the resorption, although a coloured vulvar discharge is more common the later in pregnancy that treatment commences. In mid- and later pregnancy, the outcome of termination is abortion. The efficacy of pregnancy termination appears to be reduced when aglepristone is used alone in later pregnancy, and a more successful outcome occurs if treatment also includes prostaglandin (which causes uterine contraction and aids in expulsion of the fetal material). Prostaglandins may be used alone for this purpose as long as treatment commences more than 25 days after ovulation (the early corpora lutea (CL) do not respond well to exogenous prostaglandin and require higher doses than are required later in the luteal phase), and treatment is given daily over at least 5 days. When administered in this manner, prostaglandins cause lysis of the CL, progesterone concentrations decline, and the pregnancy is lost. Disruption of the pregnancy and expulsion is aided by the spasmogenic action of prostaglandin.

Prolactin inhibitors such as cabergoline can be used to end the luteal phase and terminate pregnancy because prolactin is the most significant luteotrophic factor in the bitch and pregnant queen (Onclin et al. 1993). Administration of daily cabergoline from day 25 after ovulation onwards results in loss of luteotrophic support for the CL, and so progesterone concentrations decline, and the pregnancy is lost. Early administration results in resorption and later administration abortion. In practice, prolactin inhibitors are normally given in a combination regime with prostaglandins because this improves efficacy as the prostaglandin acts to lyse the CL and cause uterine contractions that help disrupt the pregnancy.

Managing Reproduction

Induction of Oestrus

As a seasonal breeder, most queens will return to cyclical activity if they are exposed to more than 14 hours of light per day.

In the bitch and queen with primary anoestrus (delayed puberty) or secondary anoestrus (failure to return to cyclical activity), it is possible to induce a fertile oestrus by administration of the GnRH agonist deslorelin (Kutzler et al. 2009). The initial response to inserting a deslorelin implant is the release of FSH and LH, which causes follicle growth and results in a return to oestrus. At this point the implant needs to be removed to prevent later receptor downregulation. Fertility with deslorelin-induced cycles appears good.

More complex regimes using exogenous equine chorionic gonadotrophin (eCG, which is FSH-like in activity) and human chorionic gonadotrophin (hCG, which is LH-like in activity) are not particularly efficacious and risk causing overstimulation and ovarian disease.

Prostaglandins are not efficacious for the induction of oestrus in the bitch because. although if administered during the luteal phase, they cause lysis of the CL, and the bitch then enters anoestrus. Interestingly, through an uncertain mechanism, the administration of prolactin inhibitors (e.g., cabergoline) can be used to induce oestrus in the bitch (Spattini et al. 2007). Clearly, as a prolactin inhibitor, cabergoline would shorten the luteal phase if given at this stage of the cycle, but continued administration also shortens the subsequent period of anoestrus. If treatment commences in anoestrus, then oestrus may return relatively quickly (between 2 and 6 weeks of daily treatment), and pregnancy rates are high (greater than 80%), whereas longer treatment is required and pregnancy rates are lower (approximately 60%) if treatment commences when the bitch is in the luteal phase. Prolactin inhibitors are not efficacious for induction of oestrus in the queen.

Stimulation of Ovulation

Stimulation of ovulation may be attempted in several clinical situations: (1) in the bitch in attempt to bring forward the day on which ovulation is going to occur (hastening ovulation which may be required to assist with an artificial insemination regime, for example); (2) in the bitch if oestrus has been prolonged because ovulation has not occurred; (3) in the queen when there is an inadequate mating regime such that ovulation is not stimulated by mating; (4) in the queen as part of a regime to test whether there has been incomplete ovariectomy, and there is retained ovarian tissue; and (5) very rarely in either species when follicle cysts have been identified.

What is clear is that in all circumstances to stimulate ovulation, there must be follicles present that are in a physiological state that will allow them to ovulate. (It is not possible to stimulate ovulation in an anoestrus female; first oestrus must be induced.)

A simple method for the stimulation of ovulation is the administration of hCG, which is LH-like in activity. Single or daily administration of hCG may be required based upon the clinical circumstances. A similar effect can be achieved in both species by the administration of short-acting GnRH agonists – for example, buserelin – that results in the endogenous release of LH and FSH.

Stimulation of Milk Production

Bitches and queens occasionally have inadequate milk production, usually seen in primigravida, or associated with a Caesarean operation performed before term, or, occasionally, in bitches with poor body condition or concurrent disease.

In these cases, there will be poor development of the mammary glands, and this clinical feature can be used to differentiate the condition from failure of milk let down (see next section). In both species the repeated twice daily administration of metoclopramide can be useful to increase prolactin concentrations and thus stimulate milk production. A clinical effect can be seen within approximately 4 days. Neonates should be encouraged to suck during this period, but, of course, they will need supplementary feeding.

Stimulation of Milk Let Down

Cases of inadequate milk let down are occasionally seen in nervous primigravida and may be associated with inadequate oxytocin production. Usually, the female has mammary gland development, but attempts to express milk fail. In these cases, treatment with a single low dose of oxytocin is usually effective in allowing milk to be released almost immediately.

VetBooks.ir

Treatment of Reproductive Disease

Several aspects of reproductive disease are detailed within the previous section on managing reproduction, including cases of failure to cycle and prolonged oestrus. In this section of the chapter, consideration is given to the treatment of other reproductive disease; the headings are presented in chronological order (relating to the luteal phase, pregnancy, and postpartum).

Treatment of Pseudopregnancy

In the bitch, pseudopregnancy is common and normal in all non-pregnant females. In many cases the clinical signs are minor and are overlooked by the owner, whereas in some, they are significant and serious, particularly if they result in aggressive behaviour or mastitis. Pseudopregnancy is caused by the normal increase in plasma prolactin concentrations that commence approximately 3 weeks after ovulation. Not all cases of pseudopregnancy require treatment, but in those that do, administration of progestogens causes a rapid decline in prolactin concentrations. Although a variety of progestogen regimes are efficacious and have been widely used, there are adverse effects of the progestogens at this stage of the cycle, including the risk of pyometra. It is imperative that bitches are confirmed to be pseudopregnant before treatment with progestogens. If they are pregnant (owners may be unaware of this), progestogen treatment can delay or prevent parturition, resulting in significant illness in bitches (England 1998b).

The daily administration of the prolactin inhibitor cabergoline has been used for the treatment of pseudopregnancy (Harvey et al. 1999). Shortly after commencement of treatment, prolactin concentrations decline, and both milk production and behavioural changes are reduced. Treatment for 4 to 6 days is efficacious in nearly all cases; those that have not fully resolved usually require extension of the treatment period to a total of 7 to 10 days. Inadvertent treatment of a pregnant bitch with cabergoline will result in pregnancy termination.

Cabergoline is also effective for the treatment of chronic pseudopregnancy (commonly seen as an iatrogenic problem caused by surgical neutering, by ovariectomy, during the luteal phase); here, an extended treatment period of 3 weeks using a dose-reducing regime is usually warranted.

Treatment of Pyometra

Pyometra in the bitch and queen is a condition of the luteal phase and will have been initiated when progesterone concentrations are elevated. Progesterone drives the clinical condition by closing the cervix, increasing uterine secretions, and reducing uterine contractions. The mainstay of treatment has always been surgical removal of the uterus and ovaries, and this still remains the case because recurrence after medical treatment is not uncommon.

The principle aim of medical treatment is to remove the stimulatory effect of progesterone. Prostaglandins can be extremely effective for the medical treatment of pyometra, in which repeated low dose therapy will cause lysis of the CL, resulting in cessation of progesterone secretion. In addition, prostaglandins have a uterine spasmogenic effect, and this can aid in the expulsion of uterine pus. However, stimulating uterine contractions can be dangerous if the cervix is not open (so called 'closed cervix pyometra'), as this may cause uterine rupture. The prolactin inhibitor cabergoline is also useful in the medical treatment of pyometra because it removes the support for the CL, and, as a result, progesterone concentrations decline. Prolactin inhibitors have no direct uterine spasmogenic action; therefore a common clinical regime is their combined use with a prostaglandin (England et al. 2007). The prolactin inhibitor is normally given for several days before the administration of prostaglandin; as a consequence, progesterone concentrations will have already declined, and the cervix will have opened before the prostaglandin is given.

Attempts to treat pyometra have also been made using progesterone receptor antagonists such as aglepristone (Contri et al. 2015). These drugs block the action of progesterone but are probably best used in a regime with prostaglandin to encourage evacuation of uterine contents.

A small case series recently documented the potential for treatment of pyometra using the GnRH antagonist acycline, which appeared to be principally mediated by its action blocking progesterone secretion (Gobello 2012).

Habitual Abortion

There is debate about whether low progesterone production from the CL, in the presence of an otherwise normal pregnancy, is a true clinical syndrome in the dog or cat. Most cases of pregnancy loss appear to be associated with an abnormal uterine environment, abnormal pregnancy, or due to infectious disease. It is true that females that have recently suffered resorption or abortion will have low plasma progesterone concentrations; however, this is likely to be a result of the pregnancy loss rather than the cause of the pregnancy loss. It is only in the German shepherd dog and related breeds that a syndrome of ovulation failure or short luteal phase has been documented (Gunzel-Apel et al. 2006). Females with this problem appear to suffer from a recurrence at subsequent pregnancies; so once the problem has been documented, it is possible to try to encourage ovulation with exogenous hCG (as described previously) or to consider supplementation with exogenous progesterone or progestogens after ovulation. In the latter situation, although maintenance of the pregnancy is possible, care should be taken to ensure the lowest possible dose of progestogen is used because this commonly causes reproductive tract abnormalities in the developing fetuses.

Treatment of Uterine Inertia

Primary uterine inertia is the most common cause of dystocia in the bitch and queen. Predisposing factors appear to be a large or a small litter size, or a dam that is obese, or debilitated by age or concurrent disease. In many cases, it is feasible to stimulate uterine contractions by the administration of exogenous oxytocin; however, care should be taken before implementing this treatment especially if the litter size is small (because fetuses may be large, and obstructive dystocia may result) or if the litter size is large (because multiple doses of oxytocin are often required, resulting in a prolonged parturition). Furthermore, attention must be paid to the dose of oxytocin administered; commonly, dose rates used are too high and result in a prolonged tetanic uterine contraction rather than coordinated expulsive contractions. In most cases, a dose of 0.04 IU/kg is appropriate, given every 30 minutes for three doses. Note that oxytocin administration will cause placental compression and worsen any fetal hypoxia, so may it be contraindicated if fetuses are bradycardic. Concurrent calcium administration will often help improve uterine contractions; a common regime is 1.0 mL/kg of a 2.5% calcium gluconate solution administered subcutaneously.

Retained Fetal Membranes

Retained fetal membranes are uncommon in both the postpartum bitch and queen but are often suspected because expulsion of a placenta does not always follow each fetus. Confirmation of retained

VetBooks.ir

fetal membranes can be made on ultrasound examination. In the immediate postpartum period, two or three doses of oxytocin at 0.04 IU/kg given every 30 minutes can induce expulsion; however, the number of uterine oxytocin receptors decreases quickly after parturition, and by 48 hours, there is minimal clinical response to exogenous oxytocin. Cases presented later than this time period are best managed as for metritis (see next section).

Postpartum Metritis

Metritis in the bitch and queen occurs when, after contamination of the uterus at parturition, bacteria invade uterine tissue usually at the sites of previous placental attachment. The condition is uncommon but is more likely after dystocia and placental retention. Metritis may occur rapidly in the postpartum period, but cases may not be presented for veterinary examination until 2 or 3 days postpartum; at this time, there is likely to be limited clinical response to oxytocin because of the decrease in the number of uterine oxytocin receptors. Because metritis occurs postpartum, plasma concentrations of progesterone are basal, and so progesterone receptor antagonists are ineffective. Low dose prostaglandins may, however, be useful for their uterine spasmogenic effects (rather than their luteolytic effects), which can aid expulsion of uterine fluid. Prostaglandins are metabolised quickly, and so treatment is required two or three times per day.

Testing Reproductive Function

Testing for Ovarian Tissue

Incomplete removal of ovarian tissue at the time of ovariohysterectomy for neutering is not uncommon in veterinary practice, and although in most cases it is clear that the animal has returned to oestrus, there are a number other conditions that may have similar presenting signs. These include: nonoestrous mounting behaviour, nonoestrous vulval discharge, sexual interest from males, and iatrogenic pseudopregnancy. For these reasons, it is not uncommon to consider the need for testing for the presence of ovarian tissue (England & White 2016).

In the bitch and queen, oestrous behaviour and the physical changes associated with oestrus may be sufficiently diagnostic. However, it is also relatively simple in the bitch to measure plasma progesterone in the 65 days after alleged oestrus. In the case of incomplete ovariectomy, progesterone concentrations will be elevated (> 2.0 ng/mL / 6.5 nmol/l), whereas values will be basal in the animal that has been completely ovariectomised. Because the queen is an induced ovulator, progesterone will not be elevated unless she has been induced to ovulate either as a result of mating, vaginal stimulation, or administration of hCG (see stimulation of ovulation previously discussed). Progesterone can be measured after either of these events as described in the bitch.

For the bitch and queen, measurement of basal oestrogen concentrations at the time of alleged oestrous behaviour is often not useful in the investigation of cases of presumed incomplete ovariectomy. It is, however, possible in both species to stimulate the release of oestrogen by the administration of hCG (which is LH-like in activity) or short-acting GnRH (e.g., buserelin, which stimulates an endogenous rise in LH) when the female is remote from a spontaneous oestrus. These stimulation tests are very effective in bitches that are in anoestrus or the luteal phase but are not effective when the bitch is in prooestrus or oestrus (when basal oestrogen is, or has just been, elevated). For either test, a blood sample is collected before drug administration (44 IU/kg hCG or 2.0 μg/kg GnRH intramuscularly) and repeated 2 hours later, when a two to three times increase in oestrogen concentration is diagnostic of incomplete ovariectomy.

It is also possible in the bitch and queen to measure plasma anti-Müllerian hormone, which is basal in animals with no ovaries because it is produced by granulosa cells. Both FSH and LH are elevated in animals with no ovaries, but measurement of these hormones is not feasible in clinical practice.

Male

Prevention of Breeding

Interestingly, several aspects of male behaviour are learnt and reinforced by repetition, and so although hormonal treatment may prevent a fertile mating, it may not always abolish breeding behaviour. Indeed even castrated males, particularly dogs, may continue to achieve erection and mate.

Contraception

There has always been interest in medical contraception in dogs and cats, commonly as a temporary method to prevent fertile breeding. Until recently, the most common methods have been administration of either depot progestogens or daily oral progestogen therapy (England 1997). Similar to the bitch, the use of these regimes in the male reduce FSH and LH concentrations, with a resultant inhibition of spermatogenesis and steroidogenesis. Semen quality and plasma testosterone concentrations decline quite rapidly and remain suppressed throughout the duration of treatment. It is not always the case that the male produces no fertile sperm, in which case contraception may not be complete. There are no studies on when there is a return to fertility or detail of any long-term effects. A similar reduction in FSH and LH can be achieved by administration of exogenous androgens or oestrogens, and either could be used as contraceptive agents; this is not practised, however, because the use of androgens would result in continued male behaviour, and oestrogens have significant potential adverse effects.

Recently the depot GnRH agonist implant deslorelin has been examined in clinical studies in both dogs and cats (Lucas 2014). Insertion of the implant causes an initial stimulation of FSH and LH release with few clinical manifestations of this (unlike the return to oestrus seen in the female), followed by receptor downregulation, and a rapid reduction of spermatogenesis and steroidogenesis. Testes decrease in size, semen quality deteriorates, and male behaviour is reduced. The duration of the effect is related to the length of action of the implant.

The GnRH antagonist acycline has been shown to impair spermatogenesis over a short period of time. This drug may offer an interesting opportunity as a contraceptive for the future.

Managing Reproduction

Unwanted or Antisocial Behaviour

Much normal behaviour demonstrated by entire male animals may be inconvenient or unwanted by the owner. The methods described previously for inducing contraception by impairing spermatogenesis and steroidogenesis may be useful therefore for controlling unwanted male behaviour (e.g., roaming, mounting, urine marking). Some of these behaviours may be learnt and can persist even after castration (for example, urine spraying in tomcats). In these instances, methods that reduce plasma testosterone alone are unlikely to have any beneficial effect because in the castrated

VetBooks.ir

male testosterone will be basal. The progestogens do, however, have additional effects in that they are also sedative, and they may therefore modify unwanted male behaviour that persists in castrated animals.

Poor Libido

In most cases, poor libido is associated with the experience of a male, the mating environment, his preference for particular females, and the dominance of the female. It is rare for there to be a pathological reduction of libido without testicular disease (i.e., the hypogondal male will have small testes, low testosterone production, and poor libido). Nevertheless, owners may request hormonal stimulation of libido. What is important is to recognise that, although a temporary increase in dominance and libido may be achieved by administration of androgens, their use will cause suppression of FSH and semen quality will significantly deteriorate. A short-term increase in plasma testosterone and, anecdotally, increased libido may occur after administration of hCG.

Treatment of Reproductive Disease

Prostatic Disease

Many cases of nonneoplastic prostatic disease are stimulated by androgens, such that exogenous hormone therapy, which reduces testicular androgen production, offers good short-term control of the problem. Permanent treatment can be achieved in many cases by castration, and this should be the first line of treatment that is contemplated.

In situations in which there is prostatic disease and the male is required as a breeding animal, it may be appropriate to consider medical management at least in the medium term (months). The most useful preparations are the 5α-reductase inhibitors (e.g., finasteride), which prevent the conversion of testosterone into the active dihydrotestosterone. After administration, both serum and prostatic dihydrotestosterone concentrations are significantly reduced and a significant portion of the action of testosterone blocked. There can be dramatic clinical improvements after use of finasteride, and, importantly, although ejaculate volume decreases, sperm morphology and motility are not affected, and fertility can be maintained (Iguer-Ouada & Verstegen 1997). Medium duration treatment may allow the animal to be used for breeding or for semen to be collected and preserved before, ultimately, castration is performed.

In other situations, medical management may be required in an attempt to avoid surgery, and if preservation of fertility is not important, a good clinical response can be achieved by the administration of daily oral or depot progestogens or by administration of depot GnRH agonist preparations such as deslorelin. In the latter situation, deslorelin acts as previously described in causing an initial increase in the release of LH and FSH (and thus a short-term increase in testosterone), which is followed by receptor downregulation that results in basal concentrations of testosterone.

Cryptorchidism

Treatment of cryptorchid boys, with either GnRH or hCG, has a success rate in approximately 20% of cases (Pyoral et al. 1995) when administered twice weekly for up to 4 weeks. In dogs and cats, there are no similar large scale studies demonstrating efficacy. In most cases, the condition is inherited as a sex-limited autosomal recessive trait; as such, animals are best removed from the breeding programme.

Testing Reproductive Function

Testing for Testicular Tissue

Anorchidism is very rare in dogs and cats, and most males that present with an absence of scrotal testes are either bilateral cryptorchids that have been normally castrated or, rarely, unilateral cryptorchids in which the scrotal testes have been removed. Male-like behaviour may persist after castration and is often not helpful for differentiating these cases. Although basal testosterone concentrations are higher in males with testes than those without testes, there are diurnal variations in testosterone concentration, and nadir values can be very low (0.5–1.5 ng/mL (1.7–5.2 mmol/l)). Because these are similar to those of animals with no testes (<0.5 ng/mL (<1.7 mmol/l)), it can result in a false diagnosis of the absent testicular tissue. Generally, the roughly circadian rhythm results in highest testosterone values in the morning, so sampling at this time is the optimum if a single sample is to be tested. Preferably, hCG or a GnRH analogue should be used to stimulate testosterone secretion. A basal plasma/serum sample is obtained, hCG (44 IU/kg IM) or GnRH analogue (2.0 μg/kg IM) is injected, and a second blood sample is taken 60 to 120 minutes later. In both cases, a significant increase in testosterone concentration (>5.0 ng/mL (17 mmol/l)) in the poststimulation sample is diagnostic of the presence of testicular tissue. There should be no false-positive diagnoses.

Evaluation of the Fertility of Breeding Males

MICHAEL MCGOWAN

Overall Approach

In veterinary practice, the clinical evaluation of fertility of breeding males most commonly involves conducting a systematic breeding soundness examination. The primary objective of this examination is to improve client decision making about the selection and management of their breeding male(s). Typically, breeding males are examined before purchase or selection into a herd/flock/kennel or breeding unit, annually before commencement of the breeding season, and as part of an investigation of the cause of lower than expected reproductive performance. Competent evaluation of the fertility of a breeding male requires the veterinarian to have good knowledge and understanding of the species' husbandry management, reproductive anatomy and physiology, and diseases and abnormalities affecting reproductive function. A common misconception is that the breeding soundness examination of a male consists only of examination of the reproductive tract. This ignores the close link between overall clinical health and normal reproductive function. In particular, the testes are quite susceptible to both systemic and local insults. For example, a bull that has acute footrot (foul-in-the-foot) will have, as well as the obvious reduced mating ability, reduced gonadotrophin hormone secretion due to the pain it is experiencing and significantly increased systemic concentrations of corticosteroids inflammatory cytokines. Each of these will adversely affect spermatogenesis resulting in a sustained decrease in semen quality. Thus the breeding soundness examination of a male animal is a standard clinical examination with special emphasis on evaluation of reproductive function.

When requested to conduct a breeding soundness examination a veterinarian must provide the owner/manager/agent with a professional opinion about the likely fertility of each male. This opinion is based on the findings from assessment of each male's functional capability – i.e., its ability to:

1. Maintain itself in a clinically normal state in the environment it is being managed in, or is likely to be managed in, in the near future;
2. Locate oestrous females and normally mount and serve these females;
3. Repeatedly ejaculate sufficient number of viable, morphologically normal spermatozoa, which when deposited in the reproductive tract of oestrous females are capable of fertilising ovulated ova and initiating normal embryonic development; and
4. Sire clinically normal offspring which have a normal life expectancy and probability of being selected as breeding animals.

In other words, each of the major components of the male's contribution to conception and birth of normal offspring must be examined. Unfortunately, each of these components is essentially independent, and thus failure to examine one or more components will significantly reduce the accuracy of one's evaluation of a male's likely fertility or the prognosis given in cases of subfertility/infertility. For example, a mature bull may be clinically normal, have an anatomically normal reproductive tract, and be producing good quality semen; but be incapable of serving because, during attempted mating, its penis spirals preventing intromission. However, when the presenting clinical signs are quite severe (e.g., marked lameness, severe swelling of the scrotum or sheath) the veterinarian may determine, for example, that a sample of semen cannot or should not be collected because it will compromise the affected male's welfare.

It is important to recognise that fertility is a continuous variable describing, in the case of male fertility, the probability of a male impregnating a population of clinically normal cycling females. Thus at the time of examination a male may be found to be sterile (permanent inability to impregnate females), infertile (temporary inability to impregnate females), severely, moderately, or mildly subfertile (reduced fertility), through to being normally fertile. Performing a systematic breeding soundness examination enables the veterinarian to detect sterile, infertile, and most subfertile males, but our ability to reliably identify highly fertile males remains an ongoing challenge. Cases of male sterility are quite uncommon, with cases of infertility more common. However, the most common male fertility problem detected is subfertility. Using the bull as an example, a fertile bull is a male that can impregnate by natural service at least 60% of 50 normal, cycling, disease-free females within 3 weeks, and 90% within 6 weeks. Therefore a mildly subfertile bull might only impregnate 40% to 50% of his females in each oestrous cycle, and a severely subfertile might only impregnate less than 20% of his females. Males experiencing severe disturbances in reproductive function may initially be infertile, then as they recover, progress from being severely subfertile to mildly subfertile before becoming normally fertile again. This highlights the importance when cases of infertility or subfertility are detected of recommending at least another follow-up examination to enable a more accurate prognosis to be provided to the client.

VetBooks.ir

Commonly, the duration of one or more waves of spermatogenesis is used to guide determination of the timing of the follow-up examination. Finally, it is important that clients understand that a subfertile male will be able to sire offspring; they simply will take much longer than a fertile male to impregnate all the females mated to them.

One of the more challenging situations in which veterinarians may find themselves is conducting a breeding soundness examination on a highly valuable breeding male that has been insured against loss of use. Although the dictionary definition of fertility that is most appropriate to male animals is 'the ability to reproduce prolifically', there have been legal cases in the past that have accepted the birth of a single offspring as evidence that a male is fertile. Thus it is important that not only clients, but also relevant insurance agents and legal advisors, are well acquainted with the objectives of the breeding soundness examination of male animals and that they understand that the examination determines whether a male is likely to be fertile but cannot guarantee it is fertile.

How to Conduct a Breeding Soundness Examination

McGowan (2004) provides a concise description of the approach to conducting the breeding soundness examination of bulls. This approach can be readily adapted and applied to any species.

Practical Considerations

Ideally, the breeding soundness examination of males should be done within a few months of when they are due to be mated or sold. This is primarily to minimise the risk of any change in fertility status of the males between examination and use or sale. However, provided there are no significant changes in the clinical health or plane of nutrition of the males, then the findings of a breeding soundness examination are generally repeatable, certainly over a period of 3 to 4 months in the case of rising 2-year-old bulls. This statement does not apply to young pubertal males still undergoing sexual maturation, as their semen quality changes significantly over a period of 3 to 4 months after puberty.

It is important that appropriately designed handling facilities and well-trained assistants are available to enable the examination to be conducted safely. For example, Beggs et al. (2013) describe management of the common occupational health and safety risks of conducting breeding soundness examinations on bulls. Good handling skills and patience are required when conducting breeding soundness examinations to minimise the risk of the examined males becoming reluctant to enter the handling facilities in the future.

The breeding soundness examination is like any other clinical examination, requiring a comprehensive record of what was examined and what were the findings. Various recording systems have been developed (Fig. 35.1). It is very important that veterinarians understand that regardless of whether it is one or multiple males being examined, the information recorded for each male should be sufficient to generate an individual breeding soundness examination certificate. Therefore a key piece of data that must be recorded for every examination is the male's permanent identification (electronic ID, brand, ear tattoo, ear tag).

The components of a breeding soundness examination are:

- Collection of husbandry and health history;
- General physical examination including assessment of gait;
- Detailed examination of the external and internal genitalia;
- Observation of mating behaviour and coitus; and
- Collection and microscopical evaluation of semen.

There is no set order that these components must be done in. Generally, the examination commences with the collection of the history and distance examination of general health, body condition, and conformation. If semen is to be collected using an artificial vagina (AV), then generally this should be done before the physical examination to minimise stress adversely affecting expression of sexual behaviour. When veterinarians are investigating suspected subfertile or infertile males, particularly those that could involve an insurance claim or litigation, they should strongly consider making a photographic record of all abnormal findings (e.g., video recording) the male attempting to serve.

Components of the Examination

History

The following are key questions to ask.

Age of the Male(s)

As the majority of prepurchase breeding soundness examinations are conducted on postpubertal virgin males, it is important to obtain an accurate age of the male to determine whether the male is likely to have reached puberty and whether postpubertal maturation of spermatogenesis has been completed. For example, nutritionally well-managed young bulls are expected to reach puberty at 9 to 10 months of age, but maturation of spermatogenesis will require a further 3 to 4 months. Thus, if bulls are examined at 12 months of age, it is quite common to find a high proportion of them producing ejaculates with a high percentage of morphologically abnormal sperm. Timing of birth can also affect age of onset of puberty due to interactions between quality of nutrition, day length, and genetics. For example, ram lambs that are born early in the season and have good growth rates may become pubertal in their first autumn, whereas those that are born late or do not grow so rapidly will not become pubertal until the next year. Age of onset of puberty is a moderate to highly heritable trait, and thus, although a group of males may be similarly managed, there may be considerable variation in onset of puberty and completion of maturation of spermatogenesis. As males become older, the risk of development of problems such as degenerative joint disease increases, which may adversely affect libido, mating ability, and semen quality. Bulls and boars, in particular, can become very heavy as they age, to the extent that they can injure females during mounting. Hence, there is merit in determining that the sizes of sire and females are compatible.

Intercurrent Disease

Occurrence of recent systemic or localised disease, including lameness and gait abnormalities, as well as systemic inflammation or localised inflammation either involving the scrotal contents directly or resulting in significant pain (e.g., lameness), can adversely affect spermatogenesis, resulting in a decline in semen quality of the affected male. History questions should thus focus on occurrence of any health problems during the past 2 to 4 months, which covers approximately one to two waves of spermatogenesis. Wherever possible, details of the onset, duration, and severity of health problems should be determined.

Management

As part of collection of the history, it is very useful to observe how the breeding male(s) is handled; how it is housed, fed, and

VetBooks.ir

cleaned; where it is required to serve; and how it is handled during service.

Occurrence of Changes in Management. Significant changes in management, such as relocation to a new farm/kennel/breeding unit or introduction to a new group of breeding males, can result in a significant increase in circulating cortisol that will adversely affect spermatogenesis.

Occurrence of Significant Changes in Body Weight/Body Condition. Details of the nutritional management of the male(s), including diet composition, amount fed, and growth rate, should be checked. When peripubertal males are fed to grow very rapidly (e.g., average daily weight gain of 1.5 kg per day in bulls between 6 and 12 months of age), they are at significant risk of developing degenerative joint disease with subsequent negative effects on mating ability and semen quality. Postpubertal males fed energy and protein well in excess of what is required for normal growth may become obese, with subsequent potential negative effects on semen quality (associated with scrotal insulation) and libido. However, males that lose substantial weight/condition also are at risk of significant testicular degeneration and reduced libido. In general, chronic and continuing deficiencies of protein and energy are likely to be of greater overall importance than micronutrient deficiencies, although the effects upon fertility can be severe when these occur simultaneously (Salisbury et al. 1978).

Vaccination Status. The veterinarian must check that young males have received the initial series of vaccinations to protect against infectious diseases that can cause death, illness, or infertility and that mature males have received any required booster vaccinations.

Previous Reproductive Performance

It should be ascertained whether the male has ever mated before and the circumstances of the mating. When males have been used for mating previously, details on breeding management (single sire vs multiple sire, male to female ratio, frequency of matings per week, total females mated per breeding season) and reproductive outcomes should be examined. In situations in which the breeding soundness examination is being done as part of investigation of lower than expected reproductive performance, the veterinarian must systematically determine both the males' and females' likely contributions to the problem. This will include analysis of breeding records to determine the timing of onset of a significant decline in performance and whether there were any significant changes in management, weather events, or health problems associated with this decline. Further, whenever possible, the performance of individual males mated to similar groups of females should be compared. A commonly encountered problem is that the number of matings with reproductive outcomes data for an individual male are too small to determine whether the apparent decline in performance is real or simply due to chance variation. For example, if the true conception rate in a population is 60% per oestrous cycle, and there are data available for the outcome of only 20 matings, then by chance alone the conception rate could be between 38% and 82%. Many of the causes of infertility do not manifest themselves until a considerable period of time has elapsed from the original insult, so that careful questioning of the owner, often over matters that may be considered trivial at the time of their occurrence, may be needed to elucidate such causes.

General Physical Examination

The primary objectives of this component of the breeding soundness examination are to:

- Detect abnormalities likely to significantly affect the male's reproductive function now or within a normal breeding life; and
- Accurately diagnose abnormalities to enable assessment of whether the effect on reproductive function will be temporary or permanent; also, the veterinarian must determine whether the abnormality is likely to be heritable.

A similar approach to conducting a standard clinical examination is used, commencing with a distance examination, including assessment of body condition, musculoskeletal conformation, and gait, and then continuing to an up-close examination after the animal is appropriately restrained. Males should be maintained in moderate to good body condition; they should be 'fit not fat'. Males that are to be mated to a high number of cycling females over a short period should be managed to ensure they are in good body condition before commencement of mating.

With bulls and other large animals not used to regular handling, the distance examination is best done with the animal standing freely in the race immediately before the crush/chute or in a small holding yard. The demeanour, posture, gait, and freedom from many gross physical abnormalities can be assessed. The gait of potential sires should be closely observed at both the walk and trot whenever possible as some males that appear to be able to walk normally display obvious gait abnormalities when forced to trot. With production animals in particular, males that display marked aggressive behaviour when being routinely managed through the handling facilities should be considered for culling, because temperament is moderately heritable, and the risk of safety incidents associated with handling these animals is high.

With the animal appropriately restrained, it should be systematically examined from muzzle to hindfoot on both the left and right side for the presence of any abnormalities likely to affect clinical health and reproductive function. It is important to recognise that the conformational anatomy of an animal is at least moderately heritable, and males that are to be used for producing future breeding stock should have normal anatomy. In the case of production animals, some leniency with respect to conformation can be applied if the male is to be used as a terminal sire. However, it is important for the veterinarian to carefully consider the effect of any abnormal conformation on the long-term function of the male and the health and welfare of its offspring. Normal conformation of the hindlimbs, including the hooves/feet, is particularly important in those males that will be naturally mated with groups of females or be hand mated to a large number of females. Some examples of likely heritable anatomical abnormalities encountered in bulls and other species include excessively straight hindlimbs (adversely affects mating ability and predisposes to degenerative joint disease), scissor claw, umbilical hernia, and entropion.

Whether the rectal temperature, heart rate, and respiratory rate are measured depends on the veterinarian's judgement of the usefulness of the findings. For example, when examining groups of young bulls before sale, the vital signs are generally not measured unless a bull presents showing signs of clinical illness. This is because the simple handling of bulls through a handling facility and the usual interactions between these animals can result in marked increases in the vital signs. However, in situations in which males are being examined before being insured, the vital signs should be recorded.

Although in many cases an accurate diagnosis of an abnormality can be based on visual and/or palpable findings, the use of the ancillary tests, including ultrasonography and cytology, should always be considered to enable an accurate diagnosis and prognosis to be provided to the client.

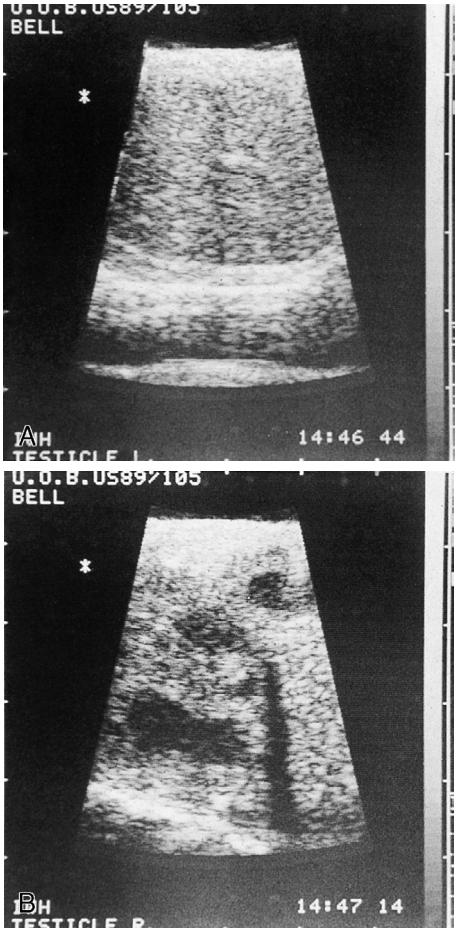
VetBooks.ir

Physical Examination of the Genital Tract

The systematic physical examination of the external and internal genitalia requires that the male be appropriately restrained. How this is achieved varies depending on the species, familiarity with handling, and temperament of the male. In some cases, simple physical restraint by an assistant is sufficient, whereas in other cases sedation and/or access to purpose-built handling facilities are required. However, before the animal is restrained it is very useful to critically observe the external genitalia for any suspected abnormalities that then can be examined in more detail when the male is restrained. One of the most useful diagnostic tools the veterinarian has to either confirm or better determine the cause of palpable abnormalities of the reproductive tract is ultrasonography. Ultrasonography enables not only rapid investigation of the nature of abnormal swellings involving the testes, epididymides, penis, and accessory sex gland in particular (Fig 35.2) but also detection of abnormalities such as calcification and abscessation within the testes.

Scrotum and Scrotal Contents

Initially, the conformation of the scrotum is assessed for normal shape and symmetry and, in species such as the ram and the bull, to determine whether the length of the scrotum is abnormally short (congenital short scrotum that affects testicular thermoregulation) or excessively long (increased risk of testicular bruising, particularly if testes are large). Then the scrotum is assessed visually and by palpation for any evidence of acute or chronic inflammation and occasionally neoplasia. Trauma (lacerations), external parasite infestations (e.g., mange, ticks), and even frostbite can all cause significant inflammation of the scrotum of bulls resulting in a local 'heating' effect with subsequent varying degrees of testicular degeneration. The scrotum should feel thin ('silky') and cooler than the external inguinal region (evidence of normal testicular thermoregulation). The testes should be freely mobile within the scrotal sac, with no evidence of adhesions or fluid/material present in the vaginal space adversely affecting the veterinarian's ability to accurately palpate the testes. Next, each spermatic cord, head of epididymis, testis, and head of the epididymis is systematically palpated to determine whether they are anatomically and palpably normal. During palpation, the presence, size, texture, tone, and symmetry of each structure is assessed. To palpate the body of the epididymis requires manipulation of each testis within the sac and is often not routinely examined in production animals. Commonly encountered abnormalities of the testes include unilateral or bilateral degeneration, hypoplasia, cryptorchidism, and, in aged males of some species, neoplasia (Leydig and Sertoli cell tumours, seminoma). Orchitis is uncommon in most species, but is encountered relatively often in the ram.



• **Fig. 35.2** Ultrasonograms of (A) normal canine testes and (B) a dog with epididymitis. (With permission from Barr (1990).)

The spermatic cord, including the ductus deferens, should be palpated up to the level of the inguinal ring for the presence of abdominal contents (scrotal hernia) and down to the level of the testis for abnormalities of spermatic vasculature (varicocele), adhesions associated with trauma or ascending infection from the testis or epididymis, and vasectomy scars. The head of the epididymis should feel firm and 'meaty', whereas the tail should feel full, firm, and resilient with a smooth surface. Neither should feel swollen and 'spongy' (acute epididymitis) or enlarged, very firm, and nodular (chronic epididymitis or spermatic granuloma).

Testicular tone is a function of the firmness and resilience of each testis and provides a useful measure of the health of the seminiferous tissue. With the testis held between thumb and fingers, firm downward pressure is applied to assess firmness and then, by releasing the downward pressure, the degree of 'springiness' or resilience of the testis can be assessed. If the majority, if not all, of the seminiferous tubules, are fully functional, the testis will feel firm and resilient. However, if many of the tubules are degenerate, the testis will feel soft and 'spongy'. The tone of each testis should be assessed along its entire length, as in some cases focal areas of excessive firmness (fibrosis, calcification) or softness (focal degeneration, abscess) or alternating excessive firmness then marked softness (chronic orchitis) may be detected. Various scoring systems for testicular tone have been developed, but to be useful, the veterinarian must fully understand the descriptor for each score. A simple 1 to 5 scoring system can be used for all species as follows: 1 = very soft or fibrous feeling, both with very poor resilience; 2 = soft with poor resilience; 3 = moderate firmness and resilience; 4 = firm with good resilience; 5 = very firm with very good resilience.

Depending on the species, either measurement of scrotal circumference (for those males that have a pendulous scrotum) or measurement of the width of scrotum has been shown to be highly correlated with the weight or volume of the testes and with daily sperm output. Critically, measurement of scrotal circumference/width enables determination of whether a male has abnormal testicular development. This is particularly important when selecting males that will be used to breed future breeding stock, as testicular development is a moderate to highly heritable trait that is genetically correlated with female fertility (primarily age of onset of puberty). Measurement of scrotal circumference requires the animal to be

VetBooks.ir

well restrained and, in the case of bulls, their hindquarters must be back firmly against a strong rail or kick gate. Both testes must be firmly massaged into the sac such that they are lying side by side, and there is no wrinkling of the scrotum. Then with the left hand clasped (with thumb pointed upwards) around the cranial aspect of the neck of the scrotum to hold both testes fully in the scrotum, the tape is looped around the broadest circumference and drawn snugly against the scrotum so that it is firmly in contact with the entire circumference. The measurement of scrotal circumference should be highly repeatable both within and between examiners. The development of scrotal tapes that enable a standard amount of tension to be applied when drawing the tape around the scrotum has greatly helped standardise this procedure (Fig. 35.3). In stallions and other males with similar scrotal anatomy, scrotal width can be readily measured either with callipers or with transscrotal ultrasound.

In young growing males, measurement of scrotal circumference/width can provide a relatively accurate guide as to whether males have reached puberty or not. For example, bulls are likely to have reached puberty when they achieve a scrotal circumference of 26 to 28 cm. Various guidelines defining the minimum scrotal circumference for young males have been published, but these must be interpreted with care as plane of nutrition, age, and breed can all strongly influence testicular development. Fordyce et al (2014) demonstrated that in young beef bulls, body weight (rate of growth) has the greatest effect on scrotal circumference. These authors defined abnormal testicular development as a scrotal circumference measurement lower than the fifth percentile at a given body weight (Fig. 35.4). When body weight data is not available, Beggs et al. (2013) have provided recommendations on minimum scrotal circumference measurements by breed and age for young bulls. A general guide is that, across breeds, if bulls have been managed on a moderate to high plane of nutrition, then at 12 months of age the scrotal circumference should be at least 30 cm, at 18 months of age at least 32 cm, and at 24 months of age at least 34 cm. Similarly, scrotal circumference of mature rams depends on body weight: values over 28 cm are acceptable for smaller breeds and over 34 cm for larger breeds. Day length can also have a significant effect in some species. The scrotal circumference of rams managed in temperate regions of the world is quite dependent on season, with a 25% to 35% increase in size between the nonbreeding and breeding season. The tone of the testes and the cauda epididymides undergo parallel changes. In young males that have passed the postpubertal peak growth phase, feeding an excessively high energy ration can result in the onset of fattening with deposition of fat in the neck of the scrotum and over the testes causing the scrotal circumference to be increased. These males are likely to have an

VetBooks.ir

increased proportion of abnormal sperm in their semen due to the fat deposition adversely affecting testicular thermoregulation.

Accessory Sex Glands

The accessory sex glands are generally examined after examination of the scrotal contents. The presence, size, texture, and tone of each structure are assessed. In the bull and the stallion, the prostate, ampullae, and vesicular glands ('seminal vesicles') can be readily palpated per rectum. In the bull, pathological changes of the prostate are exceedingly rare, of the ampullae uncommon, but seminal vesiculitis is relatively common. In the stallion the ampullae are more commonly affected than the seminal vesicular glands. The bulbourethral glands, although present, are quite difficult to palpate per rectum. In large boars, rectal examination is potentially feasible, but digital examination of smaller boars will only enable palpation of the bulbourethral glands. In smaller dogs, digital examination of the prostate is possible, but radiography or ultrasonography, which is essential when prostatic disease is suspected, is required to examine the prostate of large breed dogs. Acute inflammation of the accessory sex glands manifests as pain, swelling, and loss of normal architecture on palpation, whereas nodular fibrosis, adhesions, and sometime abscessation are typical of chronic inflammation. It should be noted that bacterial infections of the accessory glands can spread to the testes and vice versa.

Penis and Prepuce

The sheath which extends from the scrotum forward to the umbilicus supporting the penis and prepuce is observed for its conformation and evidence of any abnormal swellings, trauma, or dermatitis. *Bos indicus* bulls with excessively pendulous sheaths are considered at increased risk of developing prolapse of the prepuce. The preputial orifice should be examined for any evidence of abnormal discharge or excoriation and scabbing (e.g., ulcerative posthitis in rams and bulls). In bulls, particularly, *B. indicus* genotypes, excess preputial eversion (> 10 cm everted) should be noted as there is some evidence this is associated with an increased risk of preputial prolapse. With the bull appropriately restrained, the penis can be readily palpated within the sheath and extending caudally to the base of the scrotum for any evidence of adhesions and swellings. Whenever possible, the penis and prepuce should be extruded and systematically assessed for evidence of trauma, inflammation, and neoplasia. Commonly encountered abnormalities include lacerations, superficial trauma/microbial induced inflammation, penile papillomatosis, persistent frenulum, and acute/chronic preputial prolapse. The penis and prepuce can be most commonly visually assessed and, in some cases, palpated during collection of a sample of semen. When semen is collected using an AV, the penis and prepuce can be quickly assessed immediately after removal of the AV. Generally, a high proportion of males undergoing electroejaculation will protrude the penis, allowing visual assessment and palpation if required. In bulls, simply inserting a lubricated hand into the rectum and massaging the urethralis will often result in protrusion of the penis sufficient to enable checking for abnormalities such as penile papilloma and persistent frenulum. To diagnose penile deviations requires observation of the male attempting to serve a mount animal or oestrous female. This enables assessment of whether the male is capable of achieving a normal erection, intromission, and ejaculation. Although sedating males will often result in them protruding their penis or enable manual extrusion of the penis, palpation of painful lesions may still not be possible due to the lack of desensitisation. Thus, in a small number of cases, administration of a pudendal nerve block or general anaesthesia is required to enable accurate assessment of the penis and prepuce.

Collection and Assessment of Semen

Although measurement of scrotal circumference/width and assessment of testicular tone provide a useful estimate of semen quality, only perhaps 70% to 80% of males with well developed, firm/'springy' testes produce ejaculates with a high proportion of morphologically normal sperm. This is why collection and microscopical assessment of a sample of semen should always be done as part of a breeding soundness examination of a male. The characteristics of the semen of common domestic animals are summarised in Table 35.1. The microscopical examination of a sample of semen enables the function of the testes and epididymides to be directly assessed. Details of the methods of collecting semen from the common domestic males are provided in the next sections, but regardless, it is critical that during and after collection the semen is maintained warm and away from direct sunlight. For example, when collecting semen from bulls and rams in cold conditions, it is highly advisable to have some form of insulating (woollen gloved hand, styrofoam, or felt sleeve) or warming device (modified thermos flask) around the collection tube to eliminate the risk of cold shock.

Collection From the Bull

Semen can be collected from bulls using an AV, by electroejaculation, by massage of the ampullae, or by aspiration from the vagina of a cow immediately after service. Each of these methods has advantages and disadvantages. Collection of semen by AV enables concurrent assessment of libido and mating ability, including assessment for

TABLE 35.1 Semen characteristics of domestic animals

Characteristic	Bull	Ram	Stallion	Boar	Dog
Volume (mL)	4 (2–10)	10 (0.5–2.0)	60 (30–250)	250 (125–500)	10 (2–19)
Fractionated	N	N	Y	Y	Y
Density (x10^6/mL)	1250 (600–2800)	2000 (1250–3000)	120 (30–600)	100 (25–1000)	125 (20–540)
Motile sperm (%)	>70	>90	>60	>60	>85
Normal sperm (%)	>75	>75	>60	>60	>90

any evidence of penile deviation. However, it generally requires that the bull has been regularly handled or trained to serve into an AV, and the person collecting the ejaculate must be careful not to be struck by the bull when attempting to apply the AV over the penis. The AV (Fig. 35.5) consists of a strong outer rubber cylinder containing a latex liner. At one end of the AV, a latex extension cone carrying a graduated collecting tube is attached. The length of the AV should be adjusted so that the bull ejaculates into the extension cone, thereby producing semen that is as free as possible of particulate or bacterial contamination. The space between the outer cylinder and latex liner is filled with warm water, so that the temperature in the lumen of the AV is between 45°C and 48°C. If this temperature falls below about 43°C, ejaculation is unlikely. The main stimulus to ejaculation is the temperature of the AV, with pressure upon the bull's penis being relatively less important. A little inert lubricant (liquid paraffin or soft paraffin but not gynaecological jelly because this is usually spermicidal) is smeared around the lumen of the AV just before use.

Control of the bull and the safety of all personnel are of paramount importance during semen collection. A halter-trained, oestrous cow is the ideal mount animal (especially during training of a bull to serve an AV), although such an animal is often difficult to provide. A quiet non-oestrous cow or oestrogen-treated steer, at least two-thirds the weight of the bull, restrained in a purpose-built bail (same as is used for assessment of serving ability, Fig. 35.13) are commonly used as mount animals. When there is no restraint bail available, the haltered mount animal can be held in position by an assistant. Occasionally, the mount animal may need to be lightly sedated, but this needs to be done very carefully to avoid the mount animal collapsing under the weight of the bull. The bull is led to the mount animal, allowed to nuzzle and smell it, but then led away before mounting takes place. This usually causes complete or partial erection, with production of preejaculatory accessory gland secretions, and is considered to result in ejaculation of a greater total number of sperm when the bull is finally allowed to mount. The bull is then led up to the mount animal with the collector standing to the right of the offside shoulder of the bull. As the bull mounts, it makes small, preliminary thrusts with its penis to locate the vulva, and, during these, the collector grasps the sheath (not the penis) with the left hand and deflects the penis, guiding it into the AV. The bull will then normally make the ejaculatory thrust into the AV (Fig. 35.6). The entire procedure must be carried out quietly and methodically, keeping the bull under continual careful observation. It is important to note that many bulls are at their most aggressive immediately after ejaculation. When older bulls have been used for natural service for a number of years, they

• **Fig. 35.6** Semen collection from the bull by means of an artificial vagina. (With permission from Parkinson & Bruere 2007.)

may be unwilling to ejaculate into an AV. Providing the libido of the bull is sufficient, repeated teasing or allowing the bull to mount but deflecting his penis so he does not ejaculate will usually provide enough stimulation for ejaculation to occur when presented with the AV. More difficulty is experienced with bulls that are unwilling to mount in the presence of humans or that are no longer halter trained. In these cases, use of an intravaginal AV developed by Barth et al. (2004) should be considered.

A sample of semen adequate to enable microscopical assessment can be collected from around 99% of bulls using modern electroejaculation units that utilise either a three or two strip electrode intrarectal probe (Fig. 35.7) and enable sensitive control of the magnitude of electrical stimulus applied. The technique of electroejaculation involves the application of low level electrical stimulation in the form of a modified sine wave to selectively stimulate the nerves (parasympathetic outflow from the internal pudendal nerve, sacral plexus, and hypogastric nerve) responsible for erection, ejaculation, and emission. The major advantage of this procedure is that it enables collection of a sample of semen from rangeland bulls and bulls that either have not been trained to or will not serve into an AV. When required, several samples of semen can be collected over a short period using electroejaculation. In most cases the veterinarian will be able to observe the penis closely and can select to collect the sperm-rich fraction only. The major disadvantages are that the procedure does not allow assessment of mating ability and has a short-term, mild effect on the bull's welfare with stimulation of the sciatic and obturator

VetBooks.ir

• **Fig. 35.7** Electroejaculation equipment for use in the bull. (With permission from Parkinson & Bruere 2007.)

nerves causing increased hindlimb muscle contraction in some bulls. Before commencing the procedure, the veterinarian should check that the electrodes on the intrarectal probe are shiny and free of any tarnish and that the electrical stimulation unit is functioning normally. To perform this procedure, the bull must be restrained in a well-designed cattle crush/chute that provides good footing. Whenever possible, the bull's head should not be held in a head bail and but rather it should be held either behind the closed head bail or closed baulk gate, with its hindlegs back against the kick gate and its body held firmly from side to side by the sides of the crush/chute. Faeces must be evacuated from the rectum to allow intimate contact between the electrodes of the intrarectal probe and the rectal mucosa. Insertion of the probe is most commonly done after palpation of the accessory sex glands. Further, before insertion of the probe, it is recommended that the ampullae and urethralis be massaged for about 30 seconds to reduce the amount of electrical stimulation required to induce ejaculation. The probe is inserted as the veterinarian's hand is removed from the rectum. This is done to prevent air being sucked into the rectum, which adversely affects contact between the electrodes and the rectal mucosa. After inserting the lubricated intrarectal probe fully into the rectum, the tail is clamped down snugly behind the probe, and an assistant holds it in place, ensuring that the probe remains horizontal to the floor of the pelvis throughout the collection. Generally starting at the lowest setting, the bull is then rhythmically stimulated for alternating period of 2 to 3 seconds, with progressively increasing magnitude of the stimuli. It is critical that the veterinarian monitors the response of the bull to the stimulation applied at all times. Unfortunately, the response of individual bulls to the electroejaculation procedure cannot be predicted. Most bulls, as the stimulus is applied progressively, arch their back, thrust forward, commence protruding the penis, emit initially clear accessory gland fluids, and then emit sperm rich fluid. However, a small proportion of bulls are very sensitive to electrical stimuli and, even at low magnitude stimuli, show marked stiffening and/or knuckling of the hindlimbs. In these cases the veterinarian must only very slowly increase the magnitude of the stimuli to ensure the bull does not become recumbent. With some of these very sensitive bulls, the best approach is to initially apply electrical stimulation then remove the intrarectal probe and manually stimulate emission of semen.

• **Fig. 35.8** Electroejaculator for the ram.

Sequential per rectal massage of the ampullae and urethralis enables a sample of semen suitable for microscopical examination to be collected from about 80% to 90% of bulls, including yearling and older bulls. About 1 to 8 minutes of rectal massage is required. Initially, the ampullae are located and either repeatedly firmly pressed against the floor of the pelvis and then massaged in a caudal direction or grasped between thumbs and fingers and 'stripped' caudally. Massage of the ampullae is alternated with massage of the urethralis to stimulate emission of semen. This technique requires another person to collect the semen sample as it is emitted from the penis or from the preputial orifice. As emission of semen can take some time, it is important that the collection tube be kept warm. Use of this technique should be considered in bulls from whom a sample could not be collected by electroejaculation and those with either lower back problems or hindlimb lameness. The major disadvantages of this technique, apart from the 10% to 20% of bulls that yield no semen, are that the samples collected often have low sperm concentration and are contaminated with epithelial cells and debris from the preputial cavity and penis. Also, some bulls urinate immediately after ejaculation, contaminating the sample collected. Good palpation skills are required to consistently obtain semen samples by this method.

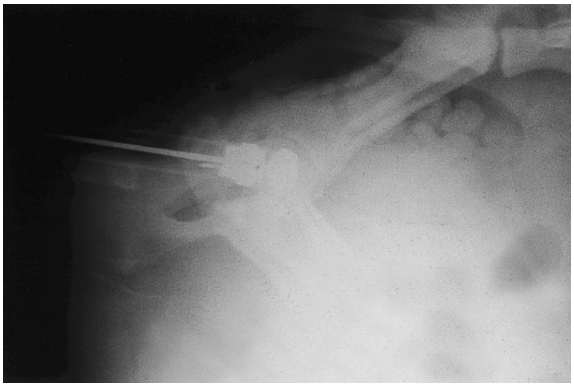
When the veterinarian wishes to collect a sample of semen from a cow after it has been served by a bull, the best approach is to infuse the vagina of the cow with a litre of saline before mating, then by rectal massage, express the saline and suspended mucous from the vagina. The semen sample collected is much easier to assess if most of the mucous has been washed from the vagina.

The Ram

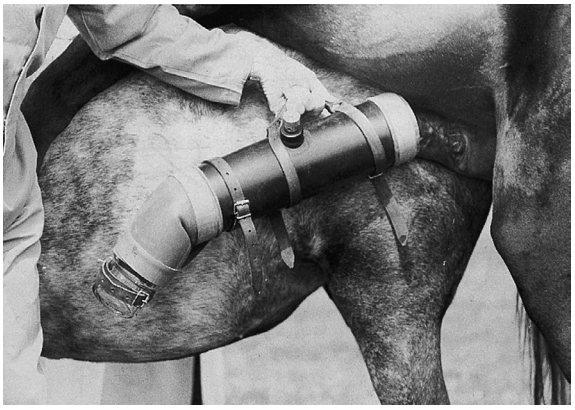
Semen is relatively easy to collect from rams by electroejaculation or by the use of an AV. Unlike bulls and stallions, in which it is not uncommon to have poor semen in the absence of other abnormalities of the genital tract, it is uncommon for this to occur in the ram. Hence physical examination of the genitalia should always be undertaken in the ram before semen collection is attempted, as many infertile rams can be detected without the need for semen examination.

Most semen examinations in the field are undertaken using samples collected by electroejaculation. Some veterinarians prefer to restrain the ram in a standing position; others lay it on its side and hold the penis in an extruded position. A lubricated probe (Fig. 35.8) is placed into the rectum of the ram with the two longitudinal electrode strips faced towards the hindfeet. The probe is located on the brim of the pelvis as shown in Fig. 35.9. Ejaculation should occur after four to six rhythmic stimulations of the ampullae and sacral nerve plexus. In many rams, erection will occur if the probe

VetBooks.ir



• **Fig. 35.9** Radiograph of the hindquarters of a ram indicating the position of the electroejaculator relative to the brim of the pelvis.



• **Fig. 35.10** Semen collection from the stallion. The urethra is palpated for the peristaltic waves that characterise ejaculation.

is correctly positioned, but a proportion of rams will ejaculate without an erection. Electroejaculation is generally well tolerated, but if there is widespread stimulation of hindlimb muscles or if the ram does not ejaculate after 4 to 6 stimulations, the ram should be rested for several minutes before repeating the procedure. When rams are taken directly from pasture and housed on straw for 1 to 2 days before attempting collection, the faeces become quite dry and firm, reducing contact between the electrodes and the rectal mucosa. This can reduce the chances of collecting a satisfactory quality sample. One of the problems with electroejaculation is that there is considerable variation between individuals in their response to electrical stimulation. Some produce semen samples which have similar volume and density to an AV ejaculate, whereas others have markedly reduced sperm concentration (i.e., appear less dense). In the latter case the veterinarian must determine, based on their assessment of the sample's mass activity or percentage progressively motile sperm, whether the sample collected is consistent with their assessment of scrotal circumference and testicular tone (i.e., the sample collected is or is not representative of what the ram is likely to ejaculate when mated). If there is any doubt, the veterinarian should always collect another sample.

Collection of semen from rams using an AV is essentially the same procedure as for the bull. Although rams generally require some training, it is surprising how many untrained rams will serve into an AV in situations when a ewe is restrained in a modified head bail (similar in design to that used for serving ability testing bulls) in a pen adjacent to where they are held and is initially served by an experienced ram. It appears that simply observing this mating behaviour stimulates many rams to serve into an AV provided the collector is experienced, and can quickly and correctly position the AV for the ram to serve into. The AV that is used for rams is essentially a smaller version of the bull AV, except that it is common to provide some means of keeping the ejaculation cone warm. Although sheep are seasonal breeders, semen can be collected from most rams throughout the year. Semen quality can be maintained to a considerable extent by regular ejaculation, a phenomenon that is used to maintain production of (frozen) semen in sheep AI centres. On the other hand, out of season collection of semen from rams managed on commercial farms is generally more difficult than during the breeding season.

The Stallion

Although the collection and microscopical examination of a sample of semen has traditionally been regarded as the most important aspect of breeding soundness examination of the stallion, Love (2007) states that it should be regarded as but one component of the examination. The preferred method of collecting semen from the stallion is by the use of an AV. The alternative, less satisfactory method is by examining the residual drops of semen emitted from the urethra after the stallion dismounts. Collection from the vagina of a mare is generally not possible because ejaculation occurs directly into the uterus.

The AV for a stallion is larger than that used for a bull and, for large stallions, may be quite heavy. The stallion is initially teased with a mare in full oestrus. The mount mare is often restrained with a twitch or service hobbles. After mounting the penis is deflected into the AV, and its lower surface is palpated for the presence of peristaltic ejaculatory waves (Fig. 35.10). Stallions can be quite fastidious about the temperature and pressure in the AV before they will ejaculate, and some stallions object so vehemently to even the sight of an AV that collection is impossible. Care must be exercised by the collector to avoid getting struck by the stallion's forelimbs or trapped between the forelegs of the stallion and the body of the mare.

The Boar

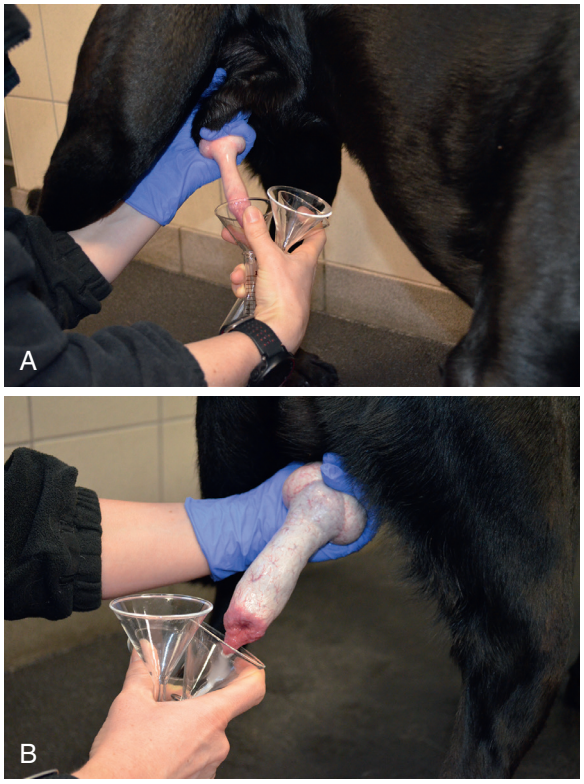
Semen is most easily collected from the boar by manual stimulation of the penis. AVs have been designed for the boar (Melrose & O'Hagen 1959) but are less effective than the manual method. The main stimulus to ejaculation in the boar is the locking of the corkscrew-shaped distal part of the penis into the spiral-shaped cervix of the sow. Hence, after mounting an oestrous sow or, if trained, a dummy, the penis is initially stimulated through the sheath then, when protruded, the corkscrew-shaped glans is firmly grasped with a lubricated, latex gloved hand, mimicking the cervical lock. Handling other parts of the penis should be avoided (Althouse 2007).

The ejaculate is collected into a warmed, insulated container, either directly or via a funnel in which gauze is placed to separate the gel fraction from the remainder of the ejaculate. Thrusting is vigorous before the start of ejaculation but becomes less vigorous as it begins. The boar begins to thrust again as the postsperm gel fraction is produced. The presperm fraction is not collected, and the gel fraction is retained by the gauze in order that the sperm-rich fraction contains minimal quantities of these components.

The Dog

Semen can be collected fairly readily from most dogs by digital stimulation of the penis. The presence of a teaser bitch, preferably in oestrus, facilitates the procedure. Because of the adverse effects

VetBooks.ir



• **Fig. 35.11** Manual collection of semen from the dog. (A) The penis is grasped behind the bulbus glandis, simulating the lock of the levator vestibuli of the bitch. (B) The different fractions of semen are collected into separate collecting vessels to minimise the dilution of the sperm-rich fraction with accessory gland fluids.

of latex rubber on canine sperm, semen collection by AV is not recommended.

In order to induce ejaculation by digital manipulation, the bulbus glandis may be rhythmically compressed (Fig. 35.11), although many dogs will ejaculate simply in response to their own thrusting. Before production of the presperm accessory fluids, quite vigorous thrusting occurs, but the dog is relatively quiet during the initial phase of ejaculation. First, during this quiescent phase, between 0.5 and 5.0 mL of watery, preejaculatory fluid is produced over a period of up to 50 seconds. Ejaculation of the sperm-rich fraction then follows immediately, when 0.5 to 2.0 mL of thick, creamy fluid is emitted within a few seconds. The dog then attempts to turn and tie, whereupon the postsperm, prostatic fluid fraction of the ejaculate is produced. This third component is again watery, comprising up to 30 mL of fluid, which is ejaculated over 3 to 30 minutes.

Semen Examination

This section will focus on examination of semen and sperm as part of a breeding soundness examination and will not include examination of frozen thawed semen. The primary objective of collecting a sample of semen from a male is to evaluate the quality of sperm. It is not always necessary to collect a complete ejaculate. All that is required is a representative sample containing sufficient number of sperm to evaluate motility and morphology. This is important when collecting semen by electroejaculation as it is quite common, especially in bulls, to collect samples containing a low concentration of sperm (200×10^6/mL). The determination of whether daily sperm production is sufficient to ensure a normally expected mating outcome is generally based on measurement of scrotal circumference/width. However, when a male is to be used for an artificial breeding programme, it is not uncommon to determine sperm concentration and total sperm in the ejaculate and then to adjust these according to one's estimate of the percentage progressively motile sperm.

It is important for veterinarians to appreciate that many of the key relationships between the semen and sperm parameters and fertility have been established under ideal laboratory conditions, and thus, especially when examining semen in the field, the veterinarian must take 'the laboratory to the field' (Fig. 35.12). It is very easy to adversely affect sperm motility. Spermatozoa are very sensitive to both 'cold shock' (sudden decrease below 30°C) and heat shock (sudden increase above 40°C), changes in pH (urine contamination), and osmotic shock (contamination with water, improperly stored/prepared semen diluents). The 'golden rule' is that, at all times, whatever the semen comes in contact with must be warm, dry, and free from any dust, mould, or chemical contaminants (important to carefully rinse collection equipment after cleaning with disinfectants/soap). Use of a microscope that has either a built-in or attached warm stage and a slide warming platform (for microscope slides and pipettes), both set at 35° to 37°C, is strongly recommended. Prepared semen stains and diluents should also be maintained warm. This can be readily done by placing them in a styrofoam box containing a hot water bottle. A microscope equipped with good quality optics and preferably 4x, 10x, 40x, and 100x objective lenses is essential. A microscope that has both bright field and phase contrast capacity is preferred as the latter greatly improves assessment of the percentage progressively motile sperm. Veterinarians should practice the semen examination procedure in their clinic before attempting to conduct examinations in the field.

The ejaculate or sample of semen should be initially inspected for the presence of urine (typical smell), fresh or degenerating blood (semen will have a pink or brown appearance), pus, and dirt/faeces/smegma contamination. Some normal bulls have semen that has a lemon yellow colour due to the presence of increased levels of riboflavin in the seminal plasma. The density (sperm concentration) of the sample is often estimated based on its colour. For example, for bull semen that appears clear to slightly cloudy, it is estimated that there are less than 200×10^6 sperm/mL, cloudy to milky appearing semen 200 to 500×10^6 sperm/mL, milky appearing semen 500 to 1000×10^6 sperm/mL, and creamy appearing semen 1000 to 1500×10^6 sperm/mL. Azoospermia is a rare problem, and thus when a sample of semen is collected containing no sperm or very few sperm, the veterinarian should always attempt to collect another sample.

Assessment of Sperm Motility

The assessment of sperm motility should be done within a couple of minutes of semen collection whenever possible. In the event that semen cannot be assessed immediately, then it should be appropriately extended and stored. For those species that produce highly concentrated semen (ram, bull), a small drop of semen is often first placed on a warm slide and examined directly using the 4x lens (with the condenser turned down) for evidence of mass activity (often scored from no swirling wave to rapid swirling wave on a 1–5 or 1–10 scale). This examination enables rapid determination of whether the sample collected is consistent with the findings from examination of the scrotal contents (i.e., is representative of what the male would ejaculate if mated). However,

VetBooks.ir

it is important to note that mass activity is a function of sperm concentration and percentage motile sperm, and when samples have low sperm concentration, typical of some species and in bulls and rams due to variable response to electroejaculation, a swirl may not be observed even though the sample contains a high proportion of motile sperm. Further, observing a swirl does not allow the veterinarian to be able to always conclude that the sample contains a high proportion of progressively motile sperm, as a swirl can be observed in samples containing a high proportion of sperm swimming backwards due to the distal-midpiece reflex defect or looped tails.

To assess the percentage of progressively motile sperm, a small drop (~3 mm in diameter) of semen is placed on a prewarmed slide, and a warm coverslip is placed over it. It is critical that the droplet is small enough to ensure that a single layer of sperm can be observed. If the microscope being used only has bright field capacity, then the condenser must be turned down, the light reduced, and the 10x or 40x lens used. If the semen sample is quite concentrated, then it is advisable to dilute a drop of semen with several drops of either phosphate buffered saline or 2.9% sodium citrate solution on a warm slide, and then draw up a drop of the diluted semen and make a wet mount preparation as described previously. It is very important that the diluent is in-date and has been appropriately stored; otherwise, the pH or osmolality may have changed, and this can negatively bias the estimate of percentage progressively motile sperm. Some experience is required to accurately estimate the percentage progressively motile sperm. The veterinarian should focus on estimating the proportion of sperm that are not moving forward and initially broadly categorise the sample as having poor, fair, or good progressive motility (< 30%, 30%–59%, and ≥ 60%, respectively). The 'golden rule' when assessing sperm motility is, if in doubt, think 'there might be a problem with how I have managed the sample, conducted the evaluation or, there could be a problem with the sample itself or the bull'. Therefore, if the mass activity or percentage progressively motile sperm is inconsistent with the findings of the physical examination of the scrotal contents, examine one or more additional droplets/wet mount preparations and/or collect another sample of semen. Also, sometimes with males who are examined out of season or have not been serving, the first sample/ejaculate may contain a relatively high number of dead sperm. In these cases the motility observed in the second sample is usually much better than initially observed.

Assessment of Sperm Morphology

If a sample of semen is collected from a male, the percentage of morphologically normal sperm should always be determined. This parameter has been consistently shown to be significantly associated with mating outcomes and is almost certainly a heritable trait. It provides a sensitive measure of the health of the testes, epididymides, and accessory sex glands. Further, when males are reared and mated in environments in which animals experience seasonal extremes in temperature/humidity, plane of nutrition, and parasitism, it can provide a useful indication of how well-adapted the animal is to its environment.

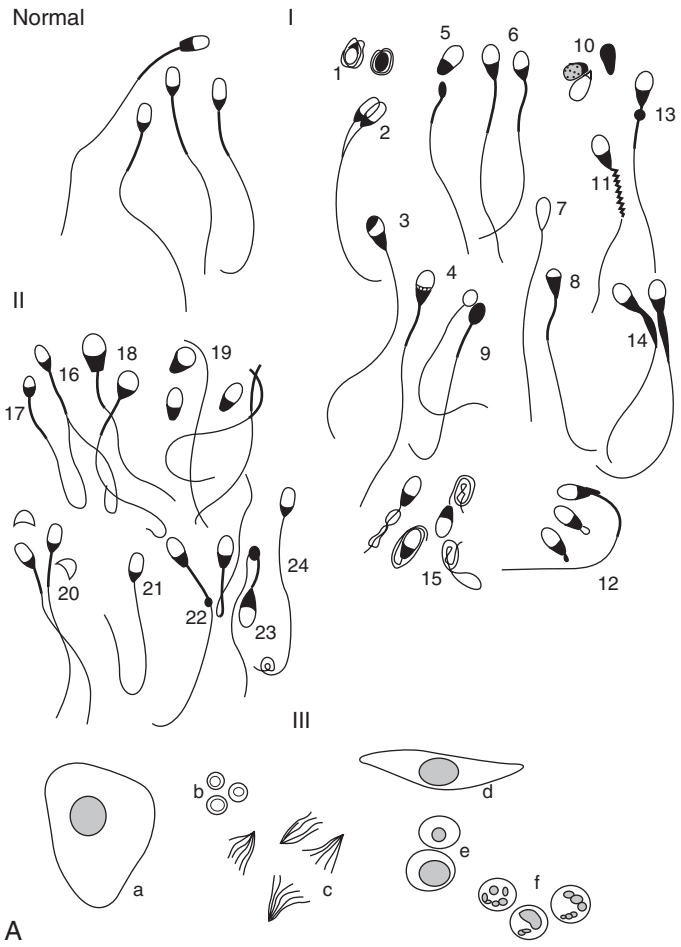
The two most common methods used for assessment of sperm morphology are:

Bright-field microscopy of sperm stained with nigrosin-eosin (NE) (Swanson & Bearden 1951). NE is a 'supravital stain' that can also be used to estimate the proportion of live and dead sperm in a sample. 'Live' sperm with intact cell membranes at the time of staining do not take up the eosin and thus appear pale white against the purple (nigrosin) background. However, 'dead' sperm have damaged cell membranes and take up the eosin, with the head of the sperm appearing partially or completely pink. To make a NE stained smear, a small drop (5–6 mm in diameter) of warm NE is placed at one end of a warm microscope slide. For samples estimated to have a very high sperm concentration, simply dipping a clean, warm pipette into the sample and then into the drop of NE will pick up sufficient sperm for a smear. With more dilute samples, a drop of semen (3–5 mm in diameter) is mixed with the drop of NE. Then, either using the edge of a microscope slide or a wooden applicator stick, these are drawn up so they just touch the droplet of NE; then they are drawn slowly across the slide to create the smear. It is critical that the smear be dried quickly to avoid cracking of the stain and hypotonic shock to the sperm. After making the smear, the male's identity and date of examination must be etched or written on one end of the slide and the slide stored in a slide box. In the field, preparation of NE smears is best performed on the slide warming platform. The smear is then examined using oil immersion at 1000x magnification. Multiple fields in which the sperm are individually dispersed (i.e., not clumped on top of each other) and can be seen very clearly are selected for examination and counting of normal and abnormal sperm. Note that both 'live' and dead sperm are to be counted.

Differential-interference phase-contrast (DIC) or high-quality **phase-contrast microscopy** of cover slip preparation of preserved semen (Aalseth & Saacke 1985). Semen can be conveniently preserved using 10% buffered formal saline (BFS). Depending on the estimated concentration of sperm, one or more drops of semen are pipetted into 1.5 to 2 mL labelled, screw top, plastic containers of BFS until the fluid appears slightly cloudy. The morphology of the preserved sperm can either be immediately assessed or examined some later time. With the latter, the preserved samples should be stored at 4°C to control bacterial multiplication. Phase contrast and, in particular, DIC microscopy is considered superior to bright field microscopy for assessment of sperm morphology, especially examination of the acrosome and detection of nuclear vacuoles. In Australia (Beggs et al. 2013), trained sperm morphologists equipped with DIC microscopes now provide a commercial sperm morphology service for practicing veterinarians.

The interpretation of the findings of the assessment of sperm morphology is a two-step process. The percentage of normal and abnormal sperm is considered first. Across species, 30% total abnormal sperm is considered the threshold above which fertility is likely to be reduced. Thus in the absence of any physical abnormalities likely to affect reproductive function, males who produce ejaculates containing 70% or more normal sperm are considered likely to be fertile. However, the distribution and percentage of individual categories of sperm abnormalities should also be considered, especially in cases in which the percentage of morphologically normal sperm is less than 70%. Examining the frequency of specific sperm abnormalities (often referred to as the spermiogram) enables the veterinarian to assess the severity of dysfunction, and, in some cases, the likely cause of the problem (e.g., high proportions of retained proximal droplets in young males undergoing maturation of spermatogenesis postpuberty). Interpreting a spermiogram requires a good understanding of the stages and timing of spermatogenesis and epididymal transport and maturation. For example, spermatogenesis in the bull takes approximately 9 weeks followed by 2 weeks transport and maturation through the epididymis (i.e., it takes almost 2.5 months from differentiation of a spermatogonium to arrival in the tail of the epididymis ready to be ejaculated; see also Chapter 2). Thus, as this is a continuous process, the analysis of the distribution of abnormal sperm in a sample provides a 'snapshot' of the function

VetBooks.ir



• **Fig. 35.12** (A) Classification of spermatozoal abnormalities into major and minor defects according to their effect upon fertility. (B) Field laboratory for bull semen examination. Note the small blow heater to the left on the bench to ensure that the entire area where semen samples are being handled, examined, and processed is kept warm. See Table 35.2 for key. TABLE 35.2 Major and minor sperm abnormalities[a]

Major Abnormalities (Group I)			
1	Underdeveloped cells	9	Small abnormal heads
2	Double forms	10	Detached abnormal heads
3	Acrosome (knobbed acrosome) defects	11	Corkscrew midpiece defect
4		12	Other midpiece defects (incl. tail stump defect)
5	Diadem defects	13	
6	Decapitated sperm (active tails)	14	Proximal cytoplasmic droplet
7		15	Other thickened midpieces
8	Pear-shaped (pyriform) head	23	Coiled tails and Dag defect
	Head narrow at the base		Looped tail, enclosed droplet
	Head abnormal contour		Looped tail, enclosed droplet (= distal midpiece reflex) (not illustrated)

Minor Abnormalities (Group II)		Other Cells (Group III)	
16	Narrow heads	a	Epithelial cells
17	Small normal heads	b	Erythrocytes
18	Giant or broad heads	c	Medusa formations
19	Detached normal heads	d	Boat cells
20	Detached acrosomal membranes	e	Mononuclear cells
21		f	Neutrophils
22	Abaxial tails		
23	Distal cytoplasmic droplets		
24	Simple bent tail		
	Terminally looped tails		

[a]As defined by Blom (1983).

of the testes and epididymis over, in the case of the bull, the 2.5 months before sample collection. Saacke et al. (2000) demonstrated that after insulation of the testes of a bull for 48 hours (which mimics a range of common testicular insults), there was subsequently sequential appearance of specific sperm abnormalities, depending on the stage of development of sperm at the time of the insulation event. Semen collected within a week of the insult contained increased proportion of immotile and dead sperm, sperm with detached heads, and sperm with retained droplets (particularly proximal droplets). Samples collected between 1 and 3 weeks after the insult contained increased proportions of sperm with abnormal heads (pyriform) and nuclear vacuoles ('diadem' defect); and those collected after 3 weeks, in addition to these abnormalities, also contained sperm with abnormalities of the acrosome.

In some species, thresholds have been set for specific sperm abnormalities or categories of abnormality (e.g., bulls; Parkinson & Bruere 2007, Beggs et al. 2013). There is some evidence that morphologically normal sperm in ejaculates with a significantly increased frequency of abnormal sperm contain aberrations in their chromatin (Saacke 2008). Thus setting a threshold of 20% for major abnormalities seems reasonable. Categorising sperm abnormalities has been proposed according to:

- Site on the sperm (acrosome, head, midpiece, tail);
- Likely effect on fertility (major and minor; Blom 1983; Fig. 35.12; Table 35.2); or
- Whether abnormalities are compensable (sperm which are grossly abnormal and are unable to traverse the reproductive tract; increasing the total number of sperm in the inseminate can potentially compensate for the presence of these sperm), or uncompensable (sperm which are capable of binding to the ovum but, due to abnormalities in the sperm chromatin, cannot initiate fertilisation or normal embryo development), increasing the total number of sperm in the inseminate cannot compensate for the presence of these sperm (Saacke 2008) (Table 35.3).

Finally, in some cases, males will produce ejaculates containing a high proportion of a single sperm abnormality. These males are likely to have a heritable disturbance in spermatogenesis.

Assessment of Sperm Concentration

For field use, sperm density can most readily be estimated using a haemocytometer. Ram and bull semen should be diluted 1:100 in 0.9% saline/0.02% formalin solution. Other species whose semen is less dense may require lower dilution factors. The total sperm count is then derived as the product of volume and density. When a large number of semen samples require evaluation, such as occurs in AI studs, estimation of sperm density can be facilitated by the use of spectrophotometry, in which the optical density of the sample is compared with a calibration curve (Salisbury et al. 1943). Alternatively, electronic particle counters can be used, although the small size and flattened shape of the sperm heads make them relatively difficult cells to count.

In vitro Assessment of Semen Quality

An array of *in vitro* tests have been developed that enable investigation of the contribution of specific components of sperm function to the outcome of deposition of semen in the female reproduction tract (Rodriguez-Martinez 2007). These tests have been developed with the aim not only of improving, in particular, the sensitivity of identification of highly fertile males but also of subfertile or infertile males that appear to have normal sperm motility and morphology. The tests include:

- Computer-assisted analysis of sperm motility (CASA);
- *In vitro* fertilisation (IVF);
- Components of IVF such as assessment of sperm attachment to the zona pellucida;
- Assessment of sperm cell membrane integrity and mitochondrial integrity and functionality using various flurophores (e.g., the acylated membrane loading dye SYBR-14); and
- Sperm chromatin structure assays (SCSA), which enable the percentage of spermatozoa with denatured DNA to be determined.

However, the results of none of these *in vitro* tests have been shown to be highly correlated with fertility, and thus none are currently routinely used in breeding soundness examinations. Furthermore, although there have been major advances in our understanding of the role of seminal plasma proteins in sperm survival, fertilisation, and early embryo development (Rodríguez-Martínez 2011), the relationship between measures of the amount of specific seminal plasma proteins and fertility have not been sufficiently well established for incorporation into breeding soundness examinations.

Assessment of Libido and Serving Ability

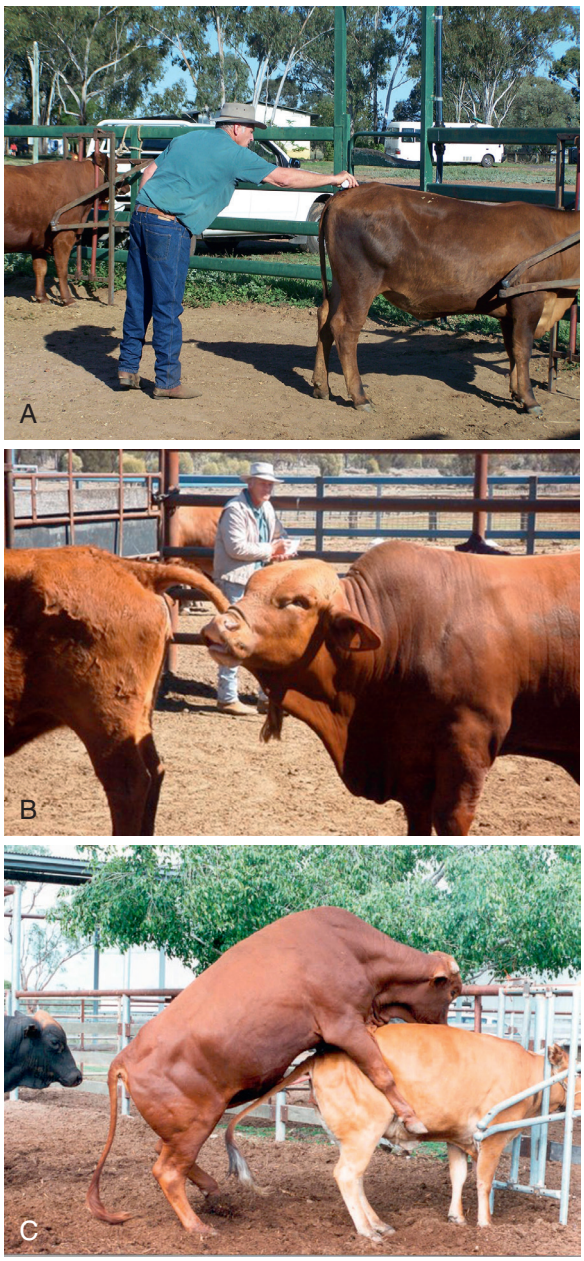
This component of the breeding soundness examination focusses on assessment of the male's ability to repeatedly mount and serve normally and almost always requires direct observation of the behaviour of the male when exposed to a free-standing female in oestrus or an appropriately restrained female. Unfortunately, it is not always assessed because of the practical difficulties of conducting the assessment, sourcing and restraining mount females, and the time (at least 10–40 minutes) required to observe each male express their mating behaviour. However, when investigating a suspected subfertile or infertile male or when a client wants to mate a few selected males to a large group of females for a short period, especially if the females have been treated to synchronise ovulation, assessment of libido and serving ability is strongly recommended. Further, it must be appreciated that the definitive test of whether a male has a normal musculoskeletal system is observation of him attempting to mount and serve. The author has been chased out of a yard by a bull that subsequently in a serving ability test showed evidence of marked hindlimb paresis caused by severe osteoarthritis affecting the lumbar spine.

Assessment of mating behaviour should be conducted in a small area (enclosed pen, holding yard) with good footing, and, wherever possible, the test site should be familiar to the male(s). Veterinarians must position themselves to ensure that they are able to clearly observe whether intromission and ejaculation occurs normally, especially in species (rams, bulls) in which the duration of coitus is very short. Testing young males that have not been mated before can be problematic as sexual behaviour is learned. Providing virgin males with a short period of sexual experience before testing therefore generally increases the expression of sexual behaviour. Whenever possible, males should be given the opportunity to serve more than once, especially older males, because if, for example, they have degenerative joint disease affecting the lower back and/or hindlimbs, they may serve normally once but, due to pain/loss of motor function, they will not serve again.

Although the veterinarian can be confident of the serving ability of males who are observed to normally serve the mount female several times, considerable caution must be applied in the interpretation of males that fail to express sexual behaviour or express only limited behaviour. Males can be readily inhibited by a range of stressors (e.g., being recently transported to the site where testing is to be conducted or being mixed with other males, especially older males). Further, for example, in cattle, *B. taurus* bulls typically achieve a significantly higher number of services in a yard test than *B. indicus* bulls.

Routine assessment of libido and serving ability is most commonly conducted on young *B. taurus* bulls before selection as sires. Also, it is routinely conducted on older herd sires, especially in intensively managed beef herds, to identify bulls with premature spiral deviation of the penis and degenerative joint disease affecting the lower back or hindlimbs. Practical guidelines for this procedure, including design of the modified head bail to restrain the mount females, have been developed (Beggs et al. 2013). Mount females should be selected on the basis that they are not pregnant, at least two-thirds the weight of the bulls to be tested, of quiet temperament, and have been vaccinated for venereal diseases. The number of mount females required is about half the number of bulls to be tested, and during the testing the welfare of the mount females

VetBooks.ir



• **Fig. 35.13** Service testing of bulls. (A) Appropriate size mount animals of good temperament are restrained in purpose-built bails and used for a defined numbers of mounts. must be regularly monitored. After infusion of obstetrical lubricant into the vagina the haltered mount females are drawn into and restrained in purpose-built bails (Fig. 35.13). Barth et al. (2004) have developed an innovative intravaginal AV that allows both assessment of libido and serving ability and enables collection of a sample of semen for microscopical examination. Blockey (1978) demonstrated that the number of services achieved by *B. taurus* bulls in a 40-minute yard test was significantly correlated with the pregnancy rate achieved after natural mating. However, the ability to reliably predict the pregnancy rate that will be achieved based on the performance of a bull in a serving test is limited because of the many other factors that contribute to this outcome. Assessment of libido and serving ability is also commonly conducted on rams, especially in intensively managed flocks employing low male to female ration and short mating periods. The procedure used is similar to that described for bulls.

Overall Determination of the Likely Fertility of a Breeding Male

Having completed a breeding soundness examination a veterinarian must then determine by careful consideration of all findings whether the male:

- Is likely to be fertile;
- Should only be used as a terminal sire;
- Should be reexamined (typically 6–9 weeks later) to better define its fertility status; or
- Is likely to be subfertile or infertile.

This is a professional opinion based on the findings of the examination performed (see Fig. 35.1). The interpretation of measurements such as scrotal circumference or diameter, percentage of progressively motile sperm, percentage of morphologically normal sperm, and number of services achieved in a serving ability test may, in some species, be supported by threshold values derived from research that has defined the relationship between these measures and mating outcomes (Coulter & Kozub 1989, Holroyd et al. 2002). For those males that are diagnosed as being subfertile or infertile/sterile, the veterinarian must provide the client with recommendations for their future management which could include reexamination, therapeutic management, temporary or permanent withdrawal from service, or culling. Various methods of classification of breeding males have been developed, particularly for bulls (Hopkins & Spitzer 1997, Parkinson & Bruere 2007, Beggs et al. 2013), to enable standardised reporting of the findings of breeding soundness examinations. Whatever system is used to report the findings of a breeding soundness examination, it is important that the wording used is unambiguous, and clear definitions are provided for the terms used.

Abnormalities Affecting Reproductive Function of Male Animals

TIMOTHY J. PARKINSON AND MICHAEL MCGOWAN

Reproductive abnormalities causing subfertility and infertility in male animals have classically been divided into two main classes: conditions causing partial or complete failure of normal service (*impotentia coeundi*) and conditions causing partial or complete inability to impregnate normal cycling females (*impotentia generandi*). The first group can be further divided into conditions causing unwillingness or inability to mount and conditions that prevent normal copulation from occurring despite normal libido. Superimposed upon both groups are considerations of whether the subfertility/infertility is due to a primary pathological abnormality or suboptimal husbandry or breeding management. Fig. 36.1 outlines the diagnostic pathways for the major causes of subfertility/infertility in bulls and can be readily adapted to other species.

Abnormalities of Coitus

Disorders associated with partial or complete failure of coitus can be considered under the following:

- Immaturity or inexperience of breeding male;
- Inability or unwillingness of the breeding male to mount;
- Inability of the breeding male to achieve intromission; and
- Failure of the breeding male to ejaculate.

Immaturity and Inexperience

Young breeding males may be presented for failure to mate simply because they are peripubertal and/or sexually inexperienced. When immaturity is suspected as the cause of poor libido, little can be achieved other than to ensure good husbandry management and exposure to cycling females. Clients must be counselled about the important role of genetics in onset of puberty: males who express delayed onset of puberty are likely to sire offspring with this trait.

Hormone therapy has been suggested. Administering large doses of human chorionic gonadotrophin (hCG) (5000–10,000 IU) or gonadotrophin-releasing hormone (GnRH) to stimulate increased secretion of testosterone has been suggested. However, considerable caution should be exercised in the use of such treatments as they may induce aggressive behaviours. Moreover, hCG, although having luteinising hormone (LH)-like properties, is not the same substance as LH and may impair spermatogenesis due to treatment associated testicular oedema. In general, the efficacy of such treatments is low. Most animals fail to respond at all, a few exhibit a short period of enhanced libido, but only in very few cases can success be attributed to the treatment.

Lack of sexual experience and/or suboptimal rearing conditions can adversely affect the expression of sexual behaviour in young males. For example, when bull calves are reared in groups, they regularly exhibit mounting behaviour as puberty approaches and usually learn to copulate quite quickly. However, when reared in isolation, such mounting behaviour does not occur and can take some time to be learnt, especially in those AI stations where steers are used as mount animals. Similarly, young colts in racing yards may be violently dissuaded from exhibiting male behaviour by their grooms. As a consequence, such negative behavioural reinforcements have to be reversed before these young horses can be used for mating.

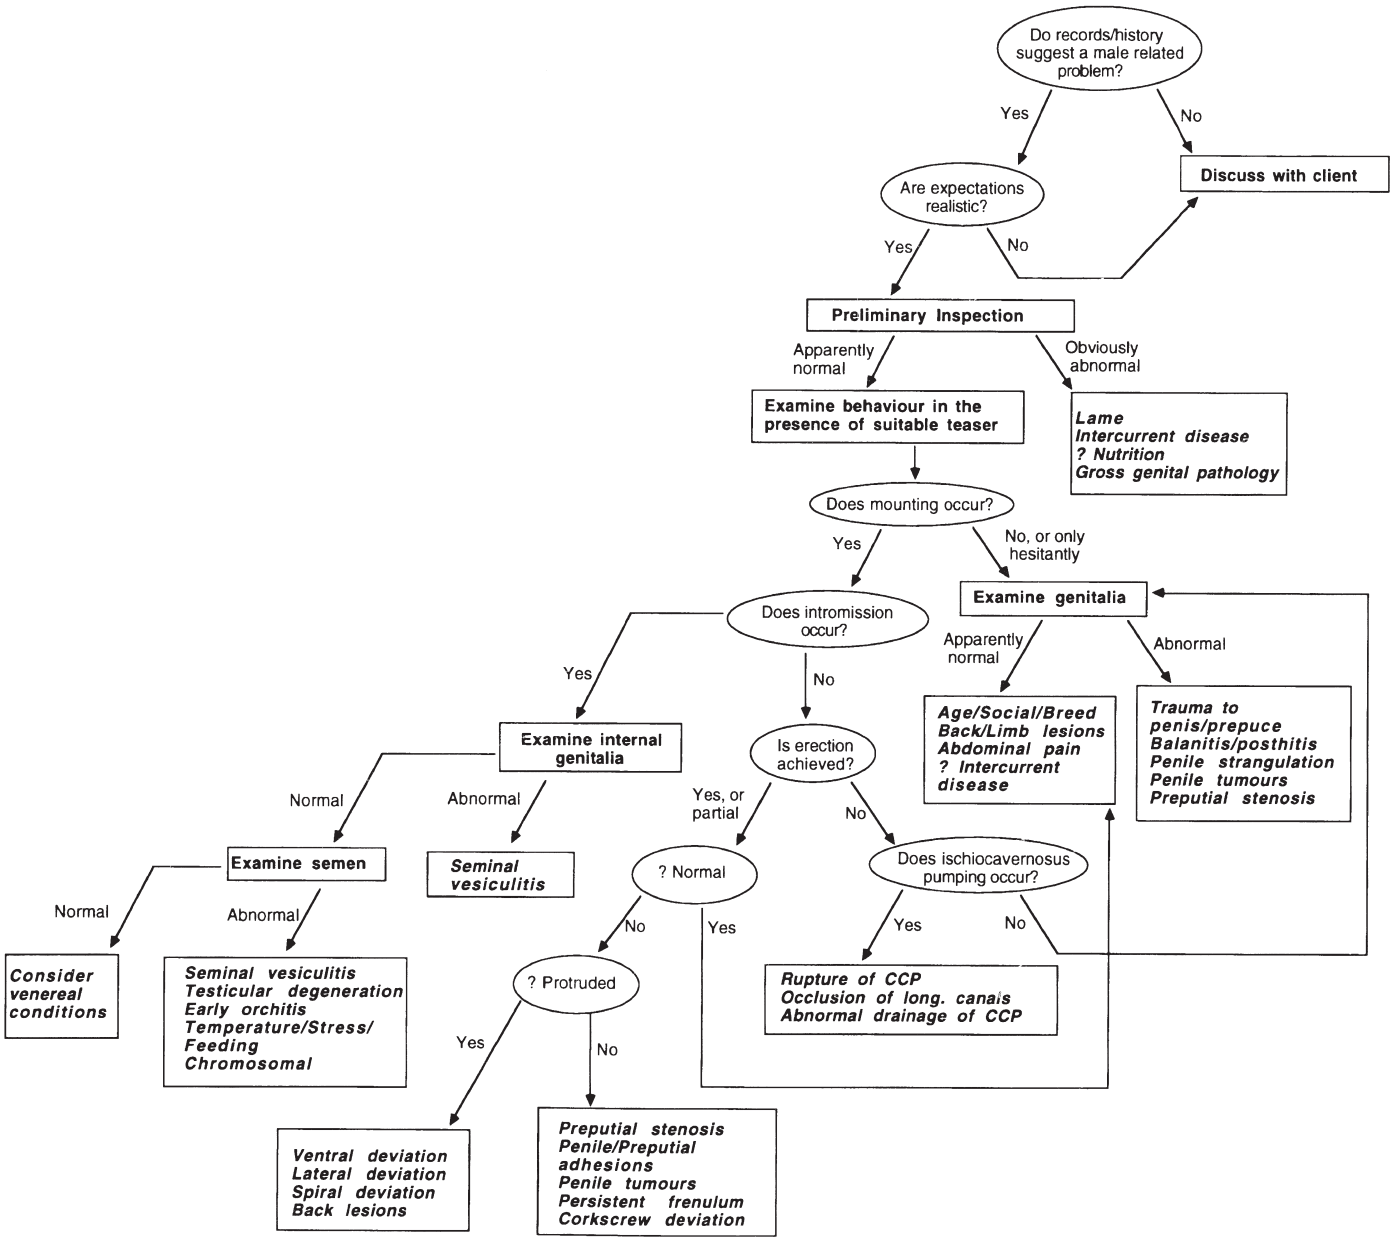
Unwillingness to copulate can also result from poor mating management. Slippery floors, roofs that are too low, females that are too big, and stockmen that are insensitive in their handling of their charges can all contribute to unwillingness to copulate. Similar problems pertain among companion animals. Tomcats frequently become conditioned to mating in one particular environment and, if that environment should later be changed, then they may become unwilling to mate. Dogs, who are frequently travelled before mating, can also have stress-induced impairment of libido. Finally, young males of many species, notably the boar and bull, are frequently unwilling to mate if within the sight or sound of an older, more dominant, male.

Inability or Unwillingness to Mount

Most lesions affecting locomotion impair ability and willingness to copulate. Lesions of the back and hindlimbs are the most important of such incapacities, but, for example, in the boar, in which the forelegs are used to clasp the female, painful lesions of the carpus can also impair mating.

In production animals and horses, foot lesions are probably of greatest significance. Gross pathology of the foot, such as sole abscess, laminitis, white line disease, infectious interdigital dermatitis, and interdigital fibroma, cause significant pain, and, as a consequence, the affected male will either be unwilling to mate or its frequency of mating will be markedly reduced. Poor conformation of the foot is less obvious but equally important as a cause of low libido. Animals with overgrown hooves, in which the distribution of weight has been adversely affected, are frequently unwilling to mount or, if they do mount, are unwilling to remain mounted for long enough for successful copulation to occur. For this reason, valuable sires in AI centres receive considerable attention to the conformation

VetBooks.ir

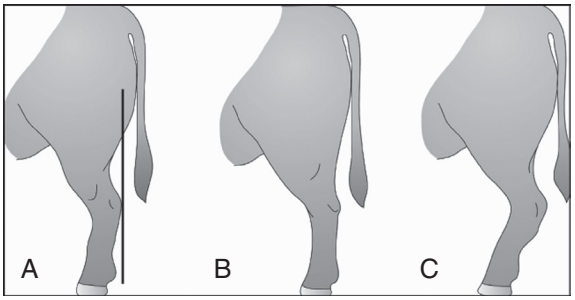


• **Fig. 36.1** Outline of the diagnostic pathways for the major causes of subfertility/infertility in bulls. CCP, corpus cavernosum penis. (With permission from Parkinson 1991.)

of their feet. By contrast, many farm sires, especially bulls, receive little such attention until overt lameness has developed.

Lesions of the joints of the hindlimb are important locomotor causes of impaired mounting behaviour in all species. Abnormalities of hindlimb conformation are also important. Older bulls whose hocks are excessively straight (a relatively common problem: Fig. 36.2a) or oversickled (Fig. 36.2c) commonly have degenerative lesions of the hock and are consequentially unwilling to mount.

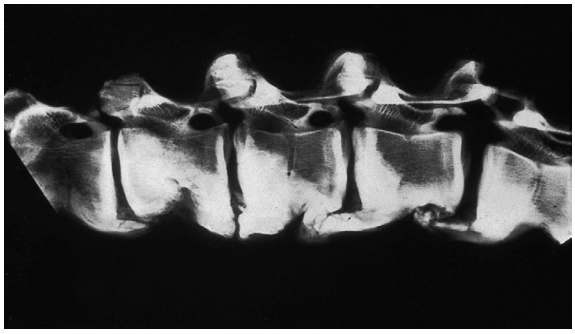
Similarly, any lesion of the vertebral column affects ability to mate; the flexure of the spine that occurs in the bull during the ejaculatory thrust is shown in Fig. 36.3. In young bulls (first mating season) that are overzealous in their early attempts to mate, the lumbodorsal fascia may rupture. In this condition the pain caused by the rupture of the fascia is such that the bull will refuse to



• **Fig. 36.2** Conformational abnormalities of the hocks (A) too straight or (C) too sickled in comparison with normal (B) predispose to reduced mating ability in older bulls. (With permission from Parkinson & Bruere 2007.)

VetBooks.ir

• **Fig. 36.3** Flexure of the spine of the bull during the ejaculatory thrust.



• **Fig. 36.4** Radiograph of the lumbar spine of an aged bull. Several of the vertebrae display significant evidence of osteoarthritis.

attempt to mount. It can be diagnosed by palpation of crepitus in the lumbodorsal region, presence of swollen firm lumbar muscles, or wasting of these muscles.

As males age, injury and degeneration of the vertebral column becomes an increasingly common cause of impaired mounting, and thus it is strongly recommended that an assessment of mating ability be routinely included in the breeding soundness examination of aged males. Breeding males with back pain may mount, but frequently dismount again quite quickly. They may rest their chin on the sacrum of the mount animal or female and tend to lever themselves upwards during mounting; they often fail to clasp the female firmly with the forelegs and their dismount is clumsy. Affected bulls are unwilling to make the ejaculatory thrust and may mount without ejaculating, or they may mount/ejaculate once but are disinclined to serve again. These bulls exhibit similar behaviour if AV collection of semen is attempted (Almquist & Thomson 1977).

A major cause of back pain in bulls is progressive degenerative joint disease affecting the intervertebral joints (Fig. 36.4), causing several related syndromes of incapacity. These conditions, which are common in housed bulls receiving diets that are relatively high in calcium (Krook et al. 1969), rarely present at less than 7 years of age (Bane & Hansen 1962). First, progressive growth of exostoses can merely make the bull appear 'stiff', and they may fail to mount and clasp the hindquarters of the cow 'cleanly'. More seriously, spondyles of bone can fracture, usually during mounting, causing immediate, acute, back pain that is accompanied by a complete, but usually temporary, unwillingness to mount. Very dramatically, when complete bridges of bone form between several adjacent vertebrae, flexing forces upon the spine can cause fractures within the spinal column, typically straight across a vertebral body. Such fractures typically occur at the moment of ejaculation, whereupon the bull becomes immediately paraplegic by spinal cord severance. The bull therefore collapses off the cow or mount animal into a dog-sitting position and exhibits partial or complete loss of sensation of its hindlimbs, depending on the severity of the spinal cord lesion.

Abnormalities of gait are a further cause of inability to mate. Details of such are beyond the scope of this chapter (for a review, see Watson 2007) other than to highlight three heritable conditions of the bull: spastic paresis, spastic syndrome, and congenital ataxia in Charolais cattle. Similar conditions occur in many other domestic species.

Finally, it should be noted that many conditions that would normally be expected to present with signs other than unwillingness to mount can, if neglected, result in a sexually uninterested animal. Lesions of the penis that prevent normal coitus (see later in this chapter) are of particular significance in this regard.

Inability to Achieve Intromission

Inability to achieve intromission is a relatively frequent cause of infertility in domestic animals. Conditions that cause failure of copulation include failure to achieve an erection, abnormalities of erection that prevent intromission, and lesions of the penis and prepuce that prevent protrusion of the penis. Most of the conditions can be differentiated relatively easily, and a prognosis can usually be given at an early stage of investigation.

Failure of Erection

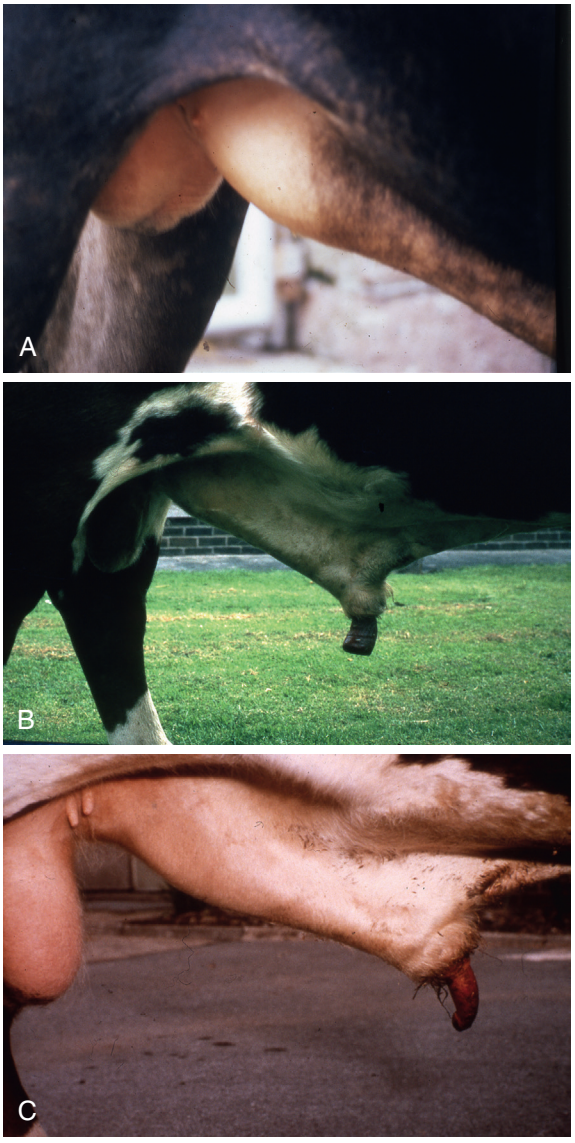
Erection is achieved by contractions of the ischiocavernosus muscles pumping blood into the corpus cavernosum penis (CCP). Because the CCP is, essentially, a blind-ending chamber, whose venous drainage is close to its arterial supply in the crura of the penis, contraction of the ischiocavernosus muscles results in occlusion of the venous return, and blood is forced into the arteries, thereby raising the hydrostatic pressure within the CCP. The hydrostatic pressure thus generated produces the lengthening and stiffening of the penis that characterises erection (Beckett et al. 1975). Thus, if any aspect of the vascular system of the CCP is perturbed, failure of erection ensues. Two main classes of abnormalities occur: those that allow blood to leak from the CCP and those that prevent normal access of blood to the CCP.

Ruptured Penis (Rupture of the CCP, Fractured Penis, and Broken Penis)

This condition has been comprehensively reviewed by Ashdown (2006). It is a common abnormality of the genital system of the bull (Hughes & Oswald 2007), and it also occurs sporadically in boars and rams. Rupture of the tunica albuginea occurs spontaneously if pressures within the CCP rise substantially higher than the pressures achieved during normal copulation (Noordsy et al. 1970, Beckett et al. 1974). Such abnormal increases in pressure can occur if the penis is suddenly subjected to shearing forces – for example, by the cow moving suddenly at the moment of ejaculation or by the ejaculatory thrust being misdirected against the perineum of the cow rather than into the vagina. Rupture (Fig. 36.5A and B) occurs most commonly either in the region of the insertion of the retractor penis muscle or on the dorsal aspect of the distal sigmoid flexure, where the trabeculae of the CCP are relatively weak. In rams, it is more common to see rupture of the CCP near the root of the penis, above the proximal sigmoid flexure, presumably as a result of being butted from behind during mating.

VetBooks.ir

• **Fig. 36.5** Ruptured corpus cavernosum penis. (A) Site of rupture of the tunica albuginea. (With permission from Parkinson & Bruere 2007.) (B) Peripenile haematoma resulting from the rupture of the CCP, sited close to the insertion of the retractor penis muscle.



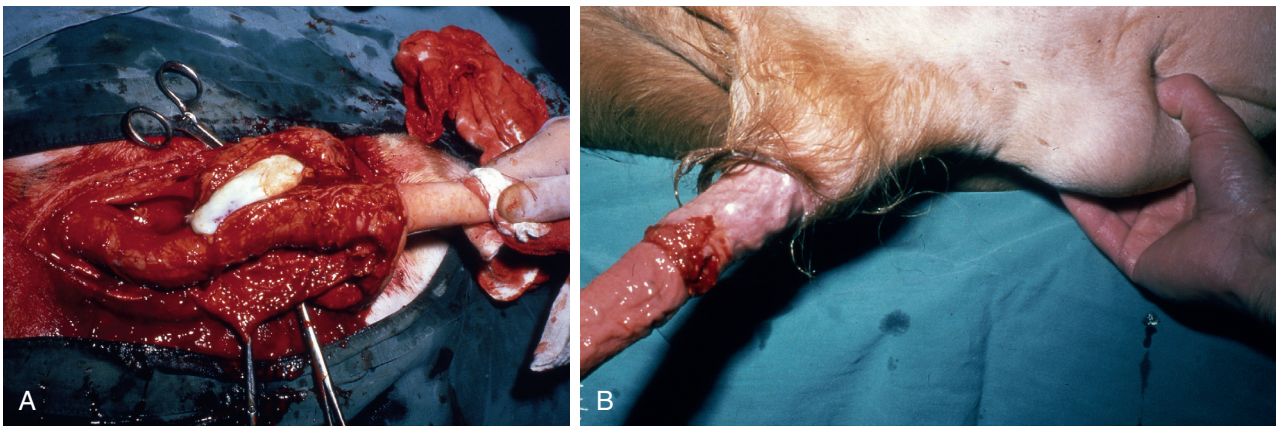
• **Fig. 36.6** (A) Prescrotal swelling due to haematoma formation after rupture of the CCP in a bull. (B) Prolapse of the preputial mucosa after rupture of the penis in a Hereford bull. (C) Prolapse of the penis secondary to rupture of the penis.

Rupture of the penis occurs more commonly in younger bulls, possibly due to a combination of over-vigorous penile thrusting and mating inexperience. Immediately after rupture, the animal may be noticeably subdued and may display signs of mild discomfort, including shortness of gait. Many, but by no means all, affected animals are subsequently unwilling to mount. Haemorrhage occurs from the site of rupture, with haematomata formation in the surrounding tissues, cranial to the scrotum in ruptures of the distal sigmoid flexure (Fig. 36.6A) and behind the scrotum with proximal ruptures. These haematomata can become very large, especially if mating behaviour is not immediately inhibited. Distal ruptures are also characterised by preputial oedema, which is often sufficiently severe to cause prolapse of the prepuce (see Fig. 36.6B). Occasionally, the penis itself may be prolapsed (see Fig. 36.6C). In light-coloured bulls, subcutaneous haemorrhage may be visible over the site of rupture of the CCP. Urination is not affected.

The haematoma is initially soft and fluctuant, but later, as the clot becomes organised, it becomes very firm. It is not possible to determine the extent of the haematoma during the initial phase when the prepuce is oedematous, so assessment must take place after the oedema has subsided. If untreated, a substantial proportion of haematomata can become infected, with subsequent formation of an abscess (Fig. 36.7A), whereas others develop fibrous adhesions between the penis and prepuce and within the fascial planes of the prepuce (see Fig. 36.7B). Diagnosis is relatively straightforward in recent cases, but chronic cases must be differentiated from preputial trauma, abscessation within the sheath, and 'water belly' after rupture of the distal urethra. Peripenile haematomata may also be caused by blunt force trauma to the sheath area during fighting (Noordsy et al. 1970).

Due to the time taken for recovery and common sequelae (adhesions, abscess, erectile dysfunction), most affected bulls, except for valuable animals, should be culled. When treatment is considered, several alternatives need to be considered, whose relative merits and demerits are still the subject of debate. Conservative treatment, consisting of sexual rest for 90 days, immediate antibiotic therapy to prevent the haematoma developing into an abscess, non-steroidal antiinflammatory treatments, and daily cold hosing of the sheath area, has been reported in some surveys to allow as many as 50% of bulls to regain the ability to serve normally. However, other surveys have indicated that a successful response to conservative therapy occurs in as few as 10% of animals. Selection of cases to which conservative treatment is applied may account for some of the variation between surveys, for bulls with relatively small, freely

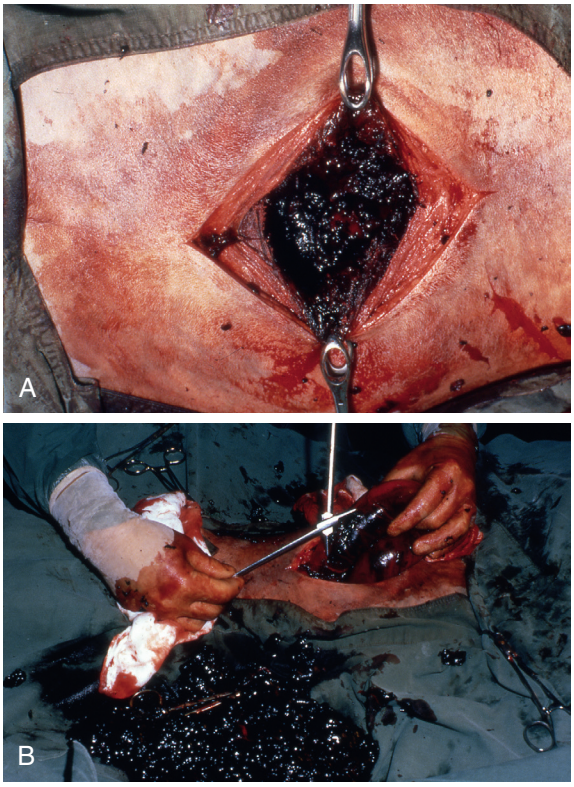
VetBooks.ir



• **Fig. 36.7** (A) Secondary abscess formation in a peripenile haematoma in a bull. (B) Preputial fibrosis in a yearling bull with a small penile haematoma. The fibrotic lesion prevented protrusion and required resection.

movable, circumscribed haematomata that are little bigger than the diameter of the normal penis respond best to conservative treatment. Larger haematomata carry a greater risk of abscess formation and development of peripenile adhesions. Surgical treatment of such cases is best confined to evacuation of the haematoma, with strict attention to asepsis (Fig. 36.8A and B). More radical surgery, in which the site of rupture of the tunica albuginea is isolated, resected, and sutured, has been suggested (Morgan 2007, Wolfe 2015a). In either case, surgery should not be delayed for more than 7 days after injury, as adhesions can become extensive thereafter. Sexual rest after surgery should only last for a few days, for a long period of inactivity also promotes peripenile adhesions. Affected bulls should be managed in a secure pen and regularly teased to induce penile movement that will reduce the risk of peripenile adhesions.

Peripenile adhesions are likely to be more severe if the clot is not removed, and even quite small areas of fibrosis can prevent penile protrusion. A small proportion of affected bulls develop ectopic veins that drain the CCP through the site of rupture, thereby preventing vascular engorgement of the CCP (Young et al. 1977). In such cases, surgical location of the site of the venous drainage and closure of the vein is often feasible (Wolfe 2015a) for, unlike congenital venous drainage of the CCP, such acquired cases usually only possess a single abnormal vein. Damage to the dorsal nerve of the penis, either at the time of injury or during surgical repair (Morgan 2007) is a well-recognised sequelae of rupture of the penis. Affected bulls often fail to achieve intromission, and, if they do, they will fail to ejaculate.



• **Fig. 36.8** (A, B) Surgical evacuation of a peripenile haematoma in a bull.

Abnormal Venous Drainage of the CCP

This rare condition (Young et al. 1977, Ashdown et al. 1979a) of young bulls presents as an animal with normal libido that is eager to mount but never achieves erection or intromission. Observation of the mating behaviour of such bulls reveals excessive ischiocavernosus muscle contractions before and during mounting, to such an extent that the tailhead appears to be pumping up and down, although the penis remains flaccid. The cause of this condition is almost invariably congenital failure of occlusion of the veins that drain the CCP (Ardalani & Ashdown 1988). A similar condition occurs in boars, in which the CCP drains into the corpus spongiosum glandis (Ashdown et al. 1982).

Diagnosis of the condition can generally be made on clinical signs and history alone. However, if further confirmation of the cause of the condition is required, the presence of ectopic veins can be confirmed by injecting radiographic contrast media into the CCP of the anaesthetised bull and then observing drainage of contrast into the dorsal veins of the penis (Fig. 36.9A and B). Because there are nearly always many small veins along both lateral edges of the CCP, surgical correction is rarely possible.

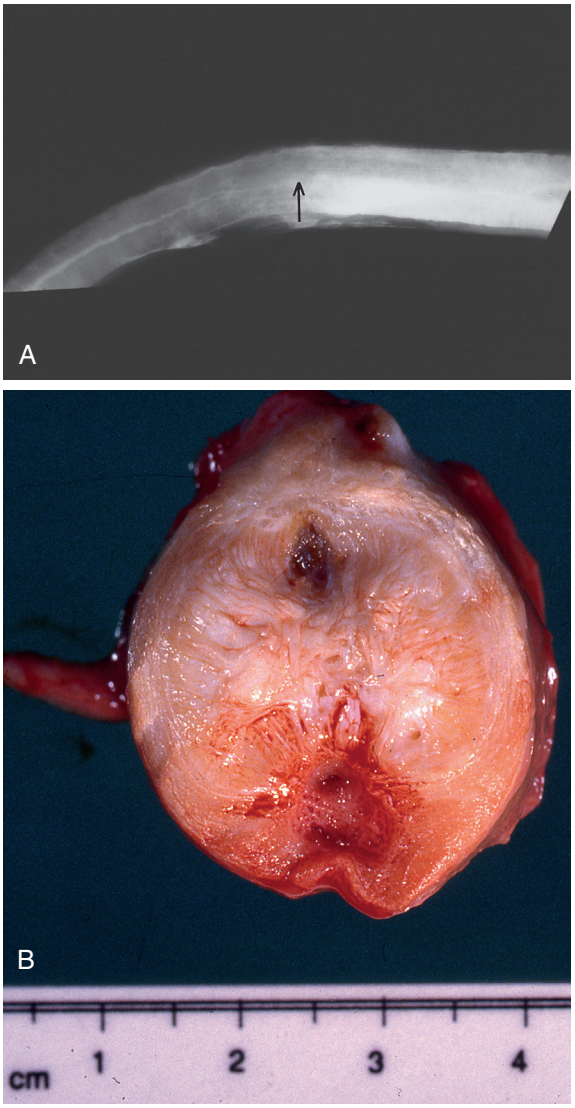
• **Fig. 36.9** Abnormal venous drainage of the CCP. Radiographs of the penis of (A) a normal and (B) an impotent bull after the injection of contrast medium into the CCP near the root of the penis. In the normal animal the contrast medium is contained within the CCP, but in the impotent animal, contrast medium is leaking into the dorsal vein of the penis, indicating the presence of ectopic veins draining the CCP.



• **Fig. 36.10** Blockage of the longitudinal canals of the penis of a bull. (A) Contrast radiography demonstrates the point at which the lumen of the dorsal longitudinal canal is blocked. (B) Transverse section of the penis, showing occlusion of the dorsal longitudinal canal with atheroma-like material.

Occlusion of the Longitudinal Canals of the Penis

During erection of the bovine penis, increased blood pressure produced by contractions of the ischiocavernosus muscles is transmitted throughout the length of the CCP by the longitudinal canals. Congenital absence or acquired blockage of these canals therefore prevents erection (Ashdown et al. 1979b). Both young bulls and animals that have been successfully used as sires over a number of years can be afflicted with this condition. Young bulls present in a very similar way to animals with abnormal venous drainage of the CCP, i.e., the penis is flaccid during attempted mating. In young bulls the condition is typically caused by a congenital failure of cannulation of the short segment of the single, dorsal longitudinal canal (between the point of fusion of the two crural canals and the origin of the first of the lateral branches that form the ventral canal). In such bulls, the condition is diagnosed by observation of mating behaviour, when the penis remains flaccid despite considerable ischiocavernosus activity. It can be differentiated from abnormal drainage of the CCP by palpation of the base of the penis. Although the great majority of the penis is flaccid, a short length of turgid tissue is present in the part of the penis proximal to the occlusion (Fig. 36.10A). This can be appreciated by palpating the root of the penis just beneath the tailhead, where the penis may become so turgid that the animal may resent it being touched. There is no treatment for this condition and affected bulls should be culled.

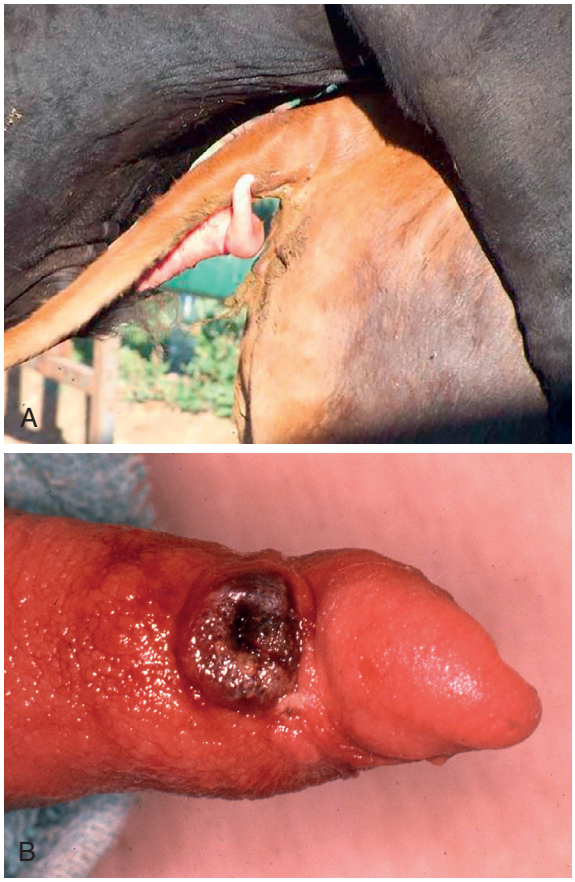
The condition in older bulls typically presents as a bull with normal libido that is observed to have a flaccid penis during attempted mating. Affected bulls typically have a history of normal service behaviour. The cause of the condition is blockage of the longitudinal canals by fibrinous or, more usually, atheromatous material (see Fig. 36.10B). This condition also occurs in rams, in which the CCP can rupture proximal to the site of obstruction, causing a peripenile haematoma in the region of the escutcheon. Similar ruptures occur infrequently in affected bulls.

Deviations of the Penis

Premature Spiral Deviation of the Penis (PSPD; Corkscrew Penis)

This is one of the most common disorders of the bovine penis (Hughes & Oswald 2007). In this condition, spiralling of the tip of the penis (which normally does not occur until the time of ejaculation) occurs before intromission (Fig. 36.11A), usually when the penis first touches the perineum of the cow (Ashdown & Coombs 1967, 1968, Ashdown et al. 1968; Seidel & Foote

VetBooks.ir



• **Fig. 36.11** (A) Premature spiral deviation of the penis (PSPD) manifested after mounting but before intromission. (B) Traumatic ulceration of the glans penis secondary to spiral deviation of the penis.

1967, 1969) or, occasionally, when the penis is still within the prepuce. Premature spiralling of the penis prevents intromission.

The onset of the condition may be at any age, although it is uncommon in yearlings and is most common in animals when they are 3 or 4 years old (Pearson & Ashdown 1976, Hughes & Oswald 2007). Hence, it is common for affected bulls to achieve normal fertility in their first year of use, then to start exhibiting premature spiralling of the penis during their second or third year. The condition is progressive, in as much as affected animals become less and less likely to achieve a normal erection with advancing age. The condition occurs more commonly in polled than horned bulls and is generally regarded as being inherited (Blockey & Taylor 1984). However, the mode of inheritance has not been proven, so culling the ancestors of affected bulls may not be warranted (Steffen 1997).

Premature spiralling of the penis can only be diagnosed by conducting a serving ability test and observing the bull attempting to serve multiple times. It is not uncommon for affected bulls to mount normally on their first attempt. The author (MMcG) has observed an affected bull show premature spiral deviation of the penis on 11 consecutive serves and then achieve normal intromission with ejaculation on the 12th serve. Affected bulls should be classified as being subfertile, as use of these bulls will cause an increase in the proportion of cows diagnosed nonpregnant or likely to calve late in herds with defined mating periods.

Frequent premature spiralling can result in the penile integument becoming traumatised as it comes into contact with the perineum of the cow. The pain caused by the consequent ulcer on the glans penis (see Fig. 36.11B) may, in time, impair the libido of the bull to the extent that he will not mount. The cause of premature spiralling of the penis has not been conclusively determined; it has variously been considered to be due to an anatomical deficiency of the dorsal apical ligament of the penis (Walker 1970), premature attainment of maximal blood pressure in the CCP, or even a neurological lesion. Given that this is a condition that is expressed in older bulls without any history of injury to the penis, it is feasible that the cause is congenital abnormal development of the dorsal apical ligament that predisposes to progressive weakening of the ligament with successive breeding seasons. Correction of the condition has been described by suturing the dorsal apical ligament to the tunica albuginea with alternating catgut and stainless steel sutures (Ashdown & Pearson 1973a) or by placement of a fascia lata graft into the ligament (Gilbert et al. 2004). However, because of the evidence that this condition is heritable, surgical repair is not recommended.

Lateral Deviation of the Penis

Lateral deviation of the penis is often attributed to injuries to the tunica albuginea of the penis but may arise from inadequate development of the dorsal apical ligament of the penis or congenital defects of the tunica albuginea; the condition has been reproduced experimentally by removal of the apical ligament of the penis in adolescent bull calves (Eurides et al. 2015). Hence, it has been suggested that some cases of right lateral deviation may sometimes be an early manifestation of premature spiral deviation of the penis. Treatment is occasionally successful, but is generally unrewarding (Boyd & Henskelka 1972, Walker & Vaughan 1980) because of the difficulty in identifying the site of the causal lesion. For valuable sires, collection of semen by electroejaculation could be considered, but the veterinarian must be confident that the problem is likely to have resulted from injury and does not have a heritable basis.

Ventral Deviation of the Penis

This condition, which is sometimes referred to as the 'rainbow' deviation (Fig. 36.12A), is commonly caused by persistence of the penile frenulum. In the absence of a persistent frenulum, the condition usually arises from defects in the fibrous architecture of the tunica albuginea. Such defects can be congenital but can also arise from injuries to the penis that result in scar formation within the tunica (see Fig. 36.12B). True ventral deviation of the penis must also be differentiated from partial failure of erection, when the penis appears deviated ventrally because of its flaccidity.

Congenital Abnormalities of the Penis Preventing Protrusion

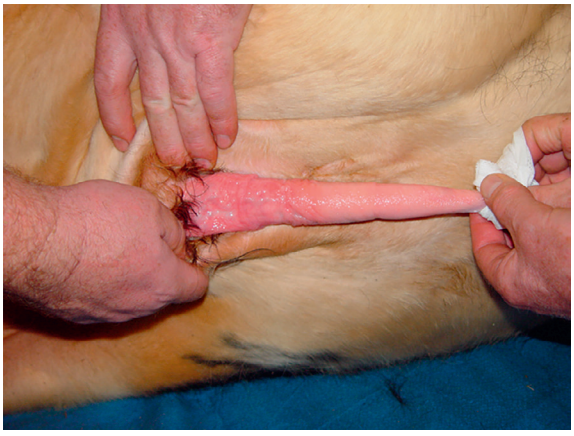
Congenital shortness of the penis (Fig. 36.13) occurs rarely and results in failure to achieve intromission (Roberts 1986). Similarly, congenital shortening of the retractor penis muscles can cause inability to protrude the penis. Although treatable by myectomy, such abnormalities are probably inherited (DeGroot & Numans 1946), so surgery should not be undertaken in future breeding animals.

Persistence of the Penile Frenulum

Persistence of the penile frenulum is most frequently encountered in bulls (Ashdown 1962, Carrol et al. 1964; Fig. 36.14A and B), but has been reported in dogs (Joshua 1962, Johnston

VetBooks.ir

• **Fig. 36.12** (A) Ventral (rainbow) deviation of the penis. (B) This can sometimes be caused by localized fibrosis. This animal was treated by excision of the lesion. (With permission from Parkinson & Bruere 2007.)



• **Fig. 36.13** Congenital shortness of the penis, which prevents intromission, is a rare abnormality of the bull.

et al. 2001) and boars. In bulls the frenulum is present at birth and should begin to break down by 4 weeks of age. Separation should be complete by 8 to 11 months of age. Persistence beyond 11 months is considered pathological (Steffen 1997). Persistent frenulum results in deviation of the glans penis, preventing full protrusion of the penis or a marked ventral deviation of the penis. Transecting the frenulum after ligating the frenular blood vessels if they are sufficiently prominent gives a good prognosis for the recovery of breeding ability (Elmore 1981, Cox 1982). There is evidence that the condition is heritable, possibly as an autosomal recessive gene in cattle (Elmore et al. 1978, Steffen 1997), so the bull's sons should not be retained for breeding.

• **Fig. 36.14** Persistent frenulum in the bull. (A) Single frenulum resulting in deviation of the penis. (B) Double frenulum in an 18-month-old Friesian bull.

Juvenile Fusion of the Penis and Prepuce

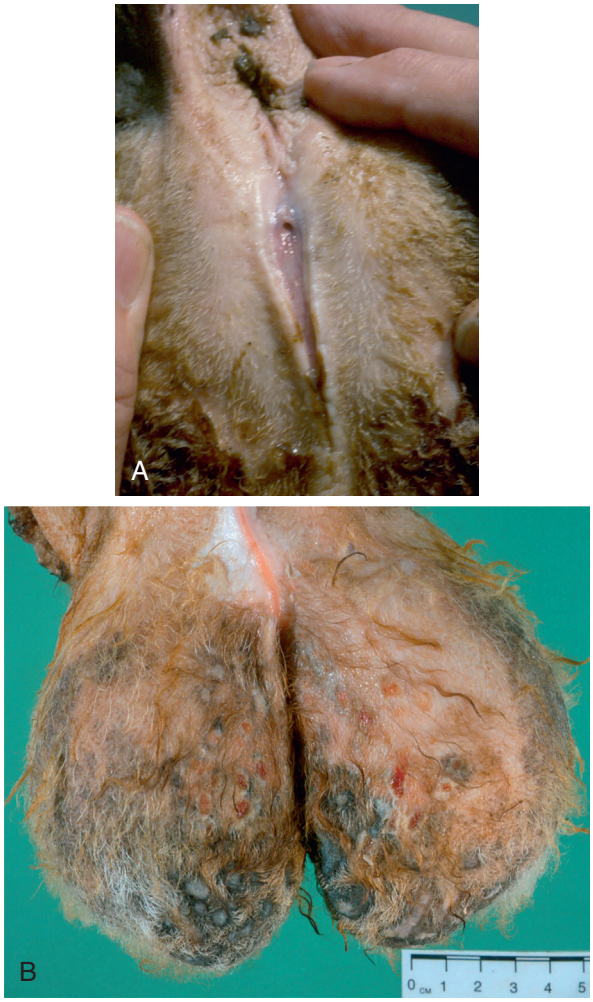
At birth, the integument of the penis and the penile part of the prepuce are fused but, during the prepubertal period, the bridging connective tissue normally breaks down (Ashdown 1962). When the connective tissue remains substantially intact, the penis cannot properly be protruded, such that only a few centimetres appear through the preputial orifice. This condition is most frequently encountered in bulls that are reared in isolation (Cox 1982). The condition is frequently self-limiting once sexual activity begins, although it may result in persistence of the frenulum. It must be differentiated from other causes of adhesions between the penis and prepuce.

Hypospadias

Hypospadias has been reported in the dog (Ader & Hobson 1978, Hayes & Wilson 1986), cat (King & Johnson 2000), boar (Langpap 1962), bull (Saunders & Ladds 1978, McEntee 1990), goat (Sahay et al. 1986, Rajankutty et al. 1994), and ram (Dennis 1979, Smith et al. 2006). This congenital abnormality of the penis results from the partial or complete failure of the two urethral folds to fuse to form the extrapelvic urethra, and failure of the median raphe of the perineum, scrotum, penis and prepuce to develop (Baskin 2000, Yamada et al. 2003).

VetBooks.ir

In the mildest cases, the genitalia appear normal, except for an abnormally sited opening of the urethra on the glans penis (Ader & Hobson 1978, Saunders & Ladds 1978). This corresponds to the classification of McFarland (1958) as a balanitic hypospadias. McFarland described three further clinical manifestations of hypospadias: (a) penile, in which the urethra opens ventrally, caudal to the glans penis and cranial to the scrotum; (b) scrotal, in which the urethra opens at the scrotum or between the left and right side of a divided scrotum; and (c) perineal, in which the urethra opens on the perineum. In the perineal form (Fig. 36.15A) the urethral orifice appears to resemble a vulva and, because such an animal also has a scrotum and penis, it may be mistaken for a hermaphrodite. The presence of a cleft scrotum (see Fig. 36.15B) is often associated with hypospadias, presumably as the presence of the urethral defect prevents the two halves of the scrotum from fusing.



• **Fig. 36.15** Hyposapdias in the ram. (A) Perineal hypospadias in a 6-month-old lamb. The urethral folds have failed to fuse over a wide area of the perineum, resulting in a large urinary meatus; the urethra is visible near the dorsal border of the meatus. (B) Incomplete separation of the scrotum in a hogget with perineal hypospadias; the mucosa is exposed above the scrotum and between the scrotum and anus, and the scrotum is severely ulcerated by urine scalding. (With permission from Smith et al. 2006.)

Lesions of the Prepuce Preventing Normal Erection

Adhesions between the peripenile tissues can arise from localised trauma, lacerations, and/or abscessation of the prepuce. Infection of the penis (balanitis) or prepuce (posthitis) is not only painful, causing unwillingness to copulate, but also can result in development of adhesions between the two, preventing protrusion of the penis.

Preputial Eversion and Trauma

Trauma occurs to the prepuce when the mucosa is not maintained within the sheath or as a result of breeding injury. Intermittent protrusion of varying lengths of preputial mucosa is a normal occurrence in many bulls, especially during sexual arousal, and in polled *Bos taurus* bulls (Long et al. 1970, Ashdown & Pearson 1973b) and *B. indicus* bulls with excessively pendulous sheaths. Aplasia or hypoplasia of the retractor muscles of the prepuce (Long 1969) predisposes *B. taurus* bulls to preputial eversion.

Laceration of the prepuce of *B. taurus* breeds does not usually lead to preputial prolapse (Wolfe 2015b). Hence, minor injuries often heal without complication with only minor superficial scarring visible on the surface epithelium of the prepuce. Damage to the prepuce occurs most commonly in the segment of preputial mucosa that is closest to the preputial orifice and therefore most likely to be everted. In such cases, trauma to the everted prepuce results in inflammation, swelling, and oedema of this tissue (Fig. 36.16A). Conversely, laceration of the prepuce and preputial prolapse occurs commonly in the pendulous sheath and long prepuce of *B. indicus* breeds. In such animals the excess prepuce is forced caudally during breeding and forms a collar at the preputial orifice, which becomes contused, lacerated, or may burst during ejaculation (Wolfe 2015b), causes the prolapse of the prepuce and, with the passage of time, the prolapse can become very large (see Fig. 36.16B). Unless replaced soon after eversion, the mucosa may become permanently prolapsed, with severe and diffuse fibrosis and thickening, often with chronic fissure formation and granulation tissue. Phimosis (i.e., inability to protrude the penis), due to stricture of the damaged prepuce, is more common in *B. taurus* than is paraphimosis (i.e., in which the penis cannot be retracted into the sheath). The development of fibrosis in the damaged prepuce results in gross impairment of penile protrusion.

Acutely affected animals may be treated by cold hosing and compression bandaging of the prolapsed prepuce to reduce swelling, disinfectant lavage and debridement, manual replacement of the everted preputial tissue, bandaging of the preputial orifice and insertion of a urine drainage tube, and, often, application of a sling to elevate the sheath against the abdominal wall (Fig. 36.17) (Walker & Vaughan 1980, Wolfe 2015b). However, chronically inflamed tissue generally requires surgical removal, with the objective of restoring free movement of the preputial mucosa during penile erection. The fibrosed preputial tissue is removed by either submucosal resection (Fig. 36.18A and B) or amputation of the prolapse if the fibrotic change extends deeply into the submucosal tissues. In principle, a circumferential incision is made in the outer layer of preputial mucosa, after which the dissection is then deepened so as to excise all the fibrotic tissue before the inner mucous membrane of the prepuce is cut. The removal of the submucosal lesions may cause considerable venous bleeding, requiring careful haemostasis. The inner layer of the mucosa is then sectioned in quadrants so that suturing of mucosal frills can be performed without risk of retraction of the inner membrane into the preputial cavity. Interrupted sutures of catgut or polyglycolic acid are suitable. Resection of lesions around the preputial orifice inevitably reduces the effective length of the penis at erection, so the amount of tissue removed should be limited to the minimum necessary to restore penile movement. Postoperative oedema may

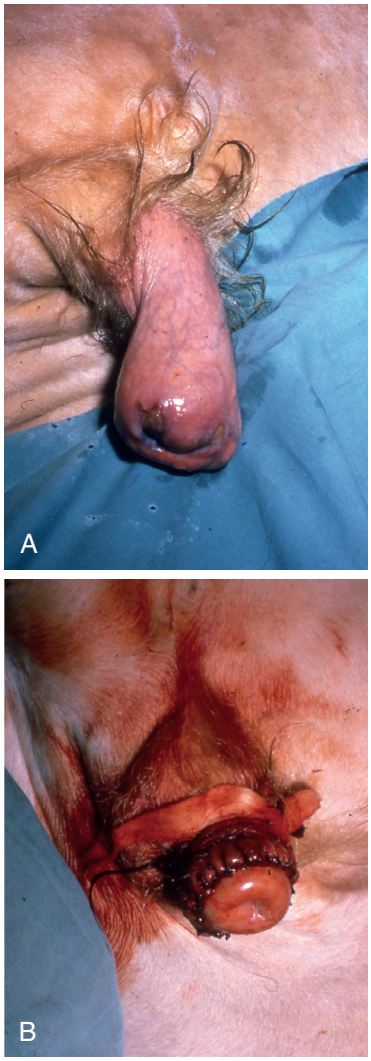
cause temporary protrusion of the sutured tissues, but this soon subsides. After 2 weeks sexual rest, the bull should be teased as frequently as possible until penile protrusion is adequate for intromission. At around 2 months post-surgery the bull should undergo a serving ability test.

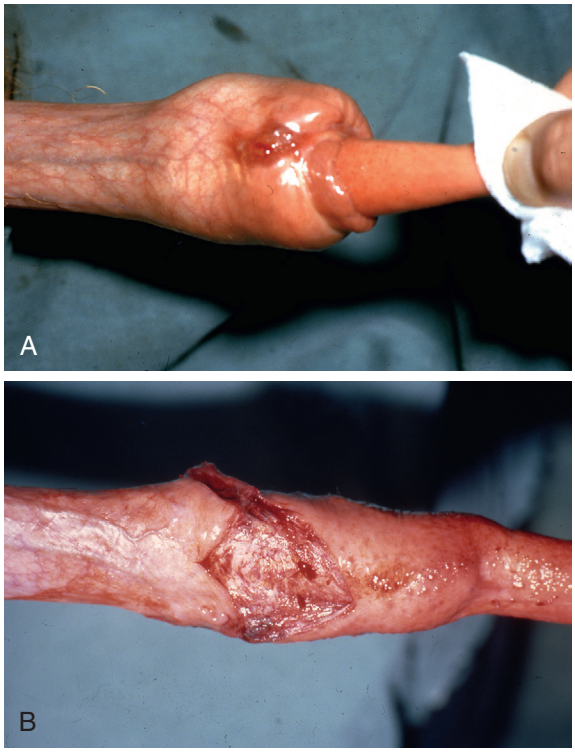


• **Fig. 36.18** (A) Chronic fibrosis in a prolapse of the distal prepuce in a Hereford bull. (B) Final repair of the lesion.

Preputial Adhesions

In the bull, preputial adhesions may occur at the site of the reflection of the preputial mucosa on to the penile integument (Fig. 36.19A). This site is less common than at the preputial orifice but presents greater difficulty in treatment. The cause of such lesions is not always clear, but may result from partial or complete avulsion of the prepuce from the penis during copulation or AV collection of semen. Alternatively, lesions may occur when the prepuce becomes lacerated deep within the preputial cavity, also as a result of the ventral prepuce bursting during the ejaculatory thrust. The site of such lesions is not always clear on clinical examination, for the changing relationships between penis and prepuce make it difficult to correlate the apparent site of a lesion with its position when the penis is protruded under anaesthesia. Intrapreputial lesions present difficulties of exposure for surgery. Even under general anaesthesia, it may be difficult to expose the penis fully without tearing the tissues at the site of fibrotic change. After the penis is extruded, forcibly if necessary (see Fig. 36.19B), all fibrotic tissue masses are excised down to the tunica albuginea between two circumferential mucosal incisions at the proximal and distal extremities of the lesion. The mucosal edges are sutured as for distal resections, and the animals are managed similarly in

VetBooks.ir



• **Fig. 36.19** Adhesions between the bovine penis and prepuce (A) at the site of the preputial reflections. (B) The adhesions shown in (A) have been forcibly torn apart as a precursor to resection of the fibrotic tissues.

the postoperative period. Such surgery is surprisingly effective, although somewhat unpredictable. Much depends on the length of mucosa that requires resection.

Phimosis

Phimosis indicates a stricture of the preputial orifice that prevents the penis from being protruded. It has been recorded in most of the domestic species.

In dogs, phimosis may be a congenital or acquired defect. Congenital forms are overrepresented in the German Shepherd and Golden Retriever breeds; aetiologies include relatively undersized preputial opening, a small or short penis, and the persistence of tissue bands that connect the penis to the preputial mucosa. Severely congenitally-affected puppies may be unable to urinate adequately, with the consequential balanoposthitis leading to septicaemia and death (Volkman 2013). Acquired lesions include strictures due to fibrosis and stenosis of the preputial orifice, balanoposthitis that causes adhesions between the penis and prepuce, and neoplasia. Balanoposthitis can also occur secondarily to dysuria. When dogs are affected by congenital lesions or a simple stricture of the preputial orifice, they may be treated by removing a wedge of preputial skin, fascia, and mucosa from just behind the ventral aspect of the preputial orifice. Mucosa and skin are then sutured together. Mild urine scalding may occur after surgery, as urine does not run away freely (Burke 1986, Allen 1992). The prognosis for survival of the animal is good; however, the prognosis for use as a breeding sire is poor, and animals that have a congenital form of the condition should not be used for breeding due to the risk of inheritance of the condition.

In the stallion, phimosis is primarily caused by congenital or acquired stricture of the preputial orifice or in neglected cases of penile carcinoma. As in the dog, the presence of the stricture can cause retention of urine within the prepuce, resulting in a secondary balanoposthitis. Congenital causes are virtually unknown in the stallion. Treatment is primarily by removal of a wedge of tissue from the ventral aspect of the prepuce.

Phimosis is not a common condition of the bull; its most frequent aetiology is large penile fibropapillomata that prevent protrusion of the penis. It can also occur as a result of preputial adhesions, especially those due to bovine herpesvirus-1 (BoHV-1)-induced balanoposthitis.

Paraphimosis

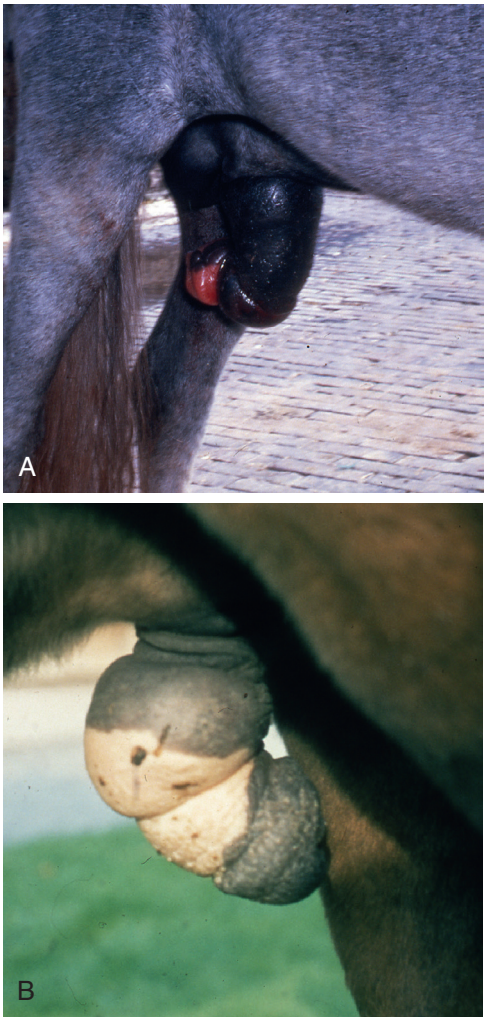
Inability to withdraw the penis into the prepuce results from congenital or acquired strictures of the prepuce, paralysis of the penis, and, occasionally, balanoposthitis. Although not strictly constituting paraphimosis, some coital injuries to the penis also prevent its return to the prepuce. The condition is most common in the dog and the stallion but is also reported occasionally in most domestic species.

Paraphimosis in the dog is relatively common after copulation or spontaneous erection. It may also occur when the preputial opening becomes constricted, preventing return of the penis to the prepuce (Kutzler 2013a) or as a sequel to fracture of the os penis, balanoposthitis, or penile neoplasias (Root Kustritz 2001). In cases that have occurred recently, the size of the penis (oedema and inflammation) can be reduced with using cold compression bandages, massage with topical hyperosmotic solutions, and systemic antiinflammatory therapy (Root Kustritz 2001), after which the penis can often be returned to the prepuce with careful manipulation and plentiful lubrication. However, in cases in which the problem is not detected quickly, the penis becomes oedematous and swollen, and the integument increasingly friable. In such cases the preputial orifice may need to be surgically enlarged before the penis can be replaced (Kutzler 2013a). In serious cases or in animals in which the penis has become strangulated, penile amputation may be required, although phallopexy has been successfully employed as a means of managing recurrent paraphimosis in the dog (Somerville & Anderson 2001). The prognosis for cases that have not been treated promptly is therefore guarded, depending on the severity of trauma and the degree of necrosis the penis has sustained. Unfortunately, the dorsal nerves of the penis are highly susceptible to ischaemic damage, and as these are required for the ejaculation reflex, inability to ejaculate is a relatively common sequel of relatively minor penile damage. Castration is not recommended as a long-term treatment for paraphimosis, as the condition also occurs in neutered dogs. However, Root Kustritz (2001) suggested that progestogen therapy may be beneficial in castrates with recurrent paraphimosis.

In the stallion, paraphimosis (Fig. 36.20A and B) usually occurs as a consequence of genital trauma, such as covering injuries, preputial laceration, penile hematoma, castration, inguinal surgery (Schumacher 2012), or other conditions that result in local or systemic oedema. It has also been associated with damage to the innervation of the penis, including disorders of the pudendal nerve or central nervous system. Paraphimosis can also be the sequel of priapism, severe systemic illness, debilitation, and exhaustion. A transient penile paralysis occurs after the administration of phenothiazide tranquilisers (Pearson & Weaver 1978, Lucke & Sansom 1979), which can progress to an irreversible paraphimosis. Paraphimosis has occasionally been reported as a consequence of malicious injury.

Schumacher (2012) described the pathology of the condition. Paraphimosis occurs primarily as the result of oedema collecting

VetBooks.ir



• **Fig. 36.20** (A) Penile prolapse in a horse after being kicked during mating. (B) Priapism, 9 days after administration of neuroleptanalgesia for castration.

in the loose connective tissue between the penis and the internal lamina of the prepuce. The weight of that oedema overcomes the tone of the retractor penis muscle, which is followed by protrusion of the penis and preputial tissue from the preputial orifice. Prolonged protrusion causes further oedema of the penis and prepuce by impairing venous and lymphatic drainage and by the preputial ring becoming a constricting cuff to the venous return from the prolapsed tissues. Additionally, the blood clots in the CCP within 2 to 5 hours of protrusion, making the penis relatively rigid. Subsequently, the penile and preputial epithelium becomes excoriated and then becomes inflamed due to bacterial invasion of the damaged tissue. Eventually, fibrosis of the penile integument and fascia occurs, causing permanent impairment of the normal telescoping action of the prepuce.

The earlier treatment is instigated, the greater the chance of obtaining a satisfactory outcome. Treatment (Cox 1982, Schumacher & Varner 2011) must aim to reduce oedema, prevent trauma to the penile integument, and provide support for the penis until it can be returned to the prepuce. In the early stages, oedema may be dissipated by the use of cold water hosing, cold packs, and compression bandaging, and the use of antiinflammatory drugs and diuretics may also be helpful. Perhaps the most important aspect of treatment is providing adequate support for the penis; drainage of fluid from the penis is greatly facilitated by reducing the tension on the lymphatics that is caused by the weight of the swollen, pendulous penis. Effective supports have been made out of nylon stocking material or U-section plastic guttering, appropriately slung around the horse's hindquarters. The surface of the penis must be protected by the use of ointments that prevent drying or by antiseptic ointments if open wounds are present. Incision of the preputial ring can sometimes be beneficial. Once fibrosis of the preputial tissue has occurred, the prognosis for recovering the animal as a breeding stallion is very poor (Schumacher 2012).

Priapism

Priapism is an uncommon disorder in male cats and dogs and in stallions. Priapism is characterised by a persistent penile erection that lasts for more than a short period of time (variously categorised as between 1 and 4 hours), resulting in pain and dysuria. Priapism is categorised into nonischaemic (arterial aetiology: 'high flow' priapism), which can occur as a result of abnormal blood flow to the penis (e.g., the presence of arteriovenous anastomoses or dysfunction of the neural control of erection) or ischaemic priapism (venoobstructive aetiology: 'low flow' priapism), which can occur due to decreased venous outflow consequent upon occlusive thromboembolic or compressive masses (e.g., tumours or abscess) within the pelvic cavity. The most common cause is trauma that occurs during mating or surgery. Sequelae of priapism are necrosis of the penis and, if it also causes obstruction of the urethra, urine retention/uraemia (Lavely 2009, Kutzler 2013b).

In the dog, the condition can be managed medically or surgically. Medical treatment consists of various combinations of cold water compresses, topical hypertonic solutions, penile lubrication, antiinflammatories, broad spectrum antibiotics, and diuretics (Kutzler 2013b), together with oral pseudoephedrine. Anticholinergic agents may also be of benefit. Surgical treatment consists of replacing the penis within the prepuce by enlargement of the preputial orifice. However, this does not necessarily resolve the congestion of the penis, which may need to be relieved by surgical drainage of the blood from the CCP. Because necrosis of the penis often follows priapism, even when the penis has been replaced into the sheath, amputation is often the final outcome of the condition.

Priapism in the stallion is almost invariably of the 'low flow' type. The most common aetiology is a sequel to the administration of a phenothiazine-derivative tranquiliser; their mode of action appears to be blocking α–adrenergic impulses that mediate detumescence. Rare causes of priapism include general anaesthesia, nematodiasis of the spinal cord, and neoplasia of the pelvic canal (Schumacher 2012). Management is similar to that of paraphimosis, especially in established cases. However, when a failure of detumescence is considered as the primary aetiology, intravenous administration of the cholinergic blocker benzatropine mesylate, plus adrenaline or phenylephrine injection into the CCP, may be beneficial in recently affected animals (Schumacher & Varner 2007). Surgical drainage or the creation of vascular shunts between the CCP and CSP has also been suggested in cases that are unresponsive to medical treatment; penile amputation is a very common outcome in cases of both paraphimosis and priapism.

Other Conditions of the Penis

Strangulation and Necrosis of the Penis

Strangulation may occur as a consequence of paraphimosis or as a result of constriction of the penis by a ring of hair from the preputial orifice or maliciously placed objects. It is most common in long-haired breeds of dog and long-woolled breeds of sheep

VetBooks.ir

• **Fig. 36.21** Strangulation of the penis of a ram after long strands of fleece became wrapped around the glans during successive copulations.

(Fig. 36.21) but has also been reported in bulls. As with paraphimosis, the prognosis depends on the duration of the vascular constriction and the degree of necrosis that has ensued. Restoration of penile anatomy is relatively easy to achieve for, providing gross necrosis has not occurred, the ability of the organ to heal is relatively good. However, loss of function, particularly impairment of the ejaculation reflex, occurs after relatively short periods of ischaemia. Therefore the prognosis should always be guarded in the first instance. When gross necrosis has occurred, amputation of the penis may be indicated.

Urolithiasis

Urolithiasis is a relatively common condition of castrated male ruminants and of intact rams and bucks (male goats). The presence of urethral calculi causes obstruction of the urethra, which can then lead to necrosis of the penis, rupture of the urethra, rupture of the bladder, tissue necrosis due to urine accumulation, and death from uraemia/toxaemia. The most common predisposing factor is rapid growth of yearlings/2-year-olds on a high concentrate diet that is also rich in magnesium, phosphorous, and/or calcium. Urolithiasis can, however, occasionally occur in any male ruminant, even in the absence of obvious predisposing factors. The most common type of calculus is struvite (magnesium ammonium phosphate); and calcium hydrogen phosphate dehydrate; silicate and calcium carbonate calculi can also occur.

In the early stages of the disease, animals may frequently attempt to urinate, but, as the condition worsens, the primary signs become anorexia and abdominal pain. On clinical examination, it may be possible to palpate a large intact bladder, or, if the bladder has ruptured, there will be a large volume of fluid (urine) within the abdomen. If the urethra ruptures, there will be progressive fluid accumulation within the ventral body wall. Rupture of bladder or urethra is accompanied by reduced signs of abdominal pain and increased signs of uraemia (Van Metre 2004).

The most common site of primary blockage of the urethra of rams and bucks is the base of the vermiform appendage. If the animal is presented in the early stages of the disease, it can be resolved by simply amputating the appendage. Recovery is rapid and fertility will not be impaired. However, it is not uncommon for calculi to completely obstruct the urethra leading to varying degrees of penile necrosis and rupture of the urethra with infiltration of urine into the surrounding sheath. In valuable animals, tube cystotomy is the preferred approach, as the alternative typically involves perineal urethrostomy, accompanied, if necessary, by penile amputation.

Cattle are also affected by urethral calculi, of which the most common forms are silicates, xanthine, and different types of carbonates and phosphates. Phosphate calculi are found mainly in feedlot cattle, whereas silicate calculi occur predominantly in grazing cattle. The site of obstruction in cattle is usually the distal sigmoid flexure, so the only feasible means of treatment is by perineal urethrostomy (Vermunt et al. 2010).

Prevention is by controlling the mineral content of the diet, feeding salt to stimulate thirst, ensuring that animals have an adequate supply of water, and adding dietary supplements to the ration to acidify the urine.

Fracture of the Os Penis

This is a relatively common problem in the dog. Clinical signs may be evident as an immediate consequence of the fracture or may present later as a cause of penile abnormalities or failure of coitus. The condition is sometimes associated with trauma to the penis, but the aetiology is often obscure (Johnston et al. 2001). Manifestations of the condition range from dysuria and haematuria through to abnormalities of erection and genital pain to renal failure. Simple acute fractures may be managed conservatively via closed reduction and placement of an indwelling urinary catheter to impart stability during healing. Long-standing fractures, particularly where callus formation causes dysuria due to constriction of the urethra, require more radical surgical intervention such as removal of the os penis or penile amputation (Voelkl 2013).

Miscellaneous Conditions

Complete avulsion of the preputial mucosa from its attachment to the glans penis is an occasional injury of bulls that usually results from careless use of an AV (Roberts 1986) but may occur in naturally mated bulls.

Diphallus, or duplication of the penis, is an exceedingly rare condition but has been occasionally reported in the bull and dog. Lesions may be confined to the penis, or there may be more generalised urogenital or skeletal abnormalities.

Disuse atrophy of the retractor penis muscle can occasionally occur in bulls that have been unable to achieve an erection over a long period of time. Although calcification of the retractor penis muscle, which occurs in aged bulls, does not affect mating ability, there is some evidence it may increase the risk of preputial eversion, one of the major predisposing factors for prolapse of the prepuce.

Balanoposthitis

Infections of the penis and prepuce are common in the dog, bull, and ram, occasional in the stallion, and rare in the boar and cat. Low grade infection of the preputial cavity is very common, and rarely causes clinical disease. Severe balanoposthitis can cause pain, unwillingness to mate, preputial stenosis, adhesions between penis and prepuce, and peripenile adhesions.

Balanoposthitis in the Dog

Mild balanoposthitis is particularly common in the dog, in which the prepuce almost always contains a mild seropurulent exudate, which is rarely indicative of clinical disease. It does cause a great deal of anxiety to some dog owners, who find both the discharge of such material from the preputial orifice and their dog's efforts to cleanse himself of it offensive. Prophylactic treatment of these mild infections is also frequently requested by owners of stud dogs. Such requests should be considered with some caution for, whereas the use of mild antiseptic douches or bland antibiotic or antiseptic ointments rapidly clear any infection, the loss of the

normal bacteriological flora from the preputial cavity can predispose to the establishment of opportunist infections by organisms of clinical significance.

More serious cases of balanoposthitis can occur in conjunction with opportunistic bacteria (particularly *Escherichia coli*), mycoplasmas (chiefly *Mycoplasma canis*), and viral infections with canine herpesvirus or, occasionally, calicivirus (Johnston et al. 2001). It can also occur in animals with atopic dermatitis (Root Kustritz 2001). Clinical signs include purulent preputial discharge, which may also be bloody, accompanied by inflammation and ulceration of the penile integument, conspicuous lymphoid nodules, and, sometimes, petechial or submucosal haemorrhages (Johnston et al. 2001). Treatment is by infusion of bovine intramammary formulations of appropriate antibiotics and flushing of the preputial cavity with water or saline.

Bovine Herpesvirus

In bulls, a severe, ulcerative balanoposthitis is caused by the genital form of BoHV-1 infection (McEntee 1990, Weiblen et al. 1992). The penile integument and preputial mucosa are initially covered with small necrotic foci, which develop into deep ulcers. In severe cases, these coalesce into large areas over which the penile integument has sloughed. Secondary bacterial infection of the ulcers results in a severe, purulent balanoposthitis, causing very considerable discomfort to the bull. Affected bulls may exhibit swelling and pain in the region of the penis and are commonly dysuric. There is characteristically a fetid, watery, preputial discharge, containing shreds of sloughed tissue and small amounts of fresh blood (Fig. 36.22). Cows that have been served by affected bulls may develop signs of infectious pustular vulvovaginitis; the bull may be relatively asymptomatic despite causing characteristic lesions of pustular vulvovaginitis in the cows (e.g., Pritchard et al. 1997). It is unusual (although not unknown) for animals with genital lesions of BoHV-1 to also show upper respiratory (infectious bovine rhinotracheitis) signs.

Mild cases of BoHV-1 balanoposthitis may heal without complication over 1 to 2 weeks, but more severe cases can develop adhesions between the penis and prepuce. Adhesions develop quickly, appearing within only about a couple of weeks of the onset of acute symptoms. Adhesions can be extensive, involving most of the free part of the penis (Fig. 36.23). Affected bulls are unable to achieve a normal erection, with only a few centimetres of the tip of the penis being protruded through the preputial orifice.

BoHV-1 is transmissible in semen, which presents considerable risk if bulls that either have active infection or are seropositive are used in AI programmes. For this reason, many regulatory authorities preclude the use of seropositive bulls as semen donors or insist on testing the semen for BoHV-1 by means of viral culture or polymerase chain reaction (OIE 2017a).

Penile Granulomas in Bulls

Bulls are also susceptible to granuloma formation on the penis, which is a nontransmissible and usually asymptomatic condition (Cox 1982, Roberts 1986). Occasionally, it causes pain and an unwillingness to mate. The condition is characterised by hypertrophy of the lymphoid nodules of the penis in the absence of an obvious, purulent balanoposthitis. Sexual rest and prophylactic infusions of oily suspensions of antibiotic into the prepuce usually produces a resolution of clinical signs. However, granuloma of the penile integument of bulls is also associated with *Ureaplasma diversum* infections (Marques et al. 2009), which are a potentially serious infectious cause of infertility and/or abortion. Tuberculous balanoposthitis has been described in areas where the disease is epizootic (Williams 1943). Its signs include enlarged, granulomatous lesions of the penis that may bleed, peripenile adhesions, and secondary phimosis. This condition must be differentiated from actinomycosis of the prepuce, which causes a similar syndrome.

Ulcerative Posthitis ('Pizzle Rot') of Rams

Balanoposthitis is a relatively common condition of male sheep, in which it is colloquially known as pizzle rot. Bacterial balanoposthitis is caused by a number of organisms, of which *Corynebacterium renale,* an organism that grows readily in alkaline urine, is the most important. The disease is more common in wethers than in rams because of the effects of early castration on development of the genitalia and the absence of circulating testosterone. The condition is most common in animals that are fed on lush pastures that contain high levels of rumen degradable protein. From the urea contained in the urine, the bacteria produce ammonia, which scalds the preputial region. Ulcers and scabs develop around the preputial orifice. Eventually, the preputial orifice may become occluded, leading to urine retention within the preputial cavity (Fig. 36.24). Treatment of advanced stages of the disease is seldom successful, but mild lesions resolve simply by reducing the urea load in the urine by restricting access to lush grass (West et al. 2018) and shearing the underside of the ram. The condition can be prevented in intact rams by keeping the belly and preputial region shorn. In wethers, especially the older animals that are kept for wool rather than for meat, testosterone implants are used prophylactically, with considerable success.

VetBooks.ir

• **Fig. 36.24** Balanoposthitis in the ram. Characteristic staining of wool around the preputial orifice. (With permission from Bruere & West 1993.)

• **Fig. 36.25** Scars left on the ovine penis by healed contagious pustular dermatitis (orf) lesions.

The same condition occurs in young bulls fed high protein rations or pasture in preparation for sale. The preputial orifice of affected bulls should be debrided followed by topical application of intramammary preparations of penicillin or cloxacillin, with more severe cases also being treated with parenteral penicillin.

Contagious Pustular Dermatitis Affecting the Genitalia of Rams and Bucks

Lesions due to contagious pustular dermatitis (*syn: orf, scabby mouth*) virus occur around the genitalia of rams and bucks – on the preputial orifice, prepuce, and glans penis – where the shallow ulcers are generally covered by a scab. There may also be lesions present in the other sites characteristic of orf, namely the lips, nostril, and feet and in females of the same flock, the vulva and teats. The disease is spread by contact, including venereal contact. Affected rams are generally unwilling to achieve intromission, but their libido is often maintained sufficiently to allow mounting to continue. Thus, the condition may escape notice for quite long periods of time until it is realised that there is a very high incidence of returns to oestrus among the ewes. In these situations the primary lesions are often healed by the time animals are presented for clinical examination with little evidence, other than the scars left on the glans penis by the healing ulcers (Fig. 36.25), that infection has occurred.

Dourine

The most serious cause of balanoposthitis in the stallion is the notifiable disease of dourine (De Vries 1993, Luckins et al. 2004). Dourine is caused by the protozoan parasite *Trypanosoma equiperdum* and occurs in the Middle East, North Africa and South America. Pockets of infection also occur in the Balkans and South Africa. The infection is the only trypanosomosis that is not transmitted by an invertebrate vector, and there is no known natural reservoir of the parasite other than infected equids (OIE 2017b). Infection is predominantly venereal, but can also be transmitted through infected AI equipment, and can be passed to foals through vaginal discharges from the mare. It affects all domestic equids, but donkeys and mules are more resistant than horses.

The incubation period, severity, and duration of the disease vary considerably. It is often fatal, but there are records of spontaneous recoveries and of latent carriers. The disease is marked by stages of exacerbation, tolerance, or relapse, which vary in duration and which may occur once or several times before death or recovery (OIE 2017b). The initial sign is oedema of the prepuce, penis, scrotum, and surrounding skin, which may be sufficiently severe to cause paraphimosis. Inguinal lymph nodes are often enlarged, and there may be a mucopurulent urethral discharge. There are also neurological signs of incoordination and facial paralysis, and a fluctuating pyrexia. A pathognomonic sign, if present, is the presence of 5 to 8 cm oedematous plaques in the skin, usually over the ribs. Death may occur within 1 to 2 months of infection (although in southern Africa it is more common for the condition to be more chronic) as the consequence of vascular degeneration causing peripheral nerve degeneration, muscle wasting, emaciation, and paralysis. The condition can be treated in its early stages by trypanocidal drugs, although in many countries (i.e., northern and western Europe, the United States, Canada, and Australasia) control is through notification and slaughter policies.

Equine Habronemiasis

In parts of the world where *Habronema muscae* occurs, larval infection produces granulomas in the equine penile and preputial integument. Cutaneous habronemiasis (*syn: granular dermatitis*) is a granulomatous, mildly pruritic disease caused by cutaneous migration and encystment of the larvae of the equine stomach worm *Habronema.* Larvae passed in the faeces are ingested by fly maggots, and after the maggot pupates, the larvae are deposited on wounds from the feeding fly. The disease is associated with the seasons in which flies are abundant and, in temperate climates, lesions commonly regress during the winter (Schumacher 2012).

Genital lesions are most commonly found at the preputial ring and the urethral process, where larval infestation causes local hypersensitivity and extensive granulomatous reactions. These bleed easily, may appear ulcerated, cause pruritus, and can cause prolapse of the affected tissue from the preputial orifice. Lesions of the urethral process can result in dysuria (Stick 1981). Treatment is by eliminating the larvae with systemic insecticides (e.g., ivermectin) or diethylcarbamazine and reducing the hypersensitivity reaction (e.g., prednisolone) (Schumacher & Varner 2011). Occasionally, surgery is required to relieve urethral obstruction or to remove the scar tissue that may form during healing (Stick 1981).

Equine Coital Exanthema

A more common condition of stallions is equine coital exanthema, or horse pox (reviewed by Barrandeguy & Thiry 2012), which is

VetBooks.ir

caused by equine herpesvirus-3 (EHV-3). The mode of transmission is predominantly venereal, which includes coitus, via a contaminated artificial vagina and through insemination with infected semen. It may also be transmitted by insect vectors (Gibbs et al. 1972) or fomites, although non-coital transmission has also been associated with the genitonasal contact via nuzzling. In common with many other herpes viruses, EHV-3 can become latent and undergo periods of reactivation (Barrandeguy et al. 2008), such that stallions can become long-term carriers and/or excreters of the virus.

Lesions occur mainly on the free part of the penis and prepuce. After serving an infected mare, small papules initially appear that, within a few days, develop into vesicles surrounded by hyperaemia and oedema. These rupture and form shallow, raw, or encrusted erosions or ulcers. Uncomplicated lesions heal within 10 to 14 days (Blanchard et al. 1992). When the density of lesions is sufficiently great, large ulcerated areas may appear. Mild infections do not impair libido, although lesions with severe secondary infection may do so. Blood may be present in the ejaculate (Ley & Slusher 2007). Diagnosis is by detection of the virus or demonstration of seroconversion. Control is achieved by preventing clinically affected animals from mating, although individual animals may need affected areas to be washed weekly with antiseptic solution to limit the establishment of secondary infection. Immunity is, however, short term, so reinfection is a distinct possibility.

Penile Neoplasia

Bull

The only common tumour of the bovine penis is the virally induced fibropapilloma. Young cattle commonly have papillomata of the skin, alimentary tract, and mucocutaneous junctions, including the genitalia. The penile integument, particularly its terminal 5 cm, is a common site for such tumours, which may be single or multiple, sessile or pedunculated (Fig. 36.26). Tumours can be found in intact and castrated animals but rarely persist beyond 3 years of age. Clinical effects vary according to the size and the morphology of the lesions. Haemorrhage and ulceration of the tumour mass caused by mating are the most common sequelae, and the associated pain is sometimes sufficiently severe to impair libido. Very large lesions can sometimes result in intermittent or complete failure of retraction of the protruded penis into the sheath, with subsequent marked to severe inflammation of the prolapsed penis. Rarely, rapid growth of fibropapilloma within the preputial cavity can result in compression and occasionally rupture of the urethra.

Fibropapillomas sometimes undergo necrosis with varying degrees of sloughing; others become detached during coitus, whereas others spontaneously regress. However, such resolutions cannot be predicted, so recourse to surgery is frequently indicated (Pearson 1972). Single, pedunculated lesions can be ligated relatively easily during electroejaculation of bulls, but excision of sessile lesions requires sedation and either local infiltration of local anaesthetic or administration of a bilateral pudendal nerve block (Morgan 2007). Very occasionally, removal of large tumours that envelop the glans penis requires general anaesthesia. Although haemorrhage from the site of removal may persist for some time, it is rarely dangerous, and, provided the tumour does not recur, the wounds generally heal quickly. Laser surgery and cryosurgery have also been used in the removal of tumours. Regardless of the method of analgesia or surgery, care must be exercised to avoid incising the urethra as its highly vascular mucosa may continue to bleed at ejaculation for long periods afterwards. Hence, catheterisation of the penile urethra is recommended if there is any risk of its involvement at the base of the tumour.

(C) Massive tumour causing penile prolapse, urethral rupture, and localised cellulitis in a 10-month-old castrate.

VetBooks.ir

Penile fibropapillomas do not metastasise, but a small proportion of tumours exhibit a remarkably aggressive recurrence after surgical removal. There is debate about the incidence of such recurrences, but possibly 10% of lesions recur with sufficient rapidity to be obvious again within 3 to 4 weeks of surgery (Pearson 1977). Administration of an autogenous tissue vaccine markedly reduces the incidence of recurrences (Desmet et al. 1974). Similarly, when clients are not prepared to pay for surgery to remove fibropapillomas, administration of an autogenous vaccine should be considered, as this approach has been shown to be moderately effective. The prognosis for use with breeding animals is generally good, although libido may take some time to recover in animals that have had long-standing, painful, ulcerated lesions. Gilbert and Fubini (2004) considered that, if aggressive recurrence occurs or if papilloma-like lesions are encountered in mature bulls, the lesion may be a malignant fibrosarcoma. This can be confirmed by histopathology. Culling is indicated in such cases.

Stallion

Neoplasia of the equine penis and prepuce are common. Tumours of the penis and prepuce include squamous papilloma, squamous cell carcinoma, sarcoid, melanoma, mastocytoma, and hemangioma (Schumacher 2012). Melanomas are occasionally found on the prepuce of aged grey horses.

Squamous cell carcinoma of the glans penis (Fig. 36.27) or prepuce are the most common genital tumours of the horse. It is believed that squame cell carcinoma develop in response to the presence of smegma in the prepuce. It was originally thought that smegma contained a specific carcinogen (Plaut & Kohn-Speyer 1947), but it is now thought that it is the chronic irritation and balanitis that it causes which induces neoplastic changes (Brinsko 1998). The tumour is therefore encountered most frequently in geldings, particularly in aged animals. Schumacher and Varner (2007) suggest that it is also more common in breeds of horses that lack pigmentation of the genitalia.

Tumours grow relatively slowly, but eventually progress to become large, ulcerated tissue masses that may cause bloody preputial discharge or penile prolapse. Metastasis is slow, although the tumour does spread within the preputial cavity and, eventually, metastasises to local lymph nodes. However, local lymphadenitis may also occur as a result of the secondary infection that invariably occurs with these tumours, so care must be exercised in giving a prognosis. Occasionally, penile carcinomas are highly invasive and rapidly destroy the body of the penis (see Fig. 36.27B).

Early cases and animals with small tumours can be treated by cryotherapy or by repeated topical applications of fluorouracil to the lesion at 14-day intervals (Fortier & MacHarg 1994). Some lesions of the more loosely attached prepuce can be dealt with by simple or reefing excision. However, more advanced penile carcinomas are best treated by radical amputation of the penis, with an urethrostomy on the penile stump within the sheath or directly to the sheath (Walker & Vaughan 1980). The recurrence rate is relatively high, around 20%, particularly in horses in whom the carcinoma has invaded along the urethra (Mair et al. 2000).

Sarcoids are also diagnosed on the penis, prepuce, and scrotum of entire and castrated horses, donkeys, and other equids. In most circumstances, such lesions can be extirpated without difficulty using a variety of surgical methods (Schumacher & Varner 2011). However, the presence of multiple, recurrent sarcoids on the sheath and prepuce (Fig. 36.28) may necessitate its complete ablation and amputation of the penis (Cox 1982). Grey horses may develop melanomas of the penis or prepuce (Fig. 36.29).

• **Fig. 36.28** Multiple sarcoids of the equine penis and prepuce.

• **Fig. 36.29** Multiple melanomata formation in the prepuce of an aged grey gelding.

VetBooks.ir

Their progress is generally slow, with only local invasion of tissue, but aggressive lesions that metastasise are also encountered.

Dog

A great many tumours affect the penis and/or prepuce of the dog. Tumours of the penis include lymphosarcoma, hemangiosarcoma, and squamous cell carcinoma; those of the prepuce include mast cell tumour, papilloma, and carcinoma. Chondrosarcoma of the urethra has been reported, and various tumours of the os penis have been described (Voelkl 2013). The most common tumour of the penis and prepuce is the transmissible venereal tumour (Jones & Joshua 1982). Most tumours of the penis present with clinical signs of difficulty of urination, progression to dysuria, and haematuria. There is distension of the bladder, abdominal pain, and enlargement of the preputial area.

Transmissible venereal tumour has been reported in most parts of the world, but is most commonly diagnosed in dogs located in large urban areas. It is transmitted during coitus and, occasionally, by nuzzling of the genitalia. The primary site for these tumours is the external genitalia of both males and females, but lesions also occur around the mouth and nose (Johnston et al. 2001, Levy et al. 2006, Marcos et al. 2006). Transmission appears to be caused by direct implantation of tumous cells that are exfoliated during coitus (Martins et al. 2005). Younger, sexually active animals (< 5 years old) are most often affected, but there is no breed predisposition. Growth is rapid, with clinical signs generally becoming apparent after a short incubation period (typically 5–6 weeks but sometimes considerably less). The rate of metastasis is relatively low, and up to 20% of animals undergo spontaneous remission (Nayak et al. 1987). A fetid, bloody preputial discharge may be present, and, on exteriorisation of the penis, characteristic fleshy, greyish-red, nodular masses are observed (Foster 2012). The tumours ulcerate easily and are friable (Fig. 36.30) and readily bleed when handled. The tumour is locally invasive in about 50% of affected animals, with metastases to local lymph nodes occurring in a small proportion of affected dogs. Rarely, widespread metastases through viscera and nervous tissues have been reported. Treatment, when this is possible, is by removal of the penis and prepuce, but the recurrence rate is relatively high. Alternatively, chemotherapy (e.g., vincristine) and/or radiotherapy (Cohen 1985, Wittrow & Susaneck 1986, Singh et al. 1996) or laser therapy (Kangasniemi et al. 2004) have been used.

Penile fibropapillomas (Fig. 36.31) also occur in the dog. Some lesions are virally induced, whereas others clearly have a non-viral aetiology. Non-viral papillomas, variously called squamous papillomas or idiopathic mucosal penile squamous papillomas, are likely to arise from local trauma or irritation (Cornegliani et al. 2007). Viral papillomas, caused by canine papilloma virus, occur on the penis or preputial mucosa where they first appear as plaque-like or raised papillomatous lesions (Foster 2012). The types of papilloma are clinically indistinguishable from each other but present in a variety of forms; they may appear as pedunculated, cauliflower-like masses arising from the penile mucosa (Voelkl 2013) or can be ulcerative, locally keratinised, and poorly circumscribed. They may also be completely sessile. Such lesions bleed profusely after mating or when the penis becomes erect, but their development may be remarkably slow, even over a number of years. Papillomas can rarely develop into squamous cell carcinomas. Non-neoplastic lesions that can have a very similar appearance include tags, hyperplastic polyps, and excessive granulation tissue (Foster 2012).

Conditions Causing Failure of Ejaculation

There are a few conditions in which ejaculation does not occur, despite normal mounting. Such conditions can be broadly divided into those in which the ejaculation reflex is impaired and those in which localised pain makes the animal unwilling to ejaculate.

VetBooks.ir

The former conditions generally occur when some damage has occurred to the neural pathways between the glans penis and the spinal cord. Strangulation of the penis, with ensuing damage to the sensory dorsal nerve of the penis, causes ejaculation failure, whereas, in older bulls, compression of the spinal nerve roots by age-related exostoses can also preclude ejaculation.

Localised pain is similarly effective in preventing ejaculation. Localised peritonitis in the caudal abdomen of ruminants causes pain during the ejaculatory thrust, so affected animals are often willing to mount but unwilling to complete an ejaculatory thrust. Animals with back pain behave similarly, although they may be less willing to mount. Finally, some painful conditions of the penis, such as orf in rams, make the animal unwilling to achieve intromission and ejaculate, despite their willingness to mount.

Haemospermia

Haemospermia, due to leakage of blood from part of the genital tract, is a significant cause of infertility in stallions and has been described in the bull. Some cases are caused by obvious lesions of the penile integument, such as trauma, neoplasia, or balanoposthitis. Seminal vesiculitis can also be associated with haemospermia, although changed (brownish) blood is more usually associated with this condition, at least in the bull. Profuse haemorrhage, arterial in appearance, has been observed in bulls and stallions at the end of ejaculation, as a result of leakage of blood from the CSP into the lumen of the urethra, typically from a lesion in the caudal/ventral wall of the urethra (Ashdown & Majeed 1978, Schumacher & Varner 2007).

Conditions Causing Failure of Fertilisation

Fertilisation failure, despite normal copulation, generally characterises diseases of the testis (including abnormalities of spermatogenesis), epididymis, and accessory glands. Many of the conditions causing failure of fertilisation can be diagnosed by an examination of the external genitalia of the male, but others can only be diagnosed by semen evaluation.

Moreover, diagnosis of failure of fertilisation on the part of the male animal requires elimination of female factors through examination either of records or of the females themselves. Likewise, causes of fertilisation failure that represent pathologies of the reproductive tract must be differentiated from management factors (e.g., overuse) that adversely affect fertility.

Conditions Affecting the Testis

Orchitis

Orchitis ranges from a mild infection of the testis, scarcely distinguishable from testicular degeneration, through to gross suppurative or necrotic destruction of the organ. Orchitis can arise from a primary infection or by the haematogenous route. In rams, it is likely that many infections become established after fighting injury to the testis. *Brucella* species cause orchitis in many domestic animals: *B. abortus, B. canis, B. melitensis,* and *B. suis* affecting bulls, dogs, sheep and goats, and boars, respectively. Granulomatous orchitis in bulls can potentially be due to tuberculosis (Adeniran et al. 1992). However, the majority of isolates from cases of orchitis are either nonspecific bacteria or mycoplasmas or are the particular pyogenic organism for the animal species (e.g., *Trueperella pyogenes* in cattle). Ascending infection from the urinary tract has been postulated, but haematogenous spread seems more probable.

In dogs, in addition to common bacteria (e.g., *E. coli,* staphylococci, streptococci), *Mycoplasma canis* and canine distemper virus are significant infectious causes of orchitis. Non-infectious causes, particularly autoimmune destruction, are also important in the dog. Autoimmune orchitis may occur in association with disruption of the blood–testis barrier, as part of a generalised autoimmune disorder or from idiopathic causes. However, because of the importance of *B. canis* as an infectious cause of infertility, dogs (in countries where it occurs) with orchitis should routinely be tested for evidence of this infection (Johnston et al. 2001). Orchitis is rare in the cat, with bite wounds as the most common aetiological agent. Feline infectious peritonitis virus can also cause orchitis.

Orchitis is more commonly unilateral than bilateral and may involve the epididymis. During the acute phase of the disease, the affected testis is inflamed, with consequent hyperaemia, heat, and oedema and swelling (Fig. 36.32A and B). The testis may become grossly enlarged – up to two or three times its normal size. The testis is often very painful, so that the animal resents it being palpated. The pain may be sufficiently severe to produce an altered gait and systemic pyrexia may occur. The localised inflammation usually causes temperature-dependent degeneration in the unaffected testis. If the condition progresses to the chronic phase, the testis becomes shrunken, fibrotic, and adherent to the tunic and scrotum. Abscesses may break through the scrotal skin.

Orchitis invariably causes a great deal of destruction of the affected testis, and medical treatment is only likely to be successful when initiated early in the course of the disease. Treatment for at least 10 days with broad spectrum antibiotics (particularly macrolides), nonsteroidal antiinflammatory drugs, and cold hosing is recommended. In advanced cases, there may be large, coalescent abscesses occupying much of the testicular parenchyma (see Fig. 36.32D), or it may be necrotic with most of the seminiferous tissue destroyed. The prognosis for saving the affected testis in cases with obvious severe palpable changes is nil. If it is hoped to salvage an affected animal for breeding, removal of a unilaterally affected testis should therefore be advocated at the earliest possible stage of the disease to limit degeneration of the unaffected testis (see Fig. 36.32C). If bilateral orchitis occurs, the prognosis for future breeding is usually very poor, and castration should be performed as soon as it is safe to do so. Pretreatment with antibiotics may reduce the risk of haematogenous spread of infection during surgery.

Testicular Hypoplasia

Testicular hypoplasia implies an incomplete development of the germinal epithelium of the seminiferous tubules due to inadequate numbers of germinal cells within the testis. Lack of germinal cells may arise through partial or complete failure of the germinal cells to develop in the yolk sac, failure to migrate to the genital ridge, failure to multiply in the developing gonad, or widespread degeneration of embryonic germinal cells within the primitive gonad. Mild cases may exhibit moderate oligospermia or poor sperm morphology, but severe cases may be aspermic.

Sporadic cases of hypoplasia occur in all species, occasionally, but not often, with a clear familial predisposition (e.g., Gunn et al. 1942, Holst 1949, McEntee 1990, Siliart et al. 1993). The condition (Fig. 36.33) is relatively common in rams (West et al. 2018) and bulls, particularly *Bos indicus* genotypes. A hereditary form of hypoplasia exists in Swedish Highland cattle (Lagerlof 1936, 1951, Eriksson 1950), affecting the left testis more commonly than the right. An animal with unilateral testicular hypoplasia is

shown in Fig. 36.33B. Arthur (1975) recorded a high incidence of hypoplasia in the Welsh Mountain pony, in which the right testis was most commonly affected and for which he considered that an inherited aetiology was likely.

Klinefelter's syndrome (karyotype XXY) is a sporadic cause of testicular hypoplasia in bulls (Logue et al. 1979) and has been reported in rams, boars, and dogs (Breeuwsma 1968, Bruere et al. 1969, Clough et al. 1970). It is also particularly associated with male tortoiseshell and calico cats (Smith & Jones 1966, Centerwall & Benirschke 1975, Long et al. 1981). The spermatogonia of such animals fail to develop, so the seminiferous tubules are virtually devoid of spermatogenic cells. The semen of such animals is therefore aspermic, although, as the Leydig cells are unaffected, libido is normal.

Diagnosis of the condition is by measurement of scrotal circumference, which is lower than acceptable limits for the species and breed. Palpation of the testes reveals one or both to be small and flabby, but regular in outline and freely movable in the scrotum. Semen analysis may reveal aspermic or oligospermic ejaculates, sometimes with markedly abnormal morphology or motility characteristics of such sperm as are present. By contrast, libido is generally normal, and, for this reason, the condition may escape the owner's attention until the failure to achieve satisfactory pregnancy rates is noticed.

VetBooks.ir

• **Fig. 36.33** (A) Testicular hypoplasia in a ram. The scrotal circumference of 22 cm was well below the 30 to 35 cm expected for a ram during the breeding season. (B) Unilateral testicular hypoplasia in a bull.

Because of the probable inherited basis of testicular hypoplasia, attempting to breed from an affected animal should be avoided and affected livestock males should be culled. Attempts at treatment with exogenous hormones are invariably unsuccessful.

Cryptorchidism

Perturbation of the normal process of testicular descent, such that one or both testes fail to complete their descent into the scrotum, results in the condition of cryptorchidism. Spermatogenesis is generally markedly impaired or absent in testes that are not scrotal due to severe disturbance in testicular thermoregulation. Animals that have a single cryptorchid testis are usually fertile, and there is often a compensatory increase in the size of the scrotal testis. When both testes are cryptorchid, the ejaculate is either aspermic or very severely oligospermic. Testosterone secretion is unaffected by cryptorchidism, so the libido of affected animals is normal. Indeed, it is far more common for cryptorchid animals to present as supposed castrates that exhibit masculine behaviour than it is to be a cause of subfertility in intact males. Cryptorchidism occurs most commonly in the stallion (Hayes 1986), boar (Huston et al. 1978) and some breeds of dog (Patterson 1977), but is rare in bulls, goats, and rams (e.g., Saunders & Ladds 1978, Janardhana et al. 1995, Greig 2000).

TABLE 36.1 Sites of testes in the cryptorchid stallion

Position of Left Testis	POSITION OF RIGHT TESTIS			
	Abdominal	Inguinal	Scrotal	All
Abdominal	125 (7.0%)	12 (0.7%)	545 (30.7%)	682
Inguinal	2 (0.001%)	69 (3.9%)	254 (14.3%)	325
Scrotal	291 (16.4%)	446 (25.1%)		
All	418	527		1744

The most common cause of cryptorchidism in ruminants is iatrogenic through unskilled use of rubber castration rings for castration. Misplacement of the ring can result in one testis being forced back either into the inguinal canal or, more commonly, into a subcutaneous position cranial to the scrotum. Occasionally, a high incidence of cryptorchidism has been recorded in individual flocks of sheep (e.g., Claxton & Yeates 1972). Such flocks, together with the clear breed incidences of the condition in other species (e.g., Red Danish cattle (Blom & Christensen 1947); Angora goat (Warwick 1961)), indicate the probability of an inherited basis for the disease. Indeed, Hobday (1903) recognised that the condition was probably inherited in the stallion. For this reason, the use of cryptorchid animals as sires should be avoided, and their castration is recommended.

In the dog, cryptorchidism is heritable and transmitted as a sex-limited autosomal recessive trait (Burke & Reynolds 1993). It is believed to be also heritable in the cat, possibly with a polygenic inheritance (Gradil & McCarthy 2013). In the dog the condition is found more commonly in smaller than larger breeds and in highly inbred lines; and cryptorchidism and other congenital defects of dogs are often found in association with each other. Retained testes exhibit a high incidence of neoplasia in both the dog and the stallion. The most common tumours of retained testes in dogs are seminomas and Sertoli cell tumours. In heavy-breed horses, many of these tumours are large teratomas. The risk of development of such tumours is a further reason for the castration of affected animals (Willis & Rudduck 1943, Pendergass & Hayes 1975).

Testes may be retained in the abdomen or inguinal canal. The incidence of different sites of retention in the stallion is shown in Table 36.1. In the dog, it is also more commonly unilateral than bilateral, with the right testis retained more often than the left (Cox et al. 1978). In supposedly castrated animals, diagnosis of the presence of a testis in the inguinal canal may be achieved by careful palpation of that region, but many cases require demonstration of the presence of male hormones for confirmation. All affected stallions exhibit testosterone concentrations that are not only higher than in castrated animals but also are responsive to LH stimulation (Cox et al. 1973, Cox 1975). After collection of an initial blood sample, 3000 IU of hCG is given intravenously, with a further blood sample collected 40 minutes later. Both are assayed for testosterone concentrations. In older animals (≥ 4 years), the presence of oestrone sulphate in the blood also confirms the presence of a retained testis. Similarly, in dogs, 2 µg/kg GnRH or 50 IU/kg hCG can be given and blood collected for testosterone concentrations about 1 hour later (doses in cats are cats 25 µg GnRH or 250 IU hCG) (Gradil & McCarthy 2013).

VetBooks.ir

Removal of retained testes from the may be effected by initial surgical exploration of the inguinal canal. Many testes will be found in this site, whereas others can be withdrawn from an abdominal position through the inguinal ring without much difficulty. Other abdominal testes can be withdrawn through a parapenile abdominal incision (Russell & Pollock 2011). Providing the gubernacular attachments of the testis are not disrupted during surgery, it is very uncommon to find an abdominal testis at a site other than near the internal inguinal ring. Gradil and McCarthy (2013) suggested that, in the dog, bilateral retained testes are often located caudal to the kidney, whereas a unilateral retained testis is more commonly located in the caudal abdomen lateral to the bladder. A unilateral retained testis should always be removed before the descended testis is removed or the animal may be falsely described as having been castrated.

Testicular Neoplasia

Testicular neoplasia is rare in the bull, ram, and boar, and, although common in dogs, rarely presents as a cause of infertility. Interstitial cell tumours are the most common tumour of the dog and are recorded occasionally as incidental findings in aged bulls; they are very rare in stallions. Seminoma, the next most common canine testicular tumour, are also occasionally found in bulls (and stallions), whereas Sertoli cell tumours rarely occur in species other than the dog. In cryptorchid stallions, a further testicular tumour is found relatively commonly: the teratoma, a benign growth that contains many different tissue types, including hair, bone, teeth, and cartilage (Fig. 36.34). Overall, testicular tumours account for over 10% of tumours in male dogs, with a considerably increased incidence in animals with cryptorchid testes (Taylor 2010).

Interstitial cell tumours usually occur in scrotal testes of aged dogs but are usually too small to be palpated. They may result in increased circulating concentrations of androgen and thereby predispose to androgen-related disease such as prostatic hyperplasia and circumanal gland adenoma. In bulls, interstitial cell tumours may cause irregular texture of the testis and, sometimes, enlargement. They cause no clinical signs in bulls and no impairment to fertility. This tumour is rare in the stallion.

The incidence of seminoma in cryptorchid dogs is about 20 times that of dogs with scrotal testes. Seminomas may become large but are generally innocuous in scrotal testes. They often grow slowly for long periods but may undergo a sudden increase in the rate of growth, for no apparent reason. The tumours may become necrotic or haemorrhagic, whereupon affected dogs may exhibit lameness, pain, crouching, or hunching. They occasionally metastasise to local lymph nodes. Seminomas are the most common equine testicular tumour.

Sertoli cell tumours are usually characterised by feminisation, in response to the tumour's oestrogen-secreting properties. Feminisation is typified by gynaecomastia, symmetrical alopecia, penile atrophy, a pendulous prepuce and attraction to male dogs, and occurs more often and to a greater extent if the neoplastic testis is inguinal or intra-abdominal than scrotal. If the tumour is unilateral, the contralateral testis is generally markedly atrophied. The oestrogenic secretion of the Sertoli cell tumour causes squamous metaplasia of the prostate gland, which may be of sufficient magnitude to cause obstructive uropathy. Metastases are uncommon but, when they occur, retain the oestrogen-secreting properties of the parent tumour. Sertoli cell tumours are rare in the station.

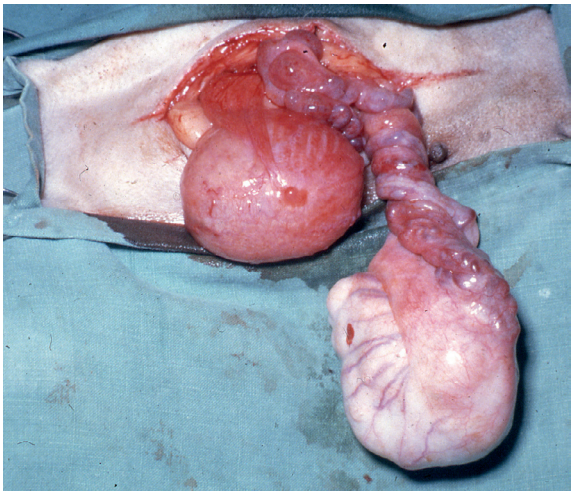
Teratoma (see Fig. 36.34) occurs most frequently in the stallion and very occasionally in other species. The tumour is most commonly found in cryptorchid testes, particularly of draught horses. They are either solid or cystic, and may have many tissue types identifiable within their substance. The tumours can become very large so that their removal may be quite difficult to achieve. However, they rarely metastasise.

In addition to their hormonal and malignant effects, tumours of undescended testes predispose to torsion of the spermatic cord, which results in gradual testicular infarction. In exceptional cases, both spermatic cords may be tightly twisted through several rotations (Fig. 36.35). Torsion of normal scrotal testes occurs occasionally (Young 1979), but the condition is most frequently associated with neoplastic changes in undescended gonads (Pearson & Kelly 1975). The susceptibility of such testes to tumour formation is therefore a strong justification for their removal.

Testicular Degeneration

The seminiferous epithelium of the testis is highly susceptible to external and internal insults that cause varying degrees of degeneration of this tissue. Testicular degeneration occurs in response to raised intratesticular temperature, toxins, endocrine disturbances, and infection (Humphrey & Ladds 1975, McEntee 1990). Some of the main causes of testicular degeneration in the bull are summarised

• **Fig. 36.34** Testicular teratoma in the undescended testis of a shire colt.



• **Fig. 36.35** Torsion of the spermatic cord of an undescended testis.

in Table 36.2. Most causes of testicular degeneration do not manifest as infertility immediately as there is an interval of 4 to 8 weeks between the time at which the susceptible stage of spermatogenesis (particularly the primary spermatocyte) is affected and the time at which the sperm are finally ejaculated.

Causes

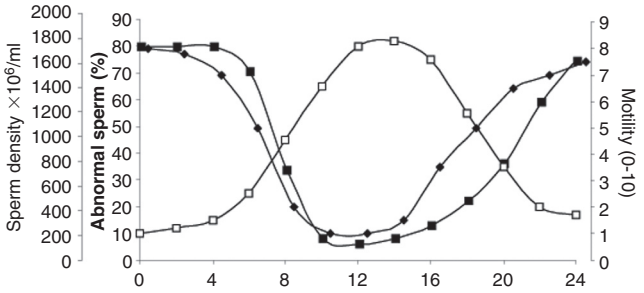
Temperature. Raised temperature in the testis can itself emanate from many causes. Many animals exhibit a period of subfertility during and after high summer temperatures. This phenomenon is well recognised in the boar (Althouse 2007), even in northern European conditions, and is sufficiently important in the bull for some AI studs to provide air conditioned accommodation for the sires to limit summer maxima of temperature (Roberts 1986). Temperature-induced summer subfertility of males has been recognised as a significant cause of poor reproductive performance of European breeds of domestic animal that are imported into tropical and subtropical regions. In rams, raised scrotal temperature can result from excessive amounts of wool over the scrotum or from leaving animals unshorn during the summer (Hulet et al. 1956). Thus showing rams in full fleece in midsummer can result in a significant proportion of such animals having reduced semen quality during the subsequent autumn breeding season. Deposition of fat in the neck of the scrotum, such as can occur in postpubertal bulls and rams fed high energy and protein diets, can prevent heat loss from the scrotum, resulting in subfertility and sometimes infertility (Jubb et al. 1993). Local inflammation to the scrotal skin or other structures in the scrotum can also raise the testicular temperature sufficiently to impair spermatogenesis (Rhodes 1976, Burke 1986, Roberts 1986). In the ram, scrotal mange, caused by *Chorioptes bovis* (Fig. 36.36), raises scrotal temperature sufficiently to cause testicular degeneration. Large numbers of rams can be affected in a flock, such that examination for the presence of the condition before the start of the breeding season is recommended (West et al. 2018). Trauma and abscessation of the scrotum (especially in rams after shearing) and facial eczema lesions on the scrotum also cause testicular degeneration, although inflammation of one testis or epididymis almost invariably causes a temperature-dependent degeneration in the opposite testis. Scrotal frostbite can cause testicular degeneration (Faulkner et al. 1967) due to the localised inflammation and necrosis.

Circulation. Abnormalities of the testicular circulation, such as occurs in varicocele, perturb the heat exchange mechanism responsible for maintaining the testis at a temperature lower than that of the body, again resulting in temperature-dependent testicular degeneration (Ott et al. 1982). This condition is rare in domestic species other than the sheep; however, in the Merino breed, it is sufficiently common to warrant routine examination of the spermatic cords during breeding soundness examination of rams (West et al. 2018). Degeneration results from inguinal or scrotal hernias for the same reason of disturbance in testicular thermoregulation. Pyrexia and often associated toxaemia caused by many infectious diseases can cause varying degrees of testicular degeneration.

Toxicities. A number of environmental and nutritional toxic causes of testicular degeneration have been recognised (Humphrey & Ladds 1975). Heavy metal or radiation contamination is a well-recognised cause of testicular degeneration, but many other materials have been implicated at various times. Over recent years, there has been increasing concern that environmental contamination with weakly oestrogenic substances has been adversely affecting human male fertility (Delbes et al. 2006). Effects of oestrogenic substances (e.g., clovers) on female fertility are well recognised (e.g., Shemesh & Shore 1994), but as yet there is little direct evidence of effects on the fertility of male domestic animals.

Stress. Stress-related degeneration occurs largely as a result of the inhibition of LH secretion by the corticosteroids that are released during stress (Welsh et al. 1981). Stress-related degeneration has been described in beef bulls after movement (Knudsen 1954, Jaskowski et al. 1961) and in other animals as a result of chronically unsuitable housing and management (Clarke & Tilbrook 1992). Hormonal degeneration is described in dogs whose gonadotrophin secretion is impaired either by a primary lesion of

VetBooks.ir



• **Fig. 36.37** Changes in semen quality of a bull during a period of testicular degeneration and the subsequent restoration of normal spermatogenesis. The cause of the degeneration was presumed to be high summer temperatures, density, motility, and proportion of abnormal sperm.

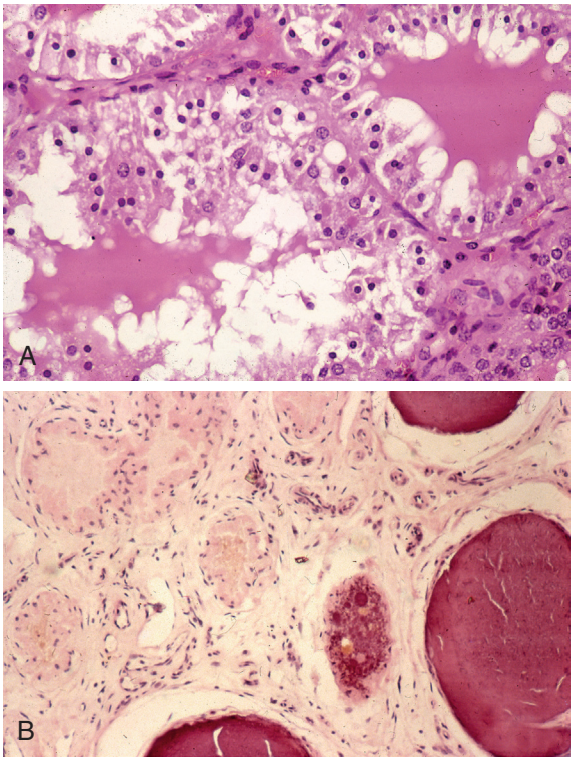
the anterior pituitary or because of the presence of oestrogenic tumours, such as Sertoli cell or adrenal tumours (Roberts 1986). Aged animals undergo a progressive, irreversible degeneration, initially characterised by increased percentages of sperm with primary abnormalities, with later oligospermia and testicular fibrosis (Bishop 1970, McEntee 1990).

Infections. Many infectious causes of degeneration have been described. The most severe of such infectious causes, orchitis, is considered under a separate heading, but many other, milder conditions affect the efficiency of spermatogenesis. Ascending infection by cytopathic bovine enteroviruses (BEV), infection with infectious bovine rhinotracheitis virus, bovine ephemeral fever virus, and, where it occurs, the epivag agent have all been specifically associated with testicular degeneration (Humphrey & Ladds 1975, Kirkland 2002). Bacterial contamination of such testes frequently leads an inherently mild bout of degeneration to progress to purulent or necrotic orchitis.

Depending on the severity and duration of insult, males may become moderate to severely subfertile or, in some cases, infertile. Libido is normally unaffected, as it is the seminiferous tubules rather than the Leydig cells that are affected by degeneration. The testes often feel softer and less resilient than normal, although they may still meet minimum thresholds for scrotal circumference. The tails of the epididymides are typically smaller and softer than normal. However, the most characteristic changes are in semen. Ejaculate volume is usually unaffected, but the number and motility of spermatozoa is reduced, and the proportion of sperm exhibiting abnormal morphology is significantly increased (Fig. 36.37). In severe cases, the ejaculate may become highly oligospermic with only morphologically abnormal sperm present. Abnormalities affecting the sperm head, midpiece, and tail may be present depending on when after the insult a sample of semen is examined.

The severity of the condition in terms of the extent to which semen quality is affected is poorly correlated with the prognosis for recovery. Some animals with severe semen changes can recover within a few weeks, whereas occasional animals with relatively mild changes never fully recover. When, or if, resolution occurs, it may be partial or complete. The extent of resolution depends on the degree of damage that is present in the seminiferous tubules. Provided that the stem cells (spermatogonia) and support cells (Sertoli cells) are undamaged and provided the lumen is not blocked with cellular debris, regeneration can take place. In more severe cases, permanent loss of seminiferous tubules occurs, with subsequent fibrosis and calcification (Fig. 36.38) of the testis. Such animals present with shrunken, firmer than normal, and very poorly resilient testes.

In the dog (Soderberg 1986) and stallion (Blanchard 2011, Threlfall 2011), testicular biopsy is potentially useful in determining



• **Fig. 36.38** Testicular degeneration in the bull. (A) Histology of the testis from bull with moderate testicular degeneration, showing loss of most meiotic and postmeiotic cells from the seminiferous epithelium. Healing may completely restore normal testicular architecture, or may result (B) in loss of seminiferous tubules, together with fibrosis and calcification of interstitial tissue. (With permission from Parkinson 1991.)

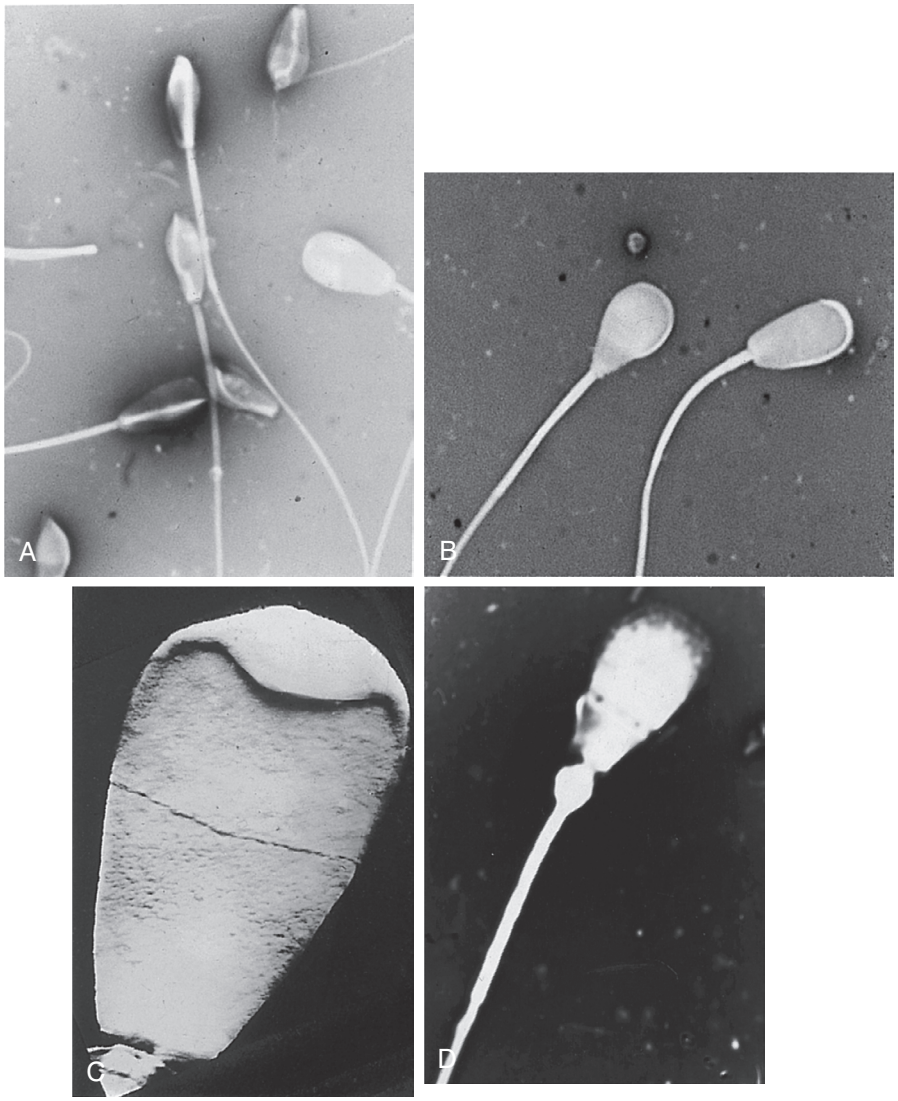
the prognosis for recovery. Intact basement membranes of the seminiferous tubules, the presence of spermatogonia within the tubules, and the patency of the lumina of the tubules all indicate a good prognosis for restoration of fertility (Kenney 1970). However, the technique should be used with great caution in these species because considerable damage to testicular parenchyma can result. In ruminants, biopsy is associated with a significant risk of haemorrhage and widespread tissue damage (Gassner & Hill 1955). Hence, it is best avoided or used with great caution. Trans-scrotal ultrasonography of the testes is potentially a much better alternative.

Hence, in practice, the only way that recovery can be demonstrated is through repeated semen examinations at 4- to 8-week intervals. Only when normal semen is present should the sire be cleared for service. An early sign of resolution, which occurs in some animals, is that the grossly abnormal morphology of the spermatozoa is replaced by relatively high percentages of cells with cytoplasmic droplets at the distal end of the midpiece.

Semen Changes During Testicular Degeneration

See Fig. 36.38. The initial changes in semen quality during testicular degeneration are a decrease in motility and an increase in the percentage of abnormal sperm, particularly sperm with proximal droplets and detached heads. If the semen is being cryopreserved, a precipitous decline in postthaw motility may occur at this stage. Subsequently, sperm numbers generally start to decline, although ejaculate volume is usually unaffected. As sperm numbers decrease, the proportion of morphologically abnormal sperm increases. These include abnormalities of the head, detached heads, and coiled

VetBooks.ir



• **Fig. 36.39** Defects of the sperm head. (A) Abnormally shaped heads, usually associated with testicular degeneration. (B) Pyriform head contrasted with normal head. (C) 'Knobbed sperm' defect. (D) 'Diadem' defect.

tails. Bizarre abnormalities also occur in cases of severe testicular degeneration, including small abnormal heads, acrosomal defects, and the presence of premeiotic cells and stellate forms in the ejaculate. Sperm numbers may decline to the extent that the ejaculate becomes virtually aspermic.

During recovery, sperm morphology and motility tend to improve before sperm numbers. The percentage of sperm with distal droplets frequently increases during the recovery phase. Recovery may occur almost immediately after the nadir of semen quality but may be protracted. The extent and severity of semen changes detected in a sample at a single point in time cannot be correlated with either the duration of illness or the likelihood of recovery.

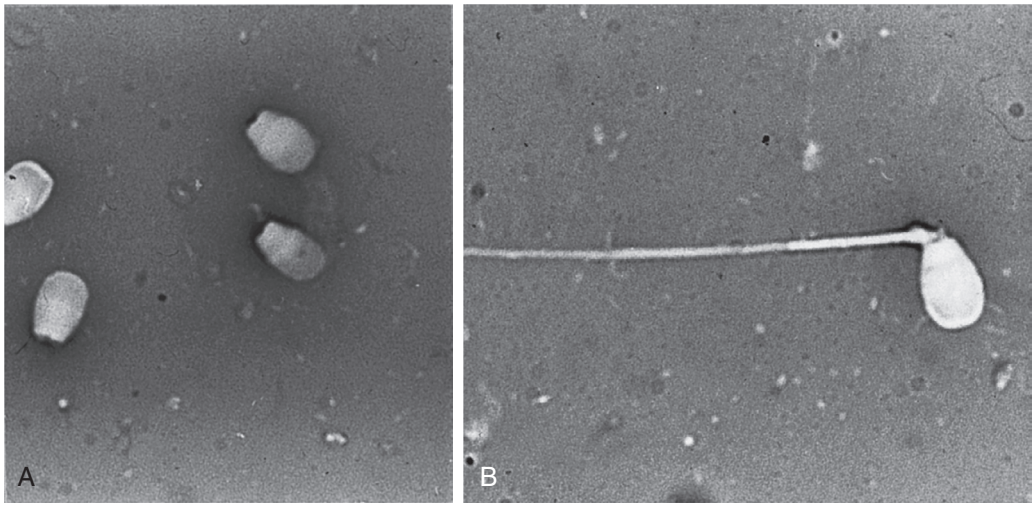
Sperm Abnormalities

Abnormalities of the Sperm Head

The sperm head consists of the genetic material, in the form of highly condensed chromatin, and key effectors of fertilisation (i.e., binding and passage through the zona pellucida) in the acrosome, inner acrosomal membrane and postequatorial zone. Most defects of the sperm head (Fig. 36.39A–D) arise as abnormalities of spermatogenesis and significantly impair fertility (Soderquist et al. 1991). It is common to find significantly raised percentages of these defects during testicular degeneration (see Fig. 36.35A), typically accompanied by a wide range of other sperm abnormalities. Abnormal condensation of chromatin (Johnson 1997) and abnormal nuclear shape (Ostermeier et al. 2001) are closely associated with reduced fertility.

Small changes in the overall size, acrosomal area, and width at the base of the head markedly reduce the ability of sperm to fertilise (reviewed by Barth & Oko 1989). The most common of such defects, the pyriform head, is readily recognisable by the narrow, elongated appearance of the head and the 'pinching' in of its postacrosomal region (see Fig. 36.39B). Nothling and Arndt (1995) reported that the pregnancy rate achieved by a bull with 36% pyriform heads was 46%, compared with 75% in a bull with normal semen. The abnormality impairs both fertilisation rate and subsequent failure of cleavage.

VetBooks.ir



• **Fig. 36.40** Defects of the attachment of the sperm head. (A) Detached normal heads and (B) fractured neck.

Acrosomal Defects

Acrosomal defects are variably associated with reduced fertility. Many acrosomal defects arise as primary abnormalities of spermatogenesis, although acrosomal damage may also arise during epididymal transit and storage, or even after ejaculation. Many of the acrosomal defects that arise during spermatogenesis are present at high percentage in the ejaculate, in which case they are usually inherited, but identical abnormalities can be found at low percentages in most ejaculates, indicating that they can also arise spontaneously. Defects of the acrosome can be difficult to see in stained preparations, so the use of phase contrast or differential interference microscopy of wet mount preparations is recommended. The knobbed acrosome defect (see Fig. 36.39C) is the best known of the acrosomal defects. It is relatively easy to detect in well-made eosin–nigrosin (EN) smears. It is a common incidental finding at low percentages but can occur at high percentages (25%–100%) as a familial, probably inherited, defect. Moderate percentages of abnormal sperm are associated with reduced conception rates, whereas sires with high percentages are virtually sterile. Interestingly, in the bull, even though sperm with knobbed acrosomes are not themselves capable of fertilisation, *in vitro* fertilisation with apparently normal sperm from the same sires produced embryos with impaired development (Thundathil et al. 2000).

Detached and Swollen Acrosomes

Detached and swollen acrosomes may be observed in stained smears, although observation under phase contrast or differential interference contrast microscopy offers the best means of evaluating the acrosome. The site of origin of such defects is not always clear, for this abnormality may arise during spermatogenesis as a degenerative change in the sperm of a bull that has not ejaculated for some time. They may also occur as a tertiary defect in frozen-thawed semen of animals whose sperm do not survive cryopreservation well. Swollen acrosomes are difficult to interpret. At low percentages, detachment of the acrosome has been regarded as a minor defect, with fertility only being impaired with higher levels of the abnormality. However, recent data from the bull indicate that the percentage of detached acrosomes may be related in a linear fashion with fertility, and the significance of this abnormality is therefore being reassessed.

Other acrosomal abnormalities, including acrosomal crests and acrosomal folds, are variably associated with reduced fertility. For example, Meyer and Barth (2001) found that bulls with high percentages of abnormal acrosomes achieved normal conception rates except in competitive mating trials.

Nuclear Vacuoles

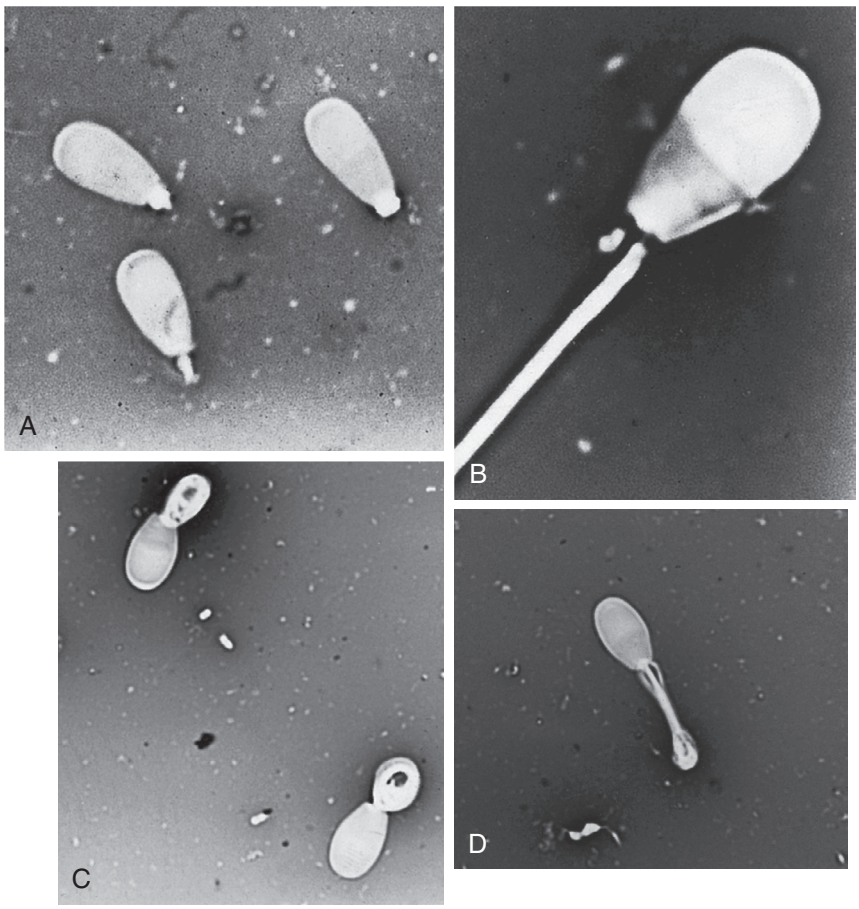
Nuclear vacuoles are abnormalities of spermatogenesis that arise either as a response to an insult to the testis or as congenital abnormalities. They are relatively difficult to visualise in EN smears but can readily be seen in wet preparations or with phase contrast microscopy. The best known is the diadem defect (see Fig. 36.39D), which can be seen as a series of refractile lesions at the base of the acrosome. Other sperm may have single or multiple apical vacuoles or large vacuoles that obviously distort the shape of the sperm head. It is common to observe occasional sperm with vacuoles in normal semen, and the abnormality can be temporarily present at high percentages for a short period after testicular degeneration (Barth & Oko 1989); however, bulls with high percentages (> 20%) of vacuolated sperm heads are considered subfertile.

Abnormalities of the Attachment of the Head, the Midpiece, and the Tail

Some abnormalities of attachment of the sperm head are inherited defects of the centriole or axoneme, occurring at high percentages, whereas others occur as acquired defects. Surprisingly, many such defects have minor effects upon fertility unless present at high percentages. Detached normal heads (Fig. 36.40A) occur commonly at low percentages in normal ejaculates, with higher percentages detected in first collections if males have not been serving or masturbating. Johnson (1997) showed that the presence of 30% to 40% of detached heads in an ejaculate was not associated with infertility. Detached heads (often accompanied by weak head–neck attachments and/or swollen acrosomes) can occur as degenerative changes in senescent sperm. The separated tails are immotile. Sperm with fractures of the attachment between head and tail (fractured neck; see Fig. 36.40B) may arise from senescent changes or due to congenital weakness of the attachment.

Two conditions that seriously affect fertility need to be differentiated from simple detached normal heads. First, there is the

VetBooks.ir



• **Fig. 36.41** Defects of the sperm midpiece. (A) 'Tail stump' defect, (B) accessory tail, (C) 'coiled tail', a defect of formation of the midpiece, and (D) the 'Dag' defect.

decapitated syndrome, which has been shown to be inherited in Guernsey and Hereford bulls (Blom & Birch-Anderson 1970, Blom 1977a), in which most sperm are decapitated, and the detached tails are motile. The semen of such bulls exhibits apparently normal wave motion. Secondly, the 'tail stump' defect occurs as an inherited condition of several breeds of bull (Blom & Birch-Anderson 1980), in which morphologically normal heads are attached to a vestigial structure that appears like a protoplasmic droplet (Fig. 36.41A). On electron microscopy, this droplet-like structure can be seen to consist of small segments of flagellar material and represents a vestigial tail. Affected bulls are sterile.

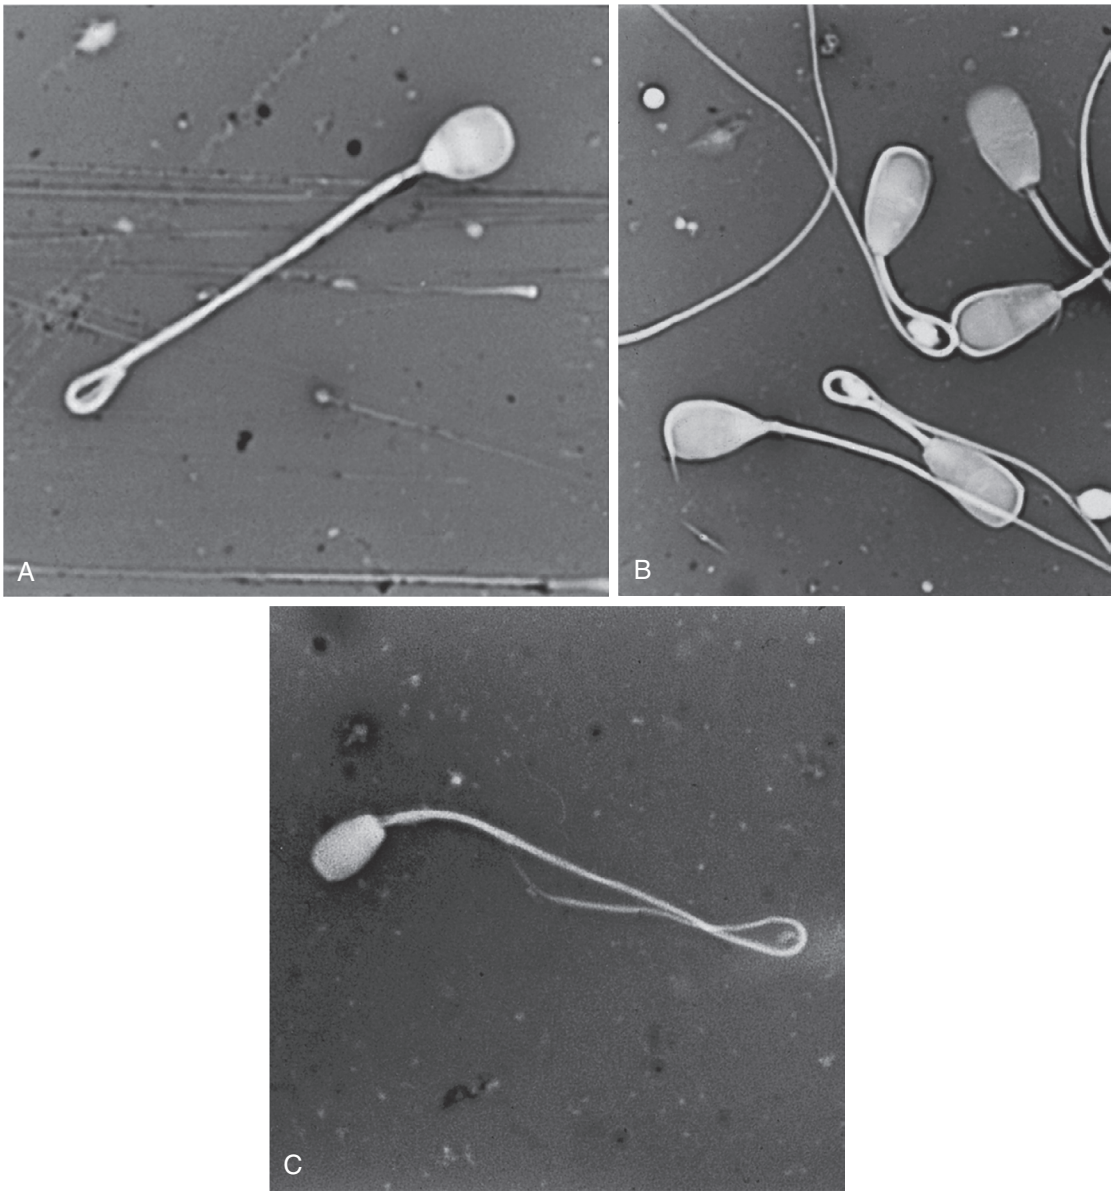
Abaxial implantation of the tail is generally of minor significance or should not be regarded as an abnormality (Barth 1989, Pant et al. 2002). Some degree of abaxial implantation may be regarded as normal in the stallion. Accessory tails, a curious, additional vestigial tail (see Fig. 36.41B) beside the main flagellum, can adversely affect fertility if the abnormality is present in a high percentage (e.g., Williams & Savage 1925).

Most other defects of development of the midpiece and tail arise as defects of spermatogenesis. Sperm with these abnormalities are either immotile or have subnormal motility and are associated with impaired fertility. Sperm with gross deformities of the tail and midpiece are often found in association with a wide range of other abnormalities (i.e., abnormal heads, detached heads, proximal droplets, etc.) in animals that are suffering from testicular degeneration (Parkinson & Bruere 2007). The coiled tail (see Fig. 36.41C) is commonly found during testicular degeneration. In the somewhat similar Dag defect (Blom 1966; see Fig. 36.41D), the apparently loose coils of the sperm tail represent a serious perturbation of the genesis of the flagellum, resulting in an immotile sperm. The defect occurs in variable percentages as a temporary acquired lesion, typically as one of the changes associated with testicular degeneration. When the condition is permanent, it is characteristically present in high (50%–100%) percentages, and in such animals, it is likely to be inherited. It is a common inherited defect of the Jersey breed.

Other, less spectacular, but nevertheless serious, defects of the midpiece occur. It is common to find sperm with an abnormally thickened midpiece, particularly at the point of attachment to the sperm head. This abnormality most often appears in conjunction with other abnormalities as a temporary response to some testicular insult. The corkscrew defect (so-called because the loose arrangement of the helix of mitochondria gives the appearance of a corkscrew to the midpiece of the sperm) is likely to be an inherited defect when present at high percentages.

Other abnormalities of the midpiece and tail include terminally coiled tails (Fig. 36.42A) and the distal midpiece reflex abnormality, which resembles a looped tail with a retained distal droplet enclosed within the loop (see Fig. 36.42B). Its significance for fertility is unclear, although it causes impaired fertility in natural service sires when present at a high (> 30%) percentage. The simple looped tail (i.e., with no enclosed droplet; see Fig. 36.42C) most commonly occurs as a postejaculation defect in response to poor temperature control of the semen, or hypotonic stress such as may

VetBooks.ir



• **Fig. 36.42** Abnormalities of the sperm tail. (A) Terminally coiled tail, (B) distal midpiece reflex (appears as a looped tail with a cytoplasmic remnant enclosed in the loop), (C) looped tail.

occur if the semen becomes contaminated by water. Departure of seminal pH from its normal range can also cause looped tails, and they may therefore be an early indicator of the increase in pH that occurs during infection of the accessory glands. Looped tails can also be present with other abnormalities in animals experiencing testicular degeneration.

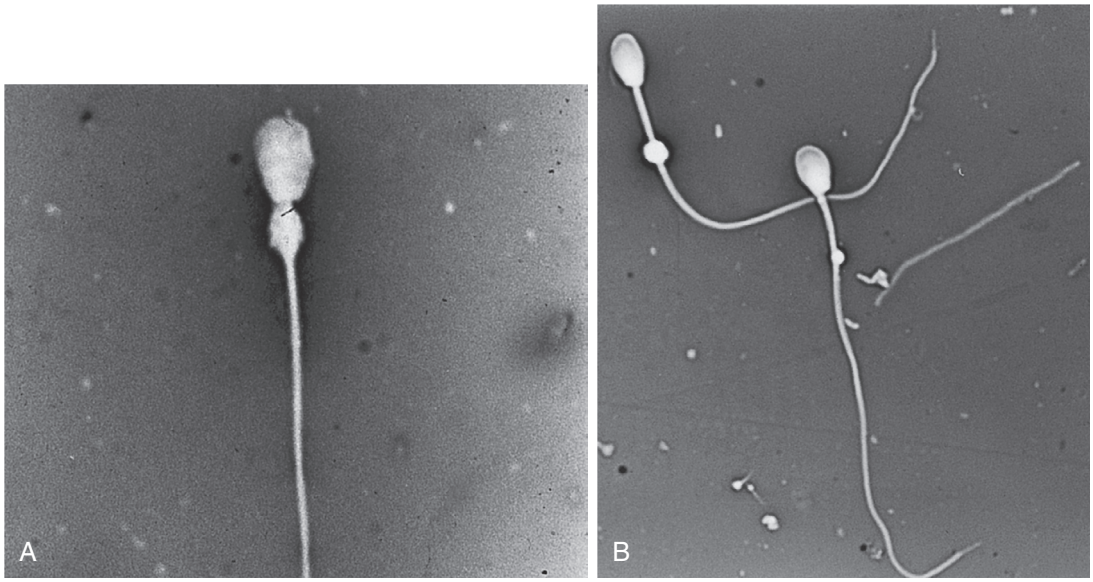
Cytoplasmic Droplets

The residual cytoplasm that remains at the end of spermiation is removed during the passage of sperm through the epididymis as a maturational change. The presence of sperm with protoplasmic droplets therefore indicates that epididymal maturation is incomplete by the time of ejaculation. Sperm with droplets close to the head (proximal droplets; Fig. 36.43A) are more immature than those with droplets at the distal end of the midpiece (distal droplets; see Fig. 36.43B).

Distal cytoplasmic droplets are not generally regarded as very significant abnormalities. High percentages of distal droplets (usually with a moderate percentage of proximal droplets) are commonly present in young bulls that are still peripubertal. The proportion of sperm with these abnormalities should decline to normal levels shortly thereafter (Evans et al. 1995, Johnson et al. 1998, Arteaga et al. 2001, Padrik & Jaakma 2002).

Proximal cytoplasmic droplets are more serious abnormalities, which result from epididymal dysfunction or (especially if present with mixed abnormalities) are a consequence of impaired spermatogenesis. When present at any more than low percentages, proximal droplets are associated with significant impairment of fertility (Soderquist et al. 1991, Saacke et al. 1995). For example, Blom (1977b), among others, suggested that ejaculates containing as little as 5% to 10% of proximal droplets are associated with reduced fertility. Furthermore, when sperm with proximal

VetBooks.ir



• **Fig. 36.43** Cytoplasmic droplets. (A) Proximal droplet and (B) distal droplet.

droplets are used in IVF, cleavage rates of embryos are poor (Amann et al. 2000).

Protoplasmic droplets are often present in the ejaculates of young sires that are being overused (Barth 1997). In such animals, daily sperm production rates are lower than in mature animals; in addition, the epididymis has not fully developed to its final length. Thus, if young sires are heavily used, as in AI centres, careful monitoring of the sperm morphology is strongly recommended. The majority of older bulls have only low but repeatable percentages of proximal droplets (Soderquist et al. 1996), but the mean percentage of affected sperm may increase during warmer seasons of the year. When increased proximal droplets occur in mature bulls (often with other abnormalities), it signifies a disturbance of spermatogenesis.

Lesions of the Epididymis and Mesonephric Ducts

Epididymitis

Epididymitis can also occur as a primary infection or by spread from an infected testis (Humphrey & Ladds 1975). Orchitis in the associated testis can also occur after a primary epididymitis. The general signs of epididymitis are similar to those of orchitis, namely heat, swelling, and pain of the affected part of the epididymis. Marked inflammation of the epididymis causes obstruction of the single, highly convoluted tube of which the organ is composed, so a loss of function normally ensues. Unilateral epididymitis typically results in some degree of subfertility, whereas bilateral obstruction can result in sterility. Furthermore, as with orchitis, unilateral epididymitis causes temperature-induced degeneration in the contralateral testis, so early antibiotic and nonsteroidal antiinflammatory therapy and cold hosing of the scrotum, or, in severe cases, orchidectomy is recommended.

Brucella ovis

In Australasia, North and South America, and central Europe, *Brucella ovis* causes epididymitis that results in epididymal obstruction and granuloma formation (West et al. 2018). It is a significant cause of infertility in rams in these countries. In an Australian (Queensland) survey, epididymitis was present in 58% of culled rams (Foster et al. 1989). Even when *B. ovis* infection is not associated with clinical evidence of epididymitis, its presence in the semen of rams is associated with impaired semen quality (Kott et al. 1988). The organism is transmitted between rams by homosexual behaviour (Jebson et al. 1954) and may be transmitted between ewes and rams as a true venereal disease (Hartley et al. 1955). It also affects stags and can be transmitted from rams to stags by direct (rather than environmental) contact (West et al. 1999, Riddler et al. 2000). Control of *B. ovis* is by identification and elimination of infected rams (Riddler 2002). False-negative serological tests (Robles et al. 1998) mean that repeated sampling and/or culture is needed to identify all infected rams. A voluntary eradication scheme in New Zealand and Australia has been successful in eliminating the infection from a large number of flocks (Riddler 2002).

Pleomorphic Gram-Negative Organisms

Ovine epididymitis also occurs as a consequence of infection with *Actinobacillus seminis* and *Histophilus ovis* (Walker et al. 1988, West 2004). Infection with these organisms is common in virgin rams and ram-lamb-producing flocks (Bagley et al. 1985), typically affecting rams in the peripubertal period. When the organism can be recovered from a high proportion of rams (Walker & LeaMaster 1986). Fortunately, only a relatively low proportion of animals progress to develop epididymitis. The possibility of venereal transmission has been suggested, and infection has been established by experimental intrapreputial and intraurethral inoculation (Al-Katib & Dennis 2005). Furthermore, these organisms undoubtedly infect ewes, causing subfertility (Lees et al. 1990), abortion (McDowell et al. 1994, Foster et al. 1999), and, at least experimentally, mastitis (Alsenosy & Dennis 1985). The infection is found in semen donor rams (Low et al. 1995), and anecdotal evidence exists for transmission between teaser ewes and semen donors. The measures for controlling the disease are poorly understood. Avoiding holding ram lambs in yards for prolonged periods and reducing pasture stocking densities have been suggested (West et al. 2018); however, culling animals with clinical epididymitis reduces the

incidence but does not eliminate the disease (Bagley et al. 1985). Lesions are most common in the tail of the epididymis of both yearling and mature rams, where they are often associated with spermatoceles (Walker et al. 1986). Lesions also commonly occur in the head of the epididymis (Fig. 36.44). Recent development of PCR methods is likely to improve the identification of infected and carrier animals (Saunders et al. 2007).

Histophilus somni infections have also been associated with orchitis (Corbel et al. 1986, Plagemann & Mutters 1991) and infertility in cattle.

Sperm Granuloma

Obstruction of the epididymis can occur after localised rupture (secondary to trauma or epididymitis) of the duct and leakage of sperm into the surrounding stromal tissue. The granuloma formed in response to the presence of foreign (sperm) antigen in the tissue cause an obstruction of the epididymides (Parkinson et al. 1993; Fig. 36.45). Leakage of sperm into the tail of the epididymis also occurs in animals that have been vasectomised. In vasectomised rams, the epididymal tail can be nearly as large as the testis (Fig. 36.46), where innumerable small sperm granulomata have formed. Surprisingly, this condition does not appear to be painful, and the libido of such vasectomised rams is normal.

Aplasia of the Mesonephric Ducts

Segmental aplasia of the mesonephric ducts (Blom & Christensen 1951) is most commonly manifested as an absence of parts of the epididymis (Fig. 36.47). In the bull, the condition is probably inherited (Konig et al. 1972). Absence of the head or tail of the epididymis can be determined relatively easily by careful palpation, but the medially sited epididymal body is often difficult to palpate. Epididymal aplasia also occurs sporadically in other species (McEntee 1990). There may be little or no effect on fertility

VetBooks.ir

of naturally mated animals as often there is some compensatory increase in the size of the unaffected testes.

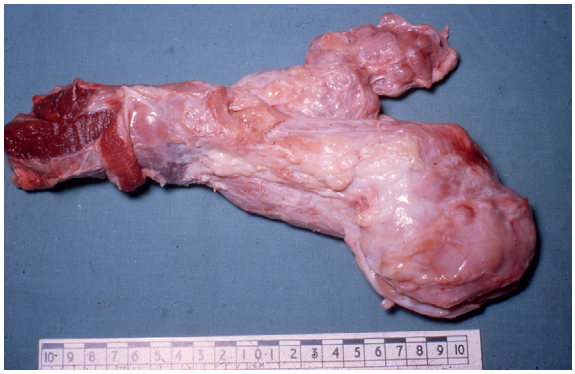
Aplasia of the ductus deferens is less common. In bulls (Blom & Christensen 1951) the condition may sometimes be diagnosed by rectal palpation, when strictures or dilations distal to the site of stricture may be discerned.

Lesions of the Accessory Glands

Vesicular Glands

Infection of the vesicular glands (*seminal vesiculitis, vesicular adenitis*) is relatively common in bulls. The incidence ranges between 0.2% (Blom 1979) and 9% (Bagshaw & Ladds 1974), and, in a more recent study (Scicchitano et al. 2006), a prevalence of 0.4% was reported. *Trueperella pyogenes* is considered the major cause of the destructive form of seminal vesiculitis (pathological changes readily detected by rectal palpation); however, a wide variety of bacteria, including *Corynebacterium renale, Actinobacillus actinoides, E. coli, Pseudomonas aeruginosa,* streptococci, and staphylococci, have been cultured from affected glands. These latter organisms are commonly regarded as causing secondary infections of a previously damaged organ. Other primary causative organisms include *B. abortus, Histophilus somni,* and *Chlamydophila* spp., as well as epivag, enteroviruses and BoHV-1. *Mycoplasma bovigenitalium* (Al-Aubaidi et al. 1972), *M. bovis* (LaFaunce & McEntee 1982), and *Ureaplasma diversum* have also been implicated as primary causes of vesiculitis. Most of these cause the degenerative form of seminal vesiculitis. Seminal vesiculitis occurs most commonly in young bulls, 1 to 3 years of age. Several routes of infection are possible including haematogenous (secondary to rumenitis or systemic infection) and extension from orchitis or epididymitis. The disease is rare in rams.

Infection is more commonly unilateral but may be bilateral. Diagnosis of the condition can be often confirmed by rectal palpation of the vesicular glands (Fig. 36.48) which, in the case of *T. pyogenes* infection, are characteristically enlarged, tense, and painful during the acute phase or lobular and fibrous in the chronic phase. In the degenerative form of seminal vesiculitis, only some peripheral thickening of the gland may be detected on rectal palpation, and in some cases, no palpable changes are detected. It is not uncommon for abscesses to form in *T. pyogenes* infected glands that can burst, causing generalised peritonitis, or fistulate either into the rectum or ischiorectal fossa. The main consequence of infection of the vesicular gland is increased polymorphonuclear leucocytes in the semen which, in the case of *T. pyogenes* infection, may present as frank pus in the ejaculate, or brownish discolouration of the semen due to degeneration of red blood cells associated with inflammation of the gland. The effect on semen quality is variable; in some cases there is decreased percentage of motile sperm and increased percentage of abnormal sperm, and in other cases there is apparently no effect on quality of sperm or fertility. Occasionally, during the acute phase of the disease, localised peritonitis may occur in the caudal abdomen, causing the bull to be reluctant to serve. Although bulls with seminal vesiculitis pose a potential risk for venereal transmission of the causative microorganism, there are few documented cases of this occurring. Cases of venereal transmission have been reported in bulls infected with streptococci (e.g., Webster 1932), with associated herd infertility, a yellowish-white postcoital discharge, and pronounced cervicitis.



• **Fig. 36.48** Seminal vesiculitis (vesicular adenitis) in the bull, showing asymmetrical enlargement of the vesicular glands.

Antimicrobial treatment is commonly attempted as the initial treatment. New, long-acting macrolides (e.g., tilmicosin, tulathromycin) have significantly improved the logistics and cost effectiveness of such treatment. It should be noted that in bulls of 9 to 12 months of age, there is a substantial spontaneous recovery rate and no benefit from early versus late start of treatment (Rovay et al. 2008), so it is probably worthwhile just waiting with such cases to see if they improve. Alternatively, direct injection of antibiotic into the affected gland has been described as being efficacious in a proportion of cases that fail to respond to parenteral antibiotics; Martinez et al. (2008) described recovery of yearling beef bulls within 3 weeks after intraglandular injection of ceftiofur and/or penicillin. Ablation of a unilaterally infected gland by intraglandular injection of 4% formaldehyde solution has been described as being moderately successful in restoring fertility to affected bulls (Waguespack et al. 2011). Alternatively, an infected vesicular gland can be surgically amputated, a procedure that is sometimes used for valuable AI sires (see Gilbert & Fubini 2004, for a description of the method).

Infection of the vesicular glands also occurs in the stallion (Blanchard et al. 1988, Varner & Schumacher 2011), from which many different organisms have been isolated (*B. abortus, Klebsiella pneumoniae, P. aeruginosa,* streptococci, and staphylococci). It may be one of the differential diagnoses of colic in the stallion (Freestone et al. 1993). Transrectal ultrasonography is a useful adjunct or, indeed, a substitute for rectal palpation in the diagnosis of such cases. Treatment may be attempted with antibiotics (Freestone et al. 1993), although such therapy is by no means always successful (Blanchard et al. 1988), possibly depending on the pharmakinetics of the antibiotic selected. Love (2007) suggested that direct administration of antibiotics into the infected gland via an endoscope is more effective than parenteral treatment.

Prostate

Prostatic disease is common in the dog (Johnston et al. 2001) but exceedingly rare in other species. Diseases of the canine prostate have been classified as: benign hyperplasia/hypertrophy; benign haemorrhage; squamous metaplasia; prostatitis (acute or chronic or resulting in abscess formation); prostatic cysts; and neoplasia (Williams & Niles 1999, Johnston et al. 2001). Many of these disorders are androgen-dependent and accompany the progressive enlargement of the prostate that is a normal part of the aging process of male dogs. When clinical signs occur, they are relatively similar regardless of the underlying pathology. Signs include urinary tract infections or dysuria, abnormalities of defecation, and haematuria or urethral bleeding. Systemic illness, alterations in gait, and infertility are less common signs (Krawiec & Heflin 1992, Williams & Niles 1999). Diagnosis is initially by digital rectal palpation, with confirmation when required by ultrasonography or radiography, biopsy or cytology (including collection of fine

VetBooks.ir

needle aspirates), and urinalysis (presence of polymorphonuclear leucocytes, bacteria, and blood). Prostatitis is probably the most significant of the disorders of the canine prostate that interfere with fertility. The route of infection is generally ascending, with a wide range of bacteria (such as *E. coli, Proteus* spp., staphylococci, streptococci, enterococci, *Pseudomonas* spp.) and mycoplasmas commonly being cultured. Prostatitis and prostatic hyperplasia often occur together, the prostate undergoing a diffuse or local suppurative reaction with a tendency to abscess formation. Prostatitis is treated with broad spectrum antibiotics, whereas hyperplasia, being androgen-dependent, is best treated by the administration of progestogens or by castration. Oestrogens, which were long considered to be of value in the treatment of prostatic hyperplasia, are now regarded as being contraindicated (Williams & Niles 1999). For males intended for use in breeding, medical therapy with the antiandrogen drug finasteride has been shown to be effective (Krekeler 2010). Finasteride blocks the action of 5α–reductase, the enzyme that converts testosterone to dihydrotestosterone (i.e., the hormone that causes prostatic hyperplasia).

Ampullae

A relatively common disorder of the stallion is partial or complete blockage of the ampullae with sperm (Love 2007). The condition typically occurs at the start of the breeding season or after a period of sexual inactivity and presents with oligospermia or ejaculation of semen containing a high proportion of immotile sperm and/or sperm with detached heads. Treatment is by ampullary massage, parenteral oxytocin, or maintaining a very high frequency of ejaculation.

Old and New World Camelids

GAYLE D. HALLOWELL

South American Camelidae

There are four species of New World camelids: *Lama glama* (llama), *Lama pacos* (alpaca), *Lama guanacoe* (guanaco), and *Vicugna vicugna* (Vicuna). They originated in North America and have the greatest numbers in South America but are now reared worldwide as companion animals and for high quality fibre production. Outside of South America, they are reared much less for their meat. Adult llamas weigh 130 to 160 kg and can reach 1.9 m in height. Alpacas weigh between 40 and 65 kg and stand up to 1.5 m in height. There are two phenotypes of alpaca – Huacaya (Fig. 37.1) and Suri; they are different in appearance and the latter is less well adapted at very high altitudes (> 4200m; Fernandez-Saga 1975). The Huacaya alpacas have a shorter, denser coat and shorter nose than the Suri. Guanaco and llamas are a similar weight and size. Vicunas are the smallest of the four species; they weigh between 30 and 50 kg and stand a maximum of 1.3 m in height. They are primarily found in Peru and are a protected species. Normally, a healthy female can produce a cria every year, with 20 crias produced in her lifetime. All four species can interbreed and produce fertile hybrids. Hybridisation between a male Arabian camel and a female guanaco has also been achieved (Skidmore et al. 2001). There are still many unknowns regarding camelid reproduction compared with other species, but this chapter will aim to present current understanding, which will primarily be based on what is known in llamas, alpacas, and then camels.

Normal Reproductive Anatomy

Female

The ovaries of the llama and alpaca are ellipsoid to globular. Their size is dependent on the structures on the ovary being approximately 1 to 2 cm in diameter. In adults, multiple follicles of 2 to 5 mm are found on the ovarian surface (Fowler et al. 1998). These can be identified using transrectal ultrasound up to 3 mm in diameter; larger follicles and corpora lutea can be palpated *per rectum*. They have long, tortuous, firm uterine tubes (1–2 cm), which lie within the mesosalpinx. The uterus is bicornuate, which resembles a letter 'Y'. The body is short (3–6 cm) and horns are long (20–25 cm), with the left horn being slightly larger than the right, even in the nulliparous female. The nongravid uterus lies within the pelvic inlet. The uterus and cervix appear heterogenous during follicular dominance, whereas cervical folds become prominent and increase in echogenicity during the luteal phase. The uterine horns become straighter and have increased tone with increased oestrogen concentrations, whereas they are curled with minimal tone with increased progesterone concentrations. The cervix is 2 to 5 cm long and 2 to 4 cm in diameter, with two to three spiral-shaped cervical rings. The vagina is 10 to 15 cm long in the alpaca and 15 to 25 cm in the llama with a diameter of 2 to 5 cm. The vulva is small and does not change in appearance with changes in hormones or pregnancy.

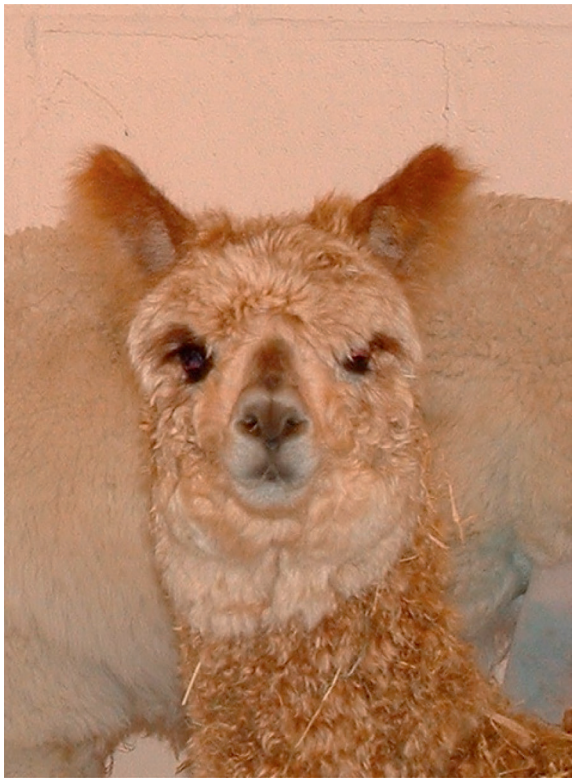
Male

The scrotum is nonpendulous and is situated high in the perineal region and level with the ischial arch. The testes are relatively small compared with ruminants of comparable body size, and the epididymis lies on the dorsal border of the testis with the head situated at the cranial pole. The testes develop slowly. They are present in the scrotum at birth but are hard to palpate; at 6 months, they are small and soft, but by 12 months, they can be easily palpated and the testis and epididymis easily differentiated. It is at around 12 months of age that future herd sires can be selected based on testis size and other physical characteristics. The prepuce, which is flattened and triangular in shape, lies in the perineal region. The glans penis and prepuce are attached until the male reaches 2 to 3 years of age, such that the penis cannot be exteriorised in young males. When animals are not sexually aroused, the preputial orifice faces caudally. When sexually aroused, the developed preputial musculature allows for redirection of the orifice cranially. The fibroelastic penis is 35 to 45 cm in length and is retracted by the presence of a prescrotal sigmoid flexure. The glans penis is 10 to 12 cm in length, and the distal tip consists of a cartilaginous process. The urethral orifice is at the base of the cartilaginous process and not at the tip (Tibary & Vaughan 2006). The curved nature of the cartilaginous process enables penetration of the cervix through rotational and thrusting movements, allowing uterine deposition of semen. A dorsal urethral diverticulum prevents insertion of a catheter along the urethra into the bladder. Camelids have no seminal vesicles but have well developed bulbourethral glands and ampullae of the vas deferens.

Safe Restraint for Reproductive Examination

The majority of llamas and alpacas are relatively easy to handle. In many animals a calm, quiet approach will allow it to be done without sedation. Halters, a stable area, a wall to prevent the animal moving away from the examiner and specific crushes, if available, can allow a reproductive examination to be performed safely and effectively. A small number of animals, usually males, may require sedation using opioids or alpha-2 agonists combined

VetBooks.ir



• **Fig. 37.1** Characteristic appearance of a Huacaya alpaca.

with opioids. Usually, adverse responses to handling include spitting, kicking, and biting.

Puberty, Sexual Maturity, and the Breeding Season

The precise onset of puberty in llamas and alpacas is unknown, but nutritional status and environmental conditions are thought to play a key role. Increases in ovarian hormone production have been recorded in well-developed llamas at 5 months, and ovarian activity detected in alpacas at 10 months. A relationship exists between successful mating and body weight with successful mating occurring in alpacas at 12 to 14 months at a body weight of 40 kg. It is recommended that llamas and alpacas are first mated at 2 years of age or at two-thirds of their final body weight to prevent stunting of the dam and dystocia.

First production of spermatozoa in ejaculate has not been studied in this group, but puberty is thought to occur between 18 months and 2 years of age. Domesticated individuals are not used for breeding until 3 years of age (Bravo 2014).

Whether these species as a group are seasonal breeders is controversial. It appears to be more closely related to environmental conditions or management strategies rather than seasons per se. In their harsh natural habitat, they are seasonal breeders, in that they display sexual activity and give birth in the warm, rainy season. However, when reared in milder climates, they mate and give birth all year round. Thus they are nonseasonal breeders but can become so if required by environmental and nutritional factors.

Ovarian Activity, Mating, and Ovulation

These species are induced ovulators, requiring mating to trigger the LH surge required for ovulation. Thus they do not have regular oestrous cycles. Ovarian activity is thus described regarding the follicular and luteal phase. It is well documented, using a variety of modalities, that there are repeated follicular waves that regress without ovulation in the absence of mating. In a follicular wave, which comprises a very large number of individual follicles, often too numerous to count, some reach 4 to 5 mm in diameter, of which one becomes the dominant follicle; the others then undergo atresia and regress. The number of follicles is inversely proportional to the size of the dominant follicle (Vaughan 2002). Before the final regression of the dominant follicle, a new follicular wave develops, resulting in the presence of simultaneously regressing and growing follicles; this is known as 'overlapping follicular waves'. These are reported to occur for about 30% of a female's lifespan. It is not possible to differentiate by transrectal palpation or ultrasonography between 5 and 6 mm follicles that are growing or regressing.

The follicular wave duration is variable within and between species of camelids, being 20 to 25 days in llamas and 12 to 22 days in alpacas (Aba 2014). In llamas, the follicular growth phase is approximately 9 days, the plateau phase is 8 days, and the regression phase 8 days. In alpacas, the plateau phase is between 2 and 8 days, and the regression phase is 3 to 8 days. The maximum preovulatory size occurs 6 to 8 days into the growth phase in llamas, with the maximum diameter of the dominant follicle being 12 mm in llamas and 8 to 12 mm in alpacas. Follicles develop equally between the two ovaries. Peak plasma oestradiol-17β concentrations correspond with the maximal preovulatory size and occur 12 and 8 days from the beginning of the growth phase in llamas and alpacas, respectively. With overlapping follicular waves, oestradiol-17β concentrations remain elevated, causing the long periods of receptivity to the male (> 3 weeks) with only short periods stages when the male is rejected. Without follicular waves, when a preovulatory follicle (> 7 mm) is present, females will be receptive for several days. Males are usually rejected when plasma oestrogen concentrations are low but can be accepted even if preovulatory follicles are absent. There is a lack of information on the mechanisms surrounding follicular growth, but it does appear to be associated with changes in FSH secretions as occurs in other species (see Chapter 1). Anovulatory follicles have been described in llamas and alpacas – they last longer and are larger. Cystic follicles are also identified as structures larger than 12 to 14 mm and persisting for 25 to 30 days. They occur more frequently in nonmated animals, and some individuals appear to be more prone. It is debatable whether cystic and haemorrhagic follicles are one and the same; they do not secrete oestrogen and do not usually affect ovarian dynamics.

The males pursue females when they are in oestrus. The flehmen response is exhibited when the male sniffs the perineum, urine, or faeces of females; this is followed by the male lifting his head and opening his mouth, sometimes shaking the head rapidly. They do not curl the upper lip as in other species. Some females 'cush', that is, assume sternal recumbency when approached by a male, whereas others do not 'cush' until the male mounts and places pressure over their hindlimbs. Other receptive females often sit close to mating pairs. During mating, the males vocalise (a guttural sound called 'orgling'), dilate their nostrils, flag their tails, and demonstrate slight tremors of ears and nostrils with excitement. The females, in contrast, are very passive, although they

VetBooks.ir

may move from sternal to lateral recumbency. Mating usually lasts 20 to 30 minutes, and ejaculation occurs throughout this period (dribble ejaculation). Females who are not receptive will spit, kick, scream, and run away but will occasionally 'cush' and submit to mating. Continuous contact between males and females inhibits the male's desire to mate, despite the presence of other receptive females. However, when males are introduced, most females will be mated in the first week (Bravo 2014).

Ovulation of one follicle occurs when a neural signal triggered by mating involving both mounting and intromission stimulates the secretion of GnRH and then LH. Ovulation is not triggered simply by mounting (Fernandez-Saga et al. 1970). Multiple matings do not improve ovulation rates. There appears to be an ovulation-inducing factor (OIF) in the seminal fluid that has a GnRH-like activity stimulating LH release, with a systemic rather than local effect (Paolicchi et al. 1999, Adams et al. 2005, Ratto et al. 2010). Injections of hCG, GnRH, and LH can also induce ovulation (Fernandez-Saga et al. 1970). Increased oestradiol 17-β concentrations are seen on the day of mating and for up to 24 hours, and then fall 2 to 3 days later. Ovulation occurs 24 to 48 hours after mating. Ovulation failure has been reported after 10% to 30% of natural matings (Bravo 1994), multiple ovulations reported in approximately 10% of natural matings (Vaughan & Tibary 2006), and spontaneous ovulations have a prevalence of 3% to 10% (Bravo & Sumar 1989, Sumar 1996), the mechanism of which is unknown (England et al. 1969). The size of the dominant follicle (> 7 mm) determines whether ovulation occurs (Bravo et al. 1991). If there is no ovulation but luteinisation of usually regressing follicles occurs, the luteinised follicles last for 5 days, and then a new dominant follicle develops in a further 5 to 7 days (Bravo et al. 1991). If there is no ovulation and no formation of a luteinised follicle, the female will remain receptive to the male.

Pregnancy Diagnosis

There are many important aspects of breeding management, but timely and accurate pregnancy diagnosis plays a fundamental role. Once a female has passed a breeding soundness examination, she should be teased until receptive to the male, when she can be bred. Females should be teased 7 to 12 days after mating. Those females that are not receptive at 14, 21, and 28 days should be examined using transrectal ultrasound. If the female is receptive to the male, then she should be mated again. If after three mating attempts the female is still receptive to the male, an infertility investigation should be performed. Pregnancy evaluation, using transrectal ultrasound, should be performed at 14, 25, and 35 days and between 45 and 60 days (Pearson et al. 2014a); further examinations should be performed beyond this date if the animal has a history of pregnancy loss. Blood progesterone concentrations greater than 1 ng/mL can be used for pregnancy diagnosis but do not provide information regarding twinning or subsequent early pregnancy failure loss; it is not as reliable as ultrasonography. Transrectal palpation in large llamas can readily be performed, but examination in smaller llamas and alpacas is dependent on the hand size of the examiner. Care is required as in the horse. However, transrectal ultrasonography can be performed without the need to insert a hand or arm into the rectum by using an adapted stiffened linear transducer with a moderate to high frequency (7.5–13 MHz), mounted on a thin piece of plastic pipe.

Plasma oestrone sulphate has two peaks during pregnancy but is most useful to measure in the last trimester (last 90 days; Bravo et al. 1996a, Aba et al. 1998). Relaxin concentrations can also be used for pregnancy diagnosis if measured after 85 days; site of production is unknown (Bravo et al. 1996a). After 85 days the uterus has extended beyond the pelvic brim so that transabdominal ultrasonography is most useful at this stage for pregnancy diagnosis and assessment of fetal viability. A lower frequency (5 MHz) microconvex or convex transducer will be optimal at this stage.

Pregnancy and Parturition

The pregnant animal does not need specific care, although it is advisable to keep males away from females in the last trimester, as placental oestrogen production can lead to inappropriate mating attempts, which can cause vaginal trauma and disruption of the cervical plug. Almost all successful pregnancies are carried in the left uterine horn. Maternal recognition of pregnancy is not fully understood, but what is known suggests it is complex and occurs over a short time period, making embryo loss likely in early pregnancy. The CL is necessary for the maintenance of pregnancy throughout gestation. Progesterone initially falls 2 weeks before parturition and plummets along with oestradiol-17β in the last 24 hours. Gestation length is traditionally reported as 335 to 360 days in llamas and alpacas but may be significantly more variable outside South America, ranging from 320 to 400 days. Factors likely to influence gestation length include breed, fetal gender, season of year, nutrition, and sire and dam effects; twinning is rare. The placenta is similar to the mare and sow (see Chapter 4) and is classified as being diffuse, epitheliochorial, and microcotyledonary (Aba 2014).

Parturition usually occurs in the early hours of the day (07:00–13:00), which compliments their natural habitat and behaviours, when ambient temperatures plummet in the evening and at night, and allows for predator avoidance. This is particularly important as the dam does not lick the neonate dry nor does she consume the placenta. There is often minimal to no warning of impending parturition. Relaxation of the sacrosciatic ligament begins 2 weeks before parturition, vulval oedema a few days before, and elongation of the vulva on the day of parturition. The udder develops in the 2 weeks before parturition, normally with mammary oedema extending to the xiphoid. Colostrum is produced from 4 to 6 days before parturition. Changes in electrolytes of mammary gland secretions are not a reliable indicator of impending parturition.

Parturition is usually swift. The first stage varies greatly in length from 3 to 48 hours and manifests as inappetence, restlessness, anxiety, increased frequency of urination and defecation, repeated standing and 'cushing' as well as separation from the herd. Second stage labour usually lasts less than 30 minutes but can be longer in primiparous females. Normally, the head, then one forelimb, and then the second are delivered. Most fetuses are expelled with the dam standing. Expulsion of the placenta usually occurs in less than 30 to 60 minutes but may take up to 4 hours. There is rarely rejection of young, even when the female has poor nutritional status and mild to moderate illness of the dam. Alpaca crias weigh 6 to 8 kg and llama crias 9 to 14 kg at birth. Birth weight increases with age of dam. Perinatal mortality is reported to be low (6%; Bravo 2009).

Females may be receptive to males 24 hours after birth but are not fertile, as uterine involution has not occurred, and ovulatory follicles have not had time to develop. It is thus recommended not to breed until 2 to 3 weeks after parturition (Bravo 1994). Fertility increases from 30% at Day 10 to 70% at Day 30 postpartum (Bravo 1995).

VetBooks.ir

Induction of Parturition

Induction of parturition can be undertaken due to fetal distress or ill health of the dam but is not an appropriate management procedure (Rodriguez et al. 2014). Before induction of parturition is attempted, the presence of uterine torsion, which is a common finding, should be ruled out (Rodriguez et al. 2014). To minimise the risk of perinatal asphyxia syndrome, induction should only be undertaken if gestation is longer than 330 days, and colostrum is being produced. Induction can be achieved (see Chapter 6) using prostaglandin F2α (dinoprost tromethamine) or its analogue cloprostenol; the latter is preferred as the former has been associated with causing respiratory distress in the dam (Rodriguez et al. 2014). Oxytocin and dexamethasone should not be used because they are ineffective, and dexamethasone can result in fetal death *in utero* (Bravo et al. 1996b).

Dystocia

This is relatively rare, with 2% to 5% of animals needing assistance. Dystocia should be suspected if first stage labour lasts more than 6 hours and with increasing levels of pain or discomfort, or if second stage labour does not progress normally. Any abnormal discharge from the vulva (haemorrhagic or purulent) requires further evaluation.

The most common maternal causes of dystocia are failure of cervical dilatation and uterine torsion, but uterine inertia and fetopelvic disproportion (small pelvis) have also been reported (Tibary et al. 2008). Hypocalcaemia can cause uterine inertia. Dystocia as a result of fetomaternal disproportion due to small dam size is avoidable if animals are not bred until they are 65% of adult body weight and height.

Dystocia of fetal origin is usually due to fetopelvic disproportion (large fetus) or abnormal fetal disposition (see Chapter 14). Older llamas and alpacas produce larger fetuses, perhaps making this more likely. Dystocia due to fetal developmental malformation is rare.

Uterine Torsion

This is a common cause of colic and occurs at 8 to 10 months gestation and at parturition. Clinical signs are variable and include general depression, excessive vocalisation, mild to severe signs of colic (circling, kicking at the abdomen, lying in lateral recumbency), diarrhoea, and anorexia. It can be corrected by rolling, or surgically after an exploratory laparotomy.

Failure of or Incomplete Cervical Dilatation

This has been linked to long-term progesterone therapy used to maintain pregnancy or abnormal fetal disposition during first stage labour. Topical PGE_1 (misoprostol) applied to the cervix can be used to aid delivery of a dead fetus. However, surgical removal of the fetus via a Caesarean is recommended if the fetus is alive.

Abnormal Presentation, Position, or Posture

Head and Neck Deviations

These are the most common cause of dystocia in camelids. Due to the very long neck, correction can be challenging. Epidural anaesthesia facilitates correction, particularly if combined with the use of a soft rope positioned in the mouth and behind the ears. If correction proves impossible, a congenital abnormality such as ankylosis should be considered, and delivery should be performed via a Caesarean section. In llamas, it is possible to perform fetotomy by removing the head and neck if the fetus is dead (see Chapters 14 and 15) with the dam heavily sedated.

Carpal Flexion

This is relatively easy to correct if the fetus is repulsed and the foot cupped and lifted over the pelvic brim.

Management After Dystocia

After dystocia, the dam is at increased risk of postpartum complications such as postpartum metabolic derangements, haemorrhage, severe metritis, peritonitis, and sepsis; these are more likely after removal of a dead fetus. Fluid therapy should be instituted in animals demonstrating signs of hypovolaemia or shock. Antimicrobial therapy may be required, ideally using an intravenous, bactericidal, and broad spectrum agent such as trimethoprim sulpha.

The neonate often requires resuscitation, with attention to the airway to ensure an unobstructed airway. Mouth-to-snout resuscitation may be undertaken, but occasionally endotracheal intubation may be required. There is evidence in other species that oxygen is not beneficial and may be harmful during resuscitation attempts. Cardiovascular compromise may require chest compressions and administration of cardiac drugs, particularly the use of intravenous epinephrine (adrenaline). Doxopram is contraindicated in dystocia cases; it is ineffective for secondary apnoea, and because it increases cerebral oxygen demand, it can further predispose to perinatal asphyxia syndrome.

Disorders and Diseases of Pregnancy

Abortion

Determining the cause of abortion can be challenging, and a specific diagnosis is only reached in 30% of cases. There are a variety of causes of abortion, and as in other species, they can be infectious and noninfectious. Of the infectious causes, bacterial infections are the most prevalent. *Leptospira spp, Chlamydophila spp, Campylobacter fetus,* and *Listeria monocytogenes* have all been identified in camelids, as has *E. coli, Streptococcus spp, Trueperella pyogenes,* and *Psuedomonas spp.* Viral infection can also play a role, the most important of which is bovine viral diarrhoea virus (BVDV); persistently infected animals can occur as in cattle. The methods of diagnosis are the same as in cattle (see Chapter 24). Other viruses linked to abortion include equine herpes virus, equine arteritis virus, and blue tongue virus. The most common protozoal cause of abortion in camelids is *Neospora caninum,* but *Toxoplasma gondii* is also a suspected cause (Pearson et al. 2014b).

Many of the noninfectious causes of abortion are similar to those in other species. Ascending placentitis is rare in camelids, due to the cartilaginous rings found in the cervix, which result in a tight cervical seal. Ketosis is also rare compared with small ruminants. Vaginal prolapse (see Chapter 10) commonly occurs in the last 2 months of gestation, particularly in older animals. The methods of treating and managing the disorder are similar to those used in other species. Because there may be a genetic predisposition resulting in reoccurrence, affected females should not be bred from again. Prolonged gestation is a common occurrence in camelids, although some of these cases may reflect and underestimate of the wide variation in gestation length that can occur. The most common reason for prolonged pregnancy is abnormal placentation resulting in intrauterine growth retardation (Pearson et al. 2014b). Other causes include fescue toxicosis, nutritional deficiencies (particularly energy deficiencies), fetal abnormalities, and harsh climatic conditions. The most appropriate course of action

VetBooks.ir

for these animals is to allow them to go to term once pregnancy has been established, assuming the fetus is alive and dam is well.

Postpartum Disorders

Similar postpartum complications are as in other species. Retained fetal membranes do occur and rarely result in any systemic effects. Systemic inflammatory response syndrome (SIRS) can be seen in those that have secondary peritonitis. Treatment is the same as for other species (Pearson et al. 2014c). Postpartum haemorrhage is rare, but when it occurs, it is usually the rupture of the vaginal branch of the internal pudendal artery. Rupture often occurs after internal manipulation to correct dystocia, especially after fetotomy in the correction of dystocia. Bleeding from the vulva or intermittent expulsion of blood requires further internal examination and, if necessary, can be treated by digital pressure on the vessel and supportive care. The risk of future haemorrhage in subsequent pregnancies is unknown (Tibary et al. 2008). Uterine tears are not as common. The cause of postpartum recumbency is multifactorial, and it most often occurs after dystocia, although it can occur after a normal birth; it more frequently occurs secondary to metritis, necrotic vaginitis, retained fetal membranes, hypocalcaemia, pelvic and other musculoskeletal injuries, postpartum haemorrhage, uterine tears, and peritonitis (Pearson et al. 2014c).

Infertility and Subfertility

Female

Infertility and subfertility is a major problem in camelids. Congenital and acquired disorders both play a role. The majority of the causes relate to repeat breeding and are due to early pregnancy failure, with fewer problems attributed to abnormal behaviour and abnormal external genitalia (Tibary 2007, Tibary 2010a).

Repeat breeders are those that have failed to become pregnant and thus return to oestrus after three breeding cycles after mating to a male of known normal fertility. Factors responsible can be categorised as either fertilisation failure or early embryonic death. Fertilisation failure is most likely due to poor breeding technique, failure of ovulation, failure of ejaculation, disease of the uterine tube and ovarian bursa preventing normal ovum transport, and poor semen quality. Early embryonic loss can be due to abnormal embryos, poor uterine environment due to infection or fibrosis, CL dysfunction and poor management of the mother due to stress, nutritional deficiencies, heat stressor, and intercurrent disease (Tibary 2010a).

Early pregnancy loss can only be assumed if the female has been positively identified as being pregnant using ultrasound, but identifying the cause can be very challenging. Potential causes of this include: CL dysfunction, in which obesity and thyroid dysfunction have been shown to play a role; genetic or environmental factors, such as heat stress, twinning, abnormal uterine environment, vitamin and mineral deficiencies (A, D, and selenium); and negative energy balance, especially in females that are producing large quantities of milk (in first 2–4 weeks postpartum).

Specific Causes of Infertility

Ovarian Disease

Ovarian disease is the second most common causes of reproductive failure (Tibary 2010b). Haemorrhagic follicles or cysts are a common finding, but their effect on fertility is not well understood. In some animals, these will luteinise and will therefore result in the female being nonreceptive to the male. However, unlike in cattle, in most cases, ovarian follicular activity is maintained (Pearson et al. 2014d). Diagnosis is by ultrasonographic examination, and similar treatments to those used to treat follicular cysts in cows have been used (see Chapter 22) without success. Ovarian hypoplasia or dysgenesis is a common finding in young animals and is diagnosed on repeated ultrasonographic examinations and laparoscopy. These animals, unlike in other species, display persistent receptivity to the male (Pearson et al. 2007).

Persistent luteal activity due to a persistent CL or luteinised haemorrhagic follicle with high blood progesterone concentrations (> 1.5 ng/mL) are permanently nonreceptive to the male. Diagnosis is relatively straightforward with ultrasonography and blood progesterone assays. Treatment with cloprostenol is recommended. Dinoprost tromethamine should be avoided due to reports of respiratory distress in some animals. Some individuals require two or three treatments, and these conditions can recur.

Uterotubal Disease

The most common disorder, which is still relatively rare, is salpingitis. The uterine tube is often fluid filled and can be identified ultrasonographically.

Uterine Disease

The most common uterine disorders reported are endometritis and endometrial fibrosis. Endometritis is the most common acquired disease resulting in infertility; little is known regarding its pathogenesis. Major contributing factors are thought to include too frequent breeding, postpartum complications that include dystocia and retained fetal membranes, inappropriate breeding practices (routine uterine lavage and antimicrobials postbreeding), selenium and copper deficiencies, and inappropriate nutrition resulting in obesity and emaciation. Diagnosis is made based on a history of repeat breeding or early embryonic death, the appearance of external genitalia where a thick mucopurulent discharge will be evident, and transrectal ultrasonography where the presence of intrauterine fluid and a thickened uterine wall will be evident. Further diagnostic tests, such as vaginoscopy, uterine cytology, swabbing and culture that include antibiotic sensitivity tests, and uterine biopsy in those animals that are barren, should be done. Many different Gram-positive and Gram-negative bacteria have been isolated as causative agents of endometritis. The approach to management of this condition is similar to the mare (Tibary 2010a).

Cervical Disease

The most common cervical abnormalities identified are acquired adhesions or tears, usually secondary to trauma at parturition or too frequent breeding. These can be identified on direct cervical examination with a speculum or with video endoscopy. This condition has a poor prognosis for future normal reproductive function.

Vaginal and Vulval Disease

The most common diseases identified are vulva hypoplasia and atresia and a persistent hymen. As these may be associated with a genetic predisposition, it is debatable whether these animals should be used for breeding. Vulvar atresia is usually noted in neonates, resulting in the accumulation of urine in the vagina, vestibule and uterus; urine can 'back up' into the bladder and even the kidneys (Hallowell et al. 2007). Persistent hymen is seen in young animals that are nonreceptive, permanently receptive, or that display pain during mating. It can also be associated with more serious congenital anomalies such as segmental aplasia, hydrometra

VetBooks.ir

and mucometra, or hydrocolpos. Diagnosis of these conditions is relatively straightforward with vaginoscopy and palpation.

Male

Similar causes of infertility are identified in these animals as in other species (Pearson et al. 2014d). They can be challenging to diagnose and treat, particularly given the limitations on semen collection in these species in which ejaculation occurs throughout the mating process with the male's legs firmly locked around the female's. Tables 37.1 and 37.2 demonstrate normal characteristics of camelid sperm.

Infertility examinations can be challenging and will require sedation and sometimes general anaesthesia. Failure of penile protrusion can be seen in males younger than 3 years of age due to the normal preputial attachment; however, this is regarded as abnormal if it persists after this age, although it may be an acquired adhesion (Cordero 2008). Trace element deficiencies of copper, zinc, and selenium have been associated with derangements in spermatogenesis (Waldridge & Pugh 1997). The prevalence of testicular hypoplasia is relatively high (10%) and is usually bilateral. Unilateral cryptorchidism is reported in 3% to 6% of male animals (Sumar 1983). Orchitis is usually caused by an infection due to a bite from another male, although it can be caused by haematogenous spread. Affected animals are systemically ill and are in pain. A diagnosis is made on palpation and ultrasonography. Treatment involves analgesia and management of SIRS. Medium term, assuming only one testis is involved, hemicastration will help preserve fertility as the affected testis will undergo degeneration.

Reproductive Biotechnology Techniques

Assisted reproductive techniques are now used in these camelids, although it has been much slower compared with many other species. Further information relating to these techniques is discussed in detail in Chapter 44.

TABLE 37.1 Characteristics of camelid semen

Parameter	Arabian	Bactrian	Llama	Alpaca
Volume (mL)	5–20	1–10	1–5	1–5
Colour	Creamy white to greyish white	Creamy white to greyish white	Milky white	Milky white
Consistency	Highly viscous	Slightly viscous	Highly viscous	Highly viscous
pH	7.0–8.0	7.2–8.0	7.8–8.3	7.2–8.0

Camels

There are two species of Old World camels (Genus *Camelus*), namely *Camelus dromedarius* (one-humped Arabian camel) and *Camelus bactrianus* (two-humped Bactrian camel). All members of the Camelidae family have 74 chromosomes, with a very similar morphology. It has been suggested that *Camelus dromedarius* and *Camelus bactrianus* are two subspecies that descended from the wild Bactrian camel *Camelus ferus* (Larson & Ho 2004). Camels are reared for meat and milk production and for racing. The adult Arabian camel weighs between 300 and 1100 kg. These animals are primarily found in sub-Saharan and North Africa, the Middle East, and the Indian subcontinent. The adult Bactrian camel weighs 300 to 800 kg and reaches 2.5 m in height and is mainly found in China, Russia, Mongolia, Iran, Afghanistan, and Kazakhstan. The crossbreeding of Arabian and Bactrian camels has been practised extensively for many years. Hybrids are larger and heavier than their purebred parents. Camels can produce offspring (a hewar) every 2 years, with a total of 8 hewars throughout their breeding life.

Normal Anatomy

Female

Camel ovaries are enclosed within an ovarian bursa. The ovaries of the camel are oval in shape and located on the cranial border of the broad ligament, just lateral to the uterine horns. Their length, width, and thickness range from 2.5 to 6.0 cm, 1.5 to 4.0 cm, and 0.5 to 1.5 cm respectively. The diameter of mature follicle ranges from 1.2 to 2.2 cm, and the mature CL ranges from 1.2 to 3.7 cm.

The most characteristic feature of the camelid uterus is that the left uterine horn is longer than the right. The uterus of the nonpregnant nulliparous female is located within the pelvic cavity, whereas with parity, the uterus extends beyond the pelvic brim into the abdomen. The uterine body is comparatively small, about 2.5 cm in length, which is less than 10% of the total uterine length.

The length of the cervix ranges from 4.0 to 6.5 cm. Because intrauterine ejaculation occurs in camels, the external cervical os can be readily dilated with a finger or catheter. The vagina is about 30 cm in length. The mammary gland comprises four quarters.

Male

The male genital system is similar to that of domestic farm animals (Fig. 37.2), except that they have well-developed bulbourethral glands and ampullae of the vas deferens; the vesicular gland is absent. Camels are distinctive in having 'poll glands', which are located on the back of the neck, near the poll. They are active

TABLE 37.2 Characteristics of camelid sperm

Parameter	Arabian	Bactrian	Llama	Alpaca
Individual motility (%)	40–60	60–80	20–60	20–60

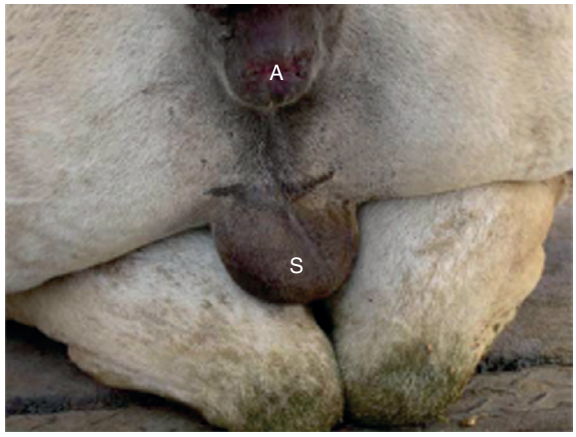
after sexual maturity and during the breeding season. Their secretion, which runs down the back of the neck, is dark brown in colour and contains a pheromone that is attractive to the female (Fig. 37.3).

The testes of camels, contained within the nonpendulous scrotum, are located in the perineal region, just ventral to the anus, with their longitudinal axes positioned between vertical and horizontal (Fig. 37.4). Testicular descent in camels commences soon after birth and is completed during the second year.

The testes are relatively small compared with other farm animals, weighing 60 to 100 g, but they do increase in size during the breeding season; this is associated with increased sperm output. The average daily sperm production per gram of parenchyma is much lower than that of other farm animals.

The epididymis is located along the dorsal border of the testis with the head curving around the cranial pole. The tail is rounded and prominent. The ductus deferens widens towards the pelvic urethra to form the ampulla. The penis is fibroelastic with



• **Fig. 37.4** Subanal perineal location of the scrotum in the camel. A, anus; S, scrotum.

a prescrotal sigmoid flexure. Separation of the penis from the prepuce at puberty is complete by the second or third year. The nonerect penis is directed caudally, so urination is directed that way. The glans penis is hook-shaped. The urethral orifice opens on the left side of the glans penis (Sumar 2000).

Safe Restraint for Reproductive Examination

Camels are restrained in sternal recumbency using a selection of ropes to facilitate clinical examination of the reproductive system; two short ropes are used to maintain flexion of both carpal joints (to prevent standing), and a long rope is attached to both hind fetlocks that passes over the vertebral column to prevent kicking.

Puberty, Sexual Maturity, and Breeding Season

Female camels reach puberty at around 3 years of age (Chen & Yuen 1979), with sexual maturity occurring at about 5 years of age, although some will show sexual interest by the second year.

Both Arabian and Bactrian camels are regarded as seasonal breeders, with a relatively short breeding season in the cooler months when grazing is optimal (Chen & Yuen 1979). Although camels live peacefully together out of the breeding season, during the breeding season males are hostile to each other (Ismail 1988).

Details on the timing of the breeding season in the Arabian camel are conflicting and vary with geographical region (Al-Eknah 2000). The breeding season in the Bactrian camel is shorter, occurring from mid-January to mid-April in China, for example (Tibary & Memon 1999). It is preferable to breed female camelids early in the season, so that calving occurs before the end of the subsequent breeding season.

Decreasing day length appears to be the stimulus to seasonality. In those living near the equator, there is no influence of photoperiod-induced seasonality, and factors such as rainfall, nutrition and management exert an influence.

Ovarian Activity, Mating, and Ovulation

Camels are induced ovulators. Follicular growth occurs in regular waves during the breeding season (Musa & Abusineina 1978,

VetBooks.ir

• **Fig. 37.5** A male Bactrian camel displaying flehmen. Note the elevated upper lip *(arrow)*.

• **Fig. 37.6** Copulation in the Arabian camel. Note that the female (cow) is recumbent.

Skidmore et al. 1996). Cyclical follicular activity can be divided into three distinct phases described as the growth phase, the mature phase, and the regression phase. There are some variations, but the duration of these three phases are 10.5 ± 0.5, 7.6 ± 0.8 and 11.9 ± 0.8 days, respectively, in the Arabian camel (Skidmore et al. 1996). The same authors observed that, in about 50% of follicular wave cycles studied, the mature follicle reached a diameter of 2.0 ± 0.1 cm before it regressed. However, in other cycles studied, the mature follicle continued growing over 18.4 ± 0.8 days, before reaching a maximum diameter of 4.1 ± 0.2 cm and, after persisting for 4.6 ± 0.5 days, finally regressing after 15.3 ± 1.1 days. The interval between two successive mature follicular phases ranges between 14 and 28 days. The duration of oestrus is dependent on whether mating occurs, lasting 3 days if it does but up to 7 days if it does not.

On transrectal palpation the uterus feels tonic and firm during oestrus with the presence of one or more mature follicles. In the Arabian camel, maximum oestradiol concentrations in the peripheral blood are about 40 pg/mL when the follicle reaches about 1.7 cm in diameter and, even though it will continue to grow, concentrations fall to basal values of 20 pg/mL. In the absence of ovulation, progesterone concentrations remain low (> 1 ng/mL). After mating and ovulation, the concentrations gradually increase, reaching maximum values close to 3 ng/mL after 8 or 9 days. In the absence of pregnancy, they decline to basal concentrations by Day 11 to 12 (Skidmore 2003).

Female camels do not usually exhibit overt signs of oestrus other than acceptance of the male when hand teased or when they observe other camels mating. Some females may show signs of a mucus discharge from the vulva.

Mature male camels in the breeding season may break out of enclosures or disrupt their tethers to seek out females in oestrus. When a male confronts a female in oestrus, or a competing male, he will extrude the soft palate while making a gurgling sound, spray urine to mark his territory, release the poll gland secretion, and grind his teeth. The Bactrian male camel does not extrude the soft palate but froths from the mouth. The male camel will seek out females in oestrus and will sniff the vulva, perineum, and urine. Pheromones in the urine of females in oestrus trigger the flehmen response in the male (Fig. 37.5); this is a behavioural olfactory response in which he fully extends the head and neck while raising the upper lip and making shallow respiration movements.

Mating occurs with the female in sternal recumbency, and the male squatting behind her with his hind legs flexed and his forelegs extended on either side of her (Fig. 37.6). The duration of copulation varies and tends to decrease as the weather becomes warmer. On average, the Arabian camel mates for 5.5 minutes (range 3–25 minutes).

Females in oestrus quickly respond to the male by becoming recumbent. However, some females, especially inexperienced females or those exhibiting sire preference, will not accept a particular male. The male will attempt to induce recumbency by pressing on the female's neck. After successful courtship, the male squats on the female, pushes himself towards the perineum of the female, and directs his penis forward to seek out the vulva. Partial erection occurs after the female is mounted, and the penis is not fully extended until after intromission is complete. Ejaculation occurs several times during copulation, when the male stretches his entire body and extends his neck.

As camels are induced ovulators, ovulation is triggered by mechanical stimulation of the female genital tract, and in the Bactrian camel, an ovulation-inducing factor has been identified in seminal fluid. This substance has been shown to be a protein or polypeptide with gonadotrophin-releasing hormone (GnRH)-like activity (Zhao et al. 1994, Pan et al. 2001) that will induce ovulation when seminal fluid is placed deep intravaginally or administered by intramuscular injection. Interestingly, in the Arabian camel it does not induce ovulation. Skidmore et al. (1996) have demonstrated that in the Arabian camel the follicle sizes of 1 to 1.9 cm are optimal for ovulation to occur.

Pregnancy and Its Diagnosis

Methods of pregnancy diagnosis described in South American camelids can also be used in camels.

Although camel ovaries are almost equally active, the embryo and fetus will only develop in the left uterine horn, although the right horn is involved in the formation of the placenta. Embryos migrate from the right horn via the uterine body into the left horn, where implantation occurs. The embryo enters the uterus from the uterine tube at 6 to 7 days after ovulation. Maternal recognition of pregnancy has to occur earlier than in other domestic species (before Day 8; Skidmore 2003), when the signal is from synthesis of oestrogens by the embryo as in the horse and pig. The amnion

VetBooks.ir

develops from Day 14 and the allantochorion is formed by Days 24 to 28 postovulation.

The length of gestation in ranges between 375 and 415 days; this variation in gestation length is influenced by husbandry, number of matings during oestrus, parity of the dam, gender of the fetus, and nutritional status.

Multiple births are uncommon in camelids with a prevalence of 0.4% (Musa & Abusineina 1978). This is of interest as the prevalence of twin ovulations is 14%, of which most are fertilised, suggesting that early death of the second embryo is very common.

The peripheral plasma progesterone concentrations in the nonpregnant camel are low. After mating, at least one CL is formed, secreting a significant amount of progesterone, and values higher than 1 ng/mL are found during pregnancy. During midgestation a rise in oestrogen concentrations is due either to continued follicular development during pregnancy, or secretion from the placenta, or both. High concentrations of oestrogen are present in allantoic fluid on the day of parturition.

The cervical plug provides an important physical seal of the external cervical os during pregnancy. The physicochemical properties of the cervical mucus are related to increases in the plasma progesterone concentrations, resulting in a parallel increase in the protein, alkaline, and acid phosphatase concentration in the mucus (Al-Eknah et al. 1997). A decrease in the degree of hydration, which is under the influence of progesterone, leads to either mucus concentration or alteration in glycoprotein and other cellular proteins, forming linkages affecting the elasticity of the mucus.

Pregnant females do not usually need special care. Frequent handling and particularly rough vaginal examinations performed by camel owners can lead to early embryonic death or abortion. Males should not be allowed access to females during the third trimester of pregnancy because placenta-derived oestrogens produced at that time may suggest that the pregnant female is in oestrus.

Differential Diagnoses for Pregnancy

A cyst-like structure formed at the infundibulum of the uterine tube of the Arabian camel can be confused with pregnancy (Ali et al. 1992) because its weight pulls the uterus over the pelvic brim and into the abdomen, thus resembling pregnancy. Ultrasound of the cyst will identify a large anechoic structure, but no embryo or fetus will be identified.

Pyometra is common in the nonpregnant Arabian camel because of the frequent and unhygienic vaginal examinations carried out by owners and the copulatory behaviour of the male camel. On transrectal palpation, it usually resembles a 2- to 3-month pregnancy (Enany et al. 1990). Ultrasonography reveals a largely hypoechoic mass with anechoic and hyperechoic areas but with no embryo or fetus. Hydrometra and mucometra occur occasionally, associated with a persistent hymen in nulliparous individuals or vaginal adhesions in parous females due to the accumulation of fluid because of impaired drainage.

Parturition and Postpartum Period

Signs of approaching parturition include separation from the herd, restlessness, relaxation of the sacrosciatic ligaments, and swelling of the vulva accompanied by a vulvar discharge resulting from liquefaction of the cervical plug. Appetite may be normal until an hour or so before the start of labour. Some of these premonitory signs may commence as early as 15 days before labour.

The first stage of labour is characterised by increased myometrial contractility and complete relaxation and passive dilatation of the cervix. The animal may look at her flank, grind her teeth, increase the frequency of urination and defecation, stand up and lie down, move around, and raise the tail. The first phase lasts 4 to 40 hours and is usually longer in primiparous than multiparous females. Camel dams give birth at any time of the day or night.

The appearance of the fetus enclosed within its membranes at the vulva and the presence of regular straining indicate the onset of the second stage of labour. The dam is very restless, standing up and lying down in either sternal or lateral recumbency. However, the fetus is normally expelled with the dam standing. The second stage of labour normally lasts 0.25 to 1 hours. The expulsion of the fetal membranes (third stage of labour) usually takes less than 1 hour. Camels do not lick the newborn or eat the afterbirth.

On the third day postpartum, the uterus in camels cannot be easily palpated transrectally because of its size. The uterine wall is still thickened with longitudinal rugae. Ten to 15 days after birth, the uterus can be readily palpated and involution is complete by 16 to 20 days postpartum. By 16 to 20 days postpartum, the cervix appears closed but with some congestion of the cervical folds, and is involuted by Day 26 to 30.

Camels normally have a long anoestrus after parturition if they naturally rear their calves, although if well fed, they can come into oestrus. This will certainly occur if the calf dies or is weaned.

Care of the Dam and Newborn

High mortality rates (> 25%) among newborn hewars have been reported, especially during the first 3 weeks of life, with causes including failure of passive transfer, sepsis that may manifest as diarrhoea, cold shock, and heat stress (Bustinza et al. 1988). Traditionally, the Bedouin do not breed in the late season to avoid the dams calving during the hot season.

Dystocia

There is a scarcity of published information on the prevalence of dystocia in camels. Bedouin camel owners report a familiarity with the recognition and treatment of dystocias due to abnormal disposition, such as carpal flexion, lateral deviation of the head and hock, and hip flexion, although posterior presentation is uncommon (Al-Eknah, personal communication). Fetopelvic disproportion, monsters, and transverse presentations are rare, and the frequency of twin births is low (0.1%–0.4%). In one study from Saudi Arabia, 43% of dystocias were due to maternal factors and 57% due to fetal factors. Of the maternal causes, uterine torsion was the most common (50%), then primary uterine inertia (20%) and incomplete cervical dilatation (20%), and vaginal and vulvar stenosis in a much smaller number of animals (10%; Aboul-Fadle et al. 1993). In the same study, abnormal fetal posture was responsible for 90% of fetal causes.

Under field conditions, the correction of limb and neck flexions, in which substantial fetal retropulsion is required, can be facilitated by casting the dam, front end first, in a deep pit or on a slope excavated in the sand, so that the rear end is raised. Head and limb extension is more difficult to achieve than in the cow. Limited evidence indicates that the camel fetus survives dystocia better than the equine fetus and that the camel is a good subject for Caesarean section. When the fetus is dead, fetotomy can be successful. For a Caesarean operation, the camel is cast on her right side under xylazine sedation, and the operation is performed

VetBooks.ir

under regional infiltration of local anaesthesia with the incision made in the caudal aspect of the left sublumbar area.

Disorders and Diseases of Pregnancy

Pregnancy failure is relatively common in camels. Early embryonic death and abortion can be as high as 40% and 20%, respectively.

Conception Failure

Fertilisation failure and early embryonic loss are common in Arabian camels. The main causes of these repeated returns to oestrus after mating are usually associated with abnormalities of the uterus or uterine tubes.

Fetal Mummification

This has been reported in camels. The sterile death of a well-developed fetus may be followed by persistence of the CL, with resorption of the fetal fluids and soft tissue, leaving a fetal mummy within the uterus.

Abortion

Infectious and noninfectious abortions are commonly identified in camels as they are in other species. Of concern is Q-fever, caused by *Coxiella burnetii,* which is a well-established cause of abortion in camels and presents serious risks to human health (Tibary 2006). Abortions have been reported in camels infected with rift valley fever in which no other clinical signs were seen. Antibodies against bluetongue virus have been reported in camels in Sudan and in Saudi Arabia. However, no clinical signs of abortion were observed.

Uterine Torsion

This is also a common problem in camels and usually requires surgical correction through a flank laparotomy.

Postpartum Problems

Uterine Prolapse

This is a common complication postpartum; Fig. 37.7 demonstrates a vaginal prolapse. Replacement under caudal epidural is very similar to that described in the cow.

Infertility in Camels

The reproductive rate in camelids is moderate to low (Gordon 1997). This was shown by studies of 30 herds in Tunisia, where there was a calving rate of 40% and a mortality rate between birth and 1 year of 17% (Djellouli & Saint-Martin 1992). However, anecdotal evidence from some Bedouins is that, for every 100 Arabian camels mated, 80 to 90 produce calves. About 1% of the camels are sterile. Their fertility is maintained throughout life, normally breeding in alternate years; a female can over her breeding life yield a total of 12 offspring, although an average of eight is more likely. One mating per oestrus is usual, and it is possible for a male to serve five or six females in a day. It is said that one male is sufficient for 200 females with controlled breeding, but a much smaller number is customary. Both male and female factors are responsible for camel subfertility.

• **Fig. 37.7** Vaginal prolapse in an Arabian camel, as indicated by the *arrow*.

Female

Congenital Anatomical Defects

Ovarian hypoplasia and agenesis, persistent hymen, and freemartinism have been reported in Arabian camels.

Acquired Anatomical Defects

Parturient trauma of the tubular genital tract, vaginal adhesions, and perineal rupture are the most common, whereas neoplasia of the genital organs occurs rarely. Cyst-like structures have been associated with the infundibulum of the uterine tube (Ali et al. 1992).

Follicular cysts are common in camels (El-Wishy & Hemeida 1984), resulting in nymphomania; they can be treated with GnRH or human chorionic gonadotrophin (hCG).

Early embryonic death with persistence of the CL can cause pseudopregnancy, which can be successfully treated with $PGF_{2\alpha}$.

Environmental Factors

Adult camels are well adapted to extremes of both heat and cold, although the newborn are susceptible to hyper- and hypothermia. The former can be avoided by providing shelters with water sprinklers and the latter by providing deep straw bedding and a dry shelter with protection from the wind.

Poor Management

The absence of breeding records can be considered one of the most important management deficiencies that results in subfertility in a herd. In addition, many camel owners do not have a strategy for selection for good fertility or for culling those that are subfertile.

Nutrition

Nutrition plays a vital role in the various physiological events leading to the attainment of sexual maturity and subsequently normal reproduction. The faster the growth rate, the earlier sexual maturity occurs. It has been found in Kenya that dam nutrition and health status have an influence on birth weight of the hewars (Wilson 1986). Undernutrition delays puberty in both young males and females and, if severe, might cause retrogressive changes in the reproductive organs after they are fully developed (Tibary and Anouassi 1997).

Infectious Agents

Metritis and endometritis is an important cause of infertility and subfertility in camelids. This can be ascribed to the following predisposing factors:

The copulation process: With the female squatting on the ground during coitus for up to 25 minutes, there is significant opportunity for the penis to transfer debris and bacteria

VetBooks.ir

• **Fig. 37.8** Vulvar discharge in an Arabian camel *(arrow)* after the surgical breakdown of vaginal adhesions.

• **Fig. 37.9** Bilateral cryptorchism in an Arabian camel. (A) Anus and (SC) scrotum with no testes present.

from the immediate environment into the uterus. This is exacerbated by repeated matings.

Unhygienic and rough intravaginal and intrauterine examinations performed by camel owners: It is believed by Bedouins that the reason for a female camel failing to conceive is incomplete intromission. As a consequence, many camel females are subjected to gentle and gradual digital dilatation of the cervix, using butter as a lubricant. After this treatment, complete intromission is said to be possible and pregnancy ensues.

Dystocia and postpartum complications: These may result in the formation of cervical and vaginal adhesions, which can interfere with uterine drainage, resulting in the accumulation of up to 15 litres of fluid or purulent material in the uterus (Fig. 37.8). Uterine infection may result in endometritis or pyometra.

Male

Male camel fertility is generally good. One male Arabian or Bactrian camel can serve up to 50 females in one breeding season. Camelid semen is characterised by the absence of mass sperm motility and the presence of gel to which the sperm are attracted (Rai et al. 1997). Liquefaction of the highly viscous semen can take place within 60 minutes at 37°C. However, if liquefaction is delayed for more than 1 hour, sperm longevity is affected. Tables 37.1 and 37.2 demonstrate the characteristics of camel sperm.

Infertility in the male can be due to poor libido, which is uncommon. Causes of inability to copulate are similar to those described in other species. One disorder peculiar to Arabian camels is trauma to the prepuce and penis due to biting injuries after fights, which may lead to penile adhesions that need surgical separation. Cryptorchidism is relatively common in camels (Fig. 37.9).

Semen Collection

Semen collection in camels is difficult due to mating occurring with the female recumbent in a sitting position (see Fig. 37.6); it can last up to 25 minutes, and during coitus, there is interlocking of the hindlimbs of male and female.

Several semen collection techniques described for other species have been modified and adapted, all with varying degrees of success. The two main methods used are the artificial vagina (AV) and electroejaculation. Collection of semen from the camel using electroejaculation requires sedation and special restraint. The ejaculate is of low volume and poor in quality, and there is the possibility of contamination with urine and cellular debris.

• **Fig. 37.10** Collection of semen from a Bactrian camel using an artificial vagina. Note that with both cow and bull recumbent the operator has to squat on one knee.

The AV is considered the most suitable means of collection (Fig. 37.10), with several studies undertaken to improve the method. Because the male camel in the breeding season can be vicious and aggressive, the most important consideration in designing facilities for semen collection is the safety of the handler and collector.

El-Hassanein (2003) described semen collection in dromedaries using an AV housed inside a dummy female. Al-Eknah et al (2001) devised a safer and more convenient method of collecting semen from the male dromedary, in which there was an excavated pit beneath the collection area where the person collecting the ejaculate using an AV could be positioned. This enabled appropriate positioning of the AV beneath the teasers' perineum and alignment with the base of the penis so that semen collection was relatively easy. In addition, ventral or lateral bending of the penis was avoided, allowing better semen discharge as well as providing the collector with a better view of the mating process and ejaculation. The main disadvantage of using such a facility, or a dummy to which the AV is attached, is the requirement for the male to be trained. However, once this is achieved, collection is rapid and efficient.

Semen used in artificial insemination (AI) programmes should be of high quality, and collected from males in good health and nutritional status.

VetBooks.ir

For preservation of camel semen, different extenders have been used, including Laiciphos, Androlep, sodium-citrate-egg yolk, Dimitropolous extender, Tris-egg yolk, and green buffer extenders (Bravo et al. 2000).

One of the obstacles for AI in camels is the relatively short life span of sperm in extended semen of 1 to 6 hours at 4°C.

Superovulation and Embryo Transfer

The small number of offspring likely to be produced by a prestigious female camel in her relatively short breeding life restricts the distribution of her desirable genetic material. Because of the restricted breeding season and the long gestation period, judicious use of embryo transfer can increase reproductive efficiency.

The optimal response to superovulatory treatment occurs after a period of progesterone priming of the ovaries. In farm animals, unlike camelids, the CL formed after spontaneous ovulation provides the progesterone priming. Thus to induce superovulation for embryo transfer, gonadotrophin is usually injected during the luteal phase, which is then shortened, 24 to 48 hours later, by the administration of a luteolytic dose of $PGF_{2\alpha}$. Because camels are induced ovulators and only have CLs after mating, it is possible that the progesterone-dominated environment of dioestrus, which is thought to be necessary to provide priming for the wave of follicular growth in spontaneously ovulating species, may not be necessary in camels.

For superovulation, equine chorionic gonadotrophin (eCG) has been used successfully to stimulate the ovaries to produce multiple follicles. However, higher doses of eCG may hyperstimulate the ovaries, resulting in the formation of follicular cysts with a diameter of more than 2.5 cm. Another method for superovulation involves the use of ovine follicle stimulating hormone (FSH) in a split dose regime over 3 to 6 days, which gives better results but is time consuming. Combined treatment with eCG and FSH has given more promising results. Recently, studies using priming with GnRH followed by eCG and/or FSH (Ismail et al. 2007) have been successful. The gonadotrophins are given just before or after the removal of the PRID or CIDR or on the last day of other progesterone therapy. Exogenous gonadotrophins may also be administered during a luteal phase created by mating the female with a sterile male.

The superovulatory response to exogenous gonadotrophin therapy varies between individuals, with embryo recovery per donor camel ranging from 0 to 30, with a mean of six per donor (Skidmore & Adams 2000).

Breeding After Superovulation

In order to achieve good superovulation rates, donors should be monitored using ultrasonography and palpation throughout the treatment regime and bred when the follicles reach a suitable size of between 13 and 16 mm.

To ensure optimum fertilisation rates of superovulated animals, a single injection of GnRH or hCG at the first mating or insemination should be given. Mating or insemination should be repeated 12 hours later. Ovulation failure can occur if animals are bred too early or if there is low luteinizing hormone (LH) response.

Flushing of Embryos

Donors are flushed 6 to 9 days from the first mating. The embryos recovered on Day 7 range from compact morulae to expanded blastocysts. Both surgical and nonsurgical embryo recovery have been performed in camels.

The type of superovulatory treatments used can also affect the embryo recovery rate. eCG treatments usually result in low recovery rates, probably due to an increase in spontaneous luteinisation associated with the high LH activity in eCG and its long half-life. The time of initiation of the superovulatory treatment also affects the embryo recovery, with the best results obtained when treatment is initiated in absence of any follicle growth. The time of flushing may also affect embryo recovery because the suggested optimum time for flushing dromedary camels is Day 7 to 9 after mating and treatment with GnRH.

Management of Recipients and Transfer of Embryos

For immediate transfer of embryos, the ovarian activity of the recipient females should be synchronised with that of the donor female. It is recommended that embryos should be transferred on Day 6 after ovulation in recipients.

Collected embryos from donors at Day 7 to 9 are generally at the hatched blastocyst stage. Embryos used for transfer should be morphologically normal. Ovulation is induced in the recipient females by the use of vasectomised males or by the injection of hCG or GnRH.

Freshly collected embryos can be stored for a few hours before transfer in DPBS media. However, long-term storage requires freezing and the use of the associated technology described for other species.

Each embryo is loaded into a 0.25 ml AI straw and, using a modified Cassou insemination gun, is introduced transcervically into the left uterine horn, irrespective of whether the CL is on the ipsilateral or contralateral ovary.

Buffalo and Related Species

OSWIN PERERA AND DAVID E. NOAKES

The domestic water buffalo (*Bubalus bubalis*) is an important livestock resource in many countries of Asia, the Mediterranean region, and Latin America (Central and South America). It plays an important role in providing milk, meat, and draught power in agricultural systems, particularly in the developing countries. The world population of water buffalo is estimated to be 194 million (FAO 2017), of which 96% are in Asia. They are classified into two main 'types' based on their preferred wallowing environment, namely running water for the river type and stagnant pools for the swamp type (Cockrill 1974). The Mediterranean buffalo, which some consider to be a third type, is derived from the river type. Systems of buffalo production vary widely through the different regions of the world (Perera et al. 2005) and are determined by several interacting factors that include climate (tropical or temperate, humid or arid), location (rural, periurban, or urban), cropping system (rain-fed or irrigated), type of operation (small or large scale, subsistence or commercial), and primary purpose (milk, meat, draught, or mixed).

The river buffalo was originally restricted to the South Asian region, has a chromosome configuration of 50, and is reared mainly for milk production. The swamp buffalo originated in Southeast and East Asia, has a chromosome configuration of 48, and is used mainly for draught purposes and meat. In these regions, buffaloes are kept mostly by small scale producers, who raise a few animals in mixed crop–livestock systems. The Mediterranean type predominates in the Middle East, North Africa, and Europe, where they are reared for milk and meat under a wide range of farming systems, including modern dairy farms as in Italy. All types of buffalo have spread beyond their traditional home regions, most notably to Latin America, where they are raised in farms ranging from small to very large scale and under systems ranging from intensive stall-fed to extensive grazing.

The main breeds of dairy buffalo belong to the river type and include the Murrah, Surti, Jafarabadi, and Nili-Ravi. The swamp type has no specialised breed, but selective breeding in some countries has resulted in populations with characteristic features. Crossbreeding between the types has been done in many countries, with the objective of combining the higher milk yield of the river buffalo with the better adaptability and working ability of the swamp buffalo. Despite their different karyotypes, the crossbreeds are fertile (Fischer & Ulbrich 1967). The hybrid female buffalo produces viable calves and the hybrid male, despite the presence of a high percentage of degenerating spermatocytes and abnormal spermatids in the testes (Bongso et al. 1983), appears to have normal fertility.

Although buffalo can adapt to harsh environments and live on low quality forage, their reproductive efficiency is often compromised by such conditions (Perera 2008). Various factors, including climatic stress, depress ovarian cyclicity, oestrous expression, and conception rates. Poor nutrition, often related to seasonal fluctuations in availability and quality of feed, delays puberty and increases the duration of postpartum anoestrus. Management factors, such as the system of feeding (free grazing, tethered, or stall-fed) and sucking by calves (restricted or *ad libitum*) also modulate reproductive functions. The relative importance of these factors varies greatly depending on ecological conditions and production systems. However, studies in Sri Lanka (Perera et al. 1987) and Brazil (Vale & Ribeiro 2005) show that they can have good fertility, provided that genotypes are matched to the environment, and they are managed and fed properly. The main reproductive characteristics of buffalo, based on reports from several countries on river and swamp types kept under a wide range of management systems, are summarised in Table 38.1 (adapted from Perera 2008).

Reproduction in the Female

Anatomy of the Reproductive Organs

The reproductive organs of the buffalo are basically similar to those of cattle, with some important differences. The vulvar labia are less tightly opposed, and the clitoris is more developed. The uterus and cervix are smaller than those in cattle, and the nonpregnant tract lies wholly within the pelvic cavity, with the uterus usually being tightly coiled. The cervical canal is narrower than that in cattle and is more difficult to negotiate during artificial insemination (AI), especially in heifers. The ovaries of cyclic buffalo heifers have a reservoir of only 10,000 to 20,000 primordial follicles, compared with over 100,000 in cattle (Danell 1987). The mature ovaries are smaller than those in cattle, weighing around 2.5 g when inactive and 4 g when active, with fewer tertiary follicles (Zicarelli 1997). Mature follicles range from 10 to 16 cm in diameter, tend to protrude from the surface of the ovary, and can be mistaken for an early corpus luteum (CL). The CL is smaller than that in cattle, ranging from 10 to 17 mm in diameter, often does not protrude markedly from the surface of the ovary, and sometimes lacks a clear crown (Fig. 38.1). These characteristics make accurate identification of ovarian structures by rectal palpation in buffalo more difficult than in cattle (Perera et al. 1987).

Puberty

Buffalo heifers usually attain puberty when they reach about 55% to 60 % of their adult body weight, but the age at which they attain

VetBooks.ir

TABLE 38.1 Summary of reproductive characteristics of buffalo

Parameter	Mean	Range
Age at puberty (months)	30	16–46
Weight at puberty (kg)	275	200–350
Length of oestrous cycle (days)	21	17–25
Length of oestrus (hr)	10	5–27
Time of ovulation:		
- After onset of oestrus (hr)	34	24–48
- After end of oestrus (hr)	14	6–21
Length of gestation (days):		
- River type	310	300–320
- Swamp type	330	320–340
Birth weight of calves (kg)	26	22–36
Involution of uterus (days)	30	25–35

From: Perera 2008.

• **Fig. 38.1** Ovaries from a buffalo cow, with the right ovary containing a corpus luteum that does not protrude markedly from the surface of the ovary and lacks a clear crown.

puberty can be highly variable, ranging from 16 to 46 months (Jainudeen & Hafez 1993). The factors that influence this are genotype, nutrition, management, social environment, climate, year or season of birth, and diseases. A review of studies from many countries (Borghese 2005) shows that, under favourable conditions, river types exhibit their first oestrus at 16 to 18 months, whereas swamp types do so at 21 to 24 months. The body weight at which puberty is attained is strongly influenced by genotype and is around 200 to 300 kg for swamp types and 250 to 350 kg for river types. Although buffalo attain puberty later than cattle, they have a longer reproductive life, which tends to compensate for this early economic disadvantage.

Seasonal Changes in Breeding Activity

Buffalo are polyoestrus and are capable of breeding throughout the year. However, in many countries, a seasonal pattern of breeding activity, and consequently of calving, has been observed. In tropical locations where photoperiod is relatively constant, annual changes in rainfall appear to influence cyclicity, acting through the availability and quality of herbage (Perera et al. 1987). In regions where hot summer months cause heat stress, acyclicity is associated with high prolactin concentrations in the blood, which is thought to influence ovarian activity as well as causing subfertility and repeat breeding by lowering progesterone secretion (Roy & Prakash 2007). In temperate regions such as Italy, where buffalo are fed with a constant balanced diet and are not exposed to heat stress, a distinct seasonal reproductive pattern is also found. This has been attributed to changes in photoperiod, mediated by melatonin secretion (Borghese 2005).

The Oestrous Cycle

The duration of the oestrous cycle in buffalo is from 17 to 25 days with a mean of around 21 days and, compared with cattle, is more variable with a higher incidence of both abnormally short and long cycles. The duration of oestrus or 'standing heat' varies between 5 and 27 hours, and ovulation occurs about 24 to 48 hours (mean 34 hours) after onset of oestrus, or 6 to 21 hours (mean 14 hours) after the end of oestrus (see Table 38.1). In hot climates the duration of oestrus tends to be short, and the signs may be exhibited only during the night or early morning. In Italian dairy buffalo, Zicarelli (1997) has recorded different durations of oestrus, categorised as short (< 12 hours), medium (13–24 hours), long (24–48 hours) and very long (> 48 hours).

Cyclical Changes of the Genitalia and Reproductive Hormones

Ovaries

During the oestrous cycle, waves of follicular recruitment, growth, and regression occur as in cattle. The number of follicular waves per cycle range from one to three, resulting in differences in the mean length of the luteal phase and the interval between ovulations (Baruselli et al. 1997). Heifers tend to have cycles of two follicular waves, resulting in shorter interoestrous intervals compared with cows (21 versus 24 days) (De Rensis & López-Gatius 2007). The mean diameter of follicles at the time of the deviation between dominant and subordinate follicles is 6.2 and 5.8 mm, respectively, and is larger than in zebu cattle but smaller than in taurine cattle. During oestrus, a mature follicle can be palpated transrectally or imaged by transrectal ultrasonography as a turgid area protruding slightly from the surface of the ovary; follicles up to 15 mm associated with the nonovulatory waves can be identified for most of the rest of the oestrous cycle. On the day of ovulation (Days 1–2), the follicle softens, and the site of ovulation is felt as a pit or depression on the surface of the ovary. Normally, one oocyte is shed per cycle. The developing CL (Days 2–7) is soft and difficult to palpate per rectum, but the mature CL (Days 8–16) is palpable as a firm structure, which may or may not protrude from the surface of the ovary (see previous mention in Anatomy section). In the absence of pregnancy, the CL regresses (Day 17) and becomes firmer, and old CLs appear as white scars on the surface of the ovary. Buffalo CLs have no yellow coloration at any stage of development due to lower amounts of beta carotene.

VetBooks.ir

Hormones

The changes in concentrations of progesterone in blood and milk during the oestrous cycle are similar to those in cattle, but the peak concentration is relatively lower (Perera 1999, Singh et al. 2001). Progesterone concentration in fat-free milk is usually less than 1 nmol/l (~ 0.3 ng/mL) during the follicular phase, and ranges from 3 to 12 nmol/l (~ 1–4 ng/mL) during the luteal phase and pregnancy. For assessing cyclic ovarian activity and for early diagnosis of nonpregnancy, progesterone concentrations greater than 3 nmol/l are considered to be indicative of the presence of luteal function, and those greater than 1 nmol/l are considered indicative of the absence of luteal function, with intermediate values being considered inconclusive. The concentration of oestradiol-17β in blood during the follicular phase of the cycle also appears to be relatively lower than that in cattle (Roy & Prakash 2009). Although this has been suggested as a possible reason for the lower intensity of oestrus exhibited by buffalos, studies on Italian buffalo have shown no differences in the endocrine profiles of those with overt and silent oestrus (Zicarelli 1997). The temporal patterns of both luteinising hormone (LH) and follicle stimulating hormone (FSH) in buffalo are basically similar to those in cattle, with a preovulatory LH surge occurring on the day of oestrus and lasting 7 to 12 hours (Kanai & Shimizu 1986).

Genital Tract

Externally detectable physical changes around the time of oestrus include swelling of the vulva and reddening of the vestibular mucosa. Vulval swelling results in effacement of the horizontal wrinkles that are present on its external surface and this, together with vestibular reddening, can be detected by regular examination of individual animals under confined systems. Mucus secreted from the cervix during oestrus is less copious than in cattle and does not usually hang as strands from the vulva, but it tends to accumulate on the floor of the vagina and be discharged when the animal is lying down. Thus in buffalo that are housed or tethered, heat detection can be aided by examining the floor near the rear of the animal each morning and evening for signs of mucus. Mucus discharge is often noticeable when palpating the genital organs per rectum during oestrus (Fig. 38.2).

The internal tubular reproductive tract undergoes changes similar to those in cattle. The uterine horns are turgid and coiled, with maximum tone during oestrus, and become oedematous at the time of ovulation. They gradually lose their turgidity and tonicity after ovulation to become almost flaccid during the luteal phase of the cycle. The cervix dilates sufficiently during oestrus to enable the passage of an insemination catheter into the uterus. The clear, copious mucus that is secreted during oestrous changes to an opaque, thick, scanty discharge after ovulation. Oedema of the vulva and hyperaemia of the vaginal mucous membrane also subside after oestrus. The 'metoestrus bleeding', often seen in cattle, rarely occurs in the buffalo.

• **Fig. 38.2** Discharge of clear mucus from the vagina during oestrus in a buffalo cow.

Behaviour During Oestrus and Mating

A major difference between buffalo and cattle is that behavioural signs of oestrus are less overt in the former, and homosexual behaviour between buffalo females is rare (Jainudeen & Hafez 1993). In the absence of a bull, the main behavioural signs are restlessness, bellowing, raising of the tail, and frequent voiding of small quantities of urine, but these are not consistently exhibited by all animals. During periods of high ambient temperature, the duration of heat may be shorter and the signs exhibited only during the night or early morning.

Mating behaviour is similar to that in cattle. When a bull approaches a female in oestrus, it exhibits sniffing and licking of the perineum and vulva, as well as a flehmen reaction. In some cases, vocalisation, tucking up of the sheath, and intermittent urination may also be seen. An oestrous female responds by standing immobile for the male to mount and perform intromission. The copulatory behaviour includes penile erection, grasping the female at the level of the pelvis, muscular contractions at the base of the tail, penile movements to locate the vulva, intromission, and an ejaculatory thrust. Mating lasts 20 to 30 seconds. The male dismounts and retracts the penis into the sheath, while the female remains with her back arched and tail elevated for a few minutes.

Methods of Oestrous Detection

Detection of oestrus by observation of changes in the external genitalia and behavioural signs is difficult due to them being less pronounced in buffalo than in cattle. In the smallholder farming systems, improved detection is possible through training and motivation of farmers to undertake regular and close observation, together with proper identification of individual animals and keeping of good records (Perera 1999). In larger farms, a vasectomised teaser bull fitted with a chin ball marking device can be used for oestrous detection. The male is either kept in a corral with females from late evening until the next morning or, if they are in stanchions, led behind them twice daily. If no male is available, a buffalo cow can be androgenised for oestrous detection. Heat detection aids used in cattle, such as KaMaR and tail paint (see Chapter 22), have been used in buffalo herds in conjunction with a teaser bull but are unreliable when wallowing is practised. More advanced automated systems, such as pressure sensing radiotelemetric detectors (HeatWatch system) developed for cattle, could be applicable under improved management systems when the costs can be justified. The use of electronic devices such as pedometers and probes to measure vaginal electrical resistance (Gupta & Purohit 2001) has yielded good results under some conditions. Alternatively, as in cattle (see Chapters 8, 25, 26), various regimens of oestrous synchronisation and oestrous induction have been used in buffalo with the object of removing the need for oestrous detection by using fixed time AI (see later under 'Improvement of Fertility').

Pregnancy

The embryo reaches the uterus by Day 4 to 5 after oestrus, and the blastocyst hatches by Day 6 to 8. As in cattle, the growing

VetBooks.ir

extraembryonic tissues produce interferon tau, which prevents luteolysis by blocking the production of prostaglandin F2α from the endometrium (Sharma et al. 2014). The duration of gestation in the buffalo is nearly 1 month longer than in cattle and ranges from 300 to 330 days, with a mean of about 310 days for river types and 320 days for swamp types (Perera & de Silva 1985, Vale et al. 1990). River and swamp hybrids have an intermediate gestation length of 315 days. Male calves are carried 1 to 2 days longer than female calves. The incidence of right horn pregnancy is higher than left horn (67% vs 33%), and transuterine migration of the embryo is rare. The synepitheliochorial placenta of the buffalo is of the cotyledonary type. The total number of placentomes in the uterus can vary from 70 to 200, with the gravid uterine horn having a higher number than the nongravid horn (Pawshe & Purohit 2013). In late pregnancy, the placentomes measure 5 to 10 cm in diameter. As in cattle, cyclical ovarian activity ceases during pregnancy, but a few buffaloes may show behavioural signs of oestrus, which is anovulatory. The CL is maintained throughout gestation, and plasma progesterone concentrations remain elevated until parturition. The role of the CL in maintenance of pregnancy during the late stages of gestation is not known.

Pregnancy Diagnosis

The techniques for pregnancy diagnosis are basically similar to those routinely used in cattle and include palpation of the genital tract via the rectum, ultrasonography, and hormone assay (see Chapter 5). An important difference is that buffalo have a longer gestation length than cattle (see Table 38.1), resulting in a slightly slower development of the fetus and corresponding differences in criteria for determining the stage of gestation.

Rectal Palpation

Enlargement of one horn of the uterus can be detected from about 35 days of gestation, and slipping of the allantochorion is possible from about 42 to 56 days. The enlarged uterus is palpable in the pelvic cavity up to the third month of gestation, thereafter descending to the abdomen. In some deep-bellied river buffalo breeds, the fetus may be difficult to palpate, particularly between the sixth and eighth months. In such cases, palpation of the hypertrophied middle uterine arteries, with fremitus, or recognition of the placentomes aids in the diagnosis.

Ultrasound Scanning

Using a 5.0 or 7.5 MHz linear array transducer designed for transrectal use, the conceptual vesicle can be detected as an anechoic area from about 20 days onwards, sometimes with an echogenic embryo (Pawshe & Purohit 2013). The fetal heart can be detected at 30 to 35 days and structures such as limbs, spinal cord, and fetal membranes by 35 to 40 days.

Hormone Assays

As in cattle, elevated progesterone concentrations in milk or plasma 20 to 23 days after breeding is a reliable indicator for the diagnosis of nonpregnancy with an accuracy of nearly 100%, but the test is only 65% to 80% accurate for a positive pregnancy diagnosis (Perera et al. 1980). The inaccuracy in the latter case is due to conditions other than pregnancy that can result in high progesterone levels at this time, such as AI during the luteal phase of the cycle, persistence of the CL due to embryo death after 15 to 16 days of gestation or pyometra, and luteal cysts. Hence rectal palpation at a later stage is necessary to make a definitive diagnosis of pregnancy. The advantage of progesterone measurement is that nonpregnant animals can be identified early, and the farmer alerted to the need for detecting heat and having the animal mated. Measurement of oestrone sulphate in blood or milk can accurately differentiate pregnant from nonpregnant females at 110 days, as reported in cattle (see Chapter 5).

Parturition

The physiological processes leading up to and during parturition, as well as the changes occurring in the main hormones, are similar to those in cattle. Commencing about 1 to 2 weeks before parturition, the female shows marked abdominal enlargement, udder development, and hypertrophy and oedema of the vulvar lips. As the time of parturition approaches, she normally isolates herself from the rest of the herd. The relaxation and sinking of the pelvic ligaments and muscles lead to an elevation of the tailhead, while liquefaction of the cervical seal of pregnancy results in a string of clear mucus hanging from the vulva, particularly when the animal is recumbent.

Plasma concentration of progesterone remains elevated throughout gestation and declines sharply at the time of parturition, whereas the concentration of both oestrone and the main metabolite of $PGF_{2\alpha}$ (PGFM) increase about 15 days before parturition and reach peak values 3 to 5 days prepartum (Perera et al. 1981). There is a significant increase in plasma concentrations of cortisol at parturition (Prakash & Madan 1984).

Stages of Labour

Stage 1 – dilation of the cervix: occurs about 12 to 24 hours before parturition, uterine contractions increase in both frequency and amplitude, causing the animal some abdominal discomfort. The cervix takes about 1 to 2 hours to dilate fully.

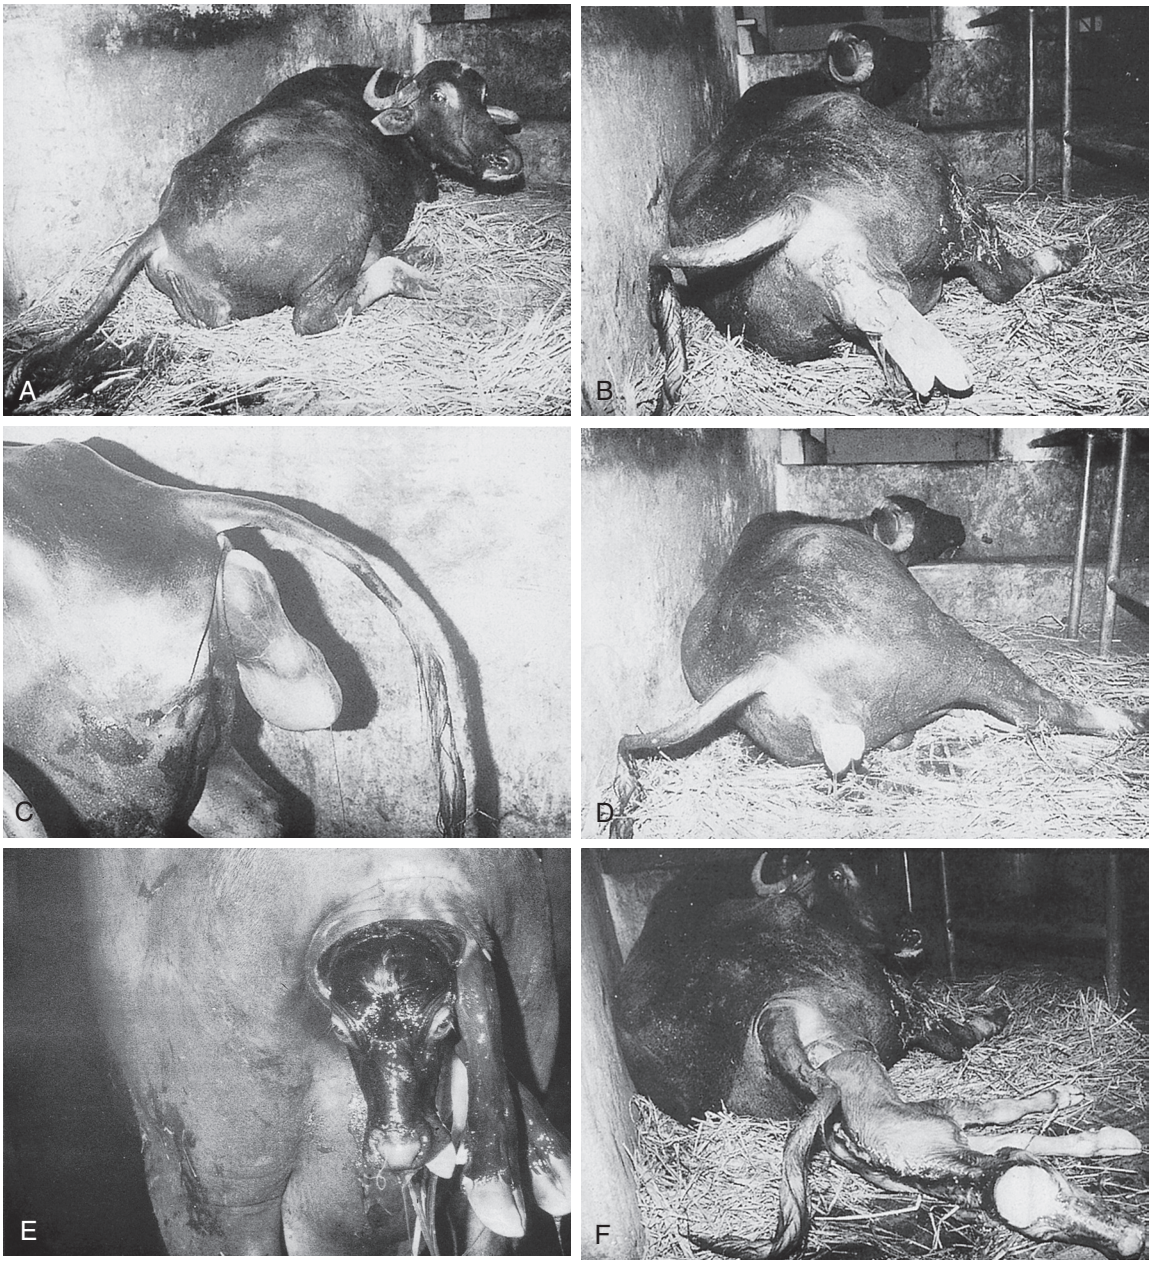
Stage 2 – delivery of the fetus (Fig. 38.3): As the fetus enters the birth canal, the dam lies down in sternal or lateral recumbency and starts straining. The allantochorion mostly ruptures before it reaches the vulva and is quickly followed by the fetus contained within the amnion, appearing at the vulva. Strong abdominal contractions lead to the rupture of the amniotic sac and the delivery of the fetus, usually in anterior longitudinal presentation and dorsal position, with extended limbs; posterior presentation is uncommon. This stage of labour lasts 30 to 60 minutes but may extend up to 6 hours, particularly in primiparae. As in the cow, the umbilical cord ruptures before the calf reaches the ground. Twinning is rare; the incidence is less than 1 in 1000 births.

Stage 3 – expulsion of the placenta: After delivery of the fetus, abdominal straining ceases and the fetal membranes are expelled, usually within 4 to 6 hours.

Dystocia

Dystocia is less common in the buffalo than in cattle; its incidence ranges from 2% to 5%. Stabled river buffaloes are more prone to dystocia than the free-ranging swamp type. The commonest cause of dystocia is fetomaternal disproportion, followed by a variety of faulty dispositions. The most frequent cause of maternal dystocia is uterine torsion, followed by incomplete dilatation of the cervix and uterine inertia. Occasional cases of hydrallantois and persistent hymen have also been reported. Most cases of uterine torsion occur at the time of parturition or during the last month of pregnancy. The direction of torsion in the buffalo in more than 90% of cases is to the right (clockwise). Predisposing factors for both torsion of the uterus and prolapse of the vagina or uterus are anatomical

VetBooks.ir



• **Fig. 38.3** Parturition in the buffalo. (A–E) Progression of second stage labour. (F) End of second stage labour.

in origin, relating to the relatively long uterine ligaments and low numbers of smooth muscle cells in the broad ligament of buffalo. The methods for correcting uterine torsion are the same as in cattle and include rotation of the fetus and uterus *per vaginum,* rolling of the animal using Schaffer's method, and laparohysterotomy (see Chapter 13).

Postpartum Disorders

The incidence of postpartum disorders is higher in the river than in the swamp buffalo. A review of reports on parturient and early postpartum disorders in the buffalo (Purohit & Markandeya 2015) shows incidences ranging from 6% to 59% for retained fetal membranes (RFM), 2% to 20% for genital prolapse, and 7% to 29% for metritis. Infections, uterine inertia, dystocia, and poor management practices have been implicated in the pathogenesis of RFM. Cervicovaginal prolapse occurs prepartum, whereas uterine prolapse occurs postpartum, usually within the first 6 hours after expulsion of the fetus and involves a complete eversion of the gravid uterine horn.

The Puerperium

Involution of the Uterus

The uterus undergoes a marked decrease in size during the first 2 weeks postpartum, and by Day 15 the gravid horn can be located at the pelvic brim, whereas the nongravid horn is in the pelvic cavity. The involution rate gradually decreases; from 21 to 25 days the rate of receding is considerably slow but progressive. The complete uterus returns to the pelvic cavity by Day 25, and the gravid horn attains normal tone and consistency by 30 to 35 days (Chauhan

VetBooks.ir

et al. 1977). The discharge of uterine lochia at first contains pure blood but changes thereafter to a chocolate colour and appears turbid due to a mixture of leucocytes and tissue debris. It increases up to about Day 7 postpartum, then decreases in volume and changes to a white mucoid discharge, which ceases within 2 to 3 weeks. Uterine involution is delayed in cases of calving problems such as dystocia, uterine prolapse, and RFM, and the discharge of lochia persists beyond the normal duration.

Resumption of Ovarian Activity

The CL of the previous pregnancy has completely regressed by Day 30 postpartum. Peripheral plasma progesterone concentrations decline rapidly after parturition to reach undetectable levels by Day 3 or 4 and remain so till the first postpartum ovulation, which occurs at about 60 days in the river buffalo and 96 days in the swamp buffalo (Jainudeen & Hafez 1993). Factors that delay resumption of cyclicity include: poor nutrition (Baruselli et al. 2001) leading to low body condition score (BCS); suckling management (Perera et al. 1987); and climate (Nanda et al. 2003) that also influences nutrition through feed quality and availability. Hand-milked river buffaloes have a lower incidence of postpartum anoestrus than suckled swamp buffaloes, and those calving during their normal calving season resume cyclical ovarian activity earlier than those calving in other seasons. A review of results from Egypt, India, and Pakistan (El-Wishy 2007) showed that only 34% to 49% of buffalo exhibited oestrus during the first 90 days after calving, and 31% to 42% remained anoestrous for more than 150 days. The first postpartum ovulation was frequently followed by one or more short oestrous cycles (< 18 days). The presence of buffalo bulls in a herd has a 'biostimulatory' effect, reducing cyclic irregularities and advancing the time of ovulation (Moioli et al. 1998). The management and treatment of postpartum anoestrus in the buffalo are discussed later in 'Female Infertility'.

Reproduction in the Male

Buffalo bulls used for breeding under farming systems that employ natural mating must be capable of efficiently detecting oestrus and serving a high proportion of cows. One bull can cover 40 to 50 cows per year, provided there is no marked seasonality in the occurrence of oestrus. In large herds requiring the use of several bulls, it may be necessary to introduce them in rotation because the presence of two or more bulls in the herd at the same time is likely to result in aggressive behaviour between them. When bulls are used as semen donors for AI, they must be of exceptionally high fertility, and the semen must be capable of withstanding the processing and storage procedures used.

Anatomy of the Reproductive Organs

The reproductive organs of buffalo bulls are similar to those of cattle bulls, but the testes and scrotum are smaller and the penile sheath is less pendulous. As in cattle, the testis and epididymis can be palpated through the scrotal wall, and the prostate gland, seminal vesicles, and ampullae of the ductus deferens can be palpated transrectally.

Puberty

The age and body weight at puberty in buffalo males is as variable as in females and is determined more by body weight than age. With adequate nutrition, the testis size increases slowly between 5 and 15 months, rapidly between 15 and 25 months, and again slowly between 25 and 38 months of age. Spermatogenic cell divisions commence at about 10 to 14 months of age, and active spermatogenesis can be seen by 14 to 16 months (Perera 1999). However, sexual maturation, as indicated by the presence of motile spermatozoa in the ejaculate, is attained between 24 to 30 months of age (Jainudeen & Hafez 1993). The faster growing F1 river and swamp crossbreeds reach puberty earlier than the slower growing swamp buffaloes. The concentration of testosterone is at basal level from birth to about 5 months of age, increases gradually up to 14 to 16 months, then increases more rapidly between 18 to 24 months, and reaches adult levels of around 3 nmol/l (~1 ng/mL) thereafter (Hemeida et al. 1985).

Seasonality and Endocrinology in Adults

Buffalo bulls are capable of breeding throughout the year, but some seasonal fluctuation in reproductive functions is evident in most countries. In India, semen volume, density, and initial sperm motility did not differ significantly between different seasons, but postfreezing motility varied significantly, being lowest during summer and highest during winter (Bahga & Khokar 1991). The concentration of LH and testosterone in the blood of buffalo bulls shows the typical episodic or pulsatile pattern of secretion that is seen in cattle and is influenced by seasonal factors (Agarwal et al. 1983).

Spermatogenesis

Among farm animals the buffalo has one of the shortest spermatogenic cycles. The durations of the seminiferous epithelial cycle and spermatogenesis are 8.6 and 38 days, respectively (Sharma & Gupta 1979). Spermatozoa of the buffalo are slightly smaller than those of cattle, and the head has a more rectangular shape. Their average measurements are: length of head 7.5 µm; width of head at widest point 4.9 µm; length of midpiece 11.7 µm; and length of tail 50 µm (Vale et al. 2014).

Examination of Semen

Semen is usually collected with a conventional bovine artificial vagina (AV); alternatively, bovine electroejaculators can also be used (see Chapter 35). Either a female or a castrated or intact male buffalo can be used as the teaser. The temperature of the water jacket of the AV should be about 42° to 46°C, and the pressure within the AV should be adjusted to suit individual bulls. Sperm concentration is increased by allowing two or three false mounts before the actual collection. The normal ejaculate collected with an AV is milky white to creamy in colour and varies from 1 to 6 mL in volume, with a sperm concentration of 500 to 1500 million cells/mL. The mass activity and individual motility of buffalo spermatozoa are lower than those in cattle. The parameters of semen quality are affected by precoital sexual excitement, number of false mounts, age, season of year, frequency of collection, diet, and fitness of the bull. The temperature/humidity index adversely affects the volume of semen produced, depresses sperm concentration and initial motility, and increases the production of dead and abnormal spermatozoa. The decline in serum thyroxine during the summer months depresses feed intake and metabolism and thus decreases sperm production. Similarly, increased body temperature has adverse effects on initial motility and the number of dead spermatozoa in the ejaculate. Bulls with obvious testicular asymmetry yield considerably fewer

VetBooks.ir

spermatozoa per ejaculate. The presence of pathogenical bacteria, e.g., *Pseudomonas* spp. and *E. coli,* can reduce sperm motility and increase the dead sperm percentage.

Artificial Insemination

In the Indian subcontinent, AI has been practised in the river buffalo for over 40 years but has lagged behind its use in cattle largely because of the difficulty of detecting oestrus. In addition, lower fertility rates obtained with chilled or frozen semen are constraints to the widespread use of AI in this species. Moioli et al. (1998) have shown that buffalo spermatozoa subjected to freezing and thawing have a shorter life span in the female genital tract than fresh semen. Buffalo semen differs from cattle semen in having higher concentrations of calcium, chloride, acid soluble phosphorus, and alkaline phosphatase, and in having lower concentrations of total electrolytes, protein, cholesterol, ascorbic acid, citric acid, and fructose (Vale et al. 2014). Because of these findings, various extenders different from those used in cattle have been developed for preserving buffalo semen in the chilled or frozen form; the results have varied. These include lactose–egg yolk–glycerol, lactose–fructose–egg yolk–glycerol, and Tris–egg yolk–glycerol. The use of more than 20% egg yolk does not enhance cryoprotection but can lessen sperm forward motility in the cervix as a result of increased viscosity. An equilibration period of 6 to 9 hours and glycerol concentrations of 5% to 7% are most frequently used. Extended semen is placed in 0.25 or 0.5 mL straws or paillettes, each containing 30 million spermatozoa. The straws are then exposed to nitrogen vapours at −120° to −140°C and stored in liquid nitrogen. Rapid thawing at 37° to 40°C for 10 to 20 seconds is preferred over slow thawing.

The postthaw progressive motility of buffalo semen varies from 35% to 60%. The timing of AI in buffalo follows the am/pm rule used in cattle (see Chapter 43). The optimum timing of AI is at the end of standing oestrus, somewhat later than in cattle (Moioli et al. 1998). One of the ways to determine this would be to assess when the cow refuses to stand to be mounted by the teaser bull. Because this is often not practicable in commercial herds, AI is usually performed 24 hours after the first signs of oestrus (Perera 1999).

As in cattle, separation of X and Y bearing sperms has been done using high-speed flow cytometric cell sorting (see Chapter 44). The use of such semen according to the 'low dose deep AI' technology, with 2.5 million sperm deposited near the uterotubal junction, has resulted in 43% conception rate with around 90% of fetuses corresponding to the predicted sex (Presicce et al. 2005).

Fertility and Infertility

Evaluation of Fertility

The overall reproductive efficiency of buffalo can vary widely between different farming systems. Animals kept under smallholder systems in some Asian countries are often subjected to harsh environments, with inadequate feed and low managerial inputs. They have poor fertility compared with those kept under improved production systems in regions with mild climates. Under optimum conditions, buffalo can achieve a first service conception rate (CR) of over 65% with natural service and of 40% to 50% with AI using frozen semen. In well-managed herds, overall annual pregnancy rates of over 80% can be achieved, with a calving interval (CI) of 14 to 15 months (Perera 2008). However, in many smallholder systems the annual pregnancy rates are only around 50% to 60%, with CIs of 18 to 24 months. In many situations, a buffalo produces, on average, two calves every 3 years.

Female Infertility

The main causes for infertility in buffalo females include delayed sexual maturity, prolonged postpartum anoestrus, repeat breeding, and abortion (see Chapter 22). The factors influencing these vary depending on the farming system and include climate, nutrition, management practices, and both specific and nonspecific infections.

Anoestrus

As in cattle, two forms of anoestrus occur in the buffalo. In the first form, the animal has small ovaries with no palpable CL and does not exhibit oestrous because she is acyclic (true anoestrus). In the second form, the animal possesses a palpable CL in one ovary but has not been detected in oestrus as a result of suboestrus or silent ovulation. A high incidence of true anoestrus occurs during the hot summer months and during periods of poor feed availability. Blood levels of calcium, phosphorus, glucose, and total proteins are lower in anoestrus than in cyclical buffalo. In most cases the disorder resolves spontaneously with the arrival of more favourable climatic conditions and adequate feeding. Restricting the suckling by calves and alleviating heat stress by wallowing or the use of water sprinklers may also help to initiate ovarian activity.

Hormonal treatment protocols for true anoestrus are similar to those developed for cattle (see Chapter 22). These include gonadotrophin-releasing hormone (GnRH) or its analogues, and progesterone or synthetic progestagens placed intravaginally or subcutaneously for 10 to 12 days, followed by equine chorionic gonadotrophin (eCG) or GnRH at the time of withdrawal (Baruselli et al. 2007). Variable results have been reported, with some successful trials showing induction of cyclicity in 81% of acyclic animals and with a conception rate of 74% at the end of the breeding period, compared with 54% for controls (Zicarelli et al. 1997). However, results were poor in some trials, particularly when other underlying causes of infertility, such as inhibitory effects of climate, management, nutrition, low BCS, and diseases had not been addressed before implementing hormonal therapy.

Suboestrus and silent ovulation were previously believed to be a major problem in buffalo breeding, but recent evidence suggests that it is due to the poor oestrous detection in these herds. The incidence has been reduced in herds in which improved oestrous detection practices have been implemented (Jainudeen & Hafez 1993). If the problem persists, hormonal treatments can be used for oestrous induction, thus removing the need for oestrous detection by using fixed time AI (see later under 'Improvement of Fertility').

Cystic Ovaries

The incidence of cystic ovaries is lower in buffalo than in cattle, and the condition is more common in the high-producing river type than in the suckled swamp type. In a survey, cystic ovaries accounted for 6% of reproductive failure in over 12,000 river buffalo in India; most cases occurred before Day 45 postpartum (Rao & Sreemannarayanan 1982). The clinical findings and treatment are similar to those in cattle (see Chapter 22).

Repeat Breeding, Endometritis, and Abortion

As in cattle, repeat breeding in buffalo could be due to either fertilisation failure or early embryonic death. The aetiologies may

VetBooks.ir

be related to disorders in either the female or male (including errors in AI), as well as to the environment and management. The incidence of repeat breeding in buffalo ranges from 8% to 32% (Rao & Sreemannarayanan 1982). It is lower in animals kept individually on smallholdings than in large herds, and in heifers compared with adult buffaloes up to the third parity; thereafter, the incidence decreases, probably because of culling of affected animals from the breeding stock.

Nonspecific uterine infections, leading to clinical or subclinical endometritis, are among the major causes of repeat breeding (Usmani et al. 2001). Factors attributed to the high incidence of endometritis in buffalo include unhygienic calving management, persistence of infection from the puerperal period, and midcycle inseminations. It can also be caused by the malpractice of stimulating milk let down through the introduction of instruments, sometimes the animal's own tail, or a hand into the vagina. Furthermore, because the vulvar labia are not closely opposed in the buffalo, wallowing in contaminated water may result in ascending infections. The common organisms isolated from cases of metritis and endometritis include *Arcanobacterium pyogenes; E. coli; Fusobacterium necrophorum;* and *Bacteroides* spp. (Azawi et al. 2008). The methods of treatment are the same as those for cattle (see Chapter 23). Other causes of repeat breeding include luteal dysfunction delayed ovulation or anovulation, and nutritional deficiencies, resulting in, for example, low serum calcium and phosphorus concentrations as well as hypoglycaemia. The factors related to AI include the quality of semen, timing of breeding, and technical skill of the inseminator.

The incidence of abortion in buffalo ranges from 1% to 6% and could be due to noninfectious or infectious causes. The specific infections that cause abortion in cattle, such as brucellosis, leptospirosis, campylobacteriosis, trichomoniasis, and infectious bovine rhinotracheitis (IBR), have a low incidence in the buffalo.

Male Infertility

The causes of infertility and sterility in buffalo bulls can be classified as either congenital or acquired. Congenital causes include structural defects in the testes (agenesis, aplasia, hypoplasia, or cryptorchidism), segmental aplasia or hypoplasia of the ductus deferens and epididymal ducts, or defects of the penis and prepuce (prolapse of prepuce, deviation of penis, or persistent frenulum). Such animals should not be used for breeding, as these disorders may be transmitted to the offspring, and they should be castrated or culled. Acquired causes of infertility include injuries and thermal stress, and specific as well as nonspecific infections that lead to inflammatory changes including orchitis, epididymitis, seminal vesiculitis, and testicular degeneration (Vale et al. 2008).

Another method of classification is based on the functional defect, as either *impotentia coeundi* (lack of sexual desire or libido and inability to copulate) or *impotentia generandi* (inability to fertilise due to poor semen production). The causes of reduced libido include age, poor nutrition, environmental stress, overuse, painful conditions, and hormonal disorders. Measures such as improved nutrition and housing, hoof care, exercise, and sexual stimulation can improve libido. Inability to copulate is caused by physical or functional defects that prevent mounting, erection, intromission, and ejaculation. The factors that lead to poor semen production are related to spermatogenesis, sperm maturation, or functions of the accessory glands.

Improving Fertility

The approach to improving fertility in buffalo includes the adoption of proven improved practices of management, including breeding, feeding, and disease control, which are suitable for the particular production system, and are cost effective using the available resources. Selective breeding among river breeds, crossbreeding between river and swamp breeds, and improvements in nutrition can advance the onset of puberty. Similarly, management practices such as early weaning, a high plane of feeding, and proper protection during the hot summer months can advance the restoration of postpartum cyclical ovarian activity, increase conception rates, and reduce the length of calving intervals. As in cattle, several assisted reproductive technologies (ARTs) have been applied in the buffalo, as described later in this chapter.

Oestrous Synchronisation and Oestrous Induction

The main objective of oestrous synchronisation (in a group of females) or oestrous induction (in individuals) is to overcome the problems in heat detection and enable fixed-time AI at a predetermined time. As in cattle, early studies were aimed at either inducing premature luteolysis of a CL, using $PGF_{2\alpha}$ or its analogues, or prolonging the luteal phase, using progesterone or progestagens (Perera 1987). However, later studies on the effect of follicular dynamics on the outcome of these procedures (Zicarelli et al. 1997) have led to methods aimed at manipulating follicular development to achieve better synchrony and improved fertility (Baruselli et al. 2007, De Rensis & Lopez-Gatius 2007). A review of results from various protocols for oestrous synchronisation (Borghese 2005) shows that CR achieved with prostaglandins, either alone or in combination with GnRH, ranged from 7% to 56%. CR using progesterone-releasing devices, either alone or in combination with eCG and in some cases further supplemented with human chorionic gonadotrophin (hCG) or GnRH, ranged from 8% to 64%. The 'Ovsynch' protocol (GnRH followed by prostaglandin 7 days later and a second GnRH 2 days later) has been used successfully in buffalo, with synchronisation of ovulation in 70% to 90% and CR of 33% to 60% (Paul & Prakash 2005). A third dose of GnRH given 6 days after insemination to induce accessory CLs has been reported to increase CR and birth rate (Carvalho et al. 2007; see also Chapters 8 and 25). In addition to the type of protocol selected, the following factors must also be addressed to achieve success in buffalo (Perera 2011): (a) selection of animals that are in good nutritional condition and free from disease; (b) prevention of stress during the procedures for treatment and AI, especially under tropical conditions when animals may be herded together, tethered, or moved to other locations; and (c) where seasonal differences exist, scheduling treatment for the more favourable periods or high breeding season when the majority of animals are likely to be cycling.

Difficulty of detecting oestrus in individual females can be overcome by oestrous induction to permit AI at a predetermined time. The two methods used are: (a) treatment with $PGF_{2\alpha}$ or a synthetic analogue to cause premature luteolysis; and (b) the creation of an artificial luteal phase by the use of a progesterone-releasing device for a period and its withdrawal. For the first method, it is necessary to confirm the presence of a CL and absence of pregnancy by rectal palpation before treatment.

Multiple Ovulation and Embryo Transfer

Although the first buffalo calf born after embryo transfer occurred in the United States in 1983 after the nonsurgical collection of

VetBooks.ir

a 7-day blastocyst and nonsurgical transfer to an unrelated river buffalo (Drost et al. 1983), the application of embryo transfer in buffaloes has lagged behind substantially that in *Bos taurus* (see Chapter 44). This has been due to several factors (Madan et al. 1996), including: (1) the poor superovulatory response using a variety of different protocols, attributed mainly to the smaller population of recruitable follicles in the ovary; and (2) a relatively low rate of transfer of oocytes to the oviduct and/or impaired transport of ova and embryos in the reproductive tract. In a large scale, multiple ovulation and embryo transfer (MOET) operation in India (Misra et al. 1994), the transfer of 469 embryos resulted in a pregnancy rate of 17% and a calving rate of 9.8%. In Italy, Campanile et al. (1995) transferred 76 buffalo embryos and obtained a pregnancy rate of 30%, with no significant difference between fresh or frozen-thawed embryos and between morulae or blastocysts. However, the overall rate of success in terms of calves born per superovulation is still too low for MOET to be widely applicable under practical farming conditions. Two situations in which it might have a role are for establishing nucleus breeding stocks or for conservation of genetic resources.

In vitro Embryo Production Including in vitro Maturation, Fertilisation and Culture

The sequence of procedures for *in vitro* embryo production (IVEP) involves recovery of oocytes from slaughtered animals by direct aspiration or from live animals by ultrasound-guided transvaginal ovum pick-up (OPU), followed by *in vitro* maturation (IVM), *in vitro* fertilisation (IVF), and *in vitro* culture (IVC). The OPU technique (see Chapter 44) can be used for repeatedly collecting oocytes in cycling buffalo once or twice every week or in prepubertal heifers and cyclic cows after treatment with FSH. The yield of cumulus–oocyte complexes (COC), using OPU in nonsuperovulated buffalo, is about 1 to 2 per ovary per collection, whereas after FSH treatment, it is about 2 to 3 per ovary. The cleavage rate of oocytes selected as being suitable for IVEP is around 50%, but only about 10% develop into morulae and blastocysts (Manik et al. 2006). Results from transfer of fresh embryos derived from repeated OPU in China show that a calving rate of 35% was obtained when recipients were normally cycling, compared with 15% in those subjected to synchronisation (Liang et al. 2007). Methods for cryopreservation of oocytes, using vitrification, are more successful than slow freezing, with ethylene glycol as the cryoprotectant. Transfer of vitrified embryos derived from oocytes collected from slaughtered river type animals resulted in a pregnancy rate of 16% and a calving rate of 10% to 11% in swamp and river type recipients (Hufana-Duran et al. 2007).

Cloning

Cloning by somatic cell nuclear transfer (SCNT) in buffalo is still in its early stages, but some basic understanding has been achieved regarding parthenogenetic, *in vitro,* and *in vivo* development of embryos reconstructed by transferring donor nuclei from fetal and adult fibroblast cells to enucleated buffalo oocytes. Embryos reconstructed using fetal fibroblasts were capable of developing to the blastocyst stage, and some pregnancies were detected after the transfer of cloned blastocysts into recipients, but none were carried to term (Saikhun et al. 2004). Cloned embryos that are capable of developing to the morula and blastocyst stages have also been constructed using enucleated rabbit oocytes as recipient cytoplasm and cow, swamp buffalo, pig, and elephant fibroblasts as donor nuclei (Numchaisrika et al. 2007). See also Chapter 44 for more information about cloning and embryo transfer.

Deer

GEOFFREY W. ASHER

The cervids are a complex assemblage of taxa showing extreme diversity in morphology, physiology, ecology, and geographical distribution. Reproductive strategies adopted by various species are also diverse and include a range from highly seasonal to completely aseasonal birth patterns. The recent growth in knowledge of cervid reproduction is strongly biased towards the larger bodied, gregarious, mixed grazer-browser species that have adapted well to human management and commercialisation. These species tend to represent 'K-selected' climax species characterised by very productive annual breeding success, singleton births, and long breeding life (10 + years). Conversely, we know relatively little about the reproductive patterns of the 'r-selected' smaller bodied, solitary (and often highly territorial), forest-dwelling browser species, often characterised by great fecundity (twinning) and shorter breeding life (< 10 years). This group includes many of the endangered cervid taxa. This chapter describes and discusses the general reproductive biology and artificial reproductive technologies of cervids, as well as including more recent studies of cervid reproductive productivity. Male cervids are referred to as stags and females as hinds.

Distribution and Diversity of Cervids

Although the taxonomy of cervids is often debated (particularly at the species/subspecies level), Whitehead (1993) considers that deer are represented by 43 species and 206 subspecies distributed widely across Europe, Asia, North America, South America, and northern Africa. Their evolution and geographical radiation over the last 20 to 40 million years has resulted in remarkable diversity in morphology, physiology, and ecology. In particular, reproductive strategies among cervids vary widely within and between regions. As such, no one species can be considered to represent a 'typical' deer in terms of reproductive function. For example, some cervids exhibit highly seasonal patterns of birth in cool temperate climes, whereas others are aseasonal in equatorial regions. Also, although many species are strictly monovular and bear single offspring annually, others are normally polyovular and bear multiple offspring. Even embryonic development and placentation vary among species (Asher et al. 1999a,b). Harrington (1985) expressed this variation in terms of 'life-history strategies', in which cervids can be classified into the two extremes; one maximises the reproductive capacity of individuals and the potential growth rate of the population (r), and the other maximises the competitive ability of individuals and the stability of the population (K). Unstable or early successional habitats favour the r-strategy, whereas stable or late successional (climax) habitats favour the K-strategy (Harper et al. 1961). The r-strategists are identified by their greater reproductive potential, exhibiting multiple births, early sexual maturation (<1 year) and short breeding life (<10 years). They are predominantly territorial browser- or concentrate-feeders adapted to rapid colonisation of early stage successional habitats, including species such as roe deer (*Capreolus capreolus*), white-tailed deer (*Odocoileus virginianus*), moose (*Alcesalces*), and numerous species of tropical, forest-dwelling deer. K-strategists have lesser reproductive potential that includes lower fecundity (i.e., singleton births) and later sexual maturation (>1 year), and are generally mixed grazer/browsers with marked gregariousness and social/behavioural plasticity. They tend to occupy climax habitats and include nearly all taxa within *Cervus* (red deer, wapiti, sika deer, sambar deer, etc.) and *Rangifer* (reindeer, caribou). Because of their ability to adapt to human management regimens, it is the K-strategists that are predominantly represented in the research literature. It is therefore important to note that, although there was an increased understanding of reproductive function in cervids over the last few decades, this relates mainly to those species of importance to agriculture (i.e., deer farming) and a few endangered species undergoing ex situ conservation efforts. In general, the research has been largely directed towards successful application of assisted reproductive technologies to manipulate the genetic composition of populations (e.g., selection for improved agricultural productivity and avoidance of inbreeding depression) (see also Chapter 44). The studies to date are clearly biased towards a few key species, particularly the larger bodied, monovulatory species with greater environmental and behavioural plasticity (K-strategists) that makes them suitable candidates for captive propagation. The smaller bodied, forest-dwelling, and solitary species (r-strategists) are clearly underrepresented in such research. This later group includes numerous species whose populations are under threat or are endangered (see Asher et al. 1999a).

Seasonality versus Aseasonality

The necessity for most cervid species to give birth at an appropriate time of year for optimal survival and growth of offspring has exerted considerable influence on their reproductive physiology (Lincoln & Short 1980). Species of northern temperate or arctic origins typically conceive in autumn and calve in summer. In contrast, species of tropical origin often exhibit limited seasonality or are completely aseasonal (Lincoln 1985). The endogenous mechanisms governing seasonal reproductive patterns in temperate species are robust, being manifest rigorously when animals are transferred between localities despite subtle variations in seasonal feed supply. The transference of temperate species across the equator results in an exact 6-month phase change (Marshall 1937), even though the

VetBooks.ir

relationship between season and feed production differs considerably between continental northern hemisphere and insular southern hemisphere environments (Asher et al. 1993a). Tropical species transferred from equatorial zones exhibit either pronounced 'reverse seasonality' (spring conceptions and autumn/winter calving; e.g., rusa deer, *Cervus timorensis,* in southern Australia), wide birth seasons (e.g., chital deer, *Axis axis,* in Australia), or complete aseasonality (e.g., Reeve's muntjac, *Muntiacusreevsii,* in UK) (Chapman et al. 1984, Loudon & Curlewis 1988, Monfort et al. 1991, Mylrea 1992). It is noteworthy that there is a general paucity of information on the birth season of tropical species in their native tropical environment, although there are well-documented examples of species that exhibit strictly seasonal patterns of birth.

For temperate and arctic species it is generally accepted that entrainment of seasonal reproductive cycles is effected by endogenous recognition of photoperiod changes, with the majority of species initiating mating activity during the decreasing day length of late summer and autumn (Lincoln & Short 1980). Variations in the actual mating season between species of up to 8 weeks usually offsets differences in the duration of gestation such that parturition generally occurs in midsummer (Lincoln 1985). A notable exception among temperate species is the Père David's deer (*Elaphurus davidianus*), which initiates mating activity in early summer and calves in late spring, despite an unusually long gestation of approximately 280 days (Wemmer et al. 1989).

There is increasing evidence that some tropical species also perceive and respond to changes in photoperiod, although in a different manner than temperate species. Rusa deer living in the tropics exhibit asynchronous antler cycles and birth timings. However, once translocated to temperate, high latitude zones, they appear to establish an evolutionary-based, 'long-day' reproductive rhythm (Van Mourik & Stelmasiak 1990). Brow-antlered Eld's deer (*Cervus eldithamin*) exhibit strong reproductive seasonality in their subtropical native range. This pattern persists after translocation to high latitudes (48°N), even though this strategy results in the birth of offspring during harsh winter months (Monfort et al. 1991). It is hypothesised that Eld's deer respond to the relatively subtle, low amplitude, photoperiodic oscillations experienced in their native subtropical latitudes. Higher latitudes simply serve to reinforce or strengthen seasonal rhythms because the direction of photoperiodic change is similar but of greater amplitude. Chital deer appear to exhibit only limited seasonality within their native tropics and after translocation to temperate zones. However, exogenous melatonin treatment has been shown to hasten and synchronise antler casting among stags (Mylrea 1992), indicating possible photoperiodic responsiveness in a species that, in other respects, appears unresponsive. In contrast, tropical sambar deer (*Cervus unicolor*) acclimatised to temperate zones in New Zealand exhibit a loose pattern of 'reverse seasonality' in calving but fail to show any discernible seasonal patterns in prolactin secretion (Asher et al. 1997a).

Because tropical cervid species are not exposed to strong circannual photoperiodic rhythms, reproductive patterns may have evolved in response to a variety of factors, including seasonal fluctuations in the availability of specific food items, local resource competition among sympatric species (species that occupy about the same area of land but do not interbreed), or predation pressure; many of these factors may be directly related to rainfall patterns. For example, it has been asserted that conceptions are timed in white-tailed deer living in Colombia (5°N) and the Everglades National Park (25°N) so that births occur during the dry season (Blouch 1987, Smith et al. 1996). The fawning season of hog deer (*Axis porcinus*) in Nepal (27°N) coincides with new vegetative growth that occurs after seasonal grass fires caused by lightning strikes or agricultural burning; it is believed to have been occurring for thousands of years (Mishra & Wemmer 1987). However, how these species synchronise their season of conceptions to achieve birth synchrony remains to be resolved. Even species such as sambar deer and chital deer, sharing the same habitat in Nepal, fawn 6 months out-of-phase to one another (Mishra & Wemmer 1987).

Cervid species occupying wide latitudinal and longitudinal ranges have generally developed discrete populations that exhibit pronounced phenotypic and genotypic differences. For example, the red deer/wapiti species *(Cervus elaphus)* includes at least 23 recognised subspecies in a west/east cline, from Western Europe to North America (Whitehead 1993). Climatic variation between subspecies zones may be associated with subtle variation in reproductive seasonality of the various subspecies. Studies have indicated that Western European (Scottish) red deer (*C.e. scoticus*) and Eastern European red deer (*C.e. hippelaphus*) farmed in New Zealand exhibit a 2- to 3-week difference in rutting activity and subsequent mean calving dates (Scott et al. 2006). These differences occur at the same latitudes in both Europe and New Zealand (and indeed within sympatric populations on New Zealand farms), indicating subtle genetic differences in subspecies responses to the prevailing photoperiodic regimen.

Nonpregnant Female

With few exceptions, female cervids (hinds) are polyoestrous, with nonpregnant animals exhibiting continuously repeated oestrous cycles (some tropical species) or, more commonly, alternating periods of oestrous cyclicity and anoestrus. Oestrous cycles have been characterised for a number of species based on studies of oestrous behaviour and/or luteal secretion of progesterone. In nonpregnant females of temperate species, such as red deer and fallow deer, the onset and termination of oestrous cyclicity occur in autumn and spring respectively, with 5 to 8 cycles expressed. Anoestrus is characterised by low peripheral plasma concentrations of progesterone indicative of complete ovulatory arrest and may persist for 4 to 6 months from spring to early autumn. In marked contrast, some tropical species, such as brow-antlered Eld's deer and rusa deer, translocated to higher, temperate latitudes, exhibit 'reverse seasonality', initiating oestrous cycles in spring and entering anoestrus in the following autumn. This 6-month phase shift in tropical species within temperate climes possibly indicates retention of photoperiodism from a temperate ancestral form. Some tropical species, such as chital deer, appear to have become completely aseasonal, with females exhibiting recurring oestrous cycles in the absence of pregnancy (Mylrea 1992). There are indications for some tropical species within temperate latitudes, such as sambar in New Zealand, that responsiveness to photoperiod has been lost, as indicated by an inability to detect measurable levels of plasma prolactin in sambar hinds during the year (Asher et al. 1997a).

The transition into the female breeding season is characterised by 'silent ovulations' (ovulations not preceded by overt oestrus) and short-lived (8–10 days) corpora lutea in most cervid species studied. In fallow deer (*Damadama*), multiple successive silent ovulations leading up to the start of the breeding season have been observed (Asher 1985). The transient nature of the preliminary corpora lutea may actually serve to promote within-herd synchrony of first overt oestrus of the season.

Subsequent oestrous cycles are generally of normal duration, as determined genetically for each species, although occasional 'long

VetBooks.ir

cycles' have been observed in some Père David's deer and Eld's deer (Curlewis et al. 1988, Monfort et al. 1991). Average duration of the normal oestrous cycle ranges from 17 days in sambar and axis deer, 18 to 20 days in red deer and Eld's deer, 21 to 23 days in fallow deer, and 24 to 27 days in moose and black-tailed deer *(Odocoileus hemionus)*. The mean duration of the oestrous cycle tends to increase progressively during the breeding season in most of these species (Guinness et al. 1971, Asher 1985, Curlewis et al. 1988, Monfort et al. 1991, Chapple et al. 1993, Schwartz & Hundertmark 1993, Wong & Parker 1993).

Overt oestrous behaviour has been observed in a number of cervid species, but the duration of mating receptivity at a single oestrus has been difficult to determine. In some species at least, including red deer and fallow deer, overt oestrus is generally terminated after successful copulation and may only persist for a matter of minutes. In the absence of copulation, oestrous behaviour in these species has been observed to occur for up to 24 hours (Asher et al. 1993b). Early studies on both of these species have shown that the onset of oestrus coincides with the onset of the preovulatory LH surge, which itself peaks about 24 hours before ovulation (Berg et al. 1994, Asher et al. 1999a).

Luteal events during the cervid oestrous cycle are similar between species. Luteinisation of postovulatory follicles is associated with increased secretion of progesterone, with maximal concentrations in peripheral blood occurring between days 10 and 16 of the oestrous cycle (Day 0 = oestrus). Although absolute plasma concentrations vary between species, the relative changes from Day 0 are quite similar between species (Asher et al. 1999a). Luteal regression, which for fallow deer involves the classic interaction between oxytocin and prostaglandin $F_{2\alpha}$ (Asher et al. 1988a), occurs rapidly about 1 to 3 days before the return to basal progesterone concentrations and return oestrus.

Ovarian follicular dynamics during the oestrous cycle have been described from ultrasonographic studies on red deer, fallow deer, and, more recently, North American Wapiti (C.e. manitobensis) (Asher et al. 1997b, 1999b, McCorkell et al. 2006). These studies, all of which involve monovulatory species, clearly demonstrated discrete, nonrandom patterns of antral follicular growth and regression during the oestrous cycle, with individual cycles characterised by two to four dominant follicle waves similar to that observed in cattle.

Female puberty, defined as the age of first ovulation, normally occurs between 1 and 3 years of age in most cervid species, although this is strongly influenced by climatic and nutritional factors. Such influences are mediated through body mass, as demonstrated for red deer hinds (Hamilton & Blaxter 1980, Clutton-Brock et al. 1982). Red deer hinds on New Zealand deer farms are expected to attain puberty at 16 months of age and produce their first calf at 24 months of age. However, high incidences of reproductive failure within populations of rising 2-year-old hinds (i.e., 10%–60% of hinds not attaining pregnancy) have been common (Asher & Pearse 2002), prompting research into factors controlling entry into puberty. Studies involving observations of over 20,000 young hinds have clearly shown a strong relationship between live weight at 16 months of age and the ability to enter puberty (Asher & Cox 2013), with hinds that fail to attain about 70% of the expected mature body mass of their genotype (subspecies) by 16 months of age, thus delaying puberty by at least 1 year. This has been termed as the 'permissive body mass threshold for entry into puberty' (Asher & Cox 2013). However, recent studies have provided support for the hypothesis that the nutritional environment in early life (birth to 3 months of age) influences the permissive body mass threshold for puberty at 16 months of age. Detailed analysis of a multiyear data set, in which the relationship between live weight and predicted pregnancy rate was modelled, demonstrated that hinds under nutritional constraints early in life had a higher permissive body mass threshold for puberty for their genotype, thus raising intriguing possibilities self-regulatory mechanisms to control reproductive processes in the face of variable environmental (e.g., climatic and nutritional) conditions (Asher & Cox 2013).

Pregnant Hind

Relatively little research has been dedicated to pregnancy establishment and maintenance in cervids. In the seasonally breeding red deer hind, conception rates after natural mating during the autumn rut appear to be high (>85% per mated oestrus), and early embryonic mortality (i.e., within 20 days of fertilisation) appears to be low (i.e., <1%; Berg et al. 1994). Given that hinds are polyoestrus, under circumstances in which nutrition and disease are not limiting, adult female red deer generally exhibit greater annual fertility (i.e., >96% pregnancy rates), albeit with lesser (i.e., <1% of pregnancies) twinning (Asher & Pearse 2002). This overall pattern of greater annual fertility appears to be a common feature of many cervids, although actual fecundity varies between species. As expected for the greater fecund species, such as white-tailed deer and roe deer, the actual fecundity (i.e., incidence of multiple fetus gestations) in a given year and locality is strongly influenced by habitat and nutritional quality variables.

Oocyte maturation, fertilisation, and early embryonic development have recently been studied *in vivo* and *in vitro* for red deer (Berg et al. 2008). These studies have shown that these events in red deer are similar to those occurring in other domestic ruminants, with the exception that the red deer embryo enters the uterus 2 to 3 days later at the blastocyst stage, 5 to 6.5 days after ovulation. Embryonic implantation in red deer occurs shortly before Day 27 after ovulation (McMahon et al. 1997).

Luteal support of pregnancy in red deer persists through the term of gestation, with peripheral blood progesterone concentrations remaining elevated to within 1 to 2 days of parturition. The contributory role of placental progesterone production in pregnancy maintenance is unknown. Studies on red deer and white-tailed deer clearly show that the presence of a functional corpus luteum is a requisite for a viable pregnancy (Asher et al. 1996, Plotka et al. 1982). However, ovariectomy of reindeer in late pregnancy was not always associated with abortion, indicating a possible contributing role of the fetoplacental unit in progesterone secretion and pregnancy maintenance in this species (Sjaastad et al. 1990).

Cervid species have gestation lengths ranging from 200 to 280 days, loosely correlated with species mature body mass. There is a general consideration that gestation length for any given species is genetically programmed and relatively robust in the face of environmental variables. Recognition is given to the influence of fetal genotype as being an important determination of gestation length (Kenneth & Ritchie 1953, Racey 1981). This is observed particularly with crossbreeding of cervid subspecies, for which there are considerable differences in their respective gestation lengths. For example, Western European red deer (*C.e. scoticus*) have an average mating–birthing interval of 233 days (Guinness et al. 1971) and that for North American wapiti (*C.e. manitobensis*) is 247 days (Haigh 2001). However, red deer hinds gestating F1 crossbred red × wapiti fetuses show an average mating–birthing interval of 239 days (Asher et al. 2005b,c). An even more extreme effect of

VetBooks.ir

fetal genotype is seen in hybridisation of red deer and Père David's deer (Asher et al. 1988b).

However, it has become apparent that gestation length within red deer subspecies is much more variable than previously thought (Asher 2007). Asher et al. (2005a) observed a marked variation in gestation length between hinds that were fed either greater or lesser amounts of nutrients during the third trimester of pregnancy. In that study, gestation length was negatively correlated with change in hind live weight, and the authors considered that under conditions of modest feed imbalance that appeared to influence fetal growth trajectory, a gestation length compensatory mechanism ensured optimal birthweight. In effect, the hypothesis argued that gestation length matched fetal growth rate to ensure optimum birthweight (possibly at the expense of optimal birth date).

Other research on red deer has demonstrated a statistically robust association between conception date and gestation length for red deer subspecies. Garcia et al. (2006) observed that Spanish red deer hinds (*C.e. hispanicus*) that were artificially induced to conceive up to 68 days before the standard mating date exhibited longer gestation lengths than those conceiving later in the natural breeding season. They postulated that hinds were able to modify gestation length to counteract out-of-season breeding to optimise calving date. However, these previous data were confounded by the fact that early conceiving hinds exhibited lower live weight gains over pregnancy, thereby adding some support to the hypothesis of Asher et al. (2005a) that nutrition was a driver of gestation length variation. Most recently, Scott et al. (2008) investigated the relationship between conception date and gestation length in Scottish and Eastern European subspecies of red deer (*C.e. scoticus* and *C.e. hippelaphus*). Their data supported a hypothesis that within-herd synchrony of red deer births is facilitated by a 'push/pull' control over gestation length such that hinds conceiving early and late in the breeding season have longer and shorter gestation periods, respectively. The individual data sets indicate that, for every 10 days difference in conception date, there was a change in gestation length of 1.9 to 4.9 days. Recent studies by Scott et al. (2015) provide support for the hypothesis that variation in fetal age during the latter stages of pregnancy, when feed quality and voluntary feed intake cycles of dams are in a state of flux, drives differential growth trajectories for early and late conceiving fetuses, leading to nutritional control over fetal maturation and initiation of parturition.

The aforementioned studies on red deer subspecies indicate a hitherto unexpected environmental control over gestation length in at least some cervids. Recent information indicates that this may also be the case for reindeer (Rowell & Shipka 2009) and sika deer *(Cervus nippon)* (Matsuura et al. 2004).

It is important to note that these studies so far cited may not be representative of cervids in general. Placentation systems vary across cervid species (McMahon et al. 1997), and in the case of one species, the roe deer, a form of embryonic diapause/delayed implantation occurs to lengthen the interval between mating and births in order to ensure optimal birth seasonality (Short & Hay 1966). This is the only ruminant species known to exhibit delayed implantation.

Ultrasonographic Pregnancy Diagnosis

Pregnancy diagnosis in deer has largely relied on real-time B mode ultrasonography to visualise the postimplantation fetus after about 25 to 30 days post-conception/mating. Again the development of this technology for use in deer has been mainly for application in the reproductive management of farmed red deer (White et al. 1989) and fallow deer (Asher et al. 1992b). Ultrasonography has more recently been refined for fetal ageing in red deer in order to estimate conception date and, hence, predict calving date (Revol & Wilson 1991) and for real-time assessment of ovarian follicle dynamics during anoestrus and the oestrous cycle in red deer (Asher et al. 1997b), wapiti (McCorkell et al. 2006, 2007), and fallow deer (Asher et al. 1999).

Reproduction in the Stag

Circannual variation in testicular function is evident in most deer species, reflecting changes in fertility, gross morphometry, and behaviour. Of the temperate species, these changes have been best described for red deer and fallow deer (see Asher et al. 1999). Episodic and pulsatile secretion of LH and testosterone change dramatically through the seasons, being maximal during 'rutting' (hypersexual activity by males around the short mating period in autumn). Similar patterns of secretion have been observed for Eld's deer, a tropical but seasonally breeding species (Monfort et al. 1993).

Testosterone-mediated changes in secondary sexual characteristics are very pronounced in both temperate and tropical cervid species. The antler cycle is linked closely to the testis cycle, with antlers cast annually when testes regress to their minimal dimensions. Casting is in response to a marked decline in testosterone secretion and can be induced by castration (Goss 1983). New antler growth occurs during the quiescent phase of the testes in the relative absence of testosterone secretion. Mineralisation (calcium phosphate deposition) of antlers coincides with increasing testicular activity and increasing testosterone secretion, and hard antlers are generally retained when testicular tissue is actively secreting moderate to high amounts of testosterone. This relationship holds for most antlered species studied (Goss 1983), although the seasonal patterns vary between species and the antler–testis cycles may not be synchronised among individuals of some tropical species (Loudon & Curlewis 1988).

Circannual patterns of testicular regression and recrudescence occurring in temperate cervid species relate to annual cycles of sperm production. Unlike most seasonally breeding domestic ruminants, which show moderate fluctuations in testicular activity (e.g., sheep), temperate cervids exhibit alternating periods of sperm production and complete spermatogenic arrest that reflect about fivefold changes in seasonal testicular volume (Lincoln 1971). Although tropical cervid species often exhibit circannual cycles of reproductive development, either in a synchronous (e.g., Eld's deer) or nonsynchronous (e.g., chital deer) manner, males appear to retain a degree of fertility throughout the year (Loudon & Curlewis 1988, Chapman & Harris 1991, Mylrea 1992, Monfort et al. 1993).

Assisted Reproductive Technologies

The application of artificial reproductive technologies to deer largely relates to genetic management of captive populations, either as farmed livestock (e.g., genetic selection for improved productivity) or as captive zoo populations of endangered species (e.g., *ex situ* management to prevent inbreeding). The developments of these technologies for deer have mostly stemmed from their application to the farming of red deer and fallow deer in New Zealand (and increasingly adopted overseas for the farming of these species), but more recently the techniques have been tested and modified,

VetBooks.ir

with variable degrees of success, for application in *ex situ* wildlife management. See also Chapter 44.

Artificial Insemination

Artificial insemination (AI) maximises the genetic influence of elite males by disseminating male gametes (spermatozoa) across a larger female base than is possible by natural mating systems. It also allows for individual sires to be used across multiple populations at the same time. This is fundamental to the application of genetic improvement programmes for livestock. Presently in the New Zealand deer farming industry, which has a national deer recording and genetic evaluation scheme (DEERSelect), between 20,000 and 30,000 red deer hinds are artificially inseminated each year, representing between 4% and 5% of the national breeding herd. The components of AI, namely semen collection/cryopreservation, oestrous synchronisation, and insemination, were developed for farmed red deer and fallow deer during the 1980s and early 1990s; however, the fallow deer industry did not gain momentum, and there is presently little adoption of AI in this species. The developments of AI techniques for red deer have been reviewed by Asher et al. (2000), Rhodes et al. (2003), and McMillan and Asher (2007), and given that AI on commercial red deer farms routinely results in average conception rates of between 65% to 75%, there have been few incentives to further improve techniques for this species (McMillan & Asher 2007). AI has also been used to produce F1 hybrid progeny between red deer and Père David's deer (Asher et al. 1988b) and between red deer and sambar deer (Muir et al. 1997).

Semen collection from male red deer is invariably done by electroejaculation after general anaesthesia or light sedation. The highly aggressive nature of reproductively-active red deer stags precludes more natural methods of collection (e.g., artificial vagina) that require the close presence of people. Ejaculates generally contain very high concentrations of spermatozoa ($1–3 \times 10^9$/mL) during the autumn/winter breeding season, but stags are effectively infertile outside of this period. Viable semen can be collected from rising 2-year-old (pubertal) stags, but generally semen volumes and spermatozoa densities increase with increasing age. Thus, although commercial operators have been able to obtain 25 to 49 straws of semen (i.e., individual AI doses) per ejaculate from younger deer, older stags generally yield 55 to 240 straws per ejaculate (McMillan & Asher 2007). Semen straws (0.25 mL volume) are generally loaded at between 5×10^6 and 20×10^6 viable (live) spermatozoa each for cryopreservation but may be loaded down to as few as 1×10^6 viable spermatozoa for fresh use within 24 to 48 hours of collection. Various citrate-based or Tris-based diluents and various cryoprotectants have been evaluated for red deer and fallow deer semen (Asher et al. 2000). All have proven to be effective for these species.

Synchronisation of oestrus in deer has been generally adopted as a more efficient and cost-effective alternative to detection of natural oestrus. As with other domestic ruminants, synchronisation can be achieved by either simulating the activity of the corpus luteum, through administration of progestogens, or by shortening the luteal phase of the oestrous cycle by administration of a luteolysin (prostaglandins). Oestrous synchronisation protocols for red deer have been described in detail by Asher et al. (2000). The vast majority of artificial inseminations in New Zealand (and probably other countries) use the CIDR device containing progesterone. Intravaginal insertion of CIDR devices for periods of between 12 and 14 days during the breeding season is generally effective in promoting a synchronised oestrus within 48 hours of device removal in red deer (Asher et al. 1992a). This regimen has also proven successful in fallow deer, chital deer, Eld's deer, and sambar deer (see Asher et al. 2000). However, the additional administration of equine chorionic gonadotrophin (eCG) at or near the CIDR device withdrawal is generally performed for red deer, particularly if synchronisatin is attempted close to the onset of the breeding season (Fennessy et al. 1990, 1991). Interestingly, the use of eCG is contraindicated in fallow deer due to the increased incidence of both anovulation and multiple ovulation as well as fertilisation failure (Jabbour et al. 1993). The ability of prostaglandins to synchronise oestrus is dependent on the presence of an active corpus luteum at the time of treatment, which limits synchronisation programmes to a period after the onset of natural ovulatory activity. Also, the red deer corpus luteum has been shown to be responsive to exogenous prostaglandin only during the latter half of the oestrous cycle, with the transition from refractoriness to responsiveness ranging from Day 6 (Asher et al. 1995a) to Day 11 (Fisher et al. 1994). Although oestrous synchronisation after injections of prostaglandin analogues has been reported for red deer, wapiti, fallow deer, Père David's deer, white-tailed deer, and reindeer (see Asher et al. 2000), the fertility of prostaglandin-induced ovulation has not been widely evaluated.

Insemination procedures for deer are either laparoscopic intrauterine insemination for smaller bodied deer of less than 100 kg body mass (e.g., fallow deer; Asher et al. 1992b) or transcervical intrauterine insemination for larger bodied deer of greater than 100 kg body mass (e.g., red deer; Rhodes et al. 2003). Whereas laparoscopic procedures invariably require general anaesthesia, transcervical inseminations, involving rectal manipulation of the reproductive tract, are generally performed without any form of chemical restraint but requiring physical restraint.

Multiple Ovulation Embryo Transfer

Multiple ovulation embryo transfer (MOET) is well-established as an applied tool for genetic improvement of agriculturally important livestock species and has the potential to assist in the genetic management of some endangered mammalian species (Wildt et al. 1992). (See also Chapter 44.) The development and application of MOET technology to cervid species has occurred sporadically over the last 30 years, with studies focussing on red deer, wapiti, fallow deer, and white-tailed deer (see Asher et al. 1995b). Success rates, in terms of multiple ovulation (superovulation), fertilisation, embryo recovery, and surrogate pregnancies, have been highly variable between studies, and for some species, results have often been disappointing (Fennessy et al. 1994). Although superovulation and embryo recovery/transfer procedures do not appear to have radically changed from those described for red deer by Fennessy et al. (1989, 1994), outcomes of continuing MOET programmes on farmed red deer in New Zealand have become more consistent and economically viable, and many stud farms run annual MOET programmes to capture more rapid genetic gains from female lineages. Publications outlining such outcomes are sparse due to commercial sensitivities. However, it is often stated by commercial operators that the biggest factor influencing outcomes is donor hind stress. Well-habituated (tame) hinds tend to produce more viable ovulations/fertilised embryos than hinds of a nervous disposition.

Superovulation programming of donor red deer hinds is similar to that employed for domestic ruminants, generally involving intravaginal progestogen synchronisation (more often than not, CIDR devices) alongside stimulation of follicle development with

VetBooks.ir

exogenous gonadotrophin (usually FSH but also may additionally include eCG) towards the final stages of progestogen treatment (Fennessy et al. 1994). Subsequent procedures for embryo recovery, recipient synchronisation, embryo transfer, and embryo cryopreservation differ little from other ruminant species and are described by Fennessy et al. (1994). Average success rates for farmed red deer in terms of viable recipient pregnancies per donor programmed are reputedly between 3 and 8 scanned pregnancies. For some donor individual hinds, the success rate has exceeded 10 to 12 surrogate pregnancies.

IVF and Cloning

The *in vitro* embryo production system developed for farmed red deer has evolved along similar lines to that pioneered for other domestic animal species and was the platform for further advanced reproductive technologies such as cloning (Berg & Asher 2003). However, applying existing *in vitro* embryo production methods from other species resulted in limited success (Fukui et al. 1991) and necessitated the development of a species-specific methodology for red deer based on their culture media system, Deer Synthetic Oviduct Fluid (DSOF); this resulted in the successful culture of red deer embryos to the blastocyst stage (Berg et al. 1995a, 2002a, 2002b) and ultimately led to the successful production of recipient pregnancies and the live birth of calves (Berg et al. 1995b, 2002c). IVF systems have also been applied, with varying degrees of success, to wapiti, sika deer, axis deer, and reindeer (see Berg & Asher 2003) but have yet to gain any significant traction in genetic management of farmed deer and captive populations of endangered deer due to overall low efficiency at various points along the pathway (i.e., oocytes recovered, oocytes fertilised, viable pregnancies, live births). Recently, red deer were cloned by somatic cell nuclear transfer (SCNT), using multipotent antler stem cells and their differentiated progeny (Berg et al. 2007). The efficiency of the system was again low throughout the process. Of 70 SCNT embryos implanted into recipient hinds, there were 22 viable pregnancies scanned at Day 35, but only 11 developed to term, of which 8 survived to weaning at 3 months of age (Berg et al. 2007). Of significance, however, the surviving clones remained healthy into adulthood.

Reproductive Productivity of Farmed Red Deer

Cervid species generally adhere to an annual reproductive cycle, whether it be seasonally delineated or aseasonal. As with all annual breeders, success or failure to annually rear an offspring (and in some cases, more than one offspring) is often driven by environmental variables that influence any one of a number of points along the reproductive cycle. Innumerable studies on free-ranging cervid populations have demonstrated causes of lost reproductive potential, ranging from nutritional effects on ovulatory success to predation effects on neonate survival. It is not the purpose of this chapter to delve into extrinsic factors influencing annual reproductive productivity of wild deer populations, as these are generally outside the scope of veterinary and husbandry practitioners. However, the reproductive management of farmed deer and captive zoo populations of deer do fall under their auspices. By far, the most important issues pertaining to reproductive management of managed deer herds are nutrition and infectious disease (and in many cases these are linked together).

Using farmed red deer in the New Zealand pastoral environment as an example, reproductive management aims to maximise annual breeding outputs by eliminating or minimising sources of reproductive wastage. Annual reproductive productivity is still a major driver of on-farm profitability and, at its simplest and most realistic, is expressed as the number of surviving offspring produced annually per breeding female (often termed 'weaning rate' in New Zealand). However, this metric hides various forms of reproductive wastage. Key areas of focus are hind fertility (ovulation), fertilisation (mating management), fetal mortality (resorption/abortion), and neonate mortality (Asher & Pearse 2002).

Infertility of Hinds

Failure of hinds to attain reproductive condition each year is essentially the failure to initiate seasonal ovulatory cycles. Although this has often been thought to be the underlying cause of low reproductive performance in farmed red deer, anovulation in adult (>2 years old) hinds appears to seldom account for more than 1% to 2% of overall wastage. Exceptions to this on individual farms in some years clearly relates to extremely harsh environmental conditions before the mating season (particularly over summer lactation) that severely compromise body condition (depleted body fat and muscle catabolism), leading to anovulation within the adjacent breeding season (Asher & Pearse 2002). This phenomenon has been very well demonstrated for wild red deer occupying marginal habitats on the Isle of Rhum, Scotland, in which hinds that invest heavily in their calf's growth during summer can fail to become pregnant in the following breeding season (Guinness et al. 1978; Clutton-Brock et al. 1982). However, these are cases of temporary cessation of ovulatory activity driven by negative energy budgets before the breeding season, and affected hinds may simply skip a single breeding season to reinstate reproductive processes in subsequent years. Studies on farmed red deer by Pollard et al. (2002) showed that modest differences in body condition score (BCS) between hinds before and during the breeding season strongly influenced conception date, with hinds of lower BCS conceiving 8 to 12 days later in the season than hinds of the highest BCS. However, this study did not investigate the lower boundaries of body condition that could lead to seasonal anovulation.

Young hinds entering their first breeding season (post-pubertal) at 16 months of age are more likely to exhibit anovulation than adult hinds. Failure of red deer hinds to attain puberty at 16 months of age has been widely reported around the world and invariably relates to poor nutrition that has compromised prepubertal growth. In such cases, puberty is delayed until successive breeding seasons (Hamilton & Blaxter 1980). The relationship between body mass (live weight) and puberty incidence was investigated in detail for a range of red deer genotypes (subspecies and their crossbreeds) of differing mature body mass by Asher and Cox (2013). Analysis of live weight and pregnancy diagnosis records of more than 6000 young hinds across several New Zealand deer farms demonstrated the profound relationship between premating season body mass (i.e., live weight at 14–16 months of age) and pregnancy success/failure, thus indicating that hinds must attain a minimum of 65% to 70% of their genotype's expected mature hind body mass by 16 months of age to enter puberty. This has been termed the 'permissive threshold body mass' for entry into a pubertal state (i.e., body mass at which there is a 50% probability of hinds attaining puberty). However, the study demonstrated that early life growth (i.e., between birth and 3 months of age) influenced the permissive body mass threshold for any given genotype,

VetBooks.ir

such that the threshold increased for hinds that had experienced growth retardation during this period. The authors postulated that early life somatic growth influences the rates at which different tissues are accreted within the body leading up to the first breeding period, such that hinds of similar body mass may vary in the ratio of muscle to fat. Thus, whereas body mass has in the past been viewed as the key determinant of permissiveness to enter a pubertal state for female red deer, it may be that it is actually components of body tissues that are the important determinants of puberty attainment (Asher & Cox 2013). This hypothesis has yet to be tested for red deer.

Embryonic Death and Abortion

Although previously considered of low importance to overall reproductive wastage in farmed red deer in New Zealand (Asher & Pearse 2002), fetal wastage has more recently received considerable attention after the demonstration by B-mode ultrasonography of fetal disappearance between early and late pregnancy (Wilson et al. 2012). Subsequent studies have demonstrated incidences of fetal loss ranging from 0% to 15% across New Zealand deer farms, with the incidences for first pregnancy (pubertal) hinds being approximately twice that of older hinds, with the overall incidence across monitored farms being approximately 2% (Patel 2016). Epidemiological studies have failed to identify a single causative factor, although there is compelling evidence implicating acute *Toxoplasma gondii* infection on some affected farms (Patel 2016).

Perinatal Calf Mortality

Perinatal calf mortality is a significant cause of lost reproductive potential on New Zealand deer farms. Although the causation is highly variable, a number of studies on farmed red deer indicate the majority (> 90%) of calf losses can be collectively attributed to the following causes: starvation/dehydration (mismothering); dystocia (birth injury); misadventure; nonviability (low birth weight); and infectious agents (Asher & Adam 1985, Gill 1985). 'Mismothering' is a euphemism for calf abandonment leading to early starvation/dehydration of the calf. It is probably exacerbated in pastoral farming systems in which hinds must compete for ideal and isolated birthing sites. Such competition can lead to severe disruption of the dam–calf bonding process immediately after birth. It has also been argued that cases of dystocia, involving a protracted and difficult parturition, and misadventure (e.g., calves migrate far from their birth sites) may also be increased due to hind–hind disturbance effects in high stocking intensity environments (Asher & Pearse 2002). Therefore it becomes apparent that a significant source of wastage through perinatal mortality is attributable to the artificial environment associated with the high intensity farming of a species that has yet to be fully domesticated. Current management practices for farming red deer in New Zealand strongly focus on providing improved calving environments to meet the behavioural needs of the species, particularly with respect to lowering stocking intensities around the birthing period and the provision of low vegetative cover for the concealment of calves within their first few weeks of life.

As deer farming intensifies, the list of potential pathogens that potentially influence calf survival grows. Although the overall recorded incidence of calf mortality through infectious agents appears relatively low (albeit that the original studies were conducted over 30 years ago), the sporadic nature of specific infections can have disastrous consequences on reproductive productivity of individual farms. High perinatal death rates (i.e., >10%) among red deer calves on New Zealand farms have occurred from acute outbreaks of *Cryptosporidia* and *Salmonella* (Asher & Pearse 2002).

Conclusions

Clearly, there is no one 'model' species that defines typical cervid reproductive cycles, attesting to the complex array of life histories and reproductive strategies of the cervids in general. Our current understanding of reproductive biology largely centres on large bodied, temperate (and highly seasonal) species that have a close association with man. In contrast, reproductive cycles of the smaller bodied, tropical (aseasonal) species are generally poorly understood, with this group represented by many taxa that are at serious risk of extinction. However, the development of large scale deer farming, in particular of red deer in New Zealand, has provided research opportunities that are starting to unravel some of the complex life histories and adaptations of key cervid species.

Laboratory and Pet Rodents, and Lagomorphs

MOLLY VARGA AND TIM MORRIS

The vast majority of small mammals (Fig. 40.1) presented to veterinarians will be kept as pets rather than animals being bred for the pet trade or other activities, such as biomedical research. Such larger breeding activities will require more of a colony management approach; this is described in Chapter 41 and for research applications by Suckow et al (2012).

With the exception of rabbits and ferrets, most of these small pet mammals are not routinely neutered, so reproductive disease is a common presenting problem. With some species, particularly those that have been used in biomedical research, much is known about the reproductive cycle, its manipulation, diseases, and disorders. However, when the species in question has only recently been introduced into the pet trade (for example, the sugar glider or African pygmy hedgehog), the knowledge base is sparse and is often reliant on largely anecdotal evidence. The species of small pet mammals covered in this chapter will include many kept around the world but also reflects the experience of the authors.

Sexing

The ability to distinguish between male and female animals is equally important when presented with individuals or in breeding facilities.

Rodents

Sexing myomorph rodents: (rats/mice/hamsters/gerbils) see Figs 41.1–41.6. In males the distance between the genital papilla and the anus is greater than in females. This is easy to determine in adults but more challenging in younger animals. Males of all species possess a true scrotum, and in mature animals the testes are easily identified. Females have separate urinary and genital tract openings; the genital opening is positioned between the anus and the urinary tract opening. Being able to compare individuals of known gender can be very helpful when attempting to determine an animal's sex (often known colloquially as 'sexing').

Sexing hystricomorph rodents: (chinchillas/guinea pigs/degus) see Fig. 41.1. These are more challenging to sex. Although the anogenital distance in the male is always greater than in the female, differentiation of the genitalia is more difficult. Male guinea pigs do not have a scrotal sac, and the testes are held against the body wall in a prescrotal sac. The genital opening in both sexes appears similar, with the shape of the anogenital opening in male guinea pigs being described as an 'I' and in the female as an inverted 'Y'. Female chinchillas have a vulvar papilla that can resemble a penis. The anogenital distance is slightly greater in the male than in the female, and the opening of the genital papilla is slit-like in females and circular in males. Male chinchillas do not have a defined scrotal sac, and the inguinal ring remains open, thus the testes can be retracted and are not always obvious. Degus are similar in appearance to chinchillas; males do not have a scrotal sac, and the anogenital distance is greater than in females. Guinea pigs, chinchillas, and degus have a vaginal closure membrane, which is only open for a few days during oestrus and at parturition.

Rabbits

Rabbits can be challenging to sex, particularly when young. The distance between the genital papilla and the anus is not greater in the male than the female (Bishop 2002). In most males, gentle pressure will extrude the end of the penis; the genital opening is circular and not slit-like as it is in the female. Unlike many other small mammals, the rabbit testes are cranial to the penis. In older neutered male rabbits, particularly those that are overweight, it can be difficult to extrude the end of the penis, making gender determination slightly more challenging.

Ferrets

In male ferrets (often known colloquially as 'hobs') the distance between the genital opening and the anus is greater than in females; the prepuce is located on the ventral caudal abdomen, with the testes located ventral to the anus. The vulva is ventral to the anus in females and encloses both the genital and urinary openings. When the vulva is engorged in a female in oestrus, it can be mistaken for testes, although gender is easy to determine in this species.

African Pygmy Hedgehogs

In African pygmy male hedgehogs, there is a greater distance between the genital opening and the anus compared with females; in fact, the prepuce is located on the ventral midabdominal surface. There is no defined scrotal sac, so the testes may not be immediately obvious. It can be difficult to visualise the genitalia, because these animals will roll up into a 'tight ball' when frightened. To overcome this, they can be placed in a clear glass or Perspex box through which

they can be viewed, thus avoiding the need for general anaesthesia, which otherwise would be necessary for this simple procedure.

Sugar Gliders

Male sugar gliders have obvious testes on the midventral abdomen, rostral to the urogenital opening/cloaca. Female sugar gliders have a ventral pouch, which opens in the midventral abdomen.

Anatomy

Rodents

Myomorph Rodents

In females the urinary and the genital tract openings are completely separate. The ovaries are located caudal to the kidneys and are readily accessed for surgical ovariectomy (Fig. 40.2). The uterus has two horns (bicornuate), with a short uterine body, single cervix, and vagina; the rat is different, with two uterine horns and a double cervix, each of which opens into a single vagina. Male myomorph rodents have large testes compared with body size; however, because the inguinal ring remains open, they can still be retracted towards the abdomen from the clearly defined scrotum. Accessory sex glands in the male comprise the prostate, seminal vesicle and coagulating glands, bulbourethral glands, and ampullary glands; there is an os penis present in male rats. Both male and female rats and mice have significant amounts of mammary tissue, which is very different from hamsters and gerbils, in which mammary tissue is more limited.

Hystricomorph Rodents

All female hystricomorph rodents have a vaginal closure membrane, which seals the end of the vagina except during oestrus and at parturition. The paired ovaries are located caudal to the kidneys. The uterus is bicornuate, terminating in a single uterine body and a single cervix in the guinea pig, whereas in the chinchilla the uterus is duplex, with two cervices present. Male hystricomorph rodents always have an open inguinal canal from which the testes can be retracted; there is no true scrotum, and the testes are held close to the body wall. Male guinea pigs have an os penis. Accessory sex glands include the seminal vesicles, bulbourethral gland, copulatory glands, and prostate gland. In male guinea pigs, the seminal vesicles are long and coiled and situated intraabdominally; they can be mistaken for uterine horns.

Rabbits

Female rabbits have paired ovaries, caudal to the kidneys; the uterine horns are long and curved, terminating in two cervices (there is no uterine body) and a single vagina. The urethral opening is found on the ventral wall of the vaginal vault. In male rabbits the inguinal canal remains open, and in mature males the testes are located in a true scrotal sac cranial to the prepuce. The accessory sex glands comprise the proprostate, the prostate, the paraprostates, and the bulbourethral glands.

Ferrets

In female ferrets, paired ovaries are located in the dorsal abdomen, caudal to the kidneys; the uterus is bicornuate, ending in a short uterine body and a single cervix. The urethral orifice is found on the floor of the vaginal vestibule so that the genital and urinary tract openings are not separate. In male ferrets the testes are located ventral to the anus in a defined scrotal sac. The inguinal ring remains open, and the testes are partially retracted somewhat during winter, when it is not breeding season. The prepuce is located on the ventral midabdomen, and there is a hook-shaped os penis that supports the glans penis. The prostate is the only accessory sex gland in male ferrets.

African Pygmy Hedgehogs

The female has paired ovaries caudal to the kidneys in the dorsal abdomen. The uterus is bicornuate with no defined uterine body, the horns terminating in a single cervix. The male has a 'snail-shaped' penis, with lateral projections on each side of the external meatus; there is no os penis. The testes are found within the lower abdomen in paraanal recesses (Bedford et al. 2000).

Sugar Gliders

Female marsupials have a reproductive tract much smaller, relative to body size, compared with placental mammals, because the

VetBooks.ir

young are born much earlier in the developmental process. Paired ovaries are located in the dorsal abdomen caudal to the kidneys. There is a paired uterus, each ending in a vaginal cul-de-sac, which is divided into right and left sides by a median septum. Each vaginal cul-de-sac is joined caudally to a median vagina through which the joey is expelled, as well as two lateral vaginas; all three vaginas terminate in a urogenital sinus that also contains the urethral opening. The male has a forked (bifid) penis; the urethral opening is at the proximal end of the penis, not at the distal tip of the fork; the forked penis is complimentary to the lateral vaginas during copulation. The prostate and the bulbourethral glands are poorly defined; there are no seminal vesicles or coagulating glands. The testes are present in a clearly defined scrotum situated on the ventral midabdomen.

Normal Reproductive Cycles

This information is described in Chapter 41, including key reproductive biological data for rodents and other species in Table 41.1.

Reproductive Diagnostics for Small Mammals

Vaginal Cytology

Examination of exfoliate vaginal cytology is a useful diagnostic procedure in a range of species. It confirms the integrity of the hypothalamus–pituitary–ovarian axis within the individual (Goldman et al. 2007) and enables identification of the stage of the oestrous cycle in a particular individual. The appearance of the stained vaginal epithelial cells correlates with changes in the circulating concentrations of reproductive hormones. In hamsters, due to the presence of vaginal pouches that retain sloughed squamous cells and leucocytes, vaginal cytology as determined by smears can be misleading, as even animals that are not in oestrus may still have cells typical of oestrus retained within the pouches. Vaginal cytology is of limited use in hystricomorph rodents because, for much of the cycle other than at oestrus, they have a vaginal membrane that 'closes off' the vagina. Vaginal cytology has not been validated in sugar gliders.

Ultrasonography

B-mode transabdominal ultrasonography can be valuable both in the diagnosis of pregnancy and in the evaluation of the reproductive tract, in both the male and the female. For smaller animals, a 10 MHz probe is preferred. Alternatively, a 'stand-off' can be used with a larger probe, although this can make examination challenging.

Endocrine Markers

Many commercial laboratories are now able to offer assays of reproductive hormones for many species. This is useful in ferrets and rabbits to show the presence of ovarian remnants or ectopic ovarian tissue (ovarian remnant test) in females and to confirm cryptorchidism ('rig test') in males, as well as for wider uses such as for other steroid hormones in adrenal disease that is associated with neutering (Wagner et al. 2005). The use of blood hormone assays in order to predict the optimum time for breeding is not commonly performed in these species; assays of reproductive hormones are not routinely used to confirm pregnancy.

Noninfectious Diseases

Diseases due to poor husbandry and feeding are relatively common in small mammals kept as pets, often affecting reproductive function.

Husbandry and Environment

Husbandry

Ensuring the correct husbandry for a particular species is important to ensure reproductive health; for example, hyperthermia has been shown to cause reduced sperm production, as well as affecting fetal development. In addition, it can also depress lactation in various rodent species (Hansen 2009). Studies have shown that overcrowding increases the time to first pregnancy and reduces the number and weight of the first offspring in mice (Burroni et al. 2014). Odours from other individual animals, particularly associated with overcrowding, can affect fertility. The odour of male mice induces oestrus in female mice, whereas the odour from a novel male can result in pregnancy failure in recently impregnated female mice. Shah et al. (1980) demonstrated that overcrowding affected the production and/or release of GnRH from the hypothalamus of male rats, resulting in impaired reproductive performance.

Social and Physical Environment

Meeting species-specific behavioural, social, and physical environmental requirements optimises reproductive capability, as animals that have their welfare needs met will demonstrate normal behaviour while being free from discomfort, distress, and disease (Whitaker et al. 2009). The scope of what is 'normal behaviour' varies between species, as do their environmental requirements, social as well as in their husbandry (Wolfe 2005). Exposure to certain electromagnetic fields has been linked to infertility in male rodents; for example, Kim et al. (2007) showed that electromagnetic fields affected proliferation and differentiation of spermatogonia in male rats.

Nutritional Problems Affecting Reproduction

Major Nutrients

Dietary protein requirements are difficult to quantify in those species that are 'hindgut fermenters', such as rabbits, guinea pigs, chinchillas, and degus, due to the bacterial synthesis of amino acids in the caecum and the reingestion by either caecotrophy or coprophagy of protein-containing faeces. In species such as the ferret, which has relatively short small and large intestines, dietary protein levels are key to good health, and levels that are too low will affect their fertility. However, there are few specific reports linking dietary protein and fertility in many of these species. Diets low in fat delay puberty in female rats (Frisch et al. 1977), leading to the conclusion that a minimum level of body fat is required for normal reproductive cyclicity in rodents.

Vitamins

Hypovitaminosis A has been shown to suppress spermatogenesis in male rats (Huang & Hembree 1979). Hogarth and Griswold (2010) demonstrated that when male rodents are vitamin A deficient, spermatogenesis ceases. Maternal vitamin A deficiency can lead to congenital malformations of offspring in many rodent species (Wilson & Warkany 1948). For example, rats with induced hypervitaminosis A displayed decreased testicle mass, focal lesions in the

VetBooks.ir

seminal tubule epithelium, and reduction in the relative volume of interstitial tissue and in the nuclear volumes of Leydig cells (Lamano et al. 1978). In female rats, placental agenesis, retarded embryonic growth, and eventual embryonic death occurred as a result of hypervitaminosis A (Love & Vickers 1976).

Vitamin C has a role in hormone synthesis, as well as protection from oxidative damage (Luck et al. 1995). Vitamin C levels significantly affect the function of both ovaries and testes. For example, its supplementation increased spermatogenesis and plasma testosterone levels in Wistar rats (Sönmez et al. 2005), as well as protecting spermatogenesis, sperm integrity, and fertility; thus hypovitaminosis C has multiple detrimental effects on fertility. It also prevents oxidative stress injury to sperm, and its antioxidant effects are closely linked with those of vitamin E.

Halloran and DeLuca (1980) examined the effects of hypovitaminosis D on the reproductive capabilities of female rats. They showed reduced fertility (by 75%), diminished litter size (by 30%), and impaired neonatal growth, although reproduction was not halted. It is not known whether it is the lack of vitamin D or the hypocalcaemia associated with hypovitaminosis D that is responsible for the observed effects. Male rats that had hypovitaminosis D showed fewer successful matings (43% less) and fewer successful pregnancies (73% less) compared with rats with sufficient vitamin D (Kwiecinski et al. 1989).

Vitamin E (along with vitamin C and selenium) is intricately involved in normal fertility. Hypovitaminosis E in pregnant female rats leads to fetal death and resorption and lack of spermatogenesis in male rats (Burton 1994). Vitamin E supplementation has been shown to protect rat testes against the oxidative damage caused by ozone (Jedlinska-Krakowska et al. 2006) and to improve sperm motility and viability (Agarwal & Said 2005).

Minerals

In male rats, selenium deficiency results in reduced circulating testosterone concentrations and testicular atrophy (Behne et al. 1996); in addition, active spermatogenesis was reduced or absent (Wu et al. 1973). Selenium deficiency in female rats results in infertility, abortions, and placental retention (Bedwal & Bahuguna 1994).

Zinc deficiency leads to impairment of angiotensin-converting enzyme and subsequent depletion of testosterone and reduced spermatogenesis; there is an increase in abnormal sperm (Millar et al. 1958). In the female, zinc deficiency results in reduced FSH/LH production, abnormal ovarian development, and disruption to the oestrous cycle. Abortion, prolonged gestation, stillbirth, dystocia, and low birth weight of offspring are also linked to zinc deficiency in rodents.

Disorders of the Oestrous Cycle

Cystic Endometrial Hyperplasia

Cystic endometrial hyperplasia (CEH) is defined as progesterone-induced hyperplasia of the endometrium, with cystic dilatation of the endometrial glands. Progesterone from the corpora lutea causes an increase in endometrial gland secretory activity, as well as a reduction in myometrial contractility. Thus when there is a closed cervix, secretions can accumulate within the uterine lumen, leading to hydrometra (in which the secretion is largely serous), and mucometra (in which the secretion is more mucoid). In both hydro- and mucometra, the internal environment of the uterus is sterile. Increased oestrogen secretion during folliculogenesis causes the cervix to dilate, providing a route for bacterial invasion of the uterus. If these bacteria become established, then pyometra develops. Oestrogen increases the number of progesterone receptors in the endometrium, so that with each subsequent cycle, there is likely to be an enhanced response to progesterone. CEH and hydro- and mucometra do not always result in the development of pyometra because it can develop independently of these conditions. Initially, affected animals may be asymptomatic, and although subsequently they may still only show nonspecific signs, eventually, affected females will develop increased abdominal girth and possibly become anorexic. Diagnosis is initially by abdominal palpation with subsequent ultrasound confirmation; treatment is by ovariohysterectomy. Fluid-filled uterine horns present an increased risk of uterine torsion, and the associated acute abdominal pain may be the primary clinical sign and the primary reason for an owner seeking a veterinary consultation.

Hydrometra

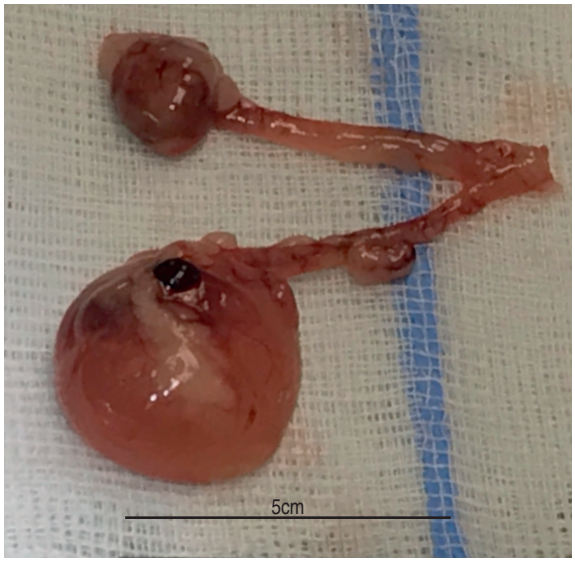
Hydrometra in ferrets is strongly associated with the presence of ovarian neoplasia (Jekl & Hauptman 2017).

Ovarian Cysts

Ovarian cysts occur in many species and have been reported in rabbits, guinea pigs, chinchillas, gerbils, rats (Fig. 40.3), golden hamsters (Fig. 40.4), and mice; it is likely that they also occur in other species. Ovarian cysts occur very commonly in the guinea pig and may cause anorexia, bilateral symmetrical alopecia, and a reduction in fertility, although some sows are asymptomatic. Three types of cysts have been identified in guinea pig ovaries: serous cysts (cystic reti ovari), which are the most common form; rarely, follicular cysts; and parovarian cysts. Serous cysts are present throughout the oestrous cycle, whereas follicular cysts were less common during dioestrus. Abnormal increases in FSH secretion have been suggested as a cause of cystic ovarian disease in the guinea pig. Diagnosis is often possible by palpation alone; however confirmation using ultrasonography is useful (Beregi et al. 2001). Treatment with human chorionic gonadotrophin (hCG) is successful in some cases in which the cyst is sensitive to the LH-like action of hCG; however, in those cases that are refractory to medical treatment, ovariectomy/ovariohysterectomy is the treatment of choice.

• **Fig. 40.3** Ovarian cyst in rat surgically exposed for ovariohysterectomy.

VetBooks.ir



• **Fig. 40.4** Hamster ovarian cyst and uterus after excision.

Hyperoestrogenism in Ferrets

Ferrets, in common with many other small mammals, are induced ovulators. Without cervical stimulation from copulation, the follicles do not ovulate and, subsequently, frequently become luteinised. However, the anovular follicles frequently persist, remain, and continue to produce oestrogens. Approximately 50% of intact female ferrets, particularly those kept alone or with other females, show signs of prolonged oestrus (Jekl & Hauptman 2017). High circulating oestrogen levels cause bone marrow suppression and reduced extrasplenic haematopoiesis, often resulting in profound anaemia, thrombocytopenia, and leucopenia; the disease can prove fatal if not treated. Clinical signs include lethargy, weight loss, prolonged signs of oestrus with vulvar enlargement, pale mucous membranes, and petechiae. Diagnosis is based on a history of prolonged oestrus, with clinical signs of an enlarged vulva and pale mucous membranes; laboratory samples provide confirmation of nonregenerative anaemia and thrombocytopenia/leucopenia. Treatment includes both the termination of oestrus and correction of anaemia; the latter can be terminated medically in various ways. Administration of proligestone (colloquially known as 'jill jab') has been used successfully for many years, whereas hCG (100 IU per ferret; two doses, 7 days apart) can be used to induce ovulation with subsequent luteinisation. GnRH can also be used to stimulate an endogenous LH surge. In early oestrus (first 1–2 weeks), Deslorelin implants can be used, although the use of implants later in oestrus may exacerbate the bone marrow suppression that is already occurring.

Fetal Resorption, Abortion, and Stillbirth

Periods of poor nutrition, stress, and ill health can all lead to failure of a pregnancy; the timing of the insult defines the outcome (resorption or abortion). Various infectious agents, such as Chlamydia, *E. coli*, *Pasturella* spp, *Salmonella* spp, and Toxoplasma, may be implicated (see later section 'Infectious Disorders'). A thorough nutritional and husbandry review is essential, particularly when several females have lost litters within a short time period. Samples should also be submitted for bacterial culture and supportive care offered to the females, pending the laboratory results. Zoonotic aspects should also be considered.

Periparturient Problems and Dystocia

Uterine Rupture in Rabbits

Uterine wall rupture occurs regularly in breeding rabbits and may be a coincidental finding. It is difficult to diagnose other than at surgery, and it may be implicated in some cases of dystocia. Treatment is surgical, and although repair of the uterine wall is possible, ovariohysterectomy is the preferred method. Ectopic abdominal pregnancies in may also occur in rabbits without uterine rupture (Gil et al. 2004).

True Dystocia

This is uncommon in most small mammals because, in most of these species, large numbers of small size offspring are normally born. In those species that have fewer, precocial offspring (e.g., guinea pig or chinchilla), then there is a higher risk of dystocia. Prolonged labour, particularly with unproductive straining, should be a cause for investigation. Radiography or ultrasonography will confirm pregnancy and show the disposition of the retained young, allowing assessment of whether vaginal birth is possible or a Caesarean surgery is preferable. Obesity, large litters resulting in maternal exhaustion, fetomaternal disproportion, faulty disposition, and ectopic pregnancies are all possible causes. The guinea pig presents an additional challenge with respect to dystocia, in that, theoretically, if a sow is not bred before 6 months of age, her symphysis pubis bones will have fused, making normal parturition much less likely. The author (MV) has found this does not always occur as several older nulliparous female guinea pigs have had a normal parturition. Similarly, it has been suggested that the pubic symphysis fuses in female African pygmy hedgehogs at around 1 year of age, leading to the suggestion that this species may also suffer from dystocia if breeding for the first time occurs after this time. This is anecdotal, and there are no confirmed reports of dystocia from this cause in the literature.

Eclampsia and Pregnancy Toxaemia

Preeclampsia

Preeclampsia develops in the later stages of pregnancy. It has been reported clinically in rabbits, ferrets, and guinea pigs; mice and guinea pigs are used as experimental models of preeclampsia in humans. Fetal factors and the pressure of the weight and size of the gravid uterus occlude the blood vessels of the uterus, leading to ischaemic necrosis, hypertension, proteinuria, and elevated creatinine levels. Frequently, there are no specific clinical signs, only nonspecific ones, with the pregnant female becoming increasingly unwell towards the end of gestation; it can be difficult to distinguish it from pregnancy-related ketosis (pregnancy toxaemia). Its presence can be confirmed by elevated blood creatinine levels and proteinuria. Treatment is emergency Caesarean surgery; however, the prognosis is poor.

Eclampsia

Eclampsia is defined as preeclampsia complicated by maternal seizures. Hamsters in late gestation display a disease very similar to eclampsia in humans. Affected hamsters have fibrin thrombi in the capillaries, disseminated intravascular coagulation, and demonstrate severe changes to the renal glomerulae and tubules. The collapse of normal renal function leads to azotaemia and seizures (Barthold et al. 2016, Richter et al. 1984). Cases of true eclampsia

VetBooks.ir

are rare; however, a history of seizure, in combination with acidosis and ketosis, is pathognomonic. Treatment is the same as for preeclampsia, with additional control of the seizures and support of renal function. Prognosis is generally very poor and euthanasia should be considered.

Pregnancy Toxaemia

Pregnancy toxaemia is a metabolic condition that usually affects obese females in late pregnancy or early lactation. A combination of factors is thought to be involved, namely: inability to meet nutritional needs due to the size of the gravid uterus; the energy drain placed on the dam by lactation; environmental factors; and other stressors. This results in a negative energy balance, and the animal becomes ketotic and acidotic. Often affected females are very poor bodily condition and are likely to be dehydrated, possibly recumbent, and are at risk of hypoglycaemic seizures. Diagnosis is by confirmatory blood analysis, demonstrating the presence of acidosis, ketosis, and hypoglycaemia; urine analysis shows a low pH (5–6 rather than the normal 9), ketonuria, and proteinuria. Cases of preeclampsia can present in a similar way. However, pregnancy toxaemia can be differentiated from preeclampsia by the presence of ketones in acidic urine; treatment is difficult and is based on the provision of fluids and correction of hypoglycaemia with frequent small feeds of a suitable support diet (Proença & Mayer 2014). It is important not to feed too much at once, as it causes a blood sugar 'spike', consequential insulin release, and the potential for hypokalemia and hypophosphataemia as glucose is forced intracellularly.

Retained Fetal Membranes

Fetal membrane retention can lead to acute metritis and septicaemia. Clinical signs include malaise, anorexia, and serosanguinous to purulent vaginal discharge; diagnosis is confirmed by a history of recent parturition, with consistent clinical signs. Treatment can be attempted medically; the use of aglepristone to cause uterine contractions and expulsion of the fetal membranes has been reported in lagomorphs and rodents (Gogny & Fieni 2015), or alternatively, oxytocin could be used to achieve the same aim. Supportive care and antibiosis are also indicated; however, care needs to be taken not to adversely affect any young still being suckled and to avoid the risk of antibiotic-induced enterocolitis (Morris 1995). Alternatively, ovariohysterectomy can be considered.

Vaginal Prolapse

This is rare but has been reported in rabbits and chinchillas. Prolapse usually occurs within a few days of parturition, and one report of a cluster of cases in related females suggests a genetic predisposition in rabbits (Becha et al. 2006); it has also been reported in postpartum guinea pigs and chinchillas (Kondert & Mayer 2017). In some instances, the uterus also prolapses. Typically, a postpartum female will be observed to be straining vigorously with a soft tissue mass visible at the vulva. Treatment of a simple nontraumatised prolapse includes cleaning and replacing the prolapse tissues and placing retention sutures in the perivulvar tissue to prevent reoccurrence. When there is a more severe prolapse or when there is significant soft tissue damage, ovariohysterectomy is the treatment of choice. The more extensive the prolapsed and the more tissue damage sustained, the worse the prognosis; in extreme cases, bladder prolapse may be associated with uterine prolapse in the rabbit (Harcourt-Brown 2017). These cases are challenging: the bladder must be gently replaced, and any necrotic or damaged portions resected, in addition to removing the genital tract. The prognosis in these cases is poor.

Neoplasia

Table 40.1 summarises the reported neoplasms of the reproductive tract in different species (Laik-Schandelmaier et al. 2017, Jekl et al. 2011, Goodman et al. 1979, Suárez-Bonnet et al. 2010). Many neoplasms of reproductive tissue origin are initially hormone-induced, although eventually the tumour will become self-sustaining, and removal of hormone stimulation (medically or surgically) will not arrest its growth. Equally, some neoplasms will themselves produce hormones, which then will affect various other parts of the genital tract. Clinical signs related to neoplasia of the genital tract include the presence of space-occupying lesions, abnormal reproductive activity, and bleeding from the genital tract.

Miscellaneous Reproductive Disorders

Adrenal Disease in Ferrets and Rabbits After Neutering

Adrenal disease commonly occurs in ferrets, and it is also increasingly being diagnosed in rabbits (Wagner et al. 2005, Lennox & Chitty 2006). Initially recognised in the United States, where ferrets are routinely desexed at 6 weeks of age, adrenal disease is caused by the failure of negative feedback on the hypothalamic–pituitary–gonadal axis after neutering. In most species, removal of the gonads initially leads to FSH and LH remaining elevated in the circulation because with the absence of organs that have receptors for these hormones, there is no negative feedback. High FSH and LH levels then depress the production of GnRH by a negative feedback loop. The reduction of GnRH leads to lower levels of LH and FSH in the blood, and the lack of gonadal tissue does not provide a continued stimulus for GnRH production. In ferrets, GnRH continues to be produced, possibly related to prolonged photoperiod; this negative feedback loop fails, resulting in chronically high LH and FSH levels in the blood. Chronically high LH and FSH levels stimulate the expression of LH receptors on the adrenal gland. These receptors, when stimulated by LH, lead to the production of active hormones, which in turn result in clinical signs being displayed (vulvar or prostatic enlargement, mammary development, bilateral symmetrical alopecia, atypical aggression in rabbits). Initially, the adrenal gland is hyperplastic; however, this progresses to an adenomatous change and eventually to adenocarcinoma.

Diagnosis is based on clinical signs (usually but not exclusively) in a neutered animal and the confirmation of elevated hormone levels (adrenal panel: oestrogen, 17-OH progesterone, and androstenedione; Wagner et al. 2005). Treatment can be either medical or surgical; the former involves implantation with Deslorelin, a GnRH agonist, which causes initial up-regulation of and then negative feedback on the hypothalamic–pituitary axis. Depending on the dose and season of the year of implantation, the effects can last 18 to 48 months. It is important to note that, in cases that have already progressed to malignancy and the tumour does not require hormonal stimulation to continue growing, implantation will only reverse the visible clinical signs. As a consequence, the malignancy will progress and must be treated separately. Surgical treatment, which involves the removal of one or both adrenal glands, is difficult, particularly because the left adrenal gland is

TABLE 40.1 Summary of Reported Neoplasms of the Reproductive Tract in Small Pet Mammals

Species	Ovary	Uterus	Cervix	Vagina	Mammary Gland	Testicles	Prostate/Accessory Sex Glands	Penis
Guinea pig	Granulosa cell tumours, teratomas, embryonic placentoma	Fibromas, leiomyoma, myxosarcoma, leiomyosarcoma	Adenoma and adenocarcinoma		Mammary adenocarcinoma, mammary gland adenoma, mixed mammary tumour	Embryonal carcinoma		
Chinchilla								
Degu		Angioleiomyoma		Vaginal leiomyosarcoma				
Rat	Tubular adenoma, tubular adenocarcinoma, malignant granulosa cell tumour, ovarian mesothelioma	Leiomyoma, uterine endometrial stromal polyps			Mammary fibroadenoma (female Sprague Dawley rats). Prolactin responsive. Adenocarcinoma	Interstitial cell tumours, mesothelioma, Sertoli cell tumour, Leydig cell tumour, preneoplastic focal hyperplasia		
Mouse	Papillary cystadenomas Ovarian tubular adenomas, granulosa cell and thecal cell tumours	Haemangioma and haemangiosarcoma Uterine endometrial stromal tumours, uterine stromal polyps, uterine adenocarcinoma, uterine wall leiomyosarcoma Histocytic sarcoma			Mammary gland adenocarcinoma (retrovirus: mouse mammary tumour virus)	Teratomas	Sebaceosquamous adenomas and carcinomas	
Hamster	Ovarian thecal cell tumours, granulosa cell tumours	Uterine adenocarcinoma			Mammary adenocarcinoma	Rarely reported		
Gerbil	Granulosa cell tumour, dysgerminomas, luteal cell tumours	Leiomyoma, uterine adenocarcinoma, oviduct adenocarcinoma			Mammary neoplasia rarely reported			
Rabbit		Uterine adenocarcinoma			Mammary dysplasia associated with prolactin producing pituitary adeonomas, mammary adenocarcinoma, leiomyoma, leiomyosarcoma	Seminoma, teratoma	Prostatic adenoma	
Ferret	Gonadostromal tumour, ovarian teratoma, thecoma, ovarian cystadenocarcinoma	Uterine teratoma, uterine leiomyoma			Papillary cystadenocarcinoma	Interstitial cell tumour, Sertoli cell tumour	Preputial gland tumour	
African Pygmy Hedgehog	Granulosa cell tumour	Uterine spindle cell tumour, leiomyoma, endometrial polyps, uterine adenosarcoma, endometrial stromal cell sarcoma, uterine adenocarcinoma			Mammary gland adenocarcinoma, papillary adenoma, mammary gland carcinoma			

closely associated with the vena cava. Removal of the adrenal gland will necessitate subsequent supplementation of corticosteroids.

Paraphimosis in Chinchillas

Paraphimosis – fur ring – in chinchillas is a condition commonly seen in male chinchillas. Clinically, the penis may be protruding or the animal is observed to be excessively grooming the perineal area. In these cases, a ring of fur becomes trapped around the base of the penis, limiting its retraction into the prepuce. The penis tip may become engorged and necrotic, and there is a risk of urethral obstruction. Treatment involves identification and removal of the fur ring and application of hypertonic glucose solution to the penis tip if it is very swollen. In cases in which the tip of the penis is necrotic, amputation should be considered.

Pseudopregnancy

Pseudopregnancy occurs in many small mammalian species, in both nonmated or in those which are mated but do not conceive. As a consequence, the subsequent luteal phase, although not supporting a pregnancy, does stimulate mammary development, as well as hyperplasia of the endometrium. As the luteal phase ends, the progesterone concentrations decline and prolactin concentrations increase, resulting in behavioural changes and sometimes lactation. Excessively long luteal phases may be seen in some pseudopregnant laboratory rodents. Treatment is not always necessary because pseudopregnancy is a normal occurrence, and once the corpora lutea regress, either normal cyclicity returns or the animal becomes anoestrus or progresses to oestrus. If the animal is lactating, then treatment is warranted, and cabergoline can be used to good effect. If repeated pseudopregnancy occurs, then the animal should either be mated or spayed.

Uterine Venous Aneurysms

Originally reported in three New Zealand white rabbits in 1992, uterine venous aneurysms are one potential cause of haematuria in the female rabbit. Varices and aneurysms of uterine subserosal and myometrial venous plexi are reported in other species, whereas endometrial aneurysms are not. These fragile blood vessels rupture and bleed into the lumen of the uterus. Clinical signs include vulva bleeding and haematuria, which may be associated with significant blood loss; however, the signs are episodic, not consistent. Treatment is ovariohysterectomy.

Uterine Torsion

Uterine torsion has been reported in a variety of species and is associated with a distended uterus (due either to gravidity or hydrometra). Affected animals may be presented in acute pain or, more commonly, collapsed and in shock; treatment is ovariohysterectomy. Prognosis is dependent on the condition of the animal before surgery, but it is generally guarded to poor.

Cryptorchidism

Cryptorchidism is the failure of the testes to descend through the inguinal canal and into the scrotal sac. The testes may remain intraabdominal, may have partially descended into the inguinal ring, or may have progressed through the inguinal ring but not into the scrotum. Retained testes (particularly in species with a defined scrotum and lower testicular temperature) may become neoplastic. Castration is indicated.

Testicular Evisceration

This is a relatively common occurrence subsequent to fighting in male rabbits. Animals will be presented with bleeding from the scrotum, or scrotal contents will be either be observed protruding from the scrotum or completely removed from the scrotum after an altercation. Treatment depends on the severity of the injuries, but it may be castration or removal of the remaining tissue with analgesia and antibiosis. Occasionally, rabbits are presented with a single testis, the missing one having been removed previously during a fight; in such animals, it can be difficult to determine whether the animal is cryptorchid or not. There may be an obvious scar where the scrotum was torn, but if not, then a hCG stimulation or 'rig' test (see previous mention) can be performed to avoid the need for exploratory laparotomy with its attendant risks of adhesion formation postoperatively.

Infectious Disorders

Bacterial

Treponema paraluis cuniculi

Treponema paraluis cuniculi is a spirochaete organism, which causes venereal syphilis in rabbits (DiGiacomo et al. 1984). It can be transmitted either by mating with an affected individual or via direct contact of kits with an affected doe; asymptomatic carriers/shedders exist within the population. *Treponema* infection manifests as papules, vesicles, ulcers, and crusting around the external genital organs and, occasionally, the eyes/nose and perineum; diagnosis can be made on clinical signs and confirmed by serology (Saito et al. 2003). Diagnosis can be aided by an ELISA test, which is available commercially, dark field microscopical examination of scabs and exudate demonstrating helical organisms, or histopathology. Treponematosis can be associated with an unwillingness to mate and abortions in affected does. Treatment is three times a week doses of procaine/benzathine penicillin. Response to treatment is rapid and is often noted after the first dose of medication; differential diagnoses include atypical myxomatosis and autoimmune skin disease.

Pasteurellaceae

Pasturella multocida and *Pasturella pneumotropica* are common pathogens of rabbits and other small mammals. Depending on the route of transmission (aerosol, direct contact, haematogenous, sexual transmission), these bacteria can cause varying clinical signs. *P. multocida* has been associated with balanoposthitis, metritis, pyometra, and mastitis in rabbits, whereas *P. pneumotropica* has been associated with mastitis, chronic metritis, infertility, bulbourethral gland infection, and abortion in rats. These bacteria less frequently affect other species. Diagnosis is by bacterial culture, and treatment depends on the clinical signs noted. Abscessation is generally better treated surgically in rabbits and rodents in particular, and infections involving the genital tract can be managed by neutering once it is certain that there is no infection elsewhere.

Staphylococcus

Staphylococcus aureus infections occur commonly in a variety of species. *S. aureus* is often opportunistic and may be carried subclinically in the nasopharynx. Transmission is usually by direct contact

VetBooks.ir

or environmental contamination, although aerosol transmission is possible. Clinical signs can include mastitis, abscessation in the preputial glands, and suppurative lesions within the genital tract of both sexes. 'Young doe syndrome' is also associated with *S. aureus,* which manifests as a toxaemia, in which young nursing does develop a fever, with anorexia and swollen lymph nodes; potentially, this infection can be fatal. Diagnosis is confirmed by bacterial culture, and treatment is based on these results. Abscesses are often best treated surgically.

Mycoplasma

Mycoplasma pulmonis infection is common in pet rats and mice and can occasionally be found in rabbits, guinea pigs, and other rodent species. Often, the infection is asymptomatic in species that are not the normal host. Clinical infection in the genital tract can lead to infertility (metritis and pyometra may occur), embryonic resorption, and reduction in litter size. Diagnosis can be challenging because culture is often negative, although serological testing is also available. Treatment is based often on known sensitivities of the organism because culture is difficult; fluoroquinolones and tetracyclines are effective and safe for most species (Morris 1995).

Listeria

Listeria monocytogenes is a Gram-positive bacterium that is implicated in cases of late term abortion (due to acute metritis and placentitis) in rabbits and chinchillas. It can cause sporadic deaths or limited epizootics in breeding establishments, leading to significant losses. Oral penicillins are the treatment of choice in many species, but these are categorically contraindicated in rabbits and rodents. Tetracyclines can be considered for treatment based on culture and sensitivity results.

Brucella

Brucella spp. have been implicated in cases of infertility in rabbits; however, rabbits and rodents are not natural hosts of these bacteria. Although infection and clinical signs related to the genital tract remain possible, clinically, this is uncommon. It has been suggested that rodents are a reservoir of Brucellosis for free ranging ungulates; however, many of the rodent species tested were not seropositive for this organism. There are no reports of Brucellosis in either the African pygmy hedgehog or the sugar glider in the literature.

Chlamydiaceae

Chlamydiaceae (*Chlamydophila caviae* and *Chlamydia muridarum*) may be transmitted venereally and can be a cause of metritis and infertility in many species of animal, including small mammals (Deeb et al. 1989). Chlamydial organisms do not damage tissues directly; rather they induce a damaging host response at the affected site, which leads to clinical signs. The zoonotic implications should be considered if Chlamydiaceae are found.

Viral

There are a wide range of viral diseases in small mammals, and several can directly or indirectly affect reproduction and fertility. Most studies on these pathogens have focused on their control in groups of animals, including susceptible strains, kept for breeding and used in biomedical research. When such pathogens are introduced into such naive populations, the acute effects of the resultant disease can be very significant. However, for pets with small numbers of immunocompetent animals that may have been exposed and recovered or when the disease remains in subclinical, the effects on reproduction may be far less obvious or even of limited significance.

Rat Parvovirus

Parvoviral infections have been recorded in several species of rodents (hamsters, rats, mice) as well as in rabbits. Parvoviruses in rodents tend to spare the gastrointestinal tract, and infection is likely to be subclinical in pet animals. In laboratory animals, fetal resorption and neonatal deformity and mortality may be seen, as well as periorchitis in infected males. There is no treatment available.

Sendai Virus

Species that are hosts of Sendai virus include mice, rats, hamsters, and guinea pigs, although chinchillas can be infected experimentally; gerbils appear to be resistant. Infection can be subclinical in rats, hamsters, guinea pigs, and rabbits. Susceptible animals show reduced breeding efficiency in addition to respiratory signs; there is no treatment.

Murine Mammary Tumour Virus

Murine mammary tumour virus (MMTV) is a retrovirus that affects mice specifically; the virus can be spread horizontally and vertically. In combination with exogenous factors such as chemical or physical carcinogens, MMTV can produce mammary tumours.

Mouse Hepatitis Virus

This is an RNA virus with numerous variants that are constantly mutating and evolving. There are two main types, polytrophic (respiratory) and enterotrophic (invades other tissues), that have distinctly different patterns of disease. The prevalence is high in both laboratory and wild mice.

Drugs Used to Manipulate the Reproductive Cycle in Small Mammals

As with other classes of drugs, those licensed for use in small mammals are small in number, but dosage information may be available in specialist formularies (Carpenter 2012).

Human Chorionic Gonadotrophin

Human chorionic gonadotrophin (hCG) is commonly used in exotic small mammal practice. Its physiological action is similar to luteinising hormone (LH) and causes follicles on the ovary to mature and ovulate, producing a corpus luteum. It stimulates testosterone secretion in males. Clinically, hCG is used to replace or supplement LH in cases of ovulation failure or delay (in rabbits), to induce lactation postpartum, to induce regression of ovarian cysts in guinea pigs, and to induce ovulation in ferrets with persistent oestrus. In males, hCG has been used to treat cryptorchidism, although this use in people is less supported (Thorsson et al. 2007), and to improve libido.

Deslorelin

A GnRH antagonist, Deslorelin desensitises GnRH receptors reducing the release of LH and FSH from the pituitary. It may be used for chemical castration (it reduces the production of both testosterone and sperm), which can last for up to 6 months. Deslorelin reliably blocks reproduction in both male and female ferrets and is an alternative to surgical neutering. It is also used as a treatment

VetBooks.ir

for adrenal disease in ferrets and rabbits and has also been used to treat ovarian cysts in guinea pigs; however, the mechanism of action is uncertain, and treatment failures have occurred. Deslorelin may also be used to treat oestrogen-induced mammary tumours in rats.

Aglepristone

A progesterone-receptor blocker, aglepristone is used for the termination of pregnancy in mammals. It has shown to be effective for this purpose in rabbits and rats, and although reproductive behaviour may be altered during the cycles immediately subsequent to treatment, there is no subsequent reduction in fertility. Aglepristone may also be used for the treatment of pyometra. Anecdotal evidence from its use in two hamsters and a guinea pig has shown that in combination with antibiosis and supportive care, it may cure pyometra with no reduction in subsequent fertility (Gogny & Fieni 2015).

Proligestone

A progestogen, whose action mimics cell metabolism changes caused by progesterone, clinically, proligestone has been used to delay oestrus in female ferrets as well as suppressing persistent oestrus in females out of season. Proligestone has also been used to treat pseudopregnancy in the rabbit. Although associated with fewer side effects than other progestogens, there is the potential for alterations to behaviour and temperament, as well as causing diabetes mellitus, cystic endometrial hyperplasia, and pyometra.

Cabergoline

Cabergoline is used to treat pseudopregnancy in many mammalian species. It is a prolactin inhibitor and has been used therapeutically to treat pituitary adenomas and mammary tumours in rats when there is a hyperprolactinaemia. Schoemaker (2017) has demonstrated that not all rats with mammary tumours and hyperprolactinaemia have pituitary adenomas, and the source of prolactin in these cases is obscure.

Veterinary Control of Reproduction in Rodent Colonies

LUCY WHITFIELD, PHIL GIBBS AND TIM MORRIS

This chapter examines the breeding of small rodents as domestic, often children's, pets, rather than breeding for biomedical research purposes and complements Chapter 40 with a particular focus on practical aspects. The range of species discussed includes not only mice and rats but also gerbils, guinea pigs, and various species of dwarf and larger hamsters. Each species has their idiosyncrasies, but there are many general principles that apply to all of them. Pet rodents are usually bred for colour and coat type, so they may appear in a variety of forms. The main aim of this chapter is to help the veterinary student, and also practitioners new to this area, to optimise breeding and management by understanding the reproductive biology and the physical, social, and behavioural requirements of these species when bred as pets.

Most animals are sold shortly after weaning, although some more enlightened pet vending companies are starting to sell older, rescued, and exbreeding animals, particularly guinea pigs. This is to be commended, as these species may live for several years longer after the end of their breeding lifetime.

There is marked variation in the nature of pet breeding facilities, ranging from those units which have expanded gradually from hobbyists to a few units that are run by trained staff who may have degree-level qualifications in small animal husbandry and management. There are relatively few purpose-built, small rodent breeding facilities and, in general, little specialist advice available to the rodent breeder. Although a great deal is known about breeding the same species in the laboratory context, this does provide useful experience for the 'herd medicine' approach that is also necessary in pet breeding facilities (Suckow et al. 2012).

Breeding rodents commercially is about much more than just pairing animals and basic reproductive biology: their physical and behavioural needs must be taken into account and a great deal of planning and oversight are required to ensure that the number and type of animals bred matches the requirements of the customer. Animals that are stressed, either nutritionally or by their environment and care, will not breed successfully, and their psychological health may also suffer.

However, although the units are generally well organised, there are certain guiding principles that will help to ensure the good health and welfare of the animals who live there and also ensure that the animals that become our pets are of high quality and have good mental and physical health.

The facility must be organised with sufficient, trained, animal care staff to manage the animals and must have suitable accommodations for the species and ages of rodent animals that are kept. The correct determination of sex ('sexing') of all rodent stock is vital to ensure that suitable pairings are established which can mate and so that groups of animals are not left in mixed sexes until they are old enough to mate.

Criteria for Successful Breeding in Small Rodents

Species Biology and Characteristics

Key reproductive biological data for rodents and the other species are described in Chapter 40 and are summarised in Table 41.1.

Guinea Pig

With guinea pigs *(Cavia porcellus)* as with all species, it is important to minimise stress when catching and handling. Most of the guinea pigs' natural predators are airborne, so approaching their enclosure from above can provoke a stress response and panic if the animals are unused to regular handling. Spending plenty of time in the animal room is helpful to accustom adults and youngsters to human presence, and it also helps to speak quietly in the presence of the animals. Approach the animals from the side, in a lower posture rather than bending right over the pen. Providing a few tunnels or boxes for hiding can reduce anxiety in floor-housed guinea pigs. Whether catching them in either a cage or on a floor pen, this should be a swift smooth affair as guinea pigs are easily stressed by chasing and will become excited and difficult to handle. To pick up the guinea pig, place the thumb and forefinger around the neck with the palm across the shoulder and use the remaining fingers to assist the lifting; they should be supported at the rear with the other hand. It is better not to lift heavily pregnant sows, unless it is essential to examine them.

To sex the guinea pig, turn it over so that the body is supported on your wrist and look at the genital area; the shape varies between the sexes. If gentle pressure is applied in front of the genital region, the penis will be expressed in the male, whereas in the female the Y shape will always remain (Fig. 41.1).

It is essential to separate male and female youngsters at weaning, around 4 to 5 weeks of age, as guinea pigs can mate at 7 weeks. They should not be mated for the first time until they are 12 to 14 weeks old in order to allow the young animal to grow. Note though, that the female guinea pig should be mated before 6 months

VetBooks.ir

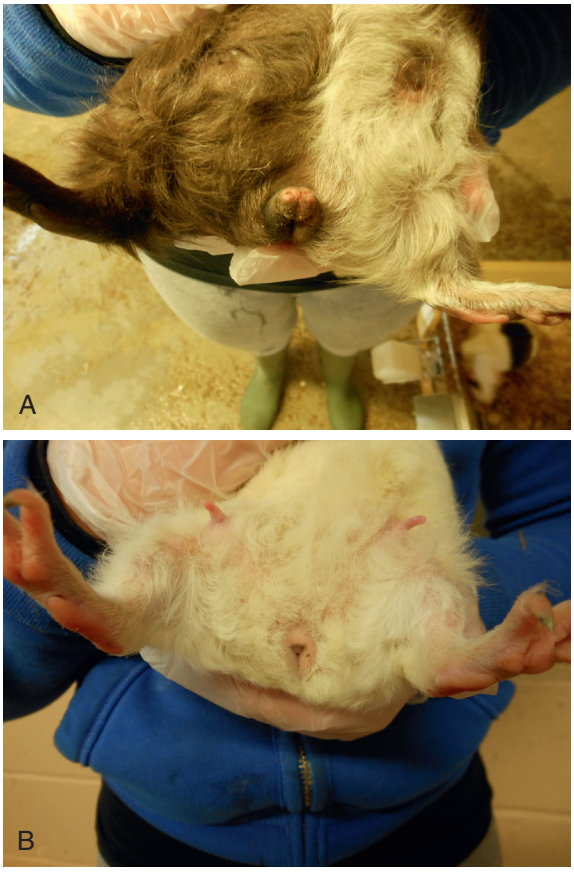
TABLE 41.1 Key reproductive biological data for rodents and other small mammals

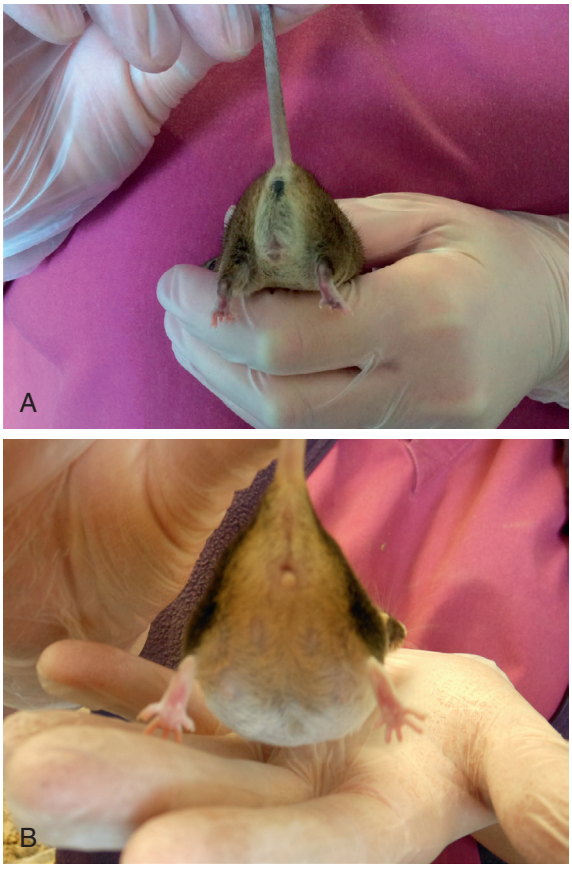
Spp	Life span	Sexual maturity	Oestrus Cycle	Gestation	Pregnancy diagnosis	Postpartum oestrus	Litter size	Age at weaning
Guinea pig	5–8 years	4–6 weeks	Nonseasonally polyoestrus. 15–17 day cycle, oestrus 1–16 hours. Spontaneous ovulators.	59–72 days	Palpation from day 15, ultrasound from day 21. Radiography from day 42.	Yes, within hours of parturition. 60–80% pregnancy rate.	3–4	14–28 days
Chinchilla	15–20 years	4–5 months in females, 7–8 months in males	Seasonally polyoestrus (November to May). Spontaneous ovulators. Cycle length 30–50 days. Oestrus 2–5 days.	105–118 days	Palpation from day 50, ultrasound or radiographs from day 60.	Yes, 2–48 hours after parturition, then 35–48 days after parturition (postlactation oestrus).	1–3	8–10 weeks
Degu	6–8 years	12–16 weeks in females, 16 weeks in males	Seasonal breeders, but in wild only breed once a year. Spontaneous ovulators. Cycle duration 21 days, oestrus 3–5 days.	90 days	Palpation from day 40. Radiography from day 50. Size limits usefulness of ultrasound, gestational sacs visible from around day 30.		3–10	4–5 weeks
Rat	2–3 years	Female 65–110 days, Male 65–110 days	Nonseasonally polyoestrus. Spontaneous ovulation. Cycle 4–5 days, oestrus 9–20 hours.	21–23 days	Ultrasonography from day 10.	Yes. Pregnancy can result, but if still lactating delayed implantation may occur: 3–10 day increase in gestation period.	9–11	20–22 days
Mouse	2–3 years	Male 50 days, Female 50–60 days	Nonseasonally polyoestrus. Spontaneous ovulation. Cycle duration 4–5 days, oestrus 9–20 hours.	19–21 days	Size limits ease of ultrasonography. Accurate diagnosis ultrasonographically from day 9.5 reported.	Yes. If lactating then delayed implantation can occur. Increases gestation by 3–10 days. Post partum matings may be infertile.	8–11	18–21 days
Hamster	3–5 years	Female 42–70 days, Male 70–98 days	Nonseasonally polyoestrus BUT reduced fertility in winter months. Spontaneous ovulation. Cycle duration 4–5 days. Oestrus 15–16 hours.	15–16 days	No definitive information.	No. Usually an anovulatory cycle.	5–10	19–21 days

VetBooks.ir

Gerbil	3–5 years	Female 65–85 days, Male 70–85 days	Nonseasonally polyoestrus. Spontaneous ovulation. Cycle duration 4–6 days, oestrus 12–18 hours.	23–26 days	No definitive information.	Yes. If lactating then delayed implantation can occur: increases gestation up to 48 days.	3–8	21–28 days
Rabbit	10–13 years	4–9 months, does generally reproductively mature earlier than bucks, but varies between breeds.	Seasonally polyoestrus: January to November. Spontaneous ovulation 9–13 hours after copulation. No defined oestrus cycle, but there are variations within their receptivity with peaks and troughs occurring every 4–6 days.	29–35 days	Visualisation of mating. Palpation at day 10–14. Ultrasound from day 14 onwards. Radiography from day 21 onwards.	Yes. Occurs within 9–13 hours after breeding. Pregnancy can occur, and proceed alongside lactation; however does may not be able to feed their offspring until normal weaning age, so supported feeding of kits and mother to reduce mortality may be required. Delayed implantation may also occur, leading to prolonged gestation.	6–8	Between 5 and 8 weeks of age
Ferret	8–10 years	Between 4–9 months, earlier in season when photoperiod is increasing and sufficiently long (12–14 hours).	Seasonally polyoestrus but between March and August approximately 50% of females remain in constant oestrus if not mated. Reflex ovulators.	39–42 days: 10–12 days preimplantation and active gestation of 30 days.	Abdominal palpation at day 12–14, ultrasonography day 12 onwards, radiography at day 30.	Varies depending on whether female still suckling young. If normal litter, then 14 days after weaning. Females with small litters may come into season earlier. Occurs within 9–17 days of parturition if kits are stillborn.	4–14	6–8 weeks
African Pygmy Hedgehog	2–3 years	8 weeks to 6 months in females, males closer to 6 months. Females may undergo pelvic symphyseal fusion by 12–18 months of age, potentially leading to dystocia if bred for the first time after this age.	Seasonally polyoestrus and probably spontaneous ovulators. Seasonality depends on weather conditions: hibernation occurs in cooler parts of range, whereas in warmer climates, African Pygmy hedgehogs will breed year round. Cycle duration 3–17 days	34–37 days. Delayed implantation may lead to prolonged apparent pregnancy.	Weight gain of 50g or more within a few weeks of breeding is suggestive. Visible abdominal swelling and mammary enlargement at day 30 onwards. Radiography from day 21. Abdominal palpation and ultrasonography may require anaesthesia and therefore the potential risk must be accounted for.		1–6	4–6 weeks
Sugar glider	6–8 years	8–12 months in females, 12–15 months in males	Seasonally polyoestrus. Primarily breed in winter and spring. Cycle is 29 days.	Gestation 15–17 days.	Difficult as conceptuses very small for ultrasound visualisation. Radiography and abdominal palpation are not appropriate.	Yes but if joeys in pouch then implantation will be delayed at blastocyst stage until joey leaves the pouch.	2–4	70 days



• **Fig. 41.1** Perineal area of male (A) and female (B) guinea pigs.



• **Fig. 41.2** Perineal area of male (A) and female (B) mice.

as after this time their pelvic bones can fuse, which possibly may interfere with natural birth (see Chapter 40).

Guinea pigs can be bred in pairs or trios in a correctly sized cage. However, in a commercial breeding environment, floor pens with one male and to up to 15 females are commonly used. This method is not as space-efficient as using cages but allows much more integration and natural behaviour for the guinea pig, as there is space and opportunity for more social and environmental enrichment than in a cage. Social housing also allows cooperation between females, in that they will help less experienced mothers and will allow other young inexperienced lactating females' young to suckle from them. Only one male should be kept with each harem group, as boars will fight in the presence of females.

Guinea pigs naturally form groups of five to six adult individuals, which will allow for social interaction among themselves and with neighbouring groups. Guinea pigs are generally very sociable, although it is not recommended to house females in groups larger than about 20 individuals; when larger numbers of animals are housed together, the groups tend to split into smaller social subunits (Kaiser et al. 2010). Guinea pigs form long-lasting bonds between each other, so moving around individual guinea pigs between pens can be very stressful. This has a bearing on breeding management, in which the number of females in a pen is reduced due to natural wastage; it is commercially advantageous to add more females to the pen in order to maximise occupancy rates and use of the floor space. 'Making up numbers' should therefore be done by combining existing groups of sows rather than adding separate individuals to the pen so that the existing social units are preserved.

Mouse

Mice (*Mus musculus domesticus*), similar to other small rodents, are prey species and careful handling is essential to reduce stress. Mice should not be caught and lifted by the tail, as this method has been shown to trigger a 'prey response' and result in high anxiety levels (Hurst & West 2010). Mice should rather be captured and lifted out of the cage in a 'tunnel' or in the cupped hands (Gouveia & Hurst 2013). The mouse can then be restrained for sexing purposes by holding the base of the tail, with the forelegs supported. Male mice can be differentiated by the greater distance of the genital opening from the anus, approximately double the distance of the female (Fig. 41.2). The scrotum can also be observed in mice of 3 weeks of age and older. An additional help in determining gender in young mice of 7 to 15 days of age is that hair does not develop around the teats of females so that it is easy to identify the spots (nipples) on the belly.

Mice should be separated at weaning (3 weeks of age) as they are capable of breeding at 6 weeks. However, it is wise to allow them to grow until at least 9 weeks before their first mating. They have an oestrous cycle length of 4 to 5 days and a gestation period of 21 days. Litter size may vary with mouse strain and the age of the female, but a good litter average is 6 to 12 pups. Commercially, a figure of 1.5 young per female per week is considered to be optimum.

Mice can be paired for life as the male will not be a threat to the pups, thus leaving the male in with the female allows for early postpartum mating, which minimises the length of time before the next litter. Mice can also be kept in trios or harems. Provided that

VetBooks.ir

there is sufficient cage space, trios are often preferred as this creates more young while still allowing for accurate breeding information on individual mice to be maintained.

Mice are usually allowed to have six or seven litters before being retired from breeding as fecundity in mice is reduced after approximately 8 months of age. Successful breeding is unlikely in individuals more than 12 months of age.

Rats

Rats (*Rattus norvegicus domesticus*) easily become accustomed to handling, and the rat can be picked up by placing the thumb and forefinger around the neck with the palm across the shoulders, using the remaining fingers to assist when lifting the animal. Care must be taken not to hold them too tightly as this will restrict breathing and cause the rat to struggle. Adult rats require support from the other hand when lifting, particularly if pregnant. Rats should not be picked up by the tail. When turning the rat over, the same anogenital distance differences described previously for the mouse can be observed; it is an easier task as structures are relatively larger (Fig. 41.3).

Rats are capable of breeding at 8 weeks of age, but it is again wise to allow further growth to occur in future breeders, with the time of first mating at 12 weeks old. They have an oestrous cycle of 5 days and a gestation length of 21 to 23 days. A good litter average is 6 to 12 pups, with a figure of 1.5 young produced per female per week being desirable. Rats are generally not kept for commercial breeding beyond 9 to 12 months of age as fertility and rearing success decline after this age.

Rats can be kept in pairs or trios; more females than this would require a very large cage for the young and would not be practical. As with mice, the male does not interfere with the young and can be seen interacting with young animals in play. Environmental enrichment is important in normal development of the pups, allowing them to experience a complex environment early in life. Exposure to ideal nesting materials at an early age ensures that future breeders will also be able to build good nests for rearing their own pups.

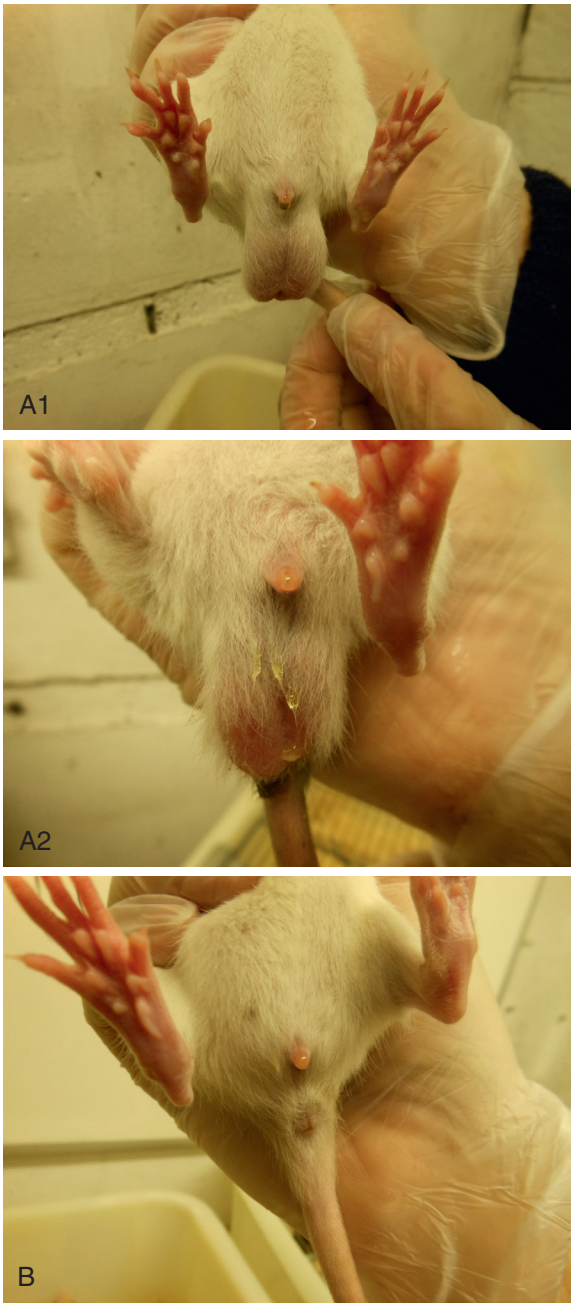
Syrian Hamster

The Syrian hamster (*Mesocricetus auratus*) can be picked up and then handled for sex determined in one of two ways. They can either be picked up by firmly but gently grasping them across the back or by grasping the scruff. Alternatively, they can be cupped using both your hands round the body, lifting the hamster up and turning it on its back by sliding the palms to the diagonal. A hamster may noisily indicate its displeasure at the intrusion, but no harm will come to either hamster or handler if no hesitation is shown on the handler's part. When the male hamster is turned on its dorsum the testes and scrotal sacs can be observed. However, in younger males, it is sometimes not obvious; in that case the comparison of the difference in the anal/genital distance between the male and the female is used. This can sometimes be a challenge especially if the hamster has long hair (Fig. 41.4).

Syrian hamsters are a solitary species so premating management is usually required. It is sometimes possible to keep Syrian hamsters in monogamous pairs if the male and female are paired at weaning and if there is enough space in the cage for them to seek solitude, although careful observation is crucial to identify signs of fighting. If fighting occurs, the male should be removed from the cage and generally cannot be reintroduced in the long term.

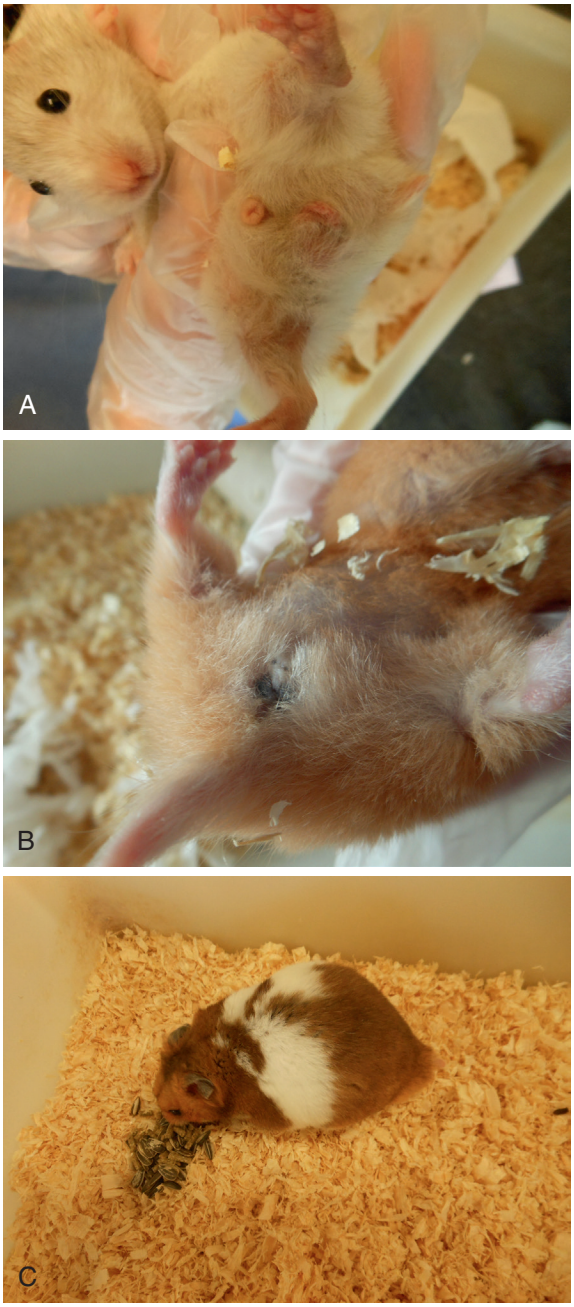
Traditional hand mating is successful, but it is a labour intensive method of breeding. Hamsters are mated soon after dark by placing the female in the cage of the male. The duration of the oestrous cycle is 4 days and thus the female will accept the male on only 1 day of the 4. If he is accepted by the female, the mating will be observed almost immediately, and the male can be removed quickly to avoid the possibility of fighting.

The third and most viable way of commercially breeding Syrian hamsters is to house a pair together for 6 days as this ensures the female will have ovulated at least once during this time. The pairing should be observed frequently to ensure there is no fighting. The male is then removed on Day 6, and the female is allowed to 'litter' and raise her young. The male can be used again to breed with other females, although it is prudent to allow a week of rest and recovery before the male is used again, so sufficient males must be present in the colony to allow for a week of mating and a week of rest. In practice, this means accommodating two males



• **Fig. 41.3** Perineal area of male (A) and female (B) rats.

VetBooks.ir



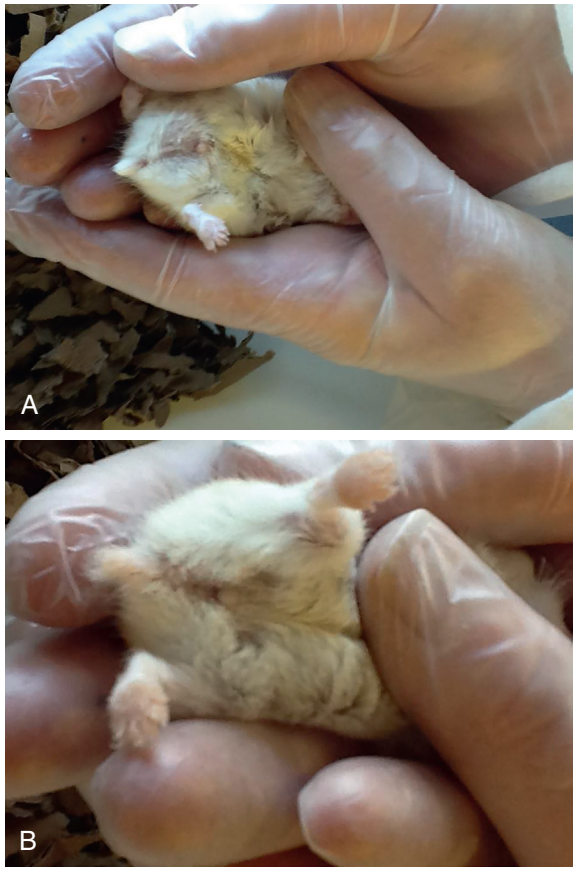
• **Fig. 41.4** Perineal area of male (A) and female (B) Syrian hamsters. (C) In some cases you are able to determine sex without the need to handle; note the obvious testicles.

per five females and rotating them over a 5-week cycle of mating, pregnancy, lactation, and resting.

The normal litter size in Syrian hamsters will be between 4 and 12, and a colony average of 6 or more is expected commercially.

Dwarf Hamsters

The most common species of Dwarf hamsters bred commercially are the Russian (*Phodopus sungorus*), Chinese (*Cricetulus griseus*), and Roborovski (*Phodopus roborovskii*). To pick up a dwarf hamster requires a speedy reaction, although the Chinese hamsters are a little less responsive to interferences. Place a cupped hand gently over the hamster, and taking the scruff between the thumb and forefinger, the hamster can be turned over to be sexed. As for the other small rodents, the anal–genital distance is the distinguishing difference, being greater in males than females. Comparing the sexes allows the handler to become proficient in observing the small difference in the distance and is essential for good colony management. The adult male Chinese hamster has easily identifiable testes (Fig. 41.5).



• **Fig. 41.5** Perineal area of male (A) and female (B) dwarf hamsters.

Monogamous pairing is the most satisfactory method of breeding dwarf hamsters, with first pairing at 12 weeks, allowing the young the correct amount of growing time. Social development is important in these species, and, similar to gerbils, dwarf hamster fathers, particularly the Russian, are interested in the preweaning young and can be observed interacting in a positive way with the young in the cage.

The species vary in the length of time from first pairing to breeding – Roborovski hamsters may take several months to produce their first litter, so the colony numbers should be adjusted to take account of the fact that up to 25% of the colony may not be breeding. This is particularly apparent in the winter months, especially when light and temperature may be lower. In contrast to the management advice for most rodents, it is recommended that Roborovski pairs are not paired before 6 months have elapsed as some do suddenly start breeding very productively even at this stage.

Mongolian Gerbils

Gerbils (*Meriones unguiculatus*) can be picked up by closing cupped hands around the animal, as tail capture is likely to be stressful and there is also a risk of a 'degloving' injury to the skin of the tail. Turning gerbils onto their dorsum causes anxiety, so they should be sexed by lifting the hind legs off the palm of the hand while supporting the front legs. The greater anal–genital distance and

VetBooks.ir

• **Fig. 41.6** Perineal area of male (A) and female (B) gerbils.

obvious scrotal sac in the males make sexing relatively straight forward (Fig. 41.6).

Gerbils naturally live in social groups consisting of the breeding adult pair and several generations of youngsters, which are usually inhibited from breeding by the dominant adults through suppression of sexual maturation in the females, although the testes and sexual characteristics of the male offspring continue to develop normally. Offspring should be separated from the parents by weaning at 3 to 4 weeks of age and kept in separate sex groups until mating.

Gerbils should be first mated at the relatively early age of 6 to 7 weeks, in order to minimise the chances of a nonreceptive female attacking the male, which often happens if individuals are paired when mature. Male gerbils are important in supporting breeding by assisting with nest building and taking care of pups by cleaning and warming them; this appears to stimulate their activity and development (Clark & Galef 2000). Breeding in monogamous pairs is the perceived wisdom in the breeding of gerbils, although breeding in trios is also successful if the male and both females are introduced early and at the same time. There should be sufficient cage space, and the use of trios maximises breeding production in a single cage. Whether pairs or trios are put together, they should be initially closely observed and separated if any aggression is seen as this can escalate, resulting in serious injury if left together. It is not known why previously compatible pairs or trios suddenly become destabilised, but if older pairs or trios lose their mates, it is unlikely that they will accept another individual (Swanson & Lockley 1977).

Gerbils will usually produce up to eight litters in a breeding lifetime, although individuals vary, and it is important to make regular assessment of breeding success.

Macro and Micro Environment

The macro environment should remain optimal at all times in order to ensure animals' comfort and to maximise breeding success. The animal holding rooms should remain within a 4°C range as variation is likely to stress the occupants; 17°C to 21°C is comfortable for both animals and technicians. The effect of higher or lower temperatures on individual animals is also considered in Chapter 40. Ventilation should be at a minimum of 10 complete air changes per hour in order to remove moisture, dust, and microorganisms without exposing any animals to direct draughts.

Lighting should be provided by full spectrum lights of the correct lux, and this should preferably be complemented with natural light, which is good for both animals and their carers. Many rodent species are nocturnal or crepuscular, so light levels lower than 300 lux allow the animal carers to make observations and carry out husbandry tasks while not disturbing the animals. Rodents should have the opportunity to 'escape the light' by hiding in nests or shelters such as tunnels or 'houses'. The light–dark cycle should remain constant throughout the year; 14 hours light to 10 hours dark is the author's preferred ratio. Shortening day length mimics autumn to rodents, and the drop in production would be marked. It is essential to check at intervals that the timing system for controlling the lights is functioning correctly as failure to turn on or off the lights at the required times can have profound effects on the animals' welfare and breeding success.

The micro environment for breeding rodents is equally important. The recommended correct cage and pen size for each of the species has always varied, the guidelines varying between licensing authorities and over time. Many commercial pet breeders use ex-laboratory caging, which no longer meets the EU specification for size. Space per se is not the only factor that affects whether or not the animal can meet its needs; proper animal care dictates that any breeding animal should have enough cage space to interact with or move away from their partner or youngsters and enough space to build a nest and raise a litter (Van de Weerd et al. 1997, Patterson-Kane et al. 2000, Young 2013). There must be enough space to have some form of environmental enrichment; small tubes or houses are a simple way to give the rodent another platform or hiding place, and swings promote physical activity and development for the youngsters (Fig. 41.7). Allowing the animals to carry out natural behaviours will safeguard their welfare; for example, rats investigate their environment by orienting on their hind legs and so require sufficient cage ceiling height to achieve this posture. Both rats and mice are agile climbers and benefit from being able to use the vertical dimension of their cages through ropes or ladders. This also allows them the opportunity to spend time away from their litters occasionally. Regular handling assists the animals to acclimate to human contact, ready for their pet homes.

Nest building is partly innate and partly a learned behaviour; thus rats or mice born in environments lacking a nest will not build such good quality nests themselves; thus provision of suitable soft, manipulable materials is essential. These may include cotton-based materials as well as paper towel, paper strands, paper 'wool', hemp strands, or hay. Providing a shelter is also helpful; these may be cardboard, plastic, or wooden and suitably sized for the animal and the cage. Breeding rodents should be disturbed as little as possible to reduce stress during late pregnancy and in the neonatal period. Small rodents use scent cues heavily, so cage cleaning can be very disruptive to the animals' social environment; moving the home nest to the new cage when cleaning out helps to provide a familiar environment for the occupants.

VetBooks.ir

• **Fig. 41.7** Examples of environmental enrichment.

• **Fig. 41.8** Tunnel to lead to nesting area.

Some species, such as gerbils, have a particular requirement for a long (> 25 cm) tunnel (Fig. 41.8) to lead to their nesting area, and providing this will increase reproductive success and reduce stereotypies. The correct nesting material gives them an opportunity to create a nest, which gives them a worthwhile activity and a comfortable area to be in and raise their young.

Sound or the lack of it plays an important part in maximising breeding production. A breeding area should be a quiet place with a minimum of sudden loud sound, particularly at the high end of the audible scale (ultrasound). Rodents are able to hear ultrasound, which humans cannot, so the squeaky extractor fan which we observe as being silent will upset them greatly. Similarly, vibrations travelling through walls or floor, such as caused by machinery or building works, are notorious for causing a sudden reduction in breeding activity. The use of radios by animal care staff is controversial as it adds noise that the animals cannot avoid. However, practical experience suggests that, provided that the noise is not loud, it becomes part of the regular routine, and, provided that it is switched off when activities cease, it does not generally cause detectable problems (Van Loo et al. 1994). It is also important that the human carers are relaxed and happy in their work, so if adding music to their routine facilitates this, then everyone benefits.

Nutrition

Breeding mothers are under considerable metabolic demand throughout their reproductive lives, and their offspring require excellent nutrition for their proper growth and development; therefore it is crucial that the nutrition is kept at a consistently high standard to provide the correct proportion of protein, carbohydrates, and fat. Rodent diets must also contain the correct balance of vitamins, amino acids, and minerals (Clarke et al. 1977, National Research Council 1995), further details are given in Chapter 40. Rodents do not generally overeat and are fed *ad lib* with a pelleted diet, although additional forage food such as sunflower seeds and cereal grains can be added on the cage/pen floor as an enrichment activity. Consistency and quality of the diet is crucial, and any reduction in diet standards leads to lower successful pregnancy rates, lower numbers born, and lower numbers of animals reared to weaning age. It is important to build a good relationship with the diet supplier or mill so that they understand the absolute need to provide a consistently high quality diet. It must be stored in a suitable cool, dry, and vermin-proof area, ensuring proper rotation of stock to prevent spoilage. In addition, guinea pigs require a good source of vitamin C; thus in addition to their pelleted diet, they should be provided daily with fresh vegetables and/or additional vitamin C in their drinking water.

Fresh water should always be provided to all animals at all times. Offering water in bottles is relatively labour intensive but does allow the technician to check water consumption as one means of assessing health daily.

Effective Management & Record Keeping

Good animal husbandry, in the form of regular cage changing, cleaning, and disinfecting, will minimise the risk of an outbreak of disease and reduce any preweaning losses. With large breeding colonies, this requires organisation to ensure every cage receives the correct level of attention while minimising labour requirements. Attention to detail is essential to ensure that stress is minimised during cage changing and pen cleaning; for example, transferring part of the animal's nest into the new cage helps ensure that there are familiar smells in the new cage and reduces the disruption of entering a new environment.

The requirements for different species vary, but in general, it is advised to leave a mother and young litter with as little disturbance as possible from the last week of pregnancy until the young have a covering of downy hair, at about 6 or 7 days. As long as the cage bedding remains dry, the hygiene risk is minimal and has to be balanced against the likelihood that disturbing the family by changing the home cage at this stage may lead to a mother abandoning or cannibalising her young.

A robust system of identifying animals or cages and record keeping is essential to a successful breeding programme. Basic information includes the number of breeding females, males, and

VetBooks.ir

• **Fig. 41.9** Example of identification and breeding details recorded on cage label.

future breeders present in the colony at any one time. The number of offspring weaned each week and 'in stock' as they grow should also be recorded on a weekly basis. Knowing the colony and the number of young required each week allows planning for the correct number of future breeders of the correct age to be available to replace the animals that need to be removed from the breeding system. Regular review meetings should be held between the unit manager and lead technicians from each species area or colony.

Inside the unit, cages should be clearly labelled (Fig. 41.9) with the identity of the animal(s) contained, including their parents, date of birth, and date that the pair was first prepared for breeding. The coat colour of the parents should also appear on the label so that any errors relating to incorrect identification can be promptly identified. For hand-mated rodents, such as hamsters, the cage card should include the identity of the stud male used in the mating so that outbreeding can be maximised. Stud males' cage cards should identify any unsuccessful matings in which pregnancy did not result so that subfertile males can be identified and removed after three unsuccessful pairings.

The breeding cage card should record the date of birth of each litter, plus the number of offspring born and weaned from the cage, including preweaning losses. By examining these records regularly, it is easy to identify any problems and take prompt remedial action. The first litter would usually be expected to be born 3 to 4 weeks after pairing (e.g., rats, mice, hamsters), and the female can be assessed for pregnancy after the first 2 to 3 weeks to confirm that all is well. Most rodents will mate postpartum, so there should be a regular production of litters. Dams or pairs who consistently fail to rear litters can also be easily identified and removed from the colony.

To maximise production, it is important to know when to stop breeding from a particular animal or pair. The litter size will naturally decline as the animal ages, so the age of the animal can be used as a guide; however, individual judgement on how each animal has and is performing will optimise a colony's breeding activity. An older mother may not produce so many young but may always rear all the young until weaning, so she may be worth retaining a little longer.

Some breeders find it helpful to arrange the colony by age, such that all animals of similar age are in a certain area of the room; therefore it is easier to identify those close to the end of their breeding lifetime or to give special attention to those littering for the first time. This is particularly helpful for managing species such as guinea pigs, which are bred in harems, so that the whole pen contains animals of a similar age. If younger and older animals are mixed together, it can be difficult to ascertain exactly what the true production level is, as the more fertile, younger dams can mask the presence of nonproductive animals.

The number of animals weaned should be recorded on a weekly basis in order to follow trends in production and to highlight any potential problems quickly. If individual animals are nonproductive, then the dam may be able to be remated with a different male (although this is not generally possible for gerbils). If the problem appears more widespread, then the primary cause should be investigated, encompassing management, diet, environment, and disease.

Typical Benchmarks for Pups Weaned by Species

The figures given here are typical production rates for each of the species, given as number of pups weaned per female per week. Note that the calculation should be made according to *all* the breeding females in the colony, not just those who are producing litters in a given week; otherwise, production rates will appear falsely elevated.

Mice:	1.5 per female per week
Rats:	1.5 per female per week
Hamsters:	6–7 per female per month
Gerbils:	2–3 per female per month
Guinea pigs:	1 per female per month

Troubleshooting: Problems With Breeding

Breeding failure is due either to failure to produce litters or to loss of pups before weaning. Although this may seem obvious, distinguishing which problem is occurring requires careful record keeping of the individual breeder's or pair's reproductive performance. Simply counting the number of pups weaned or sold is not sufficient.

For individual pet animals, it is easy to determine the reproductive success of the pair, but for a colony, analysis of the records and the production trends are required. The number of pups weaned is divided by the total number of breeding females in the colony, to give a 'number weaned per female per week' and should be calculated on a rolling basis. Downward trends or deviation of more than 10% from the weekly average should trigger investigation.

Trio or harem breeding systems can be monitored by recording the number of offspring per cage or per pen, again taking into account the number of females present. When multiple females are housed together, they should preferably be all of a similar age; otherwise, it is more difficult to determine which of the animals in the group may be nonproductive. This is particularly the case when older and younger animals are mixed together as the increased fecundity of the younger animals may partly hide that some females are not rearing young at all.

Investigating 'Failure to Litter'

Animal Causes

The first basic check is the gender of the pair. Missexing young rodents is not uncommon, and so it is worth double-checking who is in the cage. Check also for developmental defects, such as imperforate hymen in females or retained testicles in males. If the male is not a proven breeder (has produced litters with another female), then consider changing him for a new male. When hand-mating systems are used, then the male should be

VetBooks.ir

culled if none become pregnant after any of three separate matings (with different females).

Check the age of the breeding animals. Small rodents have a relatively short breeding life – for example, mice older than 7 months old are less productive, and mice over older than 12 months of age are unlikely to breed at all. Cystic endometrial hyperplasia is relatively common in older female mice, and these animals are unlikely to carry a pregnancy. Guinea pigs will breed for several years but may have fewer young and breed less regularly or with increased risk of dystocia when older than 4 years old.

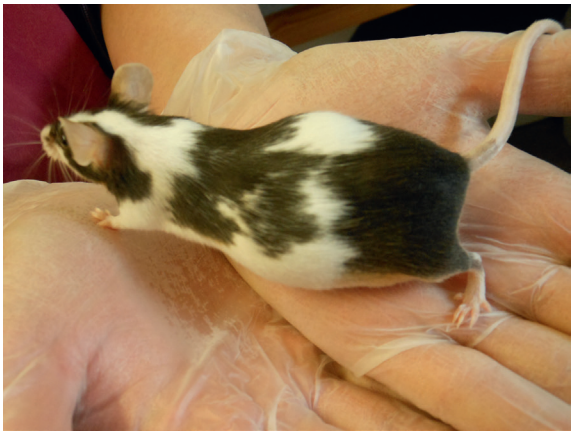
When setting up breeding pairs, it is usual to choose a male that is slightly older than the females. For small rodents, the strategy of choosing a male born a week or two before the females helps to prevent inbreeding in the colony, as the offspring must be from different parents.

Breeding for particular coat colour or other characteristics may result in inbreeding of a line, with depression in productivity. Certain matings may be incompatible and result in embryos that are not viable; therefore no pups are born. An example of this would be white-coated, long-haired hamsters, which cannot be bred together, as the resulting pups are not viable.

Nocturnal rodents generally mate during the nighttime dark period, so the event is not always observed. In rats and mice, the presence of a copulatory plug confirms that mating has taken place (although it does not confirm that pregnancy will result). The plug remains in the vagina of the female mouse overnight and can be seen the next morning, which helps to confirm the dates of mating and therefore the expected parturition date. The copulatory plug occurs in rats too, but tends to fall out, so confirmation of mating may be more difficult to detect. Plugs are not seen in guinea pigs or hamsters.

The female can be checked for evidence of pregnancy by observation for abdominal swelling at approximately halfway through the expected gestation period (Fig. 41.10). This may be more challenging in fat animals. It may be possible to gently palpate the fetus(es) in guinea pigs from an early stage and during the latter half of pregnancy in rats and mice. If available, ultrasound can be used to confirm pregnancy from approximately Day 8. The animal can be gently held for this procedure and sedation is not usually required.

If the time of mating (or setting up the pair) is known, then the cage should be carefully checked for the presence of pups at around the expected time of littering. Clear cages allow observation through the cage sides, or the cage can be gently pulled out of the rack in order to observe the nest without disturbing it. Some females (especially mice and hamsters) are very sensitive to disturbance, so there should be the minimum intervention needed to assess the health of the dam and litter. When neonatal deaths is suspected, an estimate of the litter size can be made on the day of parturition without interfering with the pups, then a more accurate count made 4 to 5 days later and again in subsequent days if required. This will distinguish whether a 'large' litter is born but then lost, or whether the litter is small from the start. Small spots of blood in the nesting material or cage may indicate that littering has taken place, even if pups have died or been cannibalised, and this will help to distinguish embryonic losses from postparturition problems.



• **Fig. 41.10** Abdominal swelling at approximately halfway through the expected gestation period in a mouse.

Management Causes

The circadian rhythm is very important in successful rearing and breeding of mice, and disturbances in the light cycle can have a significant effect on breeding success. Small rodents will breed with equal light/dark periods (i.e., 12 hours light, 12 hours dark), although conventionally, a slightly longer light period (e.g., 14 hours light, 10 hours dark) is suggested for optimising breeding. Disrupting the dark period by turning on lights (even briefly) can significantly disrupt the circadian pattern and disturb breeding. It is not uncommon that a lighting timer fails or that lights are accidentally left on at night, which may have a significant adverse effect on a colony's production.

As discussed elsewhere in this chapter, optimising the animal's environment is essential for their well being and for successful reproduction (Sherwin 2007). This includes both the quality of the animal's immediate enclosure and the wider macro environmental conditions, such as warmth, light, ventilation, and sound. Small rodents can hear ultrasound frequency ranges, as well as sounds audible to humans, so there may be disturbances occurring that are not immediately obvious to staff. Rodents recognise their human carers, and sudden changes in staff members (e.g., holiday periods) can affect breeding in sensitive animals (Sorge et al. 2014). Some technicians have better success than others with breeding colonies, so proper training, assessment of competence, and review of progress are important in ensuring a harmonious team.

The actual temperature (not just the heater's 'set point') should be checked, as variations in temperature can have a significant effect on breeding performance. A minimum/maximum thermometer should be used to record temperatures close to animal level and checked daily. For example, although guinea pigs will live at quite low ambient temperatures (and can even be kept out of doors in the UK), breeding and growth will be markedly reduced at temperatures lower than 15°C to 16°C.

Aged rodent colonies are less productive. (See also the section in this chapter regarding replacement of breeding animals.) A common cause of production decline is a failure to replace sufficient of the breeding animals, with the result that the colony ages, leading to reduced fecundity and rearing success. The breeding cycle and 'breeding lifetime' of small rodents is relatively short, so this problem can occur easily unless there is a consistently implemented system of replacement.

Investigating and Preventing Preweaning Losses

What is normal? Generally, small rodents rear their litters successfully, so preweaning losses are low. For example, typical preweaning mortality rates should be less than 5% for rats and mice and less

VetBooks.ir

than 15% for guinea pigs. Older mothers (see previous mention) may have higher loss rates. It is important to note whether the preweaning losses apply to one or two females/pairs or whether there is a more widespread issue in the colony.

Once a litter is noted, it should be recorded on the cage label or a mark placed on the cage; this provides a record for the breeder and also highlights that the cage should be subject to minimal disturbance. There are conflicting opinions concerning the age at which litters are counted; some prefer not to attempt counting until at least Day 5 after birth so as not to disturb the nest and to allow time for maternal bonding. However, counting and recording the number of pups born is part of good colony management, particularly when breeding a new line or species. Once it is clear that most of the pups born are still present at weaning, there is little need to count newborn pups routinely. Disturbing the litter may distress the mother and cause her to reject or even kill the pups.

If the pups do need to be handled, it is recommended that gloves are worn to prevent transfer of human scent onto the pups' skin and that hands are rubbed into the cage bedding to transfer the home scent onto the gloves. Pups should be returned to the nest as quickly as possible. The dams of some species, such as hamsters and rats, can be quite defensive of their litters, so removing the female from the cage before handling the pups may be advisable.

Strong maternal behaviour is essential for the well-being of pups, and this varies between individuals, strains, and parity. First-time mothers are more likely not to feed their pups and may cannibalise altricial pups at an early stage. As mentioned previously, minimal interference and providing a quiet environment with sufficient nesting material can promote good maternal behaviour. If the dam fails to rear two successive litters, then it is advisable to cull her. Breeding female replacements should be chosen from mothers with excellent maternal behaviours and rear larger litters. It is usual to choose replacement breeders from the third or fourth litters and avoid using animals from first or very late litters.

Neonatal pups of altricial species should lie together in the nest or shelter and not outside the nest. Absence of a nest (or poorly constructed nest) may indicate that the animal's environment is suboptimal and/or that the female is stressed or unwell and so would indicate investigation of the underlying cause. Disturbances, such as excessive noise, vibrations, or smell of predators may cause distress to the female. It is recommended that the home cage should not be changed for at least 7 days after a litter is born and that when the cage is cleaned, the entire nest is transferred to the new cage.

Appropriate parental behaviours (particularly maternal behaviours) are important for success in rearing young. Small rodents, such as mice, rats, and gerbils, build a secure nest during pregnancy, in which the young will be born and reared. When husbandry conditions are suboptimal, this may not occur and pups may be born outside the nest, with poor consequences for their survival. The quality of the nest can be assessed and scored (Deacon 2006); if poor nest building occurs more than very occasionally, the cause should be investigated as it may indicate poor environmental or husbandry conditions (Fig. 41.11).

It is relatively easy to determine whether or not the pups of small rodents are feeding by looking for the presence of a 'milk spot' in the stomach, which can be seen through the thin abdominal wall. Pups that are feeding normally will be pink, rounded out, and well hydrated, with translucent, clean skin. Lack of a milk spot may indicate lactation failure in the female. The dam will usually rapidly retrieve pups from outside the nest, and finding pups elsewhere in the cage may be a sign of poor maternal behaviour, disturbance of the cage, or illness in the pups.

• **Fig. 41.11** Mouse nest score 5 – full dome, with full height walls that enclose the nest.

If there is a problem with the birth mother, it may be possible to crossfoster neonatal pups onto dams with litters of similar age. Pups to be fostered should preferably be about a day older than the recipient's litter, and usually 2 to 3 pups can be added to an existing litter of up to 6 pups. Before adding the fostered pups, they should be gently rolled in the nest of the recipient and rubbed with one of the dam's own pups to help transfer scent.

Pups within the same litter normally grow at a similar rate; obvious disparity in size or body shape may be caused by congenital problems or competition for food. Once their eyes open, pups may be much more active and explore around the cage but should be found together in the nest when resting or feeding. Any pups that are obviously thin or smaller than their litter mates should be examined for abnormalities such as malocclusion teeth.

Placing a small amount of fresh soaked diet or gel on the cage floor each day may assist weaker pups to feed effectively. Commercially available jelly for human consumption can be used (it is preferable if it is made up to twice the recommended strength and fed 1–2 g per mouse pair or 5–10 g per rat). Ensure that any wet feeds are fed freshly every day, and any residue is removed in order to prevent spoilage. A small amount of seeds or wheat germ can also be added to the cage as a supplement – small rodents will forage for this foodstuff. These foods should be of food quality and appropriately stored to avoid possible microbial contamination.

Dystocia

Rats and Mice

Dystocia in most species of small rodents is uncommon and most litter without problems. If the dam is noted to be pregnant but passes the expected date of parturition without producing any pups, then she should be examined. Sometimes the abdomen takes on a 'triangular' appearance, with the base of the triangle close to the pelvis. The abdomen may be gently palpated for presence of retained pups. The small size of the vagina precludes digital manipulation of pups; thus Caesarean surgery is the only option if oxytocin (1 IU, given subcutaneously) is ineffective.

VetBooks.ir

Guinea Pigs

Dystocia is more common in guinea pigs due to the relatively large and well-developed pups. It may also result from metabolic disease (such as pregnancy toxaemia) or anatomical problems (such as a fused pubic symphysis). If the female is seen to strain for 20 to 30 minutes continuously or for a couple of hours intermittently without producing young, then dystocia should be suspected. The vagina can be carefully palpated with a finger to assess the degree of separation of the pubic symphysis, especially for primiparous sows. The bones should be separated by at least 10 mm in order to allow the pups to pass unimpeded. Provided that there is adequate separation, the sow can be given 1 to 2 IU of oxytocin subcutaneously, and allowed another 15 to 20 minutes for parturition to restart. If the pubic symphysis is fused or births do not follow the oxytocin, then a Caesarean surgery is indicated. More detail on specific issues with dystocia is provided in Chapter 40.

Laboratory Investigations of Breeding Failure

Laboratory investigations should be carried out if there are more than just occasional 'background' losses or breeding failure. The history and clinical signs will be helpful in suggesting appropriate tests; these would usually include postmortem examination of freshly dead or euthanised pups or adults and histopathological examination.

If an infectious cause is suspected, then blood samples can be taken and submitted for serology at least 2 weeks after the failure to litter, as this allows a suitable interval for seroconversion. Serology is helpful when an infectious (viral) cause is suspected; seroconversion and elevation of serum antibody levels occur approximately 14 days postinfection and may persist for several months, also enabling a retrospective diagnosis to be made. Small blood samples (20–50 µl) can be taken from the tail or saphenous vein of small rodents and blotted onto a laboratory card for serology. Alternatively, small blood samples may be collected and submitted in capillary or Eppendorf tubes.

Many laboratories can also carry out PCR testing on faecal samples or tissues to look for the pathogens themselves, which provides more immediate information in case of a suspected disease outbreak. Some viruses, e.g., parvovirus, are intermittently shed in faeces, so submission of tissues, such as mesenteric lymph nodes, may provide more accurate information about infection.

Fresh tissues may be swabbed for bacteriology, placed in formalin for histopathology, or frozen for molecular diagnostics, such as PCR testing. Animals that are found dead will usually be autolysed and unsuitable for histopathology, but PCR sampling is still possible, provided that care is taken to prevent contamination of the samples.

Suggested screening panel for reproductive problems in mice includes: mouse hepatitis virus; mouse cytomegalovirus; sendai virus; rotavirus; *Mycoplasma pulmonis; Citrobacter freundii;* cilia-associated respiratory (CAR) bacillus; *Pasteurella pneumotropica; Salmonella spp; Streptococcus pneumonia;* and *Clostridium piliforme (Tyzzers disease)*.

Suggested screening panel for reproductive problems in rats includes: parvoviruses (Toolan's H1, Kilham rat virus); sendai virus; rotavirus; *Mycoplasma pulmonis;* cilia-associated respiratory (CAR) bacillus; *Salmonella; Streptococcus pneumonia; Streptobacillus moniliformis;* and *Clostridium piliforme* (Tyzzer's disease).

Suggested screening panel for reproductive problems in hamsters and gerbils includes: LCMV; mouse parvovirus; and bacterial culture, including *Clostridium piliforme* (Tyzzer's disease).

Suggested screening panel for reproductive problems in guinea pigs includes: guinea pig cytomegalovirus; and bacteria, including *Clostridium piliforme* (Tyzzer's disease).

Additional information on specific diseases is provided in Chapter 40.

Maximising Production for Commercial Breeding

Forward Planning

A commercial breeding programme needs to produce the maximum amount of healthy stock from the minimum number of animals, thus saving space, labour, and supplies.

It is crucial that in a commercial environment, animals are produced that you actually need both for sale purpose and future breeding stock. Lacking the correct number means lost sales that cannot be retrieved at a later date. Breeding too many animals is a waste of animal lives, which is ethically unjustifiable, and has a commercial effect with ongoing animal husbandry costs.

A commercial breeder will have a core business and, consequently, a base figure of how many animals he or she needs to produce on a weekly basis, to satisfy customer requirements and put enough aside to grow as future breeding stock.

To illustrate how this works, imagine that you have a breeding colony of 200 gerbils. Assuming an economic breeding life of 8 months for the adult trios, approximately 12.5% of the colony, or 24 adults, should be replaced every month. When the gerbils are being bred as trios, this means saving 16 females and 8 males to replace those that retire each month. It is important to save future breeders every week and consistently through the year; otherwise, a decline in production may occur as the colony ages or after a sudden influx of new breeders. At busy times, it is tempting to sell all the animals produced, but this short-term action can have significant effects on later productivity.

In addition to maintaining the productive base colony, there are always trends of highs and lows in numbers sold throughout the year, such as the marked increase in guinea pig sales throughout the summer months, and a spike in small rodent sales in September as people return from their holidays and children go back to school. The period immediately after Christmas has recently become a busy time, as pet outlets prefer not to sell pets as Christmas presents, so sales in December are low.

Planning the number of animals that are required throughout the year needs forethought, similar to any farming enterprise. Before more animals can be added to the colony, there has to be a small increase in production to cover the additional future breeding stock that will be required. Assuming that the production level per animal remains constant, an increase in colony size of 20% will require 20% more breeding females, plus the corresponding increase in males depending on the particular breeding system that is used (e.g., trios, pairs, harem).

The first action is to calculate the date or period of time in which the increased production is required and then to work backwards, taking into account the biological characteristics of the species in terms of gestation and growth. To produce most small rodents, such as hamsters or rats, the time from mating until sale of the youngster comprises approximately 3 weeks' gestation, plus 3 weeks preweaning, plus 1 to 2 weeks before they are of sufficient size for sale, giving a total lead time of 7 to 8 weeks from mating to sale.

The time taken to produce adult breeders then needs to be considered, as these need to mature to the correct age for breeding

VetBooks.ir

before they can be included in the colony and begin mating – at approximately 8 to 12 weeks of age. The lead time between addition of new breeders to a colony and sale of the first pups is at least 19 weeks in advance. Where guinea pigs are concerned (gestation of 8–10 weeks), the lead-in period is nearer 6 months. It is therefore essential that plans are discussed and implemented well in advance so that production and sales of animals are well matched and under- or overbreeding are avoided for both economic and ethical reasons.

The Production Management Team

Successful rodent breeding on a commercial scale depends on the diligent input of a team, including the unit manager, technicians, nutritionist, and veterinary surgeon.

The animal carer/technician has a very significant effect on the success of breeding, and sudden changes in care staff can have an effect on breeding. The technician is seeing the individual animal and the colony every day, checking food and water intake, checking individual animals and their health status, recording all breeding activity on record cards, and recording daily events that can be quickly checked to see if anything about the colony could potentially be causing concern.

It is important that technicians are well trained in the basic biology and husbandry of the particular species with which they are working and also in identifying signs that may indicate ill health or distress in the animals of all ages. Courses run by the Institute of Animal Technology and some agricultural colleges provide helpful education and training and can lead to professional qualifications in the field.

Similarly, it is important to have veterinary input from a professional with a special interest or postgraduate qualifications in rodent medicine. As for farm animal 'herd health', this veterinary involvement should preferably take the form of strategic visits to review and advise on colony health and management rather than waiting until there is a problem or just seeing individual animals for clinical issues. Routine health screening of the colony is recommended in order to identify any organisms that may cause disease or production problems. It is essential at least to screen the colony for zoonotic organisms in order to ensure that the breeding animals do not present any risk to the unit's technicians and that the animals produced are fit and safe for sale to the public.

As for diagnostic workup, sampling need not require submitting whole animal carcasses to the laboratory as most can detect antibody in minimal volumes of blood using dried blood spots, and many organisms can be detected in faeces. A representative population of the colony should be tested, including older breeding animals and some weaned youngsters. This will ensure that both endemic and new organisms can be detected. The potential implications of any organism's presence can then be discussed with the attending veterinarian. Once an organism is known to be endemic in a population, it may not be necessary to continue testing for it in order to save costs if the assumption is that it is still present, and the decision is taken that it is not necessary to try and eradicate it.

Conclusion

Many factors need to be taken into consideration to successfully breed any species of rodent. Each species has their idiosyncrasies, but there are many general principles that apply to all of them. There is much experience in the breeding of laboratory rodents, and it is important to share the same aims of promoting excellent health and welfare for mutual benefit.

42 Elephants

ANIL PUSHPAKUMARA, CHATCHOTE THITARAM AND JANINE L. BROWN

Elephants are the largest extant land mammal. They inhabit large areas of Asia and Africa and have maintained a tenuous relationship with man for millennia (Lair 1997). Important culturally and economically, elephants have been ubiquitously used as 'beasts of burden' and played important roles in war, agricultural colonisation, economic development, religious ceremonies, tourism, entertainment, and education (Sukumar 1989). Elephants also are important ambassadors for global conservation efforts; they are keystone species with a significant effect on ecosystems, umbrella species that indirectly protect other species in the same habitats, and flagship species that raise awareness for the support of broader conservation efforts. Once common throughout their native ranges, elephant numbers were severely depleted in the 20th century and continue to be threatened by poaching, human–elephant conflict, and habitat destruction (Lee & Graham 2006, Fernando et al. 2008, Stiles 2009, Wasser et al. 2009, Jackson 2013).

There are two genera of living elephants (Order *Proboscidea,* Family *Elephantidae*): Asian (*Elephas*) and African (*Loxodonta*). The African elephant (*Loxodonta africana*) is categorised as vulnerable by the International Union for Conservation of Nature (IUCN) and listed as two subspecies: savanna (*L. a. africana*) and forest (*L. a. cyclotis*). There are approximately 500,000 elephants free-ranging in 37 countries in Africa, about 25% of which are the forest subspecies. The Convention on International Trade in Endangered Species (CITES) has an agreement between governments to ensure that international trade in wild animal or plant specimens does not threaten their survival. In 1990 after nearly a decade in which African elephant numbers declined by almost 50%, the species was moved to Appendix I of CITES, which bans all international trade in ivory and ivory products. In 1997 some recovering populations (Namibia, South Africa, Zimbabwe, and Botswana) were moved to Appendix II, with strict limitations on trade in ivory. However, continued poaching and illegal trafficking in elephant products continue to decimate wild populations, particularly the forest species.

There are three subspecies of Asian elephant: Indian (*E. maximus indicus*), Sri Lankan (*E. m. maximus*), and Sumatran (*E. m. sumatranus*), with mitochondrial and microsatellite evidence that the Borneo elephant is a fourth subspecies (*E. m. borneensis*) (Fernando et al. 2003). Asian elephants are more at risk of extinction and listed as endangered by the IUCN, with less than 50,000 remaining in 13 range states, most (~60%) being in India. Compared with African elephants, the Asian elephant (*Elephas maximus*) has been listed in Appendix I since the treaty was enacted in 1975. However, Asian elephants are being killed not only for their ivory but for other body parts: skin, trunk, feet, or penis, all of which are in demand in the Chinese market.

If left undisturbed, both species breed well in the wild, but there is no guarantee that habitat protection or limiting human interference will occur fast enough to facilitate human–elephant coexistence in the long term. Breeding of elephants in captivity has been touted as a way to maintain valuable populations, but results have been inconsistent, and many are not self-sustaining. For the foreseeable future, species survival is likely to depend on effective conservation management, potentially supported by successful breeding *ex situ.*

Female Reproduction

Anatomy of the Reproductive Organs

The female elephant has the longest reproductive tract of any land mammal, approximately 3 m from vulva to ovary (Hildebrandt et al. 2000, 2003, 2006, 2011, 2012a) (Fig. 42.1); it has a number of unusual features: 1) a vestibule that averages 1.3 m in length and opens ventrally between the hind legs rather than below the anus; 2) a permanent hymenal membrane in nulliparous females that ruptures only at parturition; 3) a small vaginal os (4 mm x 2 mm in diameter); and 4) two blind pouches of similar size on either side of the vaginal opening (Fig. 42.2). The vagina can be up to 50 cm in length, with longitudinal folds. Mucus is produced during oestrus, and the mixture of expelled urine and mucus contains pheromones that attract bulls to oestrous females. The cervix is about 10 cm long and has a prominent cone-shaped opening. The uterus is bicornuate, with a short body (< 10 cm) and long uterine horns (> 60 cm). Implantation occurs in one uterine horn, although on the rare occasion when twins are conceived, fetuses are present in each horn. The oviducts are approximately 10 cm long, and the paired ovaries that are located caudal to the kidneys are proportionally small in comparison with body size (5.5–6.5 cm).

Puberty, Fertility, and Senescence

Females reach puberty between 10 to 14 years of age in the wild (Sukumar 1989, 2003) but can mature earlier in captivity (Glaeser et al. 2012), perhaps because of improved nutrition. It is not uncommon for Asian elephants to begin cyclical ovarian activity as young as 5 years of age, with the first pubertal rise in progestagens being quantitatively and qualitatively similar to subsequent cycles (Glaeser et al. 2012) (Fig. 42.3). It has been reported that wild African

VetBooks.ir

elephants can reproduce into their 60s, but for most, fertility ceases by the 50s (Lee et al. 2016). Similar large scale demographic data are limited for Asian elephants, although Sukumar (1989) has reported that wild Asian cows over 50 years of age also are capable of reproducing. A recent study conducted in the Udawalawe National Park in Sri Lanka, which has a relatively undisturbed population of over 1000 wild elephants, found the age at first calving to be about 13 years, with females reproducing until the age of 60 years (de Silva et al. 2013). At the Pinnawala Elephant Orphanage in Sri Lanka, females conceiving by 7.5 years of age are not unusual (Brown 2014). The youngest Asian elephant cow to give birth in the Myanmar Timber Enterprise was 5.3 years, and the oldest was 65 years (Hayward et al. 2014). For zoo Asian elephants in Europe, the earliest age at first reproduction was 5 years, with the mean age being 11 to 15 years (range 5–30 years), and the mean interbirth interval was 5.5 years (range 1.0–11.7 years). In US zoos, the youngest elephants to give birth were 5 and 10 years old and the oldest 41 and 32 years for Asian and African elephants, respectively. In wild African elephants, higher rates of reproduction have been observed in daughters with simultaneously reproductively active mothers, thus suggesting advantages from maternal (and grand maternal) coexistence (Lee et al. 2016). In Myanmar timber elephants, grandmothers exert a positive effect on grand calf survival, especially among young mothers, and the

VetBooks.ir

physical presence of mothers increased rates of reproduction in their daughters (Lahdenperä et al. 2014).

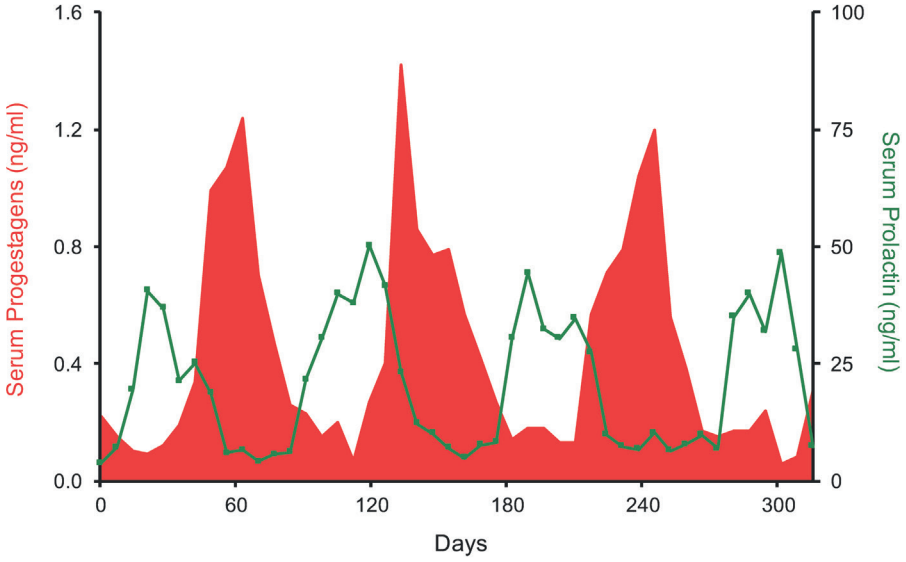
Maximum lifespan of wild African elephant females has been estimated to be 74 years, based on tooth wear (Lee et al. 2012), and approximately 80 years for Asian elephants (Lahdenperä et al. 2014). Evidence that elephants experience a true 'menopause' as in humans, with the cessation of ovarian cyclicity in midlife, is mixed. A large study of survival and reproduction of working elephants in Myanmar (> 1000 individuals) found reductions in fertility paralleled declines in survivor rate (Lahdenperä et al. 2014). By contrast, Lee et al (2016) reported a mean period of postfertile viability of 16 years in Amboseli African elephant females, which was based on an average fertility decline at 49 years and cohort longevity of 65 years. However less than 30% of that population survived after the period of fertility decline, suggesting only a small percentage exhibit this phenomenon. In that study, African elephant cows that commenced reproduction early had higher overall reproductive rates compared with those that first conceived at an older age. The early onset of reproduction did not affect survival nor did their calves experience reduced longevity (Lee et al. 2016). This is in contrast to the results from an extensive evaluation of semicaptive timber elephants in Myanmar (n = 8006), where an association between reproduction and adult survival was observed to be positive in early life but negative in later life (Robinson et al. 2012). It is not known if these contradictory data represent species differences, as evaluations of longevity, reproduction, and postfertile survival have only been conducted in a few populations.

The Ovarian Cycle

Elephants are polyoestrous and exhibit the longest spontaneous ovarian cycle of any mammal: 13 to 17 weeks in duration, with a 4- to 7-week follicular phase, and an 8- to 10-week luteal phase (Brown 2014). Based on hormonal and ultrasound assessments (Lueders et al. 2010, 2011, Brown 2014), a model of the ovarian cycle is presented in Fig. 42.4. Unlike most mammals, the major steroid produced by the corpus luteum (CL) is not progesterone, but 5α-reduced pregnanes (e.g., 5α-pregnane-3, 20-dione, 5α-pregnane-3-ol-20 one, 17α-hydroxyprogesterone), herein referred to as 'progestagens'. Oestradiol concentrations are low in the circulation due to rapid conjugation and urinary excretion (Czekala et al. 2003), and thus its measurement is of limited use for characterising follicular activity. Although elephants are easily trained for blood collection to track ovarian cycles, some hormones can be assessed noninvasively, e.g., progestagens in saliva, faeces and urine, and oestrogen-conjugates in urine (Wasser et al. 1996, Czekala et al. 2003).

A distinguishing feature of the elephant ovarian cycle is the 'double LH surge' that occurs in both species. Two precisely timed luteinising hormone (LH) surges occur 3 weeks (18–22 days) apart during the follicular phase of the cycle (see Fig. 42.4). These are referred to as LH1 (anovulatory) and LH2 (ovulatory) (Kapustin et al. 1996, Brown et al. 1999). The surges are quantitatively and qualitatively similar, although they are generally more distinct in Asian elephants. During the first wave, multiple follicles develop, but none ovulate (Hermes et al. 2000); instead, they luteinise and form accessory CLs (acCL) (Lueders et al. 2010). During the second wave, a new group of follicles develops, but only one becomes dominant, ovulates, and forms a single ovulatory CL (ovCL). All CLs persist throughout the follicular phase, with some of the larger ones remaining in subsequent luteal periods (Lueders et al. 2010). Formation of multiple CLs, in addition to the ovulatory CL, may be a mechanism to ensure there is sufficient luteal capacity for sustaining a long gestation should conception occur (Lueders et al. 2010).

As summarised by Brown (2014), inhibin secretion follows a distinct pattern in elephants (Brown et al. 1991, Kaewmanee et al. 2011a, Lueders et al. 2011, Yamamoto et al. 2012a). In other species, both small and large oestrogenic follicles can be significant sources of inhibin. However, in the elephant, circulating inhibin does not increase until after follicle luteinisation post LH1, which is about 9 days before LH2, suggesting it is the cells of luteinised follicles and acCLs that are the main source of inhibin. Inhibin also is increased during the luteal phase; immunohistochemical staining has localised inhibin subunits to the lutein cells of CLs, similar to that in primates (Yamoto et al. 1991, 1992). Follicle-stimulating



• **Fig. 42.4** Model of the elephant ovarian cycle, showing relationships between the secretion of oestradiol, progestagens, LH, and FSH, and development of follicles and corpora lutea (CL), both ovulatory (ovCL) and accessory (acCL). VetBooks.ir

hormone (FSH) secretion is inversely related to inhibin throughout the cycle in both elephant species (Brown et al. 1991, Brown et al. 1999, Kaewmanee et al. 2011a) (see Fig. 42.4). It is highest at the end of the luteal phase and through the first follicular wave when inhibin is low, then decreases to low concentrations as inhibin rises before LH2. The FSH pattern in elephants is more protracted, but similar to that of the horse, in which there are high concentrations at the end of the luteal phase that decline progressively towards ovulation (Brown et al. 1991, Brown et al. 1999, Kaewmanee et al. 2011a). Prolonged FSH stimulation may be necessary to induce the two successive follicular waves observed in the elephant, a feature that is absent in other studied mammals. In the face of declining FSH the transition of one follicle from an FSH-dependent to an independent state is likely to be required for dominant follicle selection, as described in other species.

Prolactin is increased during the follicular phase in African elephants and is believed to be important for follicular development (Yamamoto et al. 2010, Dow & Brown 2012), similar to that described for other species (Freeman et al. 2000, Frasor & Gibari 2003) (Fig. 42.5). By contrast, no such prolactin pattern is observed during the oestrous cycle in Asian elephants (Brown et al. 2004a). As discussed later, this species difference may explain why ovarian cycle aberrations related to abnormal prolactin secretion are common in African, but not Asian, elephants (Brown 2014). Recently, cortisol has been shown to exhibit a distinct pattern in both species, with concentrations being higher during the follicular phase (Fanson et al. 2014), the significance of which is unknown.

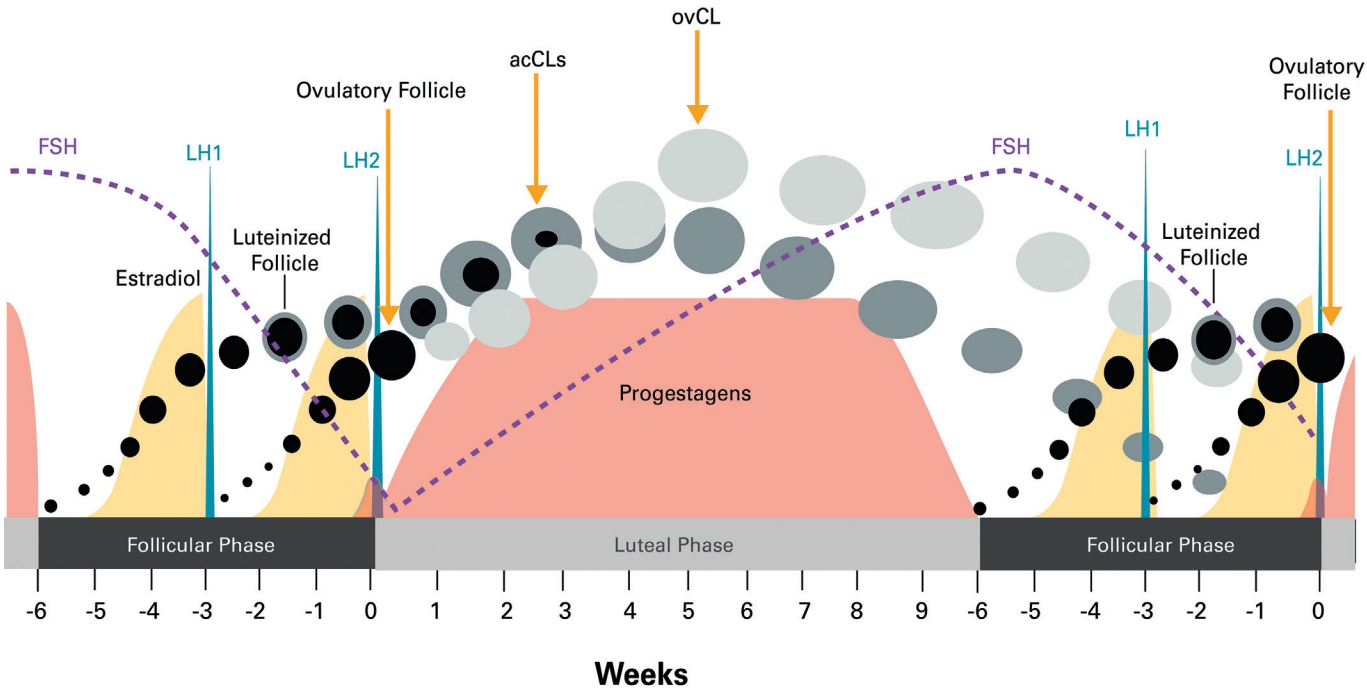
Both species advertise impending fertility through species-specific chemical signals. Female Asian elephants excrete a urinary signal, (*Z*)-7-dodecenyl acetate (*Z*7–12:Ac) that stimulates male breeding behaviour, the concentrations of which increase during the follicular phase and peak just before ovulation (Rasmussen et al. 1997, Rasmussen 2001). African elephants do not produce *Z*7-12:Ac, but excrete frontalin, exobrevicomin, endobrevicomin, (E,E)-alpha-farnesene, and (E)-beta-farnesene in urine, leading up to and during oestrus (Goodwin et al. 2006). Considering the long distances bulls travel in search of oestrous females in the wild, a prolonged pattern of pheromonal signalling would be a beneficial strategy for species survival.

Breeding and Conception

Copulation takes 2 to 3 minutes and may be repeated 4 to 6 hours later over a few days to up to a month. During copulation, the glans of the sigmoid-shaped penis is positioned at the end of the cranial vestibule (canal urogenital) and does not penetrate the vagina. The vaginal os is almost completely obstructed by an intact hymen (2 x 4 mm in diameter) in nulliparous females. The hymenal membrane remains intact during mating, rupturing only in conjunction with expulsion of the fetus. In general, semen is ejaculated at high pressure into the vagina through the vaginal os, explaining the observation of retrograde semen loss after mating and also the need for multiple matings by the male for successful impregnation. Elephants are one of the few species that have a ciliated endometrium (Mariappa 1986), presumably to facilitate sperm transport. After 8 weeks of gestation, a thick vaginal mucus plug is formed that provides a protective barrier against bacteria entering the uterus.

Pregnancy

Elephants have the longest gestation period of any mammal, lasting 20 to 23 months on average and typically giving birth to a single offspring; the birth weights of calves are 90 to 120 kg, with males generally being heavier. Lactational anoestrus lasts for 8 to 12 months, and the interbirth interval ranges between 4 and 6 years, depending on food resource availability. Calves nurse for up to 5 years, so females can be pregnant and lactating at the same time. Elephants are not obligatory seasonal breeders; however, conception rates often are higher during or shortly after peak rainfall in



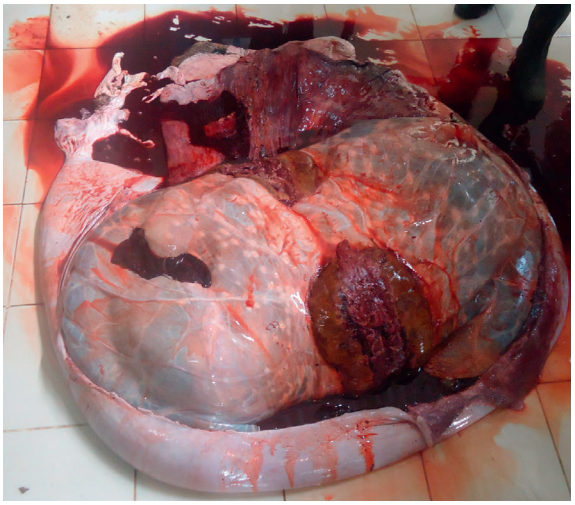
• **Fig. 42.5** Longitudinal profiles showing the relationship between progestagen and prolactin secretion across three reproductive cycles in an African elephant cow.

VetBooks.ir

seasonal regions and can be negatively affected by drought (Sukumar 2003, Wittemyer et al. 2007). Elephants have reproduced into their 50s, although conception rates decline with age and the interbirth intervals lengthen.

Placentation and Implantation

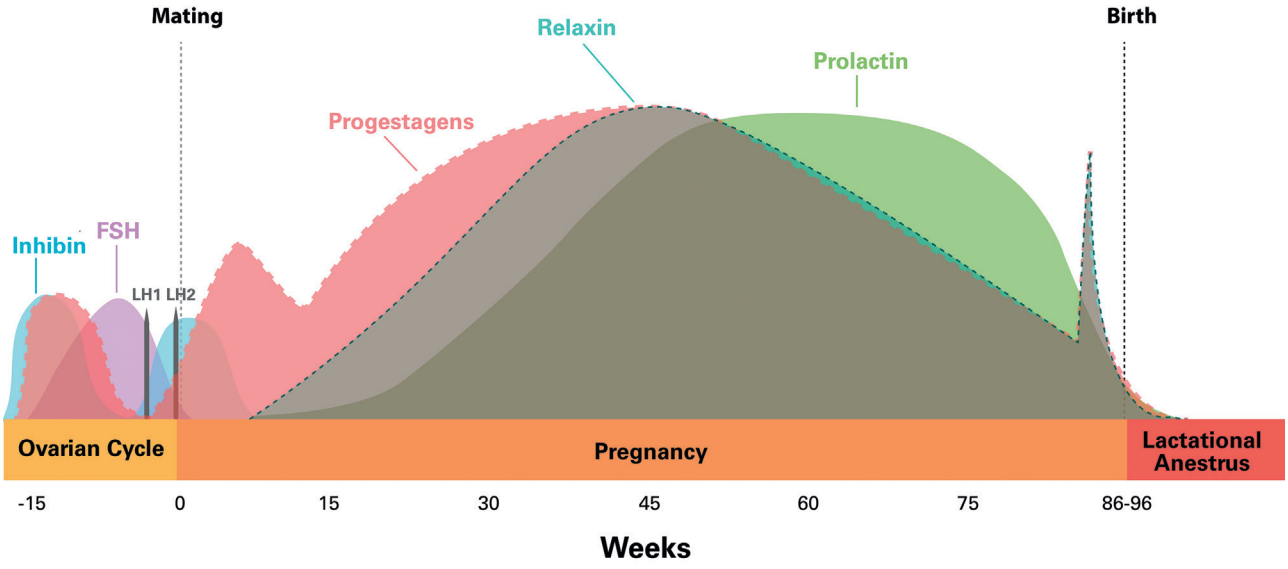
Implantation takes place in one of the uterine horns (approximately 50–70 cm in length) or in the 'pseudouterine body', as determined by postmortem analyses (Laws 1967) and ultrasonographic examinations (Hildebrandt 2006). Implantation is central and superficial, with a mesometrial orientation of the yolk sac and antimesometrial orientation of the embryo; it occurs during the second to third month of gestation (Drews et al. 2008). The placenta is zonarychorioallantoic, endotheliochorial, with some haemochorial regions (Allen 2006, Hildebrandt 2006) (Fig. 42.6). Longitudinal transrectal ultrasound has identified an initial period of comparatively slow embryonic development in both elephant species (Hildebrandt 2006, Drews et al. 2008). The embryonic vesicle is visible at approximately 8 weeks postconception, which is smaller (~ 10 mm) than that of other species at that stage (cattle, 40 mm; sheep, 70 mm; horse, 40 mm). Likewise, the time of implantation is estimated to be 20 days or less in human, dog, and sheep but 50 days or more in the elephant. The fetus then doubles in size between the fourth and fifth month and at 8 months drops into the abdominal cavity, so it is no longer is visible by transrectal ultrasound. Organogenesis is completed within about 110 to 120 days, when the end of the embryonic period is reached. Permanent uterine scars are formed by the invasive attachment of the placenta, which allows quantifying the number of pregnancies by ultrasound examination or at necropsy.



• **Fig. 42.6** Crosssection of the uterus of a full-term Asian elephant. Note the zonary type placenta.

Endocrinology of Pregnancy

A model of the hormonal relationships during gestation is presented in Fig. 42.7. Persistent acCLs are formed during successive oestrous cycles (Lueders et al. 2010, 2011), but no additional CLs are produced during gestation (Lueders et al. 2012). In both Asian and African elephants, acCLs and the ovCL begin to regress about 5 to 6 weeks after conception but then rebound and grow significantly larger than those in a nonpregnant luteal phase (Lueders et al. 2012), in conjunction with a marked secondary rise in progestagen concentrations (Meyer et al. 2004, Lueders et al. 2012) (see Figs 42.3 and 42.7). Based on histology and analysis of luteal progestagens, the CL of pregnancy is most steroidogenically active between 3 and 15 months of gestation. Inhibin is also elevated during the first 8 weeks, as in a normal luteal phase (Yamamoto et al. 2012a). However, in contrast to progestagens, which rebound to even higher concentrations, inhibin declines and remains at basal levels throughout gestation (see Fig. 42.7), suggesting that a role for inhibin in pregnancy is unlikely. After 5 to 7 months, both relaxin and prolactin markedly increase (Meyer et al. 2004, Yamamoto et al. 2012b) (see Fig. 42.7). Prolactin remains elevated throughout, whereas the relaxin profile is biphasic and concentrations start to decline after midgestation, with a secondary surge at parturition (Meyer et al. 2004). Pregnancy is typically confirmed through the longitudinal identification of serum, urine or faecal



• **Fig. 42.7** Model of the relationships between the secretion of progestagens, LH, FSH, prolactin, relaxin, and inhibin during gestation and a prior oestrous cycle in the female elephant. (Adapted from Meyer et al. 2004, Yamamoto et al. 2012a, and Lueders et al. 2012.)

progestagens, and serum prolactin (prolactin cannot be assessed noninvasively in elephants) after 7 months of gestation. To date, there is no evidence of chorionic gonadotropin-like activity in serum or placental extracts.

Gestational hormone patterns differ somewhat between the Asian and African species. For example, progestagen concentrations are higher in African elephants during the first half of gestation but then decline to levels lower than those observed in Asian elephants, which exhibit a more biphasic pattern (Meyer et al. 2004). There is also a fetal gender effect on progestagen concentration patterns but only in Asian elephants, with females carrying male calves producing more progestagens than those carrying females (Meyer et al. 2004). Because of the internal gonads, it is not possible to sex an elephant fetus by ultrasound. However, sex determination is possible after about a year of gestation, with near 100% accuracy in Asian elephants by measuring circulating maternal testosterone; it is higher in females carrying a male calf (Duer et al. 2002, Brown et al. 2004b) (Fig. 42.8). This fetal-sexing technique is less accurate in African elephants. Parturition can be predicted on the basis of a rapid fall in progestagens about 2 to 5 days before birth (Brown & Lehnhardt 1995, Carden et al. 1998). Surges in cortisol often are observed in the last 2 weeks of gestation, with a significant surge at parturition, suggesting a role in the initiation of parturition (Meyer et al. 2004).

Parturition and Lactational Anoestrus

A review of elephant obstetrics has been published by Hermes et al. (2008). A week or more before parturition the female begins showing signs of discomfort, and in many females, passage of a vaginal mucus plug or mucoid discharge occurs in the days leading up to parturition. Once labour begins, the female becomes restless and changes positions often. Abdominal contractions increase in frequency but may not always be visually apparent. The cervical canal dilates due to pressure from the allantoic sac, followed by partial entry of the fetal legs into the vagina. A large bulge appears under the tail, initially consisting of the fluid-containing amniotic sac, but eventually the calf crests the caudal rim of the pelvis and slips out between the cow's hind legs; the second stage of parturition is relatively short, being 2 to 4 hours. The majority of calves are expelled in posterior longitudinal presentation. Newborn Asian elephant calves weigh 90 to 120 kg and are able to stand on their own within minutes of birth. The mother and other usually related females help guide the calf to the mammary glands almost immediately upon standing. All mothering or nonmaternal infant care is performed by any group member other than the mother in socially bonded groups of Asian and African elephant females; it is associated with better calf survival (Lee 1987, Lahdenperä et al. 2016). Milk composition varies throughout lactation, with fat and protein percentages increasing, and water and sugar percentages decreasing over the first year or two of a calf's life (McCullagh & Widdowson 1970, Parker et al. 2013).

The postpartum anestrous period generally lasts 12 to 24 months (e.g., Fig. 42.3). Retained fetal membranes, reduced milk production, death of a calf, or premature weaning can reduce the postpartum period to as little as 8 weeks (Brown 2000). The first luteal phase increase in progestagens after lactational anoestrus, when oestrous cycles resume, is similar to subsequent cycles (Glaeser et al. 2012) (see Fig. 42.3).

Male Reproduction

Anatomy of the Reproductive Organs

A schematic diagram of the bull elephant's reproductive tract is shown in Fig. 42.9. There are a number of anatomical differences between elephants and other terrestrial mammals (Hildebrandt et al. 1998, 2000b). The most notable are testes located intraabdominally and the absence of a pampiniform plexus. Thus spermatogenesis can take place at core body temperatures as opposed to being positioned outside the body in a scrotum to maintain a slightly lower temperature. The bull elephant also has no inguinal canal or cremaster muscle. The testes of bull elephants reach a maximum diameter of 15 to 23 cm and can weigh up to 3 kg each. They are located just behind and ventral to the kidneys; in a newborn calf, they are about 2 cm in diameter.

Spermatozoa produced in the seminiferous tubules travel to the epididymis through a rete testis system. In comparison to scrotal mammals, the elephant epididymis is not tightly attached to the testis. It is, however, still a long (150–200 cm) convoluted duct with three anatomically distinct regions (head, isthmus, and tail) where the sperm mature. The vas deferens is relatively short and coiled, with a terminal portion that widens to form the ampulla. The two ampullae are located dorsal to the neck of the bladder, where the bladder joins the urethra; they serve as organs for sperm storage before ejaculation and can be visualised by transrectal

VetBooks.ir

ultrasonography. The appearance and dimensions of the ampullae are a good indicator of reproductive status, and thereby serve as an indirect indication of testicular activity in bulls. A fully dilated and 'snowy' echogenic appearance of the ampullae indicates the presence of highly concentrated spermatozoa. Functional activity of the ampullae depends on the degree of testicular development and, in particular, circulating androgen concentrations.

The paired, cigar-shaped seminal vesicles are the largest accessory sex glands; they are located lateral to the respective ampullae and dorsolateral to the bladder. The maximum diameter of the seminal vesicles is about 10 cm, and they can reach a length of up to 45 cm. Each gland consists of outer muscular (5–6 mm) and inner mucosal layers easily visualised by ultrasonography, with a single cavity that can contain up to 400 mL of seminal fluid. Seminal vesicle fluid contains no sperm and is, therefore, less echogenic than that of the ampullae. This fluid (50–200 mL) forms the bulk of normal ejaculates; it is high in fructose, which serves as the main source of energy for the spermatozoa. Reproductively quiescent and adolescent bulls have empty seminal vesicles as assessed by ultrasound.

The prostate is a paired gland located above the pelvic urethra, caudal to the attachment of the ampullae. Each half of the prostate consists of three lobes, with the two halves connected by a bridge of tissue. In Asian elephants the three lobes of the prostate fuse into a globe-shaped structure, whereas in the African elephant there are clearly distinguished lobes with separate, irregularly shaped internal cavities. The prostate is the last accessory gland to develop during puberty, doing so only after the testes have reached a diameter of 7.5 to 10 cm. Thus there is a marked difference in the size and complexity of the prostate gland between adolescent and adult males, and an undeveloped prostate gland is difficult to distinguish from the connective tissues surrounding the urethra. The prostate gland of an adult Asian elephant (~2 cm) is generally smaller than that in African elephants (~5 cm).

The paired bulbourethral glands reach 10 to 12 cm in diameter in adults and are located immediately caudal to the root of the penis alongside the dorsolateral aspect of the urethra close to the ischial arch. Bulbourethral gland secretions are sticky and clear and are thought to be involved in cleansing and balancing the pH in the bull's urethra and lubrication of the vulva before intromission.

The penis of an adult bull elephant can measure up to 1 m in length and 16 to 20 cm in diameter and may weigh over 27 kg. It does not have a true prepuce, is highly vascularised, and, when erect, has an S-shaped upwards curve. The erect penis can be moved independently of the pelvis due to the presence of large paired elevator muscles. Thus there is very little pelvic thrusting during mating to achieve ejaculation. In a few individuals, a bulge can be seen under the tail formed by the penis and associated muscles, which becomes more prominent during musth but is not related to fertility.

Puberty and Social Behaviour

The commencement of spermatogenic activity (puberty) in young bull elephants occurs between 6 and 10 years of age. In captivity, successful matings have occurred in males as young as 6 years of age, but in the wild, mating is related to dominance status, and so most do not start breeding until they are 25 years of age or older (Sukumar 2003). Onset of puberty is affected by factors such as environment (for example, wild or captive), nutrition, and growth rate. A generally held misconception is that bull elephants are solitary, when in fact in the wild they usually travel in small, bachelor groups in search of oestrous females. Both captive and wild bulls form social hierarchies that are influenced by age, size, and musth status.

Sperm Characteristics and Semen Cryopreservation

Sperm Morphology

Elephant spermatozoa, as in other mammals, consist of a head and flagellum (tail) that are joined together by a connecting piece. It contains the acrosome, a DNA-filled nucleus, some cytoskeletal structures, and a small amount of cytoplasm. The head is spatulate-shaped and slightly smaller in African than Asian elephants, with lengths and widths of 6 µm and 2.5 to 3 µm, and 7 to 8 µm and 4 to 4.5 µm, respectively (Johnson & Buss 1967, Jainudeen et al. 1971, Heath et al. 1983, Kitiyanant et al. 2000).

The acrosome is a Golgi-derived vesicular sac, located on the anterior portion of the sperm head, which covers the nucleus. It contains hydrolytic enzymes, including glycohydrolases and proteases, that are released after sperm–oocyte binding. The process of exocytosis of the acrosome, called the acrosome reaction, is the final step before fertilisation and facilitates oocyte penetration for successful fertilisation (Tulsiani et al. 1998, Abou-Haila & Tulsiani 2000). Therefore a functional and structurally intact acrosome is essential for successful sperm–oocyte binding and penetration during fertilisation (Tulsiani et al. 1998, Abou-Haila & Tulsiani 2000). In elephants, vasculation between the outer acrosomal membrane and the overlying plasma membrane, which causes leakage of acrosomal contents, is observed during the acrosome reaction (Kitiyanant et al. 2000). The presence of apical vesicles and typical membrane vesiculation in the apical portion of the sperm head but not in the equatorial segments is the earliest sign of the true acrosome reaction. By contrast the acrosome reaction induced in dead spermatozoa is characterised by a random breakdown of plasma and outer acrosomal membranes. Increased cyclic nucleotide levels are observed in acrosome-reacted elephant sperm (Kitiyanant et al. 2000). The acrosome reaction is irreversible, and any damage or premature reaction of the acrosome can result in the permanent loss of sperm function and fertilising capabilities (Senger 2003). Mammalian spermatozoa often undergo spontaneous acrosome reactions *in vitro* (Yoshida et al. 2008) in the presence of unfavourable extracellular conditions, such as dramatic changes in temperature, osmotic conditions, or suboptimal storage media (Medeiros et al. 2002).

The sperm flagellum consists of three segments: middle piece, principal piece, and end piece. The middle piece is tightly wrapped with a mitochondrial sheath, which provides energy to the flagellum for cellular propulsion and motility (Hammerstedt et al. 1990). The midpiece is 10.5 to 11.1 µm long in Asian and 8.6 µm long in African elephants (Jainudeen et al. 1971). The flagellum, including the principal and end pieces, is 40.5 µm and 47 µm in length in Asian and African elephants, respectively. Total sperm length is 59.6 to 64.0 µm in Asian elephants and 61.6 µm in African elephants (Johnson & Buss 1967, Jainudeen et al. 1971).

Semen Collection and Evaluation

Normal ejaculates range between 50 and 200 mL in volume and are white in colour, although yellow, orange, and brown colour variants can occur. The earliest study on semen characteristics in elephants was performed with samples obtained from the urogenital tract of an Asian elephant immediately after copulation (Landowski & Gill 1964). A later study described seminal characteristics of

VetBooks.ir

a male Asian bull collected passively after being stimulated by a female in oestrus (Jainudeen et al. 1971). Several investigators have used electroejaculation in standing bulls under sedation or lying lateral under general anaesthesia (Jones 1973, Howard et al. 1984, Schmidt 1993); the latter is particularly applicable to studies of wild bulls.

Today, manual rectal massage is the most common method used to collect sperm-rich samples from captive bulls. It was first described by Heath et al. (1983) and subsequently by Price et al. (1986), who used either an equine artificial vagina, or a condom made from a rectal palpation sleeve, respectively. As described later in this chapter, the quality of semen collected by transrectal massage is often highly variable within and among individuals (Schmitt & Hildebrandt 1998). Manual rectal massage, after combined chemical (xylazine hydrochloride and butorphanol) and physical restraint, was shown to be effective in collecting semen from an Asian bull elephant (Portas et al. 2007); this offers a potential method for collecting semen from captive bulls that are difficult to handle directly, similar to those in musth.

Musth

Mature bull elephants exhibit a condition known as 'musth', which is characterised by heightened sexual and aggressive behaviour, temporal gland secretions (TGS) and swelling, and urine dribbling (UD) (Jainudeen et al. 1971, 1972, Ganswindt et al. 2002, 2005, Brown et al. 2007) (Fig. 42.10). The word is derived from the Persian 'mast', which means 'intoxicated'. Musth in most bulls occurs on an annual cycle that is not tied to a specific season of the year. Most healthy adult bulls exhibit musth at a predictable time each year, although the timing can vary between individuals (Lincoln & Ratnasooriya 1996, Hall-Martin & Van der Walt 1984). The heightened aggressive behaviour can last for as little as a few days to several months, and most elephant handlers believe that musth is a sign of good health. Musth is related to age, nutrition, and social status, with older, more healthy and dominant bulls exhibiting stronger musth signals (Jainudeen et al. 1972, Niemuller & Liptrap 1991, Lincoln & Ratnasooriya 1996, Hall-Martin & Van der Walt 1984). One study showed that when a younger bull entered musth, the mature dominant bull experienced more days in musth, had higher testosterone concentrations, and an increased intensity of musth behaviour (Duer et al. 2016).

• **Fig. 42.10** Musth in wild bull elephant in Minneriya National Park in Sri Lanka. Note the profuse TG secretion and semierect penis. (Photo courtesy of Dr. Oswin Perera.)

Bull elephants advertise their musth status through a variety of chemicals present in TGS and urine. In young Asian bulls younger than 15 years of age, TGS has a sweet odour due to the presence of acetates, an alcohol (3-hexen-2-ol) that smells of leaves, and pleasant smelling ketones (acetophenone and 2-heptanone) (Rasmussen et al. 2002, Riddle et al. 2006), known as honey or 'modamusth'; the latter is associated with behaviours that are more erratic and unpredictable. In addition, it is also of a shorter duration and associated with comparatively lower androgen levels. Modamusth has not been identified in juvenile African bulls, which may be a species difference. As Asian bulls age, the musth has a stronger odour due to the presence of carboxylic acids and frontalin, a chemical signal found in insects. In older Asian and African elephant bulls, musth urine contains higher levels of alkan-2-ones, alkan-2-ols, and some aromatic compounds compared with the urine of females and nonmusth males (Rasmussen et al. 2002, Riddle et al. 2006, Goodwin et al. 2012). Elephants have well-developed primary and secondary (vomeronasal) olfactory systems (Lazar et al. 2004), and both males and females respond to these chemicals. Oestrous females seek out musth bulls, whereas subadult and nonmusth males avoid them (Riddle et al. 2006, Goodwin et al. 2012). Ultimately, the state of musth confers an advantage to adult bulls, which gain more access to oestrous females, and experience a higher paternity success (Hollister-Smith et al. 2007); it is not necessary for a male to be in musth to impregnate a female.

There are distinct characteristics of the different musth phases. Rajaram (2006) described five stages of musth: premusth, early musth, midmusth, postmusth, and nonmusth. In premusth, the temporal glands begin to swell, and some volatile compounds are secreted; the elephant will often touch this area with his trunk. Appetite is reduced, and the bull will display frequent penile erections and masturbation. Testosterone levels are slightly elevated, about two to three times baseline. The early- to midmusth stages are characterised by more TGS, which becomes odourous as the period progresses. During full musth, temporal glands secrete a thick tar-like fluid, the bull becomes even more aggressive, is unable to extrude his penis, and dribbles urine continuously, which often leads to a greenish-white discolouration of the orifice. Captive males become disobedient, unpredictable, and highly aggressive in conjunction with a significant increase (10 to 20 times baseline) in circulating androgens (Ganswindt et al. 2005, Brown et al. 2007, Yon et al. 2008). It has been suggested that UD is a better indicator of musth than TGS (Ganswindt et al. 2005), at least in African bulls. In Asian bulls, aggression is associated more with TGS (Duer et al. 2016). These signs decrease during postmusth and disappear during the nonmusth period.

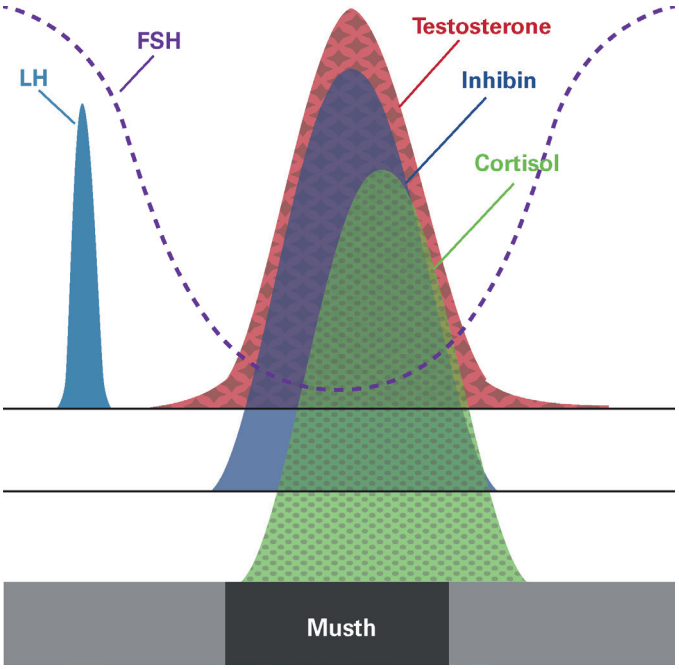
Male Endocrinology

As reviewed by Brown (2014), the endocrine control of reproduction in male elephants is similar to other mammals and includes increased secretion of GnRH from the hypothalamus, FSH and LH from the anterior pituitary gland, and the secretion of androgens (mainly testosterone) from the Leydig cells of the testes. Androgens are responsible for the development of secondary sexual characteristics and sex drive in male elephants, as in most other domestic animals. The secretion of androgens is under the direct control of LH; each pulse of LH from the pituitary gland gives rise to an associated elevation in circulating testosterone. Testosterone production in elephants is related not only to age but also to social rank, dominance, and the state of musth.

VetBooks.ir

Musth is associated with a number of endocrine changes as shown in Fig. 42.11. Circulating cortisol is often increased during musth, at least in captive bulls, and is positively correlated with serum testosterone (Brown et al. 2007, Yon et al. 2007) (Figs 42.12–42.14). Serum gonadotropin patterns are not always consistent, but in many bulls, LH is elevated for several weeks about a month before musth begins, whereas FSH concentrations are higher during the premusth period and decline during musth (Kaewmanee et al. 2011b). FSH in elephant bulls is inversely related to inhibin, which in turn correlates positively with testosterone (Kaewmanee et al. 2011b). Another hormone produced by Sertoli cells under FSH control is AMH, which can be used as a marker of FSH and testicular function. AMH is higher in prepubertal compared with postpubertal elephant bulls; however, there are no differences in concentrations between musth and nonmusth males (Dow et al. 2011b).

Examples of normal annual musth cycles associated with elevated testosterone and the positive relationship between testosterone and cortisol are shown in Fig. 42.12. However, many bulls, especially in zoos, exhibit erratic musth periods, with multiple episodes a year (see Fig. 42.13) or are in a near state of constant musth (see Fig. 42.14). In terms of age, musth does not occur in wild bulls until after they reach their mid-20s, and bouts tend to be short and sporadic until the mid-30s (Poole 1989, 1994). However, in captivity, musth has been observed in bulls as young as 7 years (Cooper et al. 1990, Niemuller & Liptrap 1991, Ganswindt et al. 2005a). Fig. 42.14 shows the gradual change in endocrine patterns in a maturing zoo Asian elephant. Both serum testosterone and cortisol concentrations increased both overall and in peak concentrations, leading up to the first period of musth symptoms at 12



• **Fig. 42.11** Model of the hormonal relationships among testosterone, LH, cortisol, and inhibin in association with musth in bull elephants. (Adapted from Brown et al. 2007 and Kaewmanee et al. 2011b.)

years of age. Early sexual maturation (i.e., increases in testosterone and musth activity) and multiple episodes of musth per year in some captive bulls may be as a result of overall better nutrition, lack of the presence of older, more sexually mature cohorts, and perhaps diminished environmental stressors (Brown et al. 2007).

Suppression of Musth

Due to the dangers associated with managing bulls in musth, especially in captivity, there is considerable interest in finding treatments that mitigate aggressive behaviours. Castration is not a practical option given the abdominal location of the testes, although it has

VetBooks.ir

been done. Musth is affected by nutritional status, so one strategy is to reduce water and food intake, although many bulls in musth reduce intake voluntarily. Musth bulls often are isolated, and in Asia they are kept on short chains away from other elephants and people. These practices raise ethical concerns, so alternative therapies that decrease androgen secretion and associated dangerous behaviours are being tested. GnRH agonists, such as leuprolide acetate, and antagonists (Detirelix) have been shown to reduce testosterone during musth but need regular injections (Brown et al. 1993, de Oliveira et al. 2004). Cyproterone acetate (an antiandrogen) has been given to Asian elephants in musth but with little effect on aggressive behaviours (Niemuller et al. 1998).

More recently GnRH vaccines have shown promise, including their use in elephant bulls, as a means of controlling reproductive and sex-related behaviours that are testosterone driven (De Nys et al. 2010, Somgird et al. 2016b). In Asian bulls, pituitary LH responses to exogenous GnRH are greatest in the premusth period (about 1–2 month before musth onset), which is when serum LH and testosterone are increasing (Somgird et al. 2016a). Therefore the assumption is that GnRH vaccination will be more effective when given before the predicted musth period to block the HPG axis; preliminary studies in Sri Lanka and Thailand have supported the theory. In Thailand, Asian bulls were given 600 μg of a GnRH vaccine (Improvac) approximately 2 months before expected musth, which resulted in a postponement of musth for 2 to 6 months, shortening or completely preventing the musth period (Somgird et al. 2016b). Serum LH and testosterone concentrations were decreased when anti-GnRH antibodies were elevated, and no UD was observed in musth bulls after completion of the vaccination programme (Somgird et al. 2016b). Similarly, African elephant bulls exhibited lower faecal androgen metabolite concentrations after GnRH vaccination, and musth behaviour was suppressed (Brown et al. 1993, Brown et al. 2007, De Nys et al. 2010). However, not all bulls respond to vaccination with a reduction in musth symptoms, which may be a learned behaviour. Long-term treatment with GnRH vaccines might also result in permanent immune castration (Lueders et al. 2014). A suppressive effect of a GnRH vaccine on reproductive organs was reported in a young Asian bull treated over several years, including reduced sperm production and size of reproductive organs (ampullae, seminal vesicles, testes, and penis; Lueders et al. 2017); thus it should be used cautiously.

Clinical Examination of the Reproductive System

The ability to conduct reproductive tract soundness examinations is important for the breeding management of captive elephants. Both male and female elephants should be trained to be subjected to transrectal palpation and ultrasonography, as well as physical restraint when needed. Elephants should not be allowed to swing their trunks or kick or walk away during the examination. Securing front and rear legs to a pole or other stationary object by ropes or chains or putting the elephant in an elephant restraint device may be needed to prevent injury to the elephant or examiner. If the elephant cannot be controlled, standing sedation with xylazine hydrochloride can be used.

Male reproductive organs, both testes and accessory sex glands, can be assessed by transrectal ultrasonography to determine the maturity of the male, as well as during the semen collection process (Hildebrandt 2000b, Imrat et al. 2014). Collected sperm should then be evaluated for quality – i.e., volume, colour, motility, viability – as a means to assess fertility (Thongtip et al. 2004b). But, as will be discussed later, it is important to note that a breeding bull who has produced a number of calves may not provide a good semen sample using artificial techniques (rectal message, electroejaculation, artificial vagina), whereas a bull who has never sired a calf may produce good quality samples. This is because the collection method itself may result in incomplete ejaculation or a poor mix of seminal fluids, which results in nonmotile spermatozoa.

In females, blood samples should be collected routinely (weekly or biweekly) for progestagen analyses (serum, faecal, urine, or saliva) to identify ovarian cyclicity status (Brown 2000, 2006, Hodges 1998, Lueders & Hildebrandt 2012). Transrectal ultrasonography is useful for evaluating urogenital tract health and identifying any reproductive pathologies, i.e., leiomyoma, fibroma, and cystic endometrial hyperplasia, which can cause reproductive failure (Hildebrandt et al. 2006b, Pringproa et al. 2015).

Reproductive Examination Tools

Ultrasonography

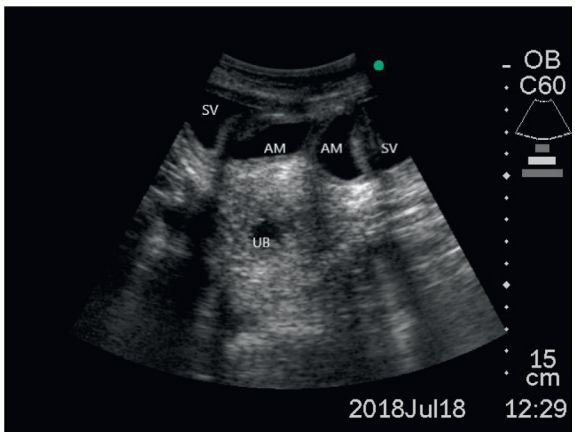
Ultrasonography is a technique used to evaluate the internal reproductive organ systems. Most ultrasonography used to monitor reproduction in male and female elephants is performed transrectally (85%) rather than transcutaneous (Hildebrandt et al. 2006b, Hildebrandt et al. 2006a) because the thickness of elephant skin (~3 cm) affects the sharpness of the ultrasound image. However, after 8 months of gestation, the fetus reaches a size that causes it to descend into the abdominal cavity, where it is no longer viewable. Thus in late pregnancy (after 16 months), transcutaneous ultrasound can be used diagnostically or to monitor fetal activity (Hildebrandt et al. 2006b).

Transrectal ultrasonography can be conducted when the elephant is standing or lying on its side without sedation. However, for the safety of the sonographer and the expensive equipment involved, the elephant must be well-trained or carefully tethered. The optimum ultrasound system in elephants is a portable, battery-powered, real-time B-mode, with the low frequency convex (3.5 MHz), middle frequency microconvex (5 MHz), and high frequency linear (7.5–10.0 MHz) transducers. Before performing transrectal ultrasonography, it is advisable to remove any faeces from the rectum and wash it out with warm water. To view organs, such as the urinary bladder, uterine body, vagina, vestibule, and seminal vesicles, a handheld ultrasound probe may be used, with the operator's arm extended to full length. However, images of deeper organs, such as kidney, testis, uterine horn, and ovary, require the use of an extension, as described by Lueders et al. (2017), to increase the length and depth of reach of the ultrasound probe.

Ultrasonography of the Male Elephant

Accessory sex glands and the intraabdominal testes can be imaged using transrectal ultrasonography. In adolescent males, this can be accomplished using a conventional ultrasound probe, whereas in adult bulls, a probe extension must be used because the testes are located approximately 0.9 to 1.5 m from the anus. Details of ultrasonography images have been described by Hildebrandt et al. (1998, 2000b). The ampullae, located bilaterally dorsal to the caudal part of urinary bladder, store spermatozoa produced by the testes. If the ampullae are full, the sonographic image will show a rounded echogenic structure filled with spermatozoa, which have a snowy appearance; this is common in the active testes of the bull. If the structure is anechoic, the ampullae will be filled with

VetBooks.ir



• **Fig. 42.15** Transrectal ultrasonography image of crosssectional plane of male reproductive organs. Ampullae are illustrated by two rounded hypoechogenic structures in the upper central region. Seminal vesicles are located lateral to the ampullae and filled with anechogenic seminal fluid. SV, seminal vesicle; AM, ampullae; UB: urinary bladder.

a spermfree secretion. Seminal vesicles are located lateral to the ampullae and filled with anechoic seminal fluid, which provides nutrients and a vehicle for sperm at ejaculation (Fig. 42.15). The testicular sonographic image is homogeneous and hypoechoic, with a hyperechoic border.

Ultrasonography of the Female Elephant

Monitoring of female reproductive organs is crucial for assessing ovarian activity in pregnancy diagnosis and to observe pathological changes in the reproductive tract that often occur in nulliparous older females (Agnew et al. 2004, Hermes et al. 2004). The vestibule is a tube-like structure that is present between the hindlegs and extends to the opening of the vagina. A crosssectional image of the vestibule shows a hypoechogenic mucosa surrounded by a hyperechogenic submucosa. The vestibular lumen is normally not detectable by ultrasonography. Longitudinal transrectal ultrasonography is very useful for vaginal diagnostic imaging. During the luteal phase, anechogenic mucus partially fills the vaginal lumen, whereas fragmented hyperechogenic mucus is observed in the homogeneous hypoechogenic vagina during oestrus. Oestrus is the most ultrasonographically active stage of the vagina and cervix, with significant changes in mucus echogenicity (Hermes et al. 2000).

A handheld ultrasound probe can reach the uterine body (5–10 cm) and externally fused uterine horn (or pseudouterine body, 50–70 cm), whereas the uterine horn can only be viewed by means of an ultrasound probe with an extension. Uterine lesions, such as benign tumours of the endometrium (leiomyoma) and cystic endometrial hyperplasia, can also be detected by transrectal ultrasonography. The ovary can only be reached by using the ultrasound probe extension; a high frequency transducer (5–7 MHz) is recommended to view the detailed structure of the ovary.

Endoscopy

Endoscopy is useful for reproductive tract health diagnosis and for conducting AI. A 3-m endoscope is guided through the genital tract via the vulva, vestibule, vagina, cervix, and uterus, where semen is deposited (Brown et al. 2004b, Thongtip et al. 2009). Endoscopy can also be used to visualise reproductive tract lesions, such as internal wounds or tumours. The endoscope can be easily damaged if the cow moves unexpectedly, however; so the technique should only be used in well-trained or sedated individuals.

Obstetrical Disorders

Retained Fetal Membranes

Normally, the fetal membranes are expelled within 10 to 12 hours after birth of the calf (Hildebrandt et al. 2006a). However, postpartum complications, including retained fetal membranes (RFM), can occur in elephants, resulting in metritis and reductions in milk production (Murray et al. 1996). Successful use of oxytocin, with or without oestradiol cypionate, and manual traction has been reported to successfully treat the problem (Murray et al. 1996, Brown et al. 2004b).

Dystocia

Dystocia is defined as a difficult birth, which in elephants can be caused by a number of conditions: excessive dam body weight and lack of exercise; advancing dam age; calf oversize; faulty disposition of the calf; small pelvis/birth canal; loss of flexibility in the pelvic region; muscle fatigue; hypocalcaemia; intact hymen obstructing the birth canal; oedema of the vestibule narrowing the birth canal; elephant endotheliotropic herpes virus infection; and cysts, polyps, and/or tumours of the urogenital tract (Hermes et al. 2008). In zoos, nulliparous females are generally considered to be beyond their normal useful reproductive life after approximately 30 years of age because of a greater risk of dystocia and stillbirth. Dystocia is suspected when there is: 1) no sign of impending parturition after progestagen concentrations have declined to baseline; 2) no relaxation of cervix based on transrectal ultrasonography; 3) no presentation of a fetus within 2 hours after rupture of the allantoic sac (Hermes et al. 2008, Hildebrandt et al. 2006a, Schaftenaar & Hildebrandt 2005) (Fig. 42.16). Of considerable concern is the tendency for older primigravida to experience dystocia and/or stillbirths. Over 50% of dystocias occur in primigravid cows older than 20 years of age or after prolonged barren periods (Hermes et al. 2008). As a management recommendation, nulliparous females in captivity are considered to be beyond their normal reproductive life after 25 to 35 years of age because of these increased risks (Hermes et al. 2004, Hildebrandt 2006).

When dystocia is diagnosed, veterinary intervention should be performed, such as transrectal manual massage of the vagina, cervix, and uterus to stimulate the Ferguson's reflex, which stimulates the release of oxytocin from the posterior hypophysis to stimulate myometrial contractions (Hermes et al. 2008, Schaftenaar 2013, Schaftenaar & Hildebrandt 2005). Medical management by administration of oxytocin and calcium can be used to stimulate uterine contractions; however, this should be avoided when there is obstruction of the birth canal. Oxytocin also should be used only in cows when it has been confirmed that the cervix is sufficiently relaxed and dilated and that the fetus is present in the birth canal in the correct disposition for birth (Hermes et al. 2008). There are several examples of how the administration of oxytocin resulted in uterine rupture because of insufficient cervical dilatation (Hermes et al. 2008). Published doses of oxytocin given IM or IV vary considerably, and range from 20 to 30 IU every 20 to 30 min, to 200 to 400 IU every 90 min. Based on one author's experience, a single dose of 40 IU oxytocin successfully induced parturition within about 20 minutes in an Asian elephant (Brown et al. 2004b).

VetBooks.ir

• **Fig. 42.16** A case of dystocia in an Asian elephant, indicating a large bulge in the perineal region with no delivery of the fetus 2 hours after rupture of the allantoic sac.

• **Fig. 42.17** Postparturient prolapse of reproductive tract organs (uterine, vaginal, and cervix) in an Asian elephant.

The only surgical option to correct a dystocia is vestibulotomy and, if necessary, a subsequent fetotomy (Schaftenaar 2013). Caesarean surgery is contraindicated in elephants because it can result in the rupture of the abdominal wound postoperatively from pressure and subsequent death of the cow from peritonitis (Hermes et al. 2008, Hildebrandt et al. 2006a, Schaftenaar & Hildebrandt 2005). Vaginal vestibulotomy is recommended to enable retraction of a dead fetus when it enters the cervical canal (Hermes et al. 2008, Hildebrandt et al. 2006a, Schaftenaar 2013, Thitaram et al. 2006). If the calf has progressed sufficiently into the vestibule, traction is usually sufficient to enable its delivery. Ventral oedema is often observed after a difficult birth and can be treated by encouraging exercise of the dam and the application of warm compresses (Murray et al. 1996, Brown unpublished).

Reproductive Tract Prolapse

Prolapse of the reproductive tract is rare, but when it occurs, it is a serious postpartum complication that often results from excessive physical activities after birth and is facilitated by an open cervix and uterine atony. Eversion and prolapse of the vagina, with or without the cervix and urinary bladder, will be apparent as a bulge in the perineal region. Rectal palpation and ultrasonography are helpful in identifying any organs entrapped within the urogenital canal. Cervicovaginal prolapse in an African elephant was first described by Mollel (1978). Successful correction of a cervicovaginal prolapse in a 47-year-old elephant that was not related to calving was described by Min Oo et al. (2016). Unsuccessful attempts to correct uterine prolapses are common, as in the reports of four cases in Thailand (Lorsanyaluck personal communication, Angkawanish et al. 2016) (Fig. 42.17), which showed varying degrees of cystocoele, uterine, vaginal, and cervical prolapse using ultrasonography. The protruded masses were repelled into the pelvic cavity after vestibulotomy, and a purse string suture used to close the end of vestibular tract to prevent prolapse reoccurrence.

Urogenital Tract Injuries

Injuries to the distal urogenital tract are possible after delivery of an oversized fetus, especially in primiparous mothers, and have been observed in both captive and wild elephants. Injuries are characterised by localised trauma and oedema of the distal urogenital tract after delivery of the calf. In captive elephants, the affected area can be observed endoscopically to assess the extent of damage, and if there is no serious damage to the vestibular canal, it can be flushed with sterile water and treated by the application of emollient creams to reduce the irritation and swelling. Tearing of the mucous membrane and/or underlying muscle layers may require parenteral and local antibiotic treatment. Fig. 42.18 shows a urogenital tract injury of a wild elephant in the Udawalawe National Park in Sri Lanka.

Female Infertility

Ovarian Acyclicity

Reproductive problems of captive elephants are well documented. In the African elephant in particular, a high rate of ovarian acyclicity, with persistent basal progestagen concentrations, hinders population sustainability (Brown 2014). In North America, 52%

VetBooks.ir

of African elephant females exhibit abnormal cycles, with 38% being completely acyclic (Brown et al. 2016). Comparatively, the acyclicity rate in Asian elephants is lower (< 20%) and affects mostly older cows (Dow et al. 2011a, Brown et al. 2016). Several conditions known to be associated with infertility in other species appear not to be related to abnormalities of the ovarian cycle in African elephants: for example, hyperandrogenism, hyperoestrogenism, hyper- or hypothyroidism, pituitary imbalances, and elevated cortisol concentrations (i.e., stress) (Brown 2014). The finding of no differences in anti-Müllerian hormone (AMH) concentrations between cyclic and acyclic elephants suggests that the problem is not due to a lack of functional follicles (Dow et al. 2011b). Notable problems associated with ovarian acyclicity in African cows are often related to abnormal prolactin secretion (Brown et al. 2004a, Yamamoto et al. 2010, Dow & Brown 2012, Prado-Oviedo et al. 2013). About half of acyclic African elephants in US zoos (the only population in which routine blood samples are collected for prolactin analysis) exhibit consistently low basal concentrations (Prado-Oviedo et al. 2013), whereas the other half produce levels that are five- to thirtyfold higher than in normal cyclic females (Fig. 42.19). This condition, called hyperprolactinaemia, is the most common disorder of the hypothalamic–pituitary axis related to infertility in women (Serri et al. 2003, Wang et al. 2012). As in other species, pituitary prolactin secretion in elephants is under inhibitory control by dopamine (Brown 2014). The dopamine agonist, cabergoline, is a common treatment for hyperprolactinaemia in women (Verhelst et al. 1999) and has been shown to effectively suppress prolactin secretion in hyperprolactinaemic elephant cows, but it has yet to result in the resumption of ovarian cyclicity in African cows even after a year of treatment (Morfeld et al. 2014a). No underlying physiological cause of hyperprolactinaemia has yet been found, but it does not appear to be related to abnormal production of cortisol, oestradiol, or thyroid hormones (TSH, T_3, T_4) (Brown et al. 2004a, 2014, Prado-Oviedo et al. 2013). Asian elephant cows rarely present with hyperprolactinaemia or prolactin-induced acyclicity (Brown et al. 2004a); this represents a significant species difference.

Several studies in the United States and Europe have applied epidemiological methods to identify factors in the zoo environment that are associated with reproductive disorders, and noted several differences between Asian and African elephants (Harris et al. 2008, Brown et al. 2016). For both species, the chance of a cow having normal cyclical ovarian activity decreases with age and is greater when they are housed in a mixed-sex herd. For African

VetBooks.ir

elephants, social compatibility, herd stability, and enrichment are important for promoting normal pituitary–ovarian function, whereas social isolation has a negative effect (Brown 2016). Behaviourally dominant females that are identified as the herd 'peacekeepers' are more likely to be acyclic (Freeman et al. 2004). There also appears to be a social aspect to hyperprolactinaemia in African elephants, which is more prevalent in cows exposed to many social groups throughout the day, again possibly reflecting the negative effects of social instability (Brown et al. 2016). Last, the majority of Asian and African zoo elephants are overweight, based on their body condition score (Harris et al. 2008, Morfeld et al. 2014b), and in African cows, a high body mass index and body condition score have been related to ovarian acyclicity, altered metabolic function (insulin and the glucose to insulin ratio), and elevated leptin (Morfeld et al. 2014b). Interestingly, ovarian cyclicity in Asian cows is less affected by a high body condition, despite the fact that over three-quarters are considered overweight or obese.

Pathology of the Female Reproductive Tract

As reviewed by Hildebrandt (2006), older nulliparous cows or those that have not calved within approximately 10 years often develop urogenital tract pathologies. The most common are cysts and tumours, with some species differences. Endometrial hyperplasia and vestibular cysts are found in both species, whereas uterine leiomyomas are present only in the Asian elephants (Fig. 42.20), and vestibular polyps are observed only in African elephants. Vaginal cysts and neoplastic formations may be extensive, occluding the lumen, obstructing semen transport, and causing discomfort during oestrus and mating. These lesions may be a consequence of continuous ovarian cyclicity and hormone exposure in unbred females. In the wild, most elephant cows are either pregnant or lactating and thus experience comparatively few oestrous cycles in their lifetime. Consequently, rates of urogenital tract pathologies are higher in captive elephants (20%–80% in Asians and 10%–33% in Africans) and relatively rare in wild elephants (< 5%). As mentioned later in this chapter, GnRH vaccines, used to inhibit pituitary FSH and LH release, reduce ovarian steroidogenic activity and have been effective in resolving uterine cysts and tumours in older Asian elephants (Boedeker et al. 2012).

• **Fig. 42.20** Cystic endometritis hyperplasia with the fibroleiomyoma *(arrow)* in the uterine body and horns in nulliparous aged Asian elephant, which occluded the lumen, obstructed semen transport, and caused discomfort during oestrus and mating.

Male Infertility

Ultrasonographic examinations and semen evaluation of bull elephants has become a valuable tool for assessing sexual maturity (Hildebrandt et al. 1998, Hildebrandt et al. 2000b), detecting reproductive pathologies, and describing the ejaculatory process (Schmitt & Hildebrandt 1998). There appear to be fewer reproductive tract pathologies or asymmetrical reproductive aging in males than in female elephants, suggesting that captivity or being in prolonged nonbreeding situations does not have as significant an effect on bull reproductive health as it does on cows (Hildebrandt et al. 2000a). Although males exhibit fewer anatomically related lesions, they nevertheless exhibit a high rate of reproductive failure caused by a lack of libido or suboptimal sperm quality.

Lack of Libido

There is evidence that some causes of reproductive dysfunction can be related to the environment in which bulls are kept, grouping of bulls, and even the effect of overly dominant animal handlers. Housing multiple bulls together in a facility may reduce fertility in some subordinate bulls particularly in the human care setting, although limited studies have been done to support this as a universal response. One study found musth suppression was more common in groups of African than Asian bulls (Brown et al. 2007). During hot seasons, especially in Asian range countries, bulls are more likely to have poor libido and hence limited interest in breeding with cows.

Poor Semen Quality

All methods of semen collection in elephant bulls (e.g., rectal message, artificial vagina, electroejaculation) can result in samples of poor quality, usually in the form of low sperm motility or a high percentage of structural abnormalities (Fig. 42.21; Table 42.1). In extensive studies of captive Asian bulls, less than a third of ejaculates exhibited more than 60% motile spermatozoa, and many were contaminated with urine (Kiso et al. 2011, 2012, 2013), a common problem in elephant bulls resulting in damaged spermatozoa. Good motility ejaculates (> 65% motility) contained higher proportions of sperm with normal morphology, particularly intact acrosomes, compared with poor motility ejaculates. Furthermore, ejaculates with higher motility were of a larger volume with a lower sperm concentration. The influence of transrectal massage of the genital tract on seminal components has been reported (Imrat et al. 2013, Kiso et al. 2013). One- and two-dimensional gel electrophoresis revealed similar seminal plasma protein profiles between good and poor motility ejaculates, with the exception of a protein

TABLE 42.1 Mean (± SD) ejaculate characteristics of Asian and African elephant bulls

Semen Parameters	Asian Elephant (N = 75 Ejaculates)	African Elephant (N = 50 Ejaculates)
Total volume (mL)	48.3 ± 53.8	31.1 ± 38.7
Total motility (%)	25.8 ± 31.4	22.9 ± 30.3
Total progressive motility (%)	15.7 ± 26.3	18.5 ± 28.6
Normal morphology (%)	56.5 ± 26.9	45.6 ± 25.6
Normal acrosome (%)	17.3 ± 23.9	23.0 ± 31.0
Sperm concentration (X 10^9)	1.3 ± 0.8	2.3 ± 0.7
pH	7.2 ± 1.1	7.2 ± 0.9
Osmolality (mOsm)	256.2 ± 55.0	356.6 ± 124.4

From Kiso et al. 2011.

of approximately 80 kDa, that was abundant in 85% to 90% of ejaculates with good motility and absent in more than 90% of poor motility ejaculates. Mass spectrometry analysis identified the protein as lactotransferrin, which was confirmed by immunoblotting (Kiso et al. 2013). Lactoferrin is a fertility marker in human semen (Milardi et al. 2012).

Poor ejaculate quality can be attributed to infrequent ejaculation, causing the accumulation of senescent spermatozoa in the excretory ducts and ampullae. Increasing the frequency of semen collection has been shown to improve semen quality in some cases. However, semen characteristics also can be negatively affected by long-term management in captivity. Semen quality has been shown to be affected by age, season, and some nutritional and endocrine factors. Lower percentages of sperm with intact membranes and a higher frequency of detached sperm heads were observed with increasing age in nonmusth captive Asian elephants. It is important to note, however, that collection of poor quality ejaculates does not necessarily mean a bull is infertile and that many that produce very poor samples collected by artificial means successfully sire calves by natural mating.

Captive Breeding

Historically, *in situ* populations of elephants in Asia and Africa served as a source of new individuals for *ex situ* populations, a practice now recognised as irresponsible and unethical. Today, though not a solution, *ex situ* breeding of elephants can be viewed as a means of maintaining important populations as 'insurance' against environmental or anthropomorphic catastrophes. Globally, there are about 1000 African elephants in captivity, mostly in zoos, and upwards of 16,000 Asian elephants in zoos, circuses, sanctuaries, logging, and tourist camps, mostly in range countries. Few captive elephant populations are self-sustaining, due to high mortality and low birth rates, and may continue to be maintained through supplementation by wild capture and/or importation. This can put pressure on the already fragile wild populations, so most countries have banned the import and export of wild elephants. Increasing the reproductive output of captive elephants has been difficult, due to both physical and physiological challenges. Zoos in the United States typically average only 3.5 births to 5 deaths, for both species (Faust & Marti 2011a,b). Some problems are logistical, such as accessing fertile males and females together in the same facility. Others are physiological and related to ovarian cycle abnormalities, uterine pathologies, gestational difficulties, and bull subfertility. Finally, behavioural issues, such as mate incompatibility and poor libido, often hamper breeding success.

As reviewed by Thitaram (2012), breeding success in Asian range countries is also limited and can be influenced by work obligations and religious factors. In Northern and Southern India, elephants that belong to Hindu institutions often are prohibited from breeding. In other regions, captive Asian elephant cows historically bred with wild bulls, making those populations more sustainable. For example, Southern Indian forest camps that allowed elephants to forage at night to breed with either captive or wild bulls had a birth rate of 13% (Taylor & Poole 1998). In Myanmar timber elephants, mating of captive or wild bulls with captive cows resulted in an average birth rate of 7.1% per year per mature female during 1991 to 1995 (Lair 1997, Taylor & Poole 1998). In Sri Lanka, although not exposed to wild bulls, free contact between resident bulls and cows during grazing and bathing periods at the

VetBooks.ir

Pinnawala Elephant Orphanage has resulted in one of the most successful breeding programmes in Asia, with 3.9 calves born per year (Pushpakumara et al. 2016) and a birth rate of 20% annually (Taylor & Poole 1998). Therefore it appears that a major limiting factor in captive breeding is a lack of male–female contact in a favourable environment to support oestrus detection and mating. Across western and range country facilities, there are commonalities in what is required for successful breeding. These are:

- **Reproductively healthy bulls and cows.** Female elephants should be recruited for breeding at a young age (8–14 years) and kept reproductively active by breeding every 4 to 6 years to lower the risk of dystocia and stillbirth in later years (Brown 2014). Healthy parous females can reproduce into their 40s, and sometimes 50s. Multiple benign uterine tumours of the myometrium (leiomyoma) can develop if reproduction has not occurred within 10 to 15 years, especially in Asian cows (Hildebrandt et al. 2006a, Hildebrandt et al. 2006b); thus cows must be bred when they are young and frequently. The availability of experienced breeding bulls is crucial, and in many facilities, despite the presence of large numbers of adult bulls, only a few actually breed and sire calves (Thongtip et al. 2008).
- **Mate compatibility.** Placing males and females of reproductive age together is no guarantee of successful breeding. Some cows refuse the attention of some or all bulls, and vice versa. Males with a good temperament show better courtship behaviour and a willingness to mount and copulate. Fetomaternal blood incompatibility can cause haematological defects that can result in abortion and neonatal anaemia and may lead to calf loss (Bansiddhi et al. 2015). To reduce embryonic loss from fetomaternal blood incompatibility, testing of bulls and cows should be performed, consequently preventing the breeding of bulls and cows with high genetic relatedness (Thitaram 2009); unfortunately, in many breeding facilities, especially in range countries, genetic testing or the maintenance of reliable studbooks is not possible.
- **Correct timing of breeding.** Some bulls and cows can be kept together, thus ensuring breeding will take place at the correct stage of the oestrous cycle, which is a 2- to 5-day window at the end of the follicular phase and start of the luteal period (Vidya & Sukumar 2005). However, often males and females are kept separately to prevent injury to, or harassment of, cows by aggressive bulls. Oestrous detection to identify the optimum time for mating introductions can be performed by sequential progestagen monitoring (Brown 2006, Hildebrandt et al. 2011) or behaviourally (Thitaram et al. 2009). When daily blood sampling is possible, detection of the double LH surge is the most reliable means of estimating time of ovulation (Brown 2014).
- **Breeding locations.** Ideally, a quiet place away from the public should be used for breeding. In Asia, natural forested spaces are preferred, with animals mixed together after the working day has ended. However, it is not always possible to provide privacy in tourist camps or public zoos, so breeding often only occurs between elephants willing to breed in the presence of people.

Assisted Reproductive Techniques

Decades of advances in endocrine monitoring, ultrasonographic imaging, and semen collection techniques have led to a better understanding of the complex mechanisms involved in controlling reproductive function in elephants. Although adapting assisted reproductive techniques developed for domestic, laboratory, and other wildlife to elephants has not always been straightforward, a variety of methods now exist to aid breeding management, including semen cryopreservation and gonadal hormone control.

Semen Extension and Cryopreservation

Immediately after collection, semen can be extended to maintain viability. However, even excellent quality samples can deteriorate rapidly, and within 12 to 24 hrs the motility can be too low for use (Kiso et al. 2011, O'Brien et al. 2013). Typically, liquid semen storage at 35°C results in a sharp decline in spermatozoal quality after a few hours in both species, whereas spermatozoa held at 22°C and 4°C retained about half of their initial motility for up to 12 h (Kiso et al. 2011). The type of semen extender affects spermatozoal longevity. In Asian elephants, diluents providing a source of lipoprotein (i.e., skim milk or egg yolk) are the most effective (Kiso et al. 2012), with skim milk often resulting in better postthaw survival rates than egg yolk (Imrat et al. 2013). The inclusion of antioxidants to reduce DNA fragmentation (e.g., BullMax) also helps to preserve sperm longevity of Asian spermatozoa during storage (Imrat et al. 2012b). By contrast, African elephant spermatozoa generally retain viability longer than those of Asian elephants, and there is little difference in spermatozoal quality parameters using different extenders when extended elephant semen is stored at temperatures below body temperature (Kiso et al. 2011). For transport to recipient institutions, Asian elephant spermatozoa should be diluted in extenders containing egg yolk or skim milk, whereas spermatozoa from African elephants have no such requirement (Graham et al. 2004, Saragusty et al. 2005, Hermes et al. 2009, Saragusty et al. 2009, Kiso et al. 2011). The identification of considerable DNA damage and morphological degeneration in ejaculates after only 24 hrs of storage indicates that sperm ageing may be a primary contributor to inconsistent semen quality even at chilled temperatures (O'Brien et al. 2013). It has been suggested that Asian elephant spermatozoa are more susceptible to DNA damage those of other mammalian species (Imrat et al. 2012a) and that the amount of disulphide bonding and number of arginine–lysine residues in protamines likely influence the relative stability of sperm DNA (Gosalvez et al. 2011). Less crosslinking in elephant sperm may make them comparatively more fragile under *in vitro* conditions.

Cryopreservation of elephant spermatozoa was first attempted 30 to 40 years ago in African elephants (Jones 1973, Howard et al. 1986) and a little more than a decade ago in Asians (Hedrick & Schmitt 2001, Thongtip et al. 2004b). Initial protocols relied on freezing samples over liquid nitrogen vapour or forming pellets on dry ice; postthaw survival was generally poor (< 50%), more so for Asian than African elephants. As such, cell damage during the freeze–thaw process has been a major limitation to successful cryopreservation. During the process of chilling and freezing, the plasma membrane lipid bilayer of spermatozoa is altered in both composition and structure. The freezing of extracellular water results in hyperosmotic conditions that draw water out of the cell and can lead to altered membrane permeability, cell dehydration and shrinkage, and death. Several studies have attempted to enhance the postthaw survival of elephant spermatozoa by adding cryoprotectants (i.e., dimethyl sulfoxide, glycerol, ethylene glycol, and propylene glycol) before cooling and freezing (Kiso 2004, Thongtip et al. 2004b, Saragusty et al. 2009, Buranaamnuay et al. 2013), with glycerol generally being the most effective. In a preliminary study, fatty acid composition of Asian and African elephant spermatozoal

VetBooks.ir

plasma membrane was found to differ (Swain & Miller 2000). A lower proportion of polyunsaturated fatty acids in Asian elephant spermatozoal membranes suggested there might be less fluid. Increasing membrane fluidity by incubating with lipids, such as egg yolk or egg–phosphatidylcholine liposomes, helps elephant spermatozoa withstand such stresses (Saragusty et al. 2005). Today, most extenders for elephant semen cryopreservation contain a minimum of 15% to 20% egg yolk. In other species, treatment of spermatozoa with membrane stabilisers before cryopreservation has improved postthaw survival by modifying phase transition characteristics and increasing tolerance of the cells to freeze–thawing (Purdy & Graham 2004). Membranes with higher cholesterol or greater cholesterol:phospholipid molar ratios tend to be more tolerant to temperature changes during cryopreservation compared with membranes with lower cholesterol levels (Amann & Pickett 1987). In a recent study in Asian elephants, cholesterol loaded into spermatozoa by coincubation with cholesterol-loaded cyclodextrins (CLC; 1.5 mg of CLC/120 × 10^6 spermatozoa) increased membrane cholesterol concentrations and significantly improved postthaw spermatozoa motility and intact acrosomes – approximately 50% compared with approximately 25% with no CLC (Kiso et al. 2012). This percentage survival should be adequate for use with AI, as the three reported pregnancies occurred with postthaw sperm motilities of 45% to 60% (Thongtip et al. 2009, Hildebrandt et al. 2012a). A newer method of semen cryopreservation involves the use of directional freezing. In conventional freezing methods, ice forms at an uncontrolled rate and can damage cellular membranes. Using large volume (2.5 or 8 mL) cryogenic tubes (HollowTubes, IMT Ltd.), semen can be moved at a constant velocity through a linear temperature gradient, which results in better control of ice crystal formation and minimum damage to cells. Postthaw motility in excess of 50% has recently been obtained using directional freezing with semen extended in an egg yolk extender (e.g., Berliner Cryomedium: 2.41% (w/v) TES, 0.58% (w/v) Tris, 0.1% (w/v) fructose and 5.5% (w/v) lactose, 15.6% (v/v) egg yolk and 20 IU α-tocopherol/mL) with 7% glycerol (Saragusty et al. 2009, Hermes et al. 2013). A recent study has shown that faster freezer rates and higher thaw temperatures can significantly improve post thaw semen quality in Asian elephants (Arnold et al. 2017).

Traditionally, zoo elephant populations have been supplemented by the selective importation of females. This is in part due to the increase in husbandry requirements and costs associated with maintaining bulls, which limits the number of facilities willing to house them. As more zoos have become involved in breeding elephants by both AI and natural mating, the number of males in captive populations is increasing. With the advent of flow cytometric methods to separate sperm based on the DNA difference between X and Y chromosomes (Johnson et al. 1987), the technology now exists to preferentially select females. One obstacle to the practical application of this technique is identifying an extender that will optimise short-term storage of spermatozoa while simultaneously being compatible with flow cytometric sorting. Egg yolk added to semen extenders must be removed before sorting because it interferes with the uniform staining of DNA that is critical to separate X- and Y-chromosome cells (Johnson & Welch 1999). This additional processing and handling usually causes sperm damage and loss in viability. Nonegg yolk or reduced egg yolk–based extenders have shown some promise. Success has been achieved in sex-sorting of Asian elephant sperm utilising a MES-HEPES skim milk–based medium (Hermes et al. 2009). Another skim milk diluent, supplemented with only 4% egg yolk (INRA96), sustained sperm as well as media containing 20% egg yolk and thus can be used to extend ejaculates for shipment to centralised sperm sorting facilities (Kiso et al. 2011, Imrat et al. 2013). African elephant spermatozoa have no lipid requirement, so both TL-Hepes and Modena, which are devoid of egg yolk, should be effective in extending African elephant ejaculates for sorting (Kiso et al. 2011). Establishing a genome resource bank for elephants, if it includes sex-sorted samples from captive and wild bulls, could greatly enhance the genetic management of elephants under human care (Hermes et al. 2013).

Artificial Insemination

As the number of wild elephants continues to decline, maintaining healthy captive populations is vital. Because of difficulties in transporting a bull elephant from one institution to another for natural breeding, AI is an alternative tool for genetic management in this species. The technique was developed by a team from the Institute for Zoo Biology and Wildlife Research (IZW) in Germany, in collaboration with the Smithsonian Conservation and Research Centre in the United States (now the Smithsonian Conservation Biology Institute). The first calf conceived by AI was an Asian elephant at the Dickerson Park Zoo (US) in 1999, followed by two African calves at the Indianapolis Zoo (US) in 2000.

Successful AI revolves around several important factors. The cow must undergo a reproductive assessment to ensure that she is cycling normally (based on longitudinal progestagen analyses) and that there are no reproductive tract pathologies (based on transrectal ultrasound). The insemination must be timed correctly to coincide with ovulation. Weekly progesterone is monitored until the hormone levels decrease to baseline at the start of the follicular phase. Within about a week from the progestagen decline, daily blood sampling is initiated to identify an LH surge. Approximately 3 weeks later, inseminations should be performed to coincide with the day before and the day of the second ovLH surge (Brown et al. 2004b, Thongtip et al. 2009); a suitable fertile bull then needs to be identified as a semen donor. Breeding soundness examinations, using reproductive tract ultrasound examination, should be performed to evaluate the reproductive performance of the bull. After collection, semen should be diluted with an appropriate extender and kept chilled for transportation directly to the cow or cryopreserved so that it can be used later. Most births have resulted from the use of fresh or chilled semen, which limits AI effectiveness if good quality ejaculates cannot be collected on peak fertility days. Several calves have been produced successfully by AI using cryopreserved semen in African elephants, including with imported semen (Hildebrandt et al. 2012a). There have been several reported pregnancies from frozen-thawed semen in African elephants to date, including in a female inseminated using frozen semen from a wild African bull, resulting in a live birth in 2013 (Hildebrandt et al. 2012b and unpublished report). Another African cow conceived, but the pregnancy failed after 5 months (Dennis L. Schmitt, personal communication). The only success with frozen sperm in an Asian elephant was a pregnancy that ended in a stillborn calf after 17 months (Thongtip et al. 2009).

Two AI techniques for elephants have been reported: surgical via vestibulotomy (Schmitt et al. 2001) and endoscopic (Brown et al. 2004a, Hildebrandt et al. 2012b, Thongtip et al. 2009). Surgical AI is more difficult because of complications with wound infections, poor healing, and concerns for animal welfare, whereas endoscopic AI requires specialised accessory equipment, including a custom-made balloon catheter to distend the reproductive tract, and use of transrectal ultrasound to guide the endoscope/semen catheter. Both techniques require a tractable elephant, well-trained staff to control the elephant (with or without sedation), proper

VetBooks.ir

preparation of semen for insemination, and proper guidance of the catheter for insemination. Altogether, endoscopic AI is more convenient, less complicated, and presently is used as the standard protocol around the world.

The insemination is performed using an endoscope and ultrasonography to visualise the location of semen deposition. The nonsurgical procedure involves the use of a custom-made balloon catheter (2.5 cm diameter, 140 cm length) lubricated with nonspermicidal sterile gel, which is inserted into the vestibule to slightly distend the reproductive tract for optimal visualisation, followed by the passage of a flexible 3.0-m endoscope containing a customised disposable insemination catheter (3 mm diameter, 300 cm length) (Brown et al. 2004b). Both endoscopic and transrectal ultrasonographic visualisations are used to guide the insemination catheter towards the cranial vagina, just caudal to the cervical os or intracervically, where semen deposition can be visualised ultrasonographically. The sterile 1.7- or 3-meter endoscope with semen catheter is inserted through the vaginal os into the vagina. An AI catheter is introduced through the endoscope and extended semen deposited in the reproductive tract, ideally in the cervix or uterine body. However, if the cervix is not dilated, or it is impossible to penetrate the cervix, vaginal deposition may be effective. One of the main obstacles in nulliparous elephants is inserting the catheter through the vaginal opening and avoiding the adjacent two blind pouches (Hildebrandt et al. 2006b).

As a management tool, AI has been in use for nearly 20 years; however, the utilisation of this technique has been hampered by: 1) the inability to consistently obtain good quality ejaculates; 2) poor spermatozoal survival after liquid storage and transport; and 3) poor postthaw recovery of cryopreserved sperm. There is little doubt that use of AI is a significant management tool for the breeding of captive elephants, but maximal effect will not be attained until good quality semen samples can be reliably obtained or cryopreserved for use with AI. It is not as simple a procedure as in most domestic livestock, and it requires an extensive amount of planning, coordination, hormonal monitoring, training, financial resources, and staffing, as well as collaboration with multiple bull holding facilities (Brown et al. 2004a). It is important to emphasise that the pregnancy rates are not as high as with natural mating (< 20%).

Contraception and Reproductive Control

Ovarian and testicular functions are under hormonal control, and thus, methods that alter hypothalamic-pituitary-gonadal (HPG) activity can be used to manipulate reproduction. Under certain managed situations, there is sometimes the need for a temporary or even permanent cessation of breeding to prevent overpopulation in restricted areas without disrupting herd dynamics (Delsink et al. 2002). It also prevents gonadal steroid-induced reproductive disorders, such as reproductive tract cysts and tumours, that can result from continuous ovarian cyclicity in older, nulliparous females (Boedeker et al. 2012). For example, in well-managed, private South African nature reserves and national parks, elephant populations increase about 3% to 6% annually. Hence, there is an urgent need for efficient population management protocols to keep the number of elephants at an ecologically acceptable level. Hormonal agonists and antagonists that disrupt the HPG axis have been used for reproductive control in elephants. Oestrogen implants have been shown to prevent pregnancy in wild African cows. However, prolonged periods of induced 'oestrus' resulted in herd disruptions, with treated females being harassed by bulls. Moreover, some young calves were harmed when cows, which were harassed by bulls, stopped lactating. Therefore to suppress the HPG axis and control sex hormone production, immunocontraceptive methods have been developed that are safe, effective, and do not disrupt the social structure of the herd.

Immunocontraception

Porcine Zona Pellucida Vaccine

The most widely applied contraceptive agent in elephants is an immunogenic preparation of porcine zona pellucida (pZP) harvested from pig ovaries (Delsink et al. 2002, 2006, Fayrer-Hosken et al. 1999). In one field study in Africa, cows were vaccinated with an initial dose of 400 µg IM, followed by two 200 µg boosters at 5 to 7 week intervals, and then subsequent 200 µg annual boosters (Ahlers et al. 2012). This vaccination programme decreased the population growth rate from 10% to 0% in just a few years. PZP vaccine has many advantages, including: 1) a high contraceptive efficacy (at least 90%) with no negative effects on social behaviour; 2) safe and with no adverse effect on health or pregnancy; 3) highly cost effective; and 4) not entering the food chain (Delsink et al. 2007, Delsink et al. 2013, Kirkpatrick et al. 1996). However, pZP vaccination only blocks the sperm receptor on eggs and does not appear to have an effect on suppressing ovarian cyclicity.

Gonadotropin-Releasing Hormone Vaccine

Gonadotropin-releasing hormone (GnRH) vaccines stimulate the production of anti-GnRH antibodies that block the binding of endogenous GnRH to gonadotrophin receptors in the pituitary gland (Conforti et al. 2008) and inhibit the release of FSH and LH from the anterior pituitary, thereby causing the cessation of cyclic ovarian steroidogenic activity. They have been used in domestic and wild species for contraceptive and aggression-related behavioural control (De Nys et al. 2010, Somgird et al. 2016a).

The most useful application of GnRH vaccination in elephants has been related to the treatment of reproductive tract pathologies, which develop in older females that exhibit continuous ovarian cyclicity. In the first study, a CpG motif–based adjuvant in a recombinant GnRH vaccine (Repro-BLOC, Amplicon Vaccine, LLC, Pullman, WA) suppressed ovarian cyclical activity and resolved haemorrhage and anaemia associated with a vascular reproductive tract tumour in a 59-year-old Asian elephant (Boedeker et al. 2012). Synthetic oligodeoxynucleotides (ODNs), containing unmethylated CpG motifs, directly stimulate B cells and plasmacytoid dendritic cells, thereby promoting the production of cytokines and the maturation/activation of antigen-presenting cells (Klinman 2006). These activities enable CpG ODNs to act as immune adjuvants, accelerating and boosting antigen-specific immune responses by 5- to 500-fold over traditional Freund's adjuvants. Ten years after initial vaccination, the cow continues to lack distinct ovarian cycles but is otherwise healthy. In follow-up studies, administration of three doses of GnRH vaccine (800 µg, Bopriva, Pfizer Animal Health, Australia) 4 weeks apart induced anoestrus in cyclical captive Asian cows based on progestagen analyses (Rajapaksha, Pushpakumara, Perera & Brown, unpublished data). Continued trials in the United States utilise commercial GnRH vaccines, Bopriva and Improvest (Pfizer Animal Health), at doses of 400 to 1000 mg, boosted at monthly intervals for 3 to 5 months. Effects are fairly short term, with most cows resuming cyclical activity within 1 to 6 months of the last booster (Boedeker and Brown, unpublished data). A recent GnRH vaccination (1000 µg, Imrovac, Pfizer Animal Health) study conducted in wild and captive African bulls has shown that regular vaccine boosters can be used as contraceptive method in this species (Lueders et al. 2017).

Artificial Insemination

TIMOTHY J. PARKINSON AND JANE M. MORRELL

The successful use of artificial insemination (AI) as a means of animal breeding relies upon three major premises: first, that spermatozoa can survive outside the body; second, that they can be reintroduced into the female genital tract in a way that results in an acceptable conception rate; and third, that the fertile period of the female can be identified.

The degree to which these underlying premises can be fulfilled dictates the success with which AI can be applied to an animal species. For example, in cattle, the spermatozoa can be preserved outside the body almost indefinitely (after cryopreservation). A technically straightforward intrauterine insemination means that the number of spermatozoa needed for each insemination dose is low; hence, each ejaculate can be used for breeding many females. Conception rates with AI are identical to those of natural service, whilst the visible oestrous behaviour of cows means that detection of the fertile period is not difficult. Hence, in this species, in which all three premises are fulfilled, the use of AI is widespread. Conversely, in many other species, in which one or more of the premises are less adequately fulfilled, AI is less successful and therefore less widely used.

AI regimens have been developed for most domestic and many semidomestic species. It is routinely practiced in cattle, sheep, pigs, goats, fowl, turkeys, salmon, and trout and is used in dogs, domestic foxes, buffalo, horses, and even bees. Of these, cattle, pigs, and sheep/goats account for the vast majority of mammalian inseminations. The use of AI is essential in turkey breeding as natural mating is not possible in this species, so that very large numbers of inseminations are performed. AI in salmonid farming is also very widespread. The discussion of AI in this chapter will be limited to the major domestic mammals.

Advantages and Disadvantages of Artificial Insemination

Artificial insemination offers several potential advantages over natural service. Historically, the most important reason was the control of venereal diseases, particularly in cattle. Nowadays, the most commonly advocated reason is as a means of genetic improvement.

The potential for AI to be used to control venereal disease was a major impetus to the development of cattle AI in the UK during the 1940s. At that time, the venereal pathogens *Tritrichomonas foetus* and *Campylobacter fetus* subsp. *venerealis* were epizootic in most cattle populations, but in the UK, in common with most countries in which bovine AI was introduced in the face of trichomonosis and campylobacteriosis, these pathogens were virtually eliminated by its use (see Chapter 24). However, the converse is also true: uncontrolled use of sires in AI can disseminate disease. Many diseases are transmissible through semen, including not only the classic venereal diseases, but also other conditions that would not generally be regarded as primarily venereal (Roberts 1986). Rigorous monitoring of the health of AI donor sires is therefore regarded in many countries as an integral part of national disease control programmes.

The use of AI as a means of genetic improvement stems from the fact that, in most food-producing animals, each ejaculate can be divided into many insemination doses, such that each sire can potentially be used to breed a very large number of females. Hence, the total number of sires needed is reduced, with a consequential increase in the selection intensity that can be applied to the male side. In dairy cattle, only the best 1% of cows is selected as potential bull mothers and only about the best 1% to 3% of their male progeny eventually become sires of the next generation. In beef cattle and pigs, the selection intensity is not quite so great but, nevertheless, is very much more intense than can be achieved in natural breeding.

Direct genetic selection of sires is only one of the ways in which AI can be used for achieving genetic improvement, inasmuch as AI allows rapid dissemination and/or substitution of new breeds. In the UK, AI was one of the main means whereby the Friesian breed of cattle displaced the indigenous British dairy breeds. Subsequently, AI has also been the means by which the Friesian has been displaced by the Holstein. In such breed substitution programmes, AI can be used to change the gene pool of a national herd rapidly; a technique that is also used for upgrading unimproved cattle in remote areas. In this process, AI has the advantage of being both cheap and simple, inasmuch as local distribution of extended and cooled semen from a small number of imported sires is within the economic capabilities of even the poorest countries.

International trade in livestock is also facilitated by AI. Improved stock can be imported in the form of semen for AI rather than having to move animals themselves. By this means, many of the problems of acclimatisation, such as a lack of resistance to local diseases, can be eliminated. Importing semen also allows the importing country to exert a far greater level of effective control over the health status of the donor sires than if the livestock itself were imported.

The third major advantage of AI is the reduction in the number of sires that individual farmers need to maintain. The males of agricultural species generally require accommodation in which they can be segregated from the breeding females, so that breeding can be controlled; these buildings should also preclude, as far as

VetBooks.ir

possible, injury to farm staff. The significant housing and labour costs involved in keeping such animals can be obviated by the use of AI. Moreover, farmers generally have access to genetic material through AI centres that would be far beyond their financial ability to buy outright.

Nevertheless, although AI carries many advantages over natural breeding, the technique is not without drawbacks. Detection of the fertile period in the female oestrous cycle is potentially the most problematic aspect of AI programmes. In cattle, the prominent behaviour of oestrous females in which they repeatedly mount each other allows relatively accurate human identification of the fertile period. Likewise in pigs, receptive females 'freeze' when pressure is applied to their back. However, in most other species, detection of the most fertile period is less easy. In such species, detection of oestrus therefore requires the presence of infertile (e.g., vasectomised) males, or the timing of oestrus must be controlled by pharmacological regimens (e.g., oestrus synchronisation/induction; see Chapter 8), or management procedures (e.g., timing of weaning in sows). Thus for ewes, which do not normally display any signs of oestrus in the absence of a male, AI requires either the presence of vasectomised rams to detect oestrus or pharmacological manipulation of oestrus to define the timing of the fertile period. Hence, detection of the fertile period of the ewe is, to a greater or lesser extent, a costly procedure, thereby detracting from the appeal of AI in this species. It may therefore be considered that an economic 'trade-off' exists in such species between the genetic advantages conferred by the use of superior AI sires on one hand and the costs of maintaining teaser males or pharmacological manipulation on the other.

Once oestrus has been identified, the female animal has to be restrained for insemination, which generally requires separation from the herd or flock and holding in specialised pens. The process of insemination also requires trained personnel with a certain degree of technical proficiency, as with insemination of sows; however, in some cases the procedure may be technically demanding, as in the case of laparoscopic intrauterine insemination of ewes.

It is also necessary to log insemination dates into an adequate recording system so that expected dates of return to oestrus are known and in order to allow birth dates to be calculated, thus allowing appropriate observations to be made. In addition, the identity of the sire needs to be recorded (and his pedigree known) to avoid inbreeding. Some form of positive pregnancy diagnosis is advantageous, especially when males are not present in the herd, to ensure that non-returns to oestrus signify pregnancy rather than anoestrus.

The value of AI as a rapid means of transmission of the genes of superior sires has already been identified. However, a corresponding disadvantage exists, inasmuch as genetic faults can also be widely disseminated if they are present in an AI sire. Dominant traits should rarely be transmitted in this way, but recessive traits may be very widely transmitted, especially if the recessive gene is present in the general population at such a low incidence that many individuals may have to be bred before the condition is expressed in a homozygous progeny. Hence, AI programmes should be underpinned by an efficient reporting system for monitoring abnormalities in the progeny, with clearly defined criteria for the withdrawal from use of sires that carry deleterious genes. For example, in cattle, achondroplasia is transmitted as a simple recessive gene (Jones et al. 1978) that, when present in the homozygous condition, causes failure of long bone development, resulting in the birth of so-called 'bulldog' (achondroplastic) calves (see Chapter 9). The incidence of this gene in the general cattle population is so low that the birth of one or two calves with this deformity is regarded as sufficient reason to slaughter the bull and withdraw all stocks of its semen. Spastic paresis, which is probably genetically transmitted, is dealt with in a similar manner (Keith 1981). More recently, a complex vertebral malformation was identified in Holstein cattle in many countries (Agerholm et al. 2001), but affected sires could be effectively removed from the breeding pool by rapid identification through breeding records and genomic analysis (Thomsen et al. 2006). Moreover, it is also possible to disseminate conformational faults which, although not initially undesirable, can still have a significant effect upon the progeny (e.g., poor hind leg/foot conformation or poor udder attachment in cattle).

Concern over the possibility of inbreeding and reduction of the effective population of a breed has been suggested as a consequence of the widespread use of AI from a small number of highly selected blood lines. There is evidence that this may be taking place, particularly within the Holstein breed of cattle. A number of studies have identified real or potential negative effects of inbreeding on traits such as dystocia and reproduction (Adamec et al. 2006, McParland et al. 2007a), culling rate (Sewalem et al. 2006), and production traits (Biffani et al. 2002, Croquet et al. 2006), but generally not on type/conformational traits. Estimates of coefficients of inbreeding in Holstein cattle have shown a period of rapid increase during the 1990s, whilst the numbers of effective contributors to the breed is declining (Sorensen et al. 2005, Koenig & Simianer 2006, Kim & Kirkpatrick 2009). The rate of increase of inbreeding may have reduced in recent years (Stachowicz et al. 2011). This trend is also seen in beef cattle such as the Hereford and Charolais breeds (McParland et al. 2007b). McParland et al. (2007a) noted that although these effects were statistically significant, they were small and were unlikely to cause great financial loss at present levels. However, others advocate a more active role in the management of inbreeding (Kearney et al. 2004, Colleau & Moureaux 2006, Haile-Mariam et al. 2007).

Preparation of Semen for Use in Artificial Insemination

The methods for collection of semen from domestic mammals are described in Chapter 35. In most AI regimens, semen evaluation is limited to measuring numbers of spermatozoa, motility, and, usually, morphology. More sophisticated analyses may be used in determining whether an individual sire produces semen of a sufficiently high quality for acceptance into an AI programme, but such evaluations are rarely carried out on day-to-day collections of semen. Unless the semen is to be directly inseminated without delay into a single female, it is then extended and either cooled or frozen. Direct inseminations are performed most commonly in the bitch, usually in response to some incapacity of the sire that precludes normal mating (Roberts 1986) or the mare with chronic endometritis (Asbury 1986). Even in these circumstances, it is more common to place the semen in an extender before insemination. The major properties of semen extenders (Watson 1979) are described here.

Extension

The ejaculates of most domestic animals contain more spermatozoa than are needed for achieving a pregnancy. Hence, by diluting the semen, it can potentially be used for several inseminations. In species such as the dog and the horse, the whole sperm-rich

VetBooks.ir

fraction of the ejaculate is diluted and cooled, then used either for sequential inseminations of the same female over her extended oestrus period or after various determinations of the fertile period (Jeffcoate & Lindsay 1989, Brinsko & Varner 1993). In food animal species, the ejaculate is generally diluted so that it can be used to inseminate many females.

In either case, the maximum degree of dilution is determined from the minimum number of spermatozoa and the volume of inseminate that is deemed necessary to achieve acceptable pregnancy rates. These factors are themselves determined by the site of insemination, the survival of spermatozoa in extender, and the idiosyncrasies of individual species and sires. In general, when an intrauterine insemination can be achieved, the minimum numbers of spermatozoa are one or two orders of magnitude lower than for an intracervical insemination, which is itself one or two orders of magnitude lower than for an intravaginal insemination. Hence, when widespread use of sires is required, a great advantage exists in devising methods of achieving intrauterine insemination, even when this requires as complex a procedure as laparoscopic insemination, as in the ewe.

Addition of Volume

Insemination doses must be prepared in a volume that is a compromise between ease of handling and an appropriate volume for the site of insemination. Thus for ovine intracervical inseminations, minimising volume is important to reduce retrograde loss from the cervix (Evans & Maxwell 1987), whereas for porcine intrauterine inseminations, a minimum volume of 50 mL is required to spread the semen through the capacious uterus of the sow (Reed 1982).

Dilution of semen is not entirely straightforward, for mammalian spermatozoa placed in simple diluents exhibit an initial increase in motility, which is then rapidly followed by a loss of motility and increase in vital staining (Mann 1964). This phenomenon, known as the 'dilution effect', represents a loss of cell viability, probably through leaching of structural components of the cell membrane. Although it was of great concern among the early practitioners of AI, the use of extenders containing macromolecules such as proteins or polyvinyl alcohol was subsequently found to abrogate the dilution effect (Suter et al. 1979, Clay et al. 1984).

Buffering

Spermatozoa have a narrow range of tolerance to changes in pH, so provision of buffering capacity is necessary. Buffering is especially important when the semen is only to be cooled and not cryopreserved, as the metabolic activity of cooled spermatozoa remains appreciable (Salisbury et al. 1978). Although in many diluents the major volume component is also the major buffering agent, buffers are a minor constituent of some diluents. Simple buffers are effective, with citrate originally being widely used (Willett & Salisbury 1942). Phosphate-buffered saline is rather less suitable, as it predisposes to head-to-head agglutination of sperm. More recently, organic buffers have been used. Tris (tris(hydroxymethyl) aminomethane) is probably the most widely employed of such buffers, but the successful use of many similar materials (e.g., TES, HEPES, Tricene) has been described. The proteins contained in skimmed milk products also provide considerable buffering capacity to diluents. More recently, there has been a move away from using material of animal origin in semen extenders because of the risks of inadvertently transmitting disease. Lecithins from plants and liposomes have been used as substitutes for skimmed milk and egg yolk in semen extenders.

Maintenance of Osmotic Pressure

Seminal plasma has an osmotic pressure of 285 mOsmol, although spermatozoa can tolerate a moderate range of tonicity (Foote 1969). Some debate has centred on whether spermatozoa respond better to a slightly hyperosmotic (Foote 1970) or isosmotic diluent, with the former being generally favoured. Apart from the osmotic activity of the ionic component of diluents, a substantial contribution is made by proteins and, particularly, by sugars, which are added to provide nutrition for the spermatozoa or to contribute to the cryoprotective properties (Watson 1990) of the diluent.

Provision of an Energy Substrate

Most diluents make some provision of energy substrates for sperm. In general, simple sugars such as glucose, fructose, mannose, and arabinose are suitable substrates, although the rate at which these sugars are metabolised varies substantially between species (reviewed by Bedford & Hoskins 1990). Lactose, which is present in milk-based diluents, is not metabolised to any appreciable extent. However, egg yolk, also a component of many diluents, provides many substrates for the metabolism of spermatozoa (Salisbury et al. 1978). The provision of energy is relatively less important when semen is to be frozen, for the spermatozoa will only remain active for a few hours at most before freezing suspends metabolic activity. However, when the metabolism of spermatozoa has to be sustained for several days (e.g., if cooled semen is to be used) provision of energy is important.

Antimicrobial Activity

Antibiotics are added to most semen diluents as a prophylactic measure against the transmission of pathogenical bacteria and to reduce the load of nonpathogenical organisms that contaminate the semen. In cattle AI, benzylpenicillin and streptomycin (Melrose 1962) are the most widely used antibiotics, for these are efficacious against *C. fetus.* Most other antibiotics either fail to control this organism or are directly detrimental to sperm. Concern over the potential transmission of *Mycoplasma* and *Ureaplasma* species in bovine semen has led to the incorporation of lincomycin and spectinomycin (Almquist & Zaugg 1974) into semen diluents in an effort to control these organisms. There is evidence that the efficiency of antibiotics may be reduced in the presence of some components of diluents, notably egg yolk (Morgan et al. 1959); hence, the practice in some bovine AI centres is to preincubate the raw semen with antibiotic cocktails before the main dilution occurs. This procedure is commonplace in the United States but is rarely undertaken in Europe. Nowadays, there is increasing concern over the spread of antimicrobial resistance, which raises questions about whether the inclusion of antibiotics in semen extenders is justifiable because it has a prophylactic rather than a therapeutic purpose. Alternatives to antibiotics, such as the removal of contaminating bacteria during processing of the semen, would be preferable (Morrell & Wallgren 2014).

Extending Life Span

The life span of spermatozoa of most other species can be prolonged more conveniently by:

- Cooling to a temperature well below ambient;
- Freezing (cryopreservation); and
- Suspending the metabolic activity of the spermatozoa while maintaining it at ambient or cooled temperatures.

VetBooks.ir

Cooling and Cold Shock

Semen can be stored in a liquid form if the metabolic activity of the spermatozoa is reduced by cooling. The process of cooling from body temperature to 5°C results in considerable damage to the cells unless they are protected from the effects of the 'cold shock'. The development of cold shock is exacerbated by rapid cooling rates but cannot be entirely prevented even by slow cooling.

Cold shock results in damage to cell membranes, causing leakage of intracellular potassium, enzymes, lipids, cholesterol, lipoprotein, and adenosine triphosphate (ATP) (Salisbury et al. 1978). How this affects spermatozoon function remains incompletely understood, although it is clear that most of the effects are mediated through changes in the properties of cell membranes. Lowering temperature causes membrane phospholipids to change from a fluid to a gel phase, which, because this occurs at different temperatures for different structural lipids, can lead to phase separation. As a consequence, membrane proteins become irreversibly clustered, leading to loss of function (De Leeuw et al. 1990). Thus cold-shocked spermatozoa are more permeable, especially to calcium (Robertson & Watson 1986). The membranes are also more fusogenic, leading to alterations in the capacitation process (Johnson et al. 2000). Together, these changes are referred to as 'cryocapacitation'. Species differences and probably differences between individual sires depend on the composition of the membranes: ratios of different phospholipids and the concentration of cholesterol in the membranes appear to be critical determinants of the response to cold shock.

The most effective way of protecting spermatozoa against the detrimental effects of cooling is by the inclusion of egg yolk or milk in the diluent. Diluents for cooled storage of semen therefore typically contain approximately 20% of egg yolk plus a buffer. Skimmed milk, whole milk, and coconut milk have also been used successfully, although egg yolk is by far the most commonly used additive (Vishwanath & Shannon 2000). Whole milk contains a protein, lactenin, which is spermicidal, so milk for use as a semen diluent must be heat-treated (e.g., in the skimming process) to inactivate this toxic factor (Flipsse et al. 1954). Chemically defined extenders containing phosphocaseinate have now been developed (Batellier et al. 1998) and are tending to replace skimmed milk extenders. Early diluents were based on phosphate buffer, but citrate soon proved to be better, probably because it improves the solubility of egg yolk proteins. More recently, zwitterion buffers have also been used; Tris has been the most widely used but good results have also been achieved with TES (N-tris (hydroxymethyl) methyl-2-aminoethane sulphonic acid) or TEST (Tris titrated with TES) (Holt 2000).

Detailed understanding of the mechanisms by which egg yolk and other natural products prevent cold shock have been elusive, with the result that it has been difficult to produce chemically defined diluents. Early work identified that the key components of these materials were lecithins, proteins, lipoproteins, and similar complexes of large molecules (reviewed by Salisbury et al. 1978). Studies in the 1970s and 1980s (e.g., Watson 1976, 1981, Foulkes 1977) showed that the low density lipoprotein (LDL) fraction is the key component of egg yolk, with lipoproteins probably being the most important (Watson 1990). In the last 20 years it has been shown that lecithins from plants, e.g., soy lecithin, also have a protective effect and can be substituted for egg yolk (Hinsch et al. 1997) at least for some species. The evolution of soy-based extenders has been reviewed recently (Layek et al. 2016).

It has been suggested that LDL stabilises the spermatozoal membrane (Watson 1975), or protects the spermatozoon by forming a protective layer over its surface (Quinn et al. 1980) or by replacing membrane phospholipids that become lost or damaged (Foulkes et al. 1980). LDL, glycolipids, and cholesterol become incorporated into membranes, reducing their tendency to change from a liquid to a gel phase during cooling (Isachenko et al. 2004). Further studies focused upon the interaction of LDL with protein components in the seminal plasma (Vishwanath et al. 1992). Bergeron and Manjunath (2006) developed this idea further based upon their work on bovine seminal plasma proteins (BSP). They suggested that, *in vivo*, BSP bind to the membrane of the spermatozoa during ejaculation, facilitating the process of capacitation in the female tract. During storage, BSP binds to spermatozoal membranes and causes loss of phospholipid and cholesterol, thereby inducing one of the main mechanisms of cold shock. It is suggested that LDL, particularly phosphatidylcholine, binds BSP in the extender, preventing its interaction with the spermatozoa and hence protecting the membranes from damage.

The possibility of including liposomes in extenders to stabilise spermatozoal membranes during cryopreservation is also attracting attention (Röpke et al. 2011). Phosphatidylcholine liposomes have been incorporated into commercial extenders and used successfully for several species, e.g., bull (Röpke et al. 2011), dog (Belala et al. 2016), buffalo (Kumar et al. 2015), and stallion (Pillet et al. 2012).

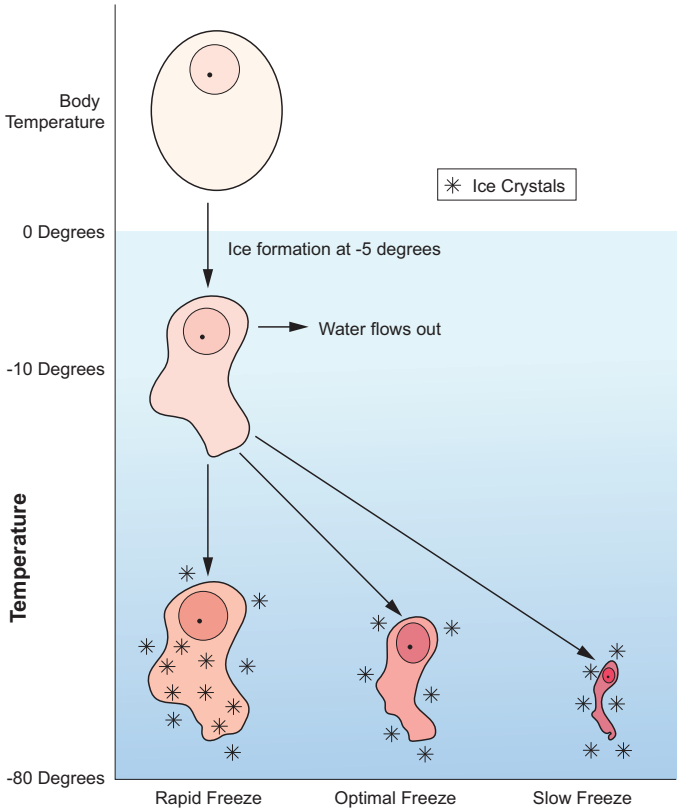
The fertility of bovine semen stored at 5°C in such diluents remains acceptable for 2 to 4 days (Foote et al. 1960), although that of ram semen only persists for 12 to 24 hours (Evans & Maxwell 1987). The decline in fertility that occurs after this time is initially due to decreased motility and survival in the female genital tract rather than to the death of spermatozoa per se. Short-term storage of semen by chilling to 5°C is, however, a very cheap and effective way of establishing an AI programme for cattle and is of value for on-farm collection and insemination of sheep, whereas the use of liquid boar semen at ambient temperatures remains, effectively, the basis of the technique in that species. Short-term 5°C storage is also widely used in the horse and the dog as it avoids the unpredictable response to freezing that characterises the semen of these species.

Cryopreservation and Cryoprotectants

Longer term storage of semen is achieved through cryopreservation, which facilitates dissemination of desirable genetic material to most parts of the world. Semen doses can be quarantined until the male has been shown to be free of disease at the time of semen collection. Cryopreservation maintains the fertile life of spermatozoa virtually indefinitely, although a large proportion of individual spermatozoa fail to survive the considerable stresses of freezing and thawing. To survive freezing, an extender is used that contains not only substances that protect against cold shock but also cryoprotectants such as glycerol (Polge et al. 1949), which protect them from the deleterious consequences of ice crystal formation.

The general responses of cells to freezing (reviewed by Farrant 1980, Watson 1990) were not understood until long after empirical methods of cryopreservation had become widely adopted. Initially, as the temperature of the external medium falls below its freezing point, crystals of pure water start to form. The concentration of solutes in the unfrozen part of the medium therefore rises as does its osmotic pressure. Ice crystals do not extend into the cell at this stage as they are excluded by the cell membrane. Thus the intracellular contents undergo a period of supercooling, during which the cell loses water to the unfrozen part of the extracellular

VetBooks.ir



• **Fig. 43.1** Shrinkage of cells during cryopreservation. Extracellular freezing induces conditions that allow osmotically induced loss of water from cells during slow freezing. This correlates with survival on thawing. Rapidly cooled cells do not have time to shrink, form intracellular ice, and are dead on thawing.

medium by osmosis (Fig. 43.1). A variable degree of cell dehydration follows, which is terminated by the formation of intracellular ice crystals. Thus damage can occur to cells in one of two ways. When a substantial degree of cellular dehydration occurs, the high concentrations of solutes in the residual intracellular water can be damaging, whereas, if only slight dehydration occurs, large ice crystals can form within the cell, which cause physical damage to its internal and bounding membranes. The degree to which each affects the cell is determined by the size of the cell and the rate of cooling. Thus the larger the cell, the slower its inherent rate of dehydration; the slower the rate, the more dehydration; the faster the rate, the greater the damage by ice formation.

However, the effects of freezing and thawing also need to be explained in terms beyond those of osmotic effects and ice crystal damage. Spermatozoal membranes are unusual in terms of the lipids of which they are composed and of the arrangements of lipids within the membranes. Cooling and cryopreservation causes phase changes in membrane lipids, which results in loss of integrity, loss of control of calcium movement, and loss of membrane ATPase activity (Holt 2000). Many spermatozoa do not survive these processes – typically less than 50% of the viable spermatozoa that were present before cryopreservation. Moreover, even for the spermatozoa that do survive, capacitation-like changes to the head occur (Curry 2000, Thomas et al. 2006), which alter the duration of their survival in the female reproductive tract. It has been suggested that species-to-species variations in the ability of spermatozoa to survive cryopreservation, as well as some sire-to-sire variability within species, can be attributed to the ability of membranes to withstand or accommodate these changes.

Responses of spermatozoa to cryopreservation can be improved by the use of cryoprotectants, the composition of the extender and the rate at which spermatozoa are frozen and thawed. Cryoprotective agents are classified as those that enter the cell (permeating) or that are retained in the extracellular fluids (non-permeating). The actions of cryoprotectants were originally thought to be mediated solely through hydrogen-bonding of water, thereby reducing the availability of water either for dehydration or for ice crystal formation. Penetrating cryoprotectants (e.g., glycerol or dimethyl sulphoxide (DMSO)) reduce the loss of water from the cell, thereby reducing solute damage, and bind it in a form that renders it unavailable for ice crystal formation. Non-penetrating cryoprotectants, such as disaccharides or proteins, may hasten dehydration during very rapid cooling, thereby minimising intracellular ice formation.

However, other mechanisms are also involved. Polar molecules such as glycerol and sugars appear to form hydrogen bonds with the polar head groups of membrane lipids (Vishwanath & Shannon 2000), stabilising the membranes during transition through critical temperature zones (Woelders 1997). Likewise, insertion of glycerol into the membrane bilayer also appears to affect stability and water permeability of the membranes through altering the physical properties of the membrane lipids (Holt 2000). Sugars such as glycerol alter the mechanical properties of the diluent by increasing its viscosity. This prevents crystallisation of solutes and increases the glass-forming tendency of the medium (a property that is exploited in vitrification methods of freezing larger cells; Isachenko et al. 2004).

Unfortunately, permeating cryoprotectants are relatively toxic to spermatozoa. Glycerol, which is the main primary cryoprotectant used in freezing mammalian sperm, has direct toxic effects upon spermatozoa (Watson 1979, 1990). Concentrations of glycerol that can be tolerated by spermatozoa depend on the species and the other components of the diluent. For example, extenders for bovine semen that contain disaccharides can use lower percentages (3%–4%) of glycerol than diluents that lack such disaccharides, which have a final glycerol concentration of at least 7% (Unal et al. 1978). Bulls' spermatozoa seem to be relatively resistant to the toxic effects of glycerol, whereas boars' spermatozoa, for example, tolerate much lower concentrations before toxic effects start to occur.

Whether the toxic effects of glycerol are exacerbated at high temperatures has been a matter of debate. Early studies (Polge 1953) showed that the addition of glycerol at 28°C was more damaging to bovine spermatozoa than its addition at 4°C, although Salisbury et al. (1978), reviewing the (by then) copious literature, concluded that the effects of temperature were equivocal. It was subsequently suggested that multistep addition of glycerol avoids excessive changes in cell volume that can result in membrane rupture (Gao et al. 1993, 1995). Nevertheless, normal practice in commercial bovine AI centres is that, when the final concentration of glycerol is high (≈7%), a primary dilution of the semen is made with a diluent containing little or no glycerol, with glycerolisation being carried out after reducing the temperature to 4°C. However, diluents that use lower final concentrations (< 5%) are added in one step at 30°C. With boar semen, the toxicity of glycerol at high temperatures is much less equivocal, and low-temperature glycerolisation is desirable (Paquignon 1985). It is possible that the spermatozoa from individual sires may show less tolerance to glycerol than others.

The potential toxicity of glycerol has led to the search for other, less toxic, cryoprotectants. Whereas substances such as ethylene

VetBooks.ir

glycol and propanediol can be used to cryopreserve embryos, they do not have any advantage over glycerol for freezing spermatozoa. Various amides, however, have been shown to be beneficial, at least for the semen of some individuals and depending on which cryoextender is used as the base (see review by Alvarenga et al. 2005). A combination of dimethylformamide and glycerol in INRA96 was a useful cryoprotectant for stallion semen (Alvarez et al. 2014). In contrast, dimethylacetamide did not improve the survival of boars' spermatozoa (Yang et al. 2016).

Oxidative damage also occurs to the membranes of spermatozoa during the freezing process. A number of studies have implicated membrane lipid peroxidation as a cause of defective spermatozoal function after cryopreservation (Salamon & Maxwell 1995). Attempts to overcome this problem have included the addition of antioxidants such as glutathione peroxidase (Slaweta & Laskowska 1987) or catalase (Shannon 1972), although it has also been suggested that the measurement of the degree of oxidation of membrane phospholipids may be a useful means of assessing the quality of frozen–thawed spermatozoa (Neild et al. 2005).

The first methods for freezing semen involved placing diluted semen in glass ampoules for freezing in a mixture of alcohol and solid carbon dioxide at −79°C, or drops of diluted semen were placed directly on to the surface of a block of solid carbon dioxide where they froze in pellet form (Salisbury et al. 1978). Long-term storage at −79°C was not satisfactory, however, as deterioration occurred at that temperature (Pickett et al. 1961, Stewart 1964). Storage in liquid nitrogen at −196°C has subsequently become established as the standard method for long-term preservation of semen and, over the 40 years for which it has been practised, has maintained semen fertility unscathed. At the present time, semen is frozen in the vapour of liquid nitrogen and then stored long-term in liquid nitrogen. Diluted semen is packed into thin, plastic tubes ('straws' or 'paillettes') of 0.25 or 0.5 mL capacity, then in the simpler techniques, these tubes are suspended in the vapour of liquid nitrogen, which is at about −120°C, for about 10 minutes (Cassou 1964, Jondet 1964). The straws are then plunged into the liquid nitrogen. Subsequently, it was found that a greater degree of control of freezing rate could be achieved by the use of microprocessor-controlled freezers. Some studies have suggested that improved survival of spermatozoa may be sufficient to justify the increased cost of the processing (e.g., Landa & Almquist 1979, Parkinson & Whitfield 1987). On the other hand, although the control of freezing rate is not as good in open tank methods as in programmable freezers, the latter are not as amenable to processing large batches of semen, or if large batchers are processed, there can be significant variation in cooling rate (and hence post-thaw survival) across the cooling chamber. Hence many organisations have chosen to continue to use the less well-controlled open tank methods (Vishwanath & Shannon 2000). Boar semen may be frozen in larger volumes of 5 mL in flat packs (Eriksson et al. 2002).

New Methods of Cryopreservation

Vitrification, a process in which a liquid turns into a solid without the formation of ice crystals, has been evaluated for cryopreservation of cell types that do not survive traditional freezing methods particularly well. Spermatozoa are particularly sensitive to ice crystal formation because their long tail is likely to span regions in the freezing diluent that contain both ice crystals and hyperosmotic diluent (Holt 2000). These random patterns of extracellular ice, together with the intracellular ice that can also be formed during the cooling process, are a significant source of cell damage. In freezing large cells, such as embryos or oocytes, vitrification processes normally require high concentrations of cryoprotectants, which themselves impede cell survival through their toxic effects (Vajta et al. 1997; Vajta 2000). However, recent studies have suggested that ultrafast freezing of spermatozoa can result in vitrification without the presence of a cryoprotectant (Isachenko et al. 2004) and, providing ice recrystallisation during thawing is prevented, results in acceptable post-thaw recovery rates. As yet, it has not been possible to recover motile spermatozoa post-vitrification. However, offspring have been produced after intracytoplasmic injection of reconstituted vitrified spermatozoa (Sánchez et al. 2011, Isachenko et al. 2012), leading to the hope that refinements in the procedure may eventually lead to the retention of spermatozoal motility.

A further new technique is the development of a 'multithermal gradient' as a means of controlling and optimising the formation of ice during the freezing process (Arav et al. 2002). Samples are moved at a constant velocity through a linear temperature gradient (Gacitua & Arav 2005), which controls the point at which ice forms and the morphological characteristics of the ice crystals. This method appears to result in good post-thaw recovery rates (ranging from 45% in the boar to 65% in the bull; Arav et al. 2002) and has the advantage that semen can be frozen in bulk, rather than necessitating the small volumes of pellets or paillettes (Gacitua & Arav 2005).

Thawing

Thawing of the semen needs to be rapid, since slow thawing allows recrystallisation of ice within the cells, causing membrane damage (Salisbury et al. 1978). In practice, the rate of thawing is rarely critical, although thawing at 30° to 37°C for 10 to 60 seconds is commonly recommended for bovine semen (see Fig. 43.3B). Much higher temperatures (e.g., 60°C) for a short period of time have sometimes been recommended as a means of improving recovery rates; however, the practical difficulties of using such methods in the field have meant that they have not been widely adopted. Of far greater importance is the temperature control of the thawed semen, which should not be allowed to cool lower than the final temperature achieved during thawing; otherwise, substantial losses of spermatozoa can occur. Rethawed spermatozoa are as sensitive to fluctuations in temperature as are their unfrozen counterparts (Roberts 1986) and cold shock can easily be induced if post-thaw cooling occurs (Nebel 2007). In addition, controlling the temperature of semen during withdrawal from storage flasks is important (see Fig. 43.3A): temperatures in the top third of the neck of the flask are high enough for ice recrystallisation to occur in the straws, resulting in markedly reduced post-thaw survival (Nebel 2007).

Ambient Temperature Preservation

For spermatozoa to be stored at ambient temperatures, alternatives to cooling have to be found to slow down their metabolic rate. There may also be advantages to ambient temperature preservation of semen because both cooling and cryopreservation are associated with a significant loss of both numbers and functionality of sperm. Moreover, some species do not tolerate cooling or cryopreservation well (e.g., the boar), so for these species, ambient temperature dilution is imperative. Strategies that have been used for ambient temperature diluents include:

- Decreasing the proportion of egg yolk to a level at which the beneficial effects on cold shock are retained but the toxic effects of other yolk components are avoided;

VetBooks.ir

- Lowering pH to approximately 5.5, resulting in a reversible inhibition of spermatozoal motility (although reducing the pH below 5.5 is spermicidal);
- Saturating the diluent with carbon dioxide also causes a reversible inhibition of motility; diluents, such as the Illinois Variable Temperature (IVT) diluent, that were based on this principle were able to maintain the viability of spermatozoa for approximately 48 hours; longer term maintenance (up to 5 days) is achieved in diluents (e.g., the Cornell University Extender (CUE) or Caprogen diluent) that are self-carbonating from the reaction of citrate and bicarbonate (Vishwanath & Shannon 2000);
- Gassing with nitrogen; this reduces oxygen tension in the diluent, thereby inhibiting the motility of spermatozoa without the need to lower pH; this is used in the Caprogen diluent; and
- A combination of buffers, glucose, and antibiotics (Beltsville Thawing solution) sufficient to maintain boar spermatozoa for several days; longer term storage (up to 7 days) requires a more complex mixture of buffers and also additional antibiotics.

Other components of ambient temperature diluents (simple sugars, buffers, egg yolk/milk, antibiotics, catalase) are similar to those used in diluents for cooled or cryopreserved semen.

Microencapsulation

Encapsulation has also been investigated as a means of preserving spermatozoa without the need for recourse to cryopreservation. Sperm encapsulation is the process of enclosing spermatozoa within a semipermeable membrane (Nebel et al. 1985). Spermatozoa remain viable within the microcapsules because the semipermeable membrane permits the exchange of low molecular–weight nutrients and metabolites with the medium within which they are contained (Roca et al. 2006a), but prevents transfer of large molecules.

The process of microencapsulation has been described by Nebel et al. (1993). After extension in an ambient temperature diluent, spermatozoa are suspended in a sodium alginate solution. Spraying into a high calcium buffer solidifies droplets of diluted sperm, after which the semipermeable membrane is constructed on the surface of the droplet. Polyamines such as protamine sulphate, polyvinylamine, and poly L-lysine have been used successfully. Calcium is then chelated, which converts the gel core of the microcapsule back to a liquid phase. Barium has been used as an alternative to calcium, with the advantage that it does not precipitate premature capacitation (Torre et al. 2007).

Microencapsulation has been used for the ram (Maxwell et al. 1996), the boar (Faustini et al. 2004), and the bull (Vishwanath et al. 1997) semen. Spermatozoa are released from the capsules over a period of at least 24 hours, and in the case of the bull, this may be extended to 96 hours. Preliminary results show that acceptable conception rates can be achieved with encapsulated spermatozoa and that the timing of insemination in relation to the time of ovulation is less critical than with other forms of preserved semen. However, limited development of the technology has taken place for use in insemination, although it is more widely used for other forms of cell preservation (Torre et al. 2007). One such development is to use a solid gel network to immobilise the spermatozoa instead of enclosing them in gel microcapsules to mimic the conditions in the epididymis (Standerholen et al. 2015). Insemination trials in cattle indicate that 56-day non-return rates were similar between conventional frozen thawed semen doses (72.5%) and frozen–thawed, gel-immobilised doses (72.7%) (Standerholen et al. 2015).

The possibility of encapsulating sexed spermatozoa as an attempt to compensate for low spermatozoa numbers is of interest. Use of encapsulated sexed boar spermatozoa reduced the incidence of polyspermy in *in vitro* fertilisation (IVF) and did not produce any additional damage to the spermatozoa during storage for 72 hours (Spinaci et al. 2013).

Spermatozoa Selection

It is possible to improve semen quality by selecting functional spermatozoa from a semen sample. Various methods have been proposed over several decades, as reviewed by Morrell and Rodriguez-Martinez (2016), but only colloid centrifugation of stallion spermatozoa has proved to be practical in the field. Basically, these methods mimic the selection for 'normal' spermatozoa that is believed to occur in the female reproductive tract (Suarez 2007) and can therefore be described as 'biomimetic' (Morrell & Rodriguez-Martinez 2009). These methods rely on one or more physical attributes of functional spermatozoa, namely that they are motile and have normal morphology as well as intact plasma and acrosomal membranes. Thus migration techniques such as 'swim-up' rely on motile spermatozoa being able to move away from an area containing many spermatozoa to one containing relatively few. Passage through Sephadex gel, glass wool, or colloids impedes spermatozoa with reacted acrosomes, damaged membranes, or abnormal morphology. Colloid centrifugation also separates spermatozoa with mature chromatin from those with immature or damaged chromatin.

Colloid-Selected Spermatozoa

Colloids consist of nano-sized particles in suspension; both silica colloids and iodixanol are suitable for the preparation of spermatozoa. Initially, polyvinylpyrrolidone-coated silica was used in density gradients to prepare human spermatozoa for assisted reproduction (Bolton & Braude 1984), and it was also used in this form to prepare animal spermatozoa for IVF. There was some concern that this type of coated silica was toxic to bull spermatozoa (Avery & Greve 1995), but this issue has since been resolved by replacing the PVP-coated silica with silane-coated silica. From 2008, silane-coated silica has been used as a single layer instead of a density gradient (single layer centrifugation; SLC), thus facilitating scaling up of the method to process whole animal ejaculates (Morrell et al. 2009a), even from boars (Morrell et al. 2011). Such SLC-selected spermatozoa samples contain a higher proportion of morphologically normal spermatozoa, which have good motility, intact membranes and good chromatin integrity, than unselected controls (Morrell et al. 2009b). Selected stallion spermatozoa samples survive longer during cooled storage and also show enhanced cryosurvival (Hoogewijs et al. 2011, Martinez-Alborcia et al. 2012); pregnancy rates after insemination are better than controls (Morrell et al. 2014).

There has been some debate whether the apparently enhanced spermatozoa quality after colloid centrifugation is due to selection for a particular spermatozoa subpopulation, or merely to exclusion of immotile or damaged spermatozoa. There is some evidence that the spermatozoa that pass through the colloid produce less hydrogen peroxide as a by-product of metabolism than controls (Morrell et al. 2017), lending credence to the theory that there is selection for a particular spermatozoa subpopulation. However, further research is needed to verify this suggestion. Whatever the mechanism of action, the use of good quality spermatozoa samples for assisted reproduction is associated with enhanced fertility, and therefore this method of processing semen samples is worth pursuing.

VetBooks.ir

Sexed Semen

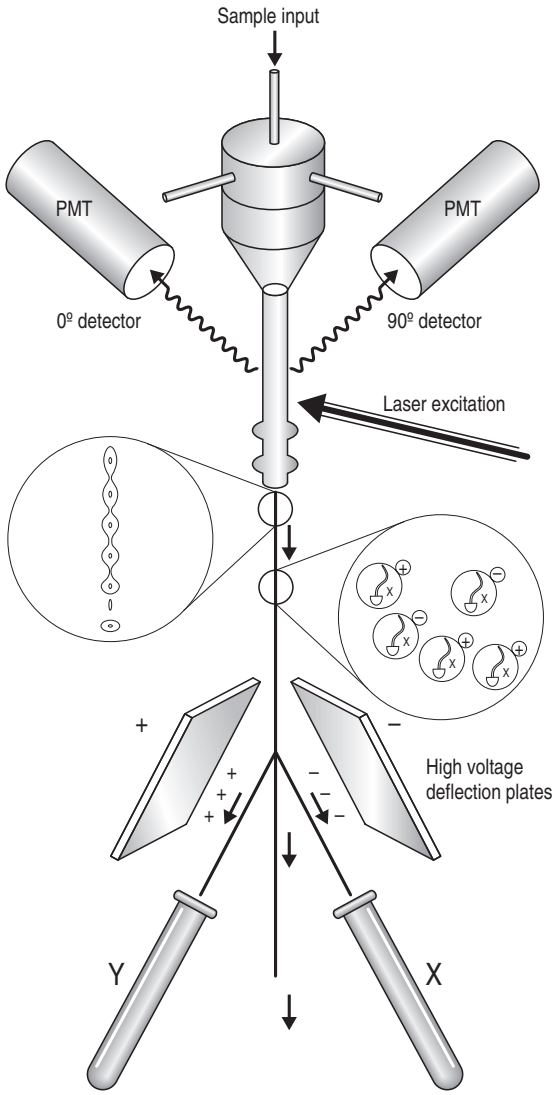
A long-standing goal of the AI industries has been to be able to control the sex of offspring, by separating X- and Y-bearing sperm. Many methods have been developed in attempts to achieve this goal. Most of these proved impractical or ineffective, but in recent years, flow cytometry has been developed to a point at which spermatozoa sexing is available as a commercial service. The technique of sexing semen has been reviewed by Seidel and Garner (2002), Garner (2006), and Seidel (2007).

Separation of spermatozoa on the basis of surface antigens is an attractive option, as it would allow bulk processing of semen. However, early attempts, based on the H-Y antigen, and more recent investigations, based on sex-specific proteins, have yet to yield practical sorting methods. Major problems with this approach are the limited transcription that takes place in the haploid cell and the cytoplasmic bridges that join spermatozoa until just before their release from the seminiferous epithelium. Electrophoresis methods based on the principle that X- and Y-bearing spermatozoa may have different surface charges have also only had limited success to date.

Hence most attention has been upon the using the different mass of DNA in the X- and Y-bearing spermatozoa as the basis for sorting and separation: X-bearing spermatozoa of domestic animals contain approximately 4% more DNA than Y-bearing sperm. The principle of sexing semen is to stain the DNA with a fluorescent dye that binds to the DNA but does not damage it. The difference in fluorescence between the X- and Y-bearing spermatozoa can then be measured and cells sorted accordingly (Keeler et al. 1983, Johnson et al. 1987). DNA is stained with the membrane-permeable agent bisbenzimidazole DNA-binding dye, Hoechst 33342 (Morrell et al. 1988, Garner 2006), which binds specifically to A-T pairs along the minor groove of the DNA (Seidel & Garner 2002). Spermatozoa are separated from live cells by further staining with a food dye, FD&C#40, which permeates dead cells and quenches the fluorescence of Hoechst 33342 but is excluded from living cells. The stained cells are then passed through a flow cytometer for sorting, based on fluorescence from the stained DNA.

After measuring the amount of DNA, the vibrating nozzle in the flow cytometer breaks the solution containing the spermatozoa into tiny droplets, most of which contain a single spermatozoon (some droplets contain no sperm, a few contain two sperm). A charge is placed on the droplet as it leaves the sorter such that droplets containing spermatozoa with Y chromosomes are given a negative charge and those containing spermatozoa with an X chromosome are given a positive charge. The droplets then pass through an electromagnetic field, which deflects droplets with a positive charge (X chromosomes) towards the negative side (and vice versa for negatively charged droplets). Somewhere in the region of 20% of spermatozoa are successfully sorted as X-bearing, 20% as Y-bearing, with the remainder unidentified or dead. This process is illustrated in Fig. 43.2.

The process is relatively slow, however. Currently, 14 insemination doses of 2×10^6 live spermatozoa of each sex can be produced per hour (Seidel 2014). Moreover, the spermatozoa have been subjected to a number of insults during the separation process (staining, laser, high pressure, electrical charge), which impair their subsequent function. There is evidence of more chromatin abnormalities in sorted spermatozoa (Bochenek et al. 2006), but H33342 does not appear to cause any mutagenic damage to the genome. Altering the conditions for the cell sorting process can reduce the overall level of spermatozoa losses (Schenk & Seidel 2007). Recent developments by the patent holders have apparently improved the sex-sorting conditions such that conception rates are now similar between nonsexed and sexed spermatozoa doses (Lenz et al. 2016). However, no details of the process were provided. It remains to be seen whether similar results can be obtained in field AI under conventional conditions.



• **Fig. 43.2** Flow cytometric sorting of X- and Y-bearing sperm. After staining, the sperm are passed by photomultiplier tubes (PMT). The electronic signals from the PMT are sent to a computer for analysis. Thereafter the fluid stream is broken into droplets and a positive charge is placed on droplets identified to contain a Y-bearing sperm and negative charge on droplets with X-bearing sperm. The drops then travel between high voltage fields, which direct them to their respective collection tubes. (Derived from Johnson & Welch 1999, Seidel & Garner 2002.)

Sorted spermatozoa can survive cryopreservation, but the low numbers of spermatozoa that are present generally require specialised insemination routes to achieve acceptable pregnancy rates (see later in this chapter). Alternatively, sexed semen can be used in *in vitro* fertilisation (cattle) or intracytoplasmic spermatozoa injection (horse) for the production of embryos of known sex (Wheeler et al. 2006). However, as noted by Garner (2006), the effective use of sexed semen in animal breeding industries requires further development in the speed and efficiency of sex sorting, as

well as development in the technology of AI in order to utilise such spermatozoa efficiently. The idea of combining encapsulation and sex-sorting, as previously mentioned, may represent one such development (Spinaci et al. 2013).

Diseases Transmissible in Semen

Many infectious agents can be transmitted through semen. Foot and mouth virus can be transmitted in the semen of all species that are susceptible to this infection (Callis & McKercher 1980, Radostits et al. 2007). Indeed, control of foot and mouth transmission has, until recently, underpinned the UK legislation controlling AI of cattle, with broadly similar regulations in force throughout much of the developed world. Diseases of cattle, small ruminants, and horses that are potentially transmissible in semen are listed in Table 43.1.

The World Organisation for Animal Health (OIE) therefore stipulates that sires that are to be used in AI centres for international trade should be tested for freedom from a number of diseases. Many importing countries also require animals to be free of additional diseases. When semen is diluted in egg yolk, there is generally a requirement that the eggs are derived from specific-pathogen-free (SPF) flocks. These regulations are also applied to use of semen in domestic trade within the European Union.

Artificial Insemination of Cattle

Collection and Storage of Semen

Semen is usually collected by an artificial vagina, although electroejaculation is occasionally used (see Chapter 35). After assessment for motility, the concentration of spermatozoa, and, occasionally, their morphology, the semen is extended into insemination doses. The degree of extension and the extenders used depend on its intended application. Most bull semen is cryopreserved, although some is used after simple extension and chilling to 4°C. The practice of using an ambient temperature extender for bull semen is virtually unique to New Zealand, where the practice is made possible by the low incidence of infectious disease, and is required for the highly seasonal pattern of reproduction in its dairy cows.

For cryopreservation or for use at 4°C, the semen is first extended with an extender based on either egg yolk or skimmed milk (Salisbury et al. 1978, Vishwanath & Shannon 2000); see Table 43.2. The semen is then cooled to the appropriate storage temperature. If it is destined for use cooled, spermatozoal motility will be reassessed before releasing the semen for use. If the semen is destined for cryopreservation, glycerol is also added; then the semen is packed into 0.25 or 0.5 mL paillettes (or, rarely, 0.5 or 1.0 mL glass ampoules). The semen is then 'equilibrated' for 1 to 4 hours. It was originally considered that this was the period in which glycerol penetrated the sperm, although subsequent observations indicate that the penetration of glycerol is very rapid and that most of the equilibration period is concerned with membrane stabilisation during exposure to low temperatures (Watson 1979). Recently, there has been a trend to equilibrating the semen in cryoprotectant overnight before freezing (Anzar et al. 2011), which may be more compatible with the routines on the bull station. The semen is then frozen in liquid nitrogen vapour or in a microprocessor-controlled freezer. The semen thereafter remains in liquid nitrogen until thawed for use. Freezing in alcohol and solid carbon dioxide or in pellets on blocks of solid carbon dioxide, although formerly used widely, has now virtually ceased.

The ability to perform an intrauterine insemination in cattle means that a relatively low dose of spermatozoa is required to achieve acceptable pregnancy rates. Typically, of the 10 to 25 × 10^6 spermatozoa that are required in each insemination dose, 6

to 7×10^6 survive freezing, a figure that is generally regarded as the minimum dose compatible with acceptable fertility (Milk Marketing Board 1967, Sullivan & Elliott 1968). An exception is when sexed semen doses are used because the sexing procedure takes such a long time: typically 1.5 to 2.0×10^6 spermatozoa are inseminated, although pregnancy rates tend to be 80% of those obtained with unsexed spermatozoa (Garner 2006). Lower numbers of spermatozoa can be used for fresh semen (Salisbury & VanDemark 1961).

The use of ambient temperature extenders for bull semen is precluded in most countries by the risk of contamination of the semen with foot-and-mouth disease virus. However, it has many advantages over other methods of extension because many more spermatozoa survive in the absence of freezing, albeit for a limited time. Whereas cryopreserved bull semen requires about 10 to 25×10^6 spermatozoa per insemination, semen extended in an ambient temperature extender can achieve acceptable fertility with fewer than 2.5×10^6 spermatozoa per insemination (Shannon et al. 1984). Initial work on ambient temperature diluents for bovine semen was based upon the use of the IVT diluent (Salisbury & VanDemark 1961, Melrose 1962), but the development of ambient temperature dilution has subsequently been based upon the use of the CUE and Caprogen diluents (Shannon 1965; Table 43.3). With the subsequent modifications that have taken place, these diluents are now capable of maintaining spermatozoa viability and acceptable conception rates for up to 5 days, with an insemination dose of between 0.5 and 2.5×10^6 spermatozoa.

TABLE 43.3 Diluents for ambient temperature extension of bovine semen

Basic Diluent (g/Litre)	Cornell University Extender	Caprogen Diluent
Sodium citrate	14.5	20
Citric acid	0.87	
Sodium bicarbonate	2.1	
Glycine	20	10
Glycerol		12.5
Glucose	3	3
Potassium chloride	0.4	
Caproic acid		0.3125
Preparation of Diluent		
Basic diluent	80%	80%
Egg yolk	20%	20%
Nitrogen gas		Bubbled for 20 min at 5°C
Catalase		4.5 mg/L

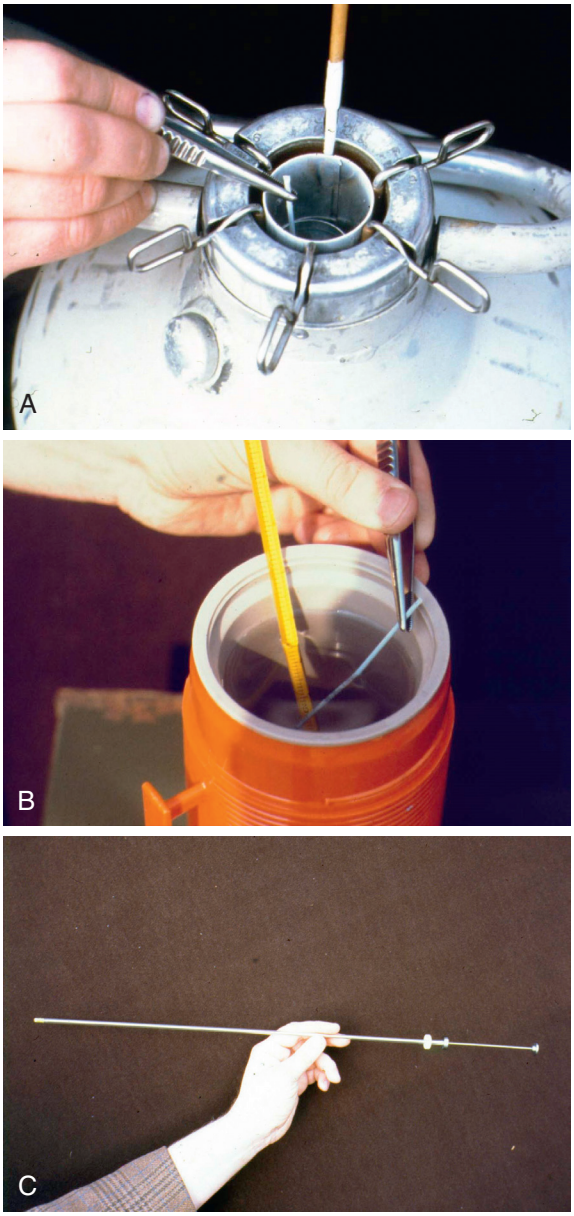
Insemination

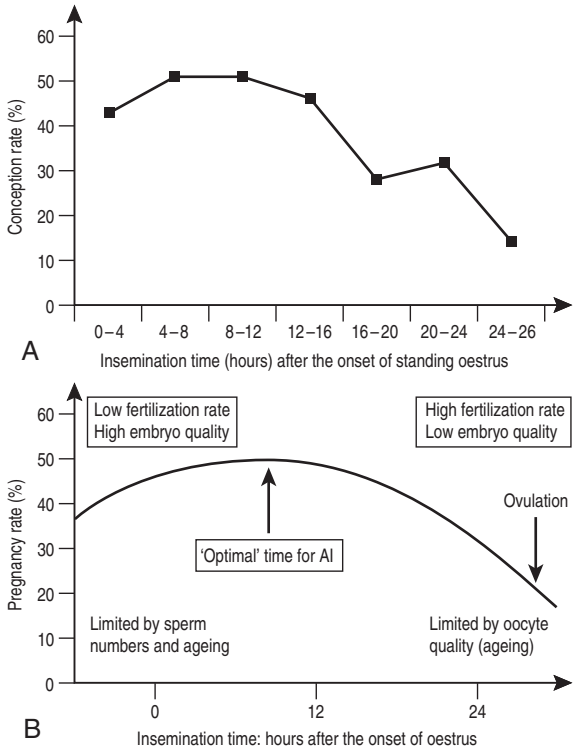
Before insemination, straws of semen are withdrawn from liquid nitrogen storage, ensuring that the canister containing the frozen semen remains contained within the neck of the storage flask (Fig. 43.3A). After identification of the sire, excess liquid nitrogen

VetBooks.ir



• **Fig. 43.3** Semen handling for bovine artificial insemination. (A) Withdrawing a straw of frozen semen from the liquid nitrogen flask. The canister containing the semen should not be lifted higher than the level of the top of the neck of the flask. (B) Thawing. After checking the identity of the sire, the straw is thawed. Water temperature is not really critical but placing the straw in water at 37°C for 10 seconds is a typical thawing regime. (C) The straw is placed in an insemination catheter, which is then covered with a plastic sheath. The catheter is then ready for use, but care must be exercised not to allow the semen to become chilled again before it is inseminated.

is flicked out of the end of the straw before it is deposited into thawing water (Fig. 43.3B). After thawing, the straw is dried and the identity of the sire is rechecked, before loading it into the insemination catheter (Fig. 43.3C). It is important that the temperature remains constant after thawing, as semen must not be allowed to cool lower than the temperature at which it was removed from the thawing water. Hence, it is generally preferable to thaw small numbers of straws at a time, depending on the proficiency of the inseminator and the temperature of the environment.



• **Fig. 43.4** Optimal timing of insemination in cattle (A) derived from observations of the onset of oestrus; (B) as a compromise between fertilisation rate and embryo survival rate. (Redrawn from Saacke et al. 2000.)

Timing

Cows ovulate approximately 12 hours after the end of oestrus. The ideal time for insemination is therefore 6 to 24 hours before ovulation (Roberts 1986). Observations of conception rates of animals that were inseminated at different times after oestrus (Fig. 43.4A) led to the development of the 'a.m.–p.m.' rule, by which cows first seen in heat in the morning were inseminated that afternoon, whereas those first seen in heat in the afternoon were inseminated the next morning (Olds & Sheath 1954, Foote 1979).

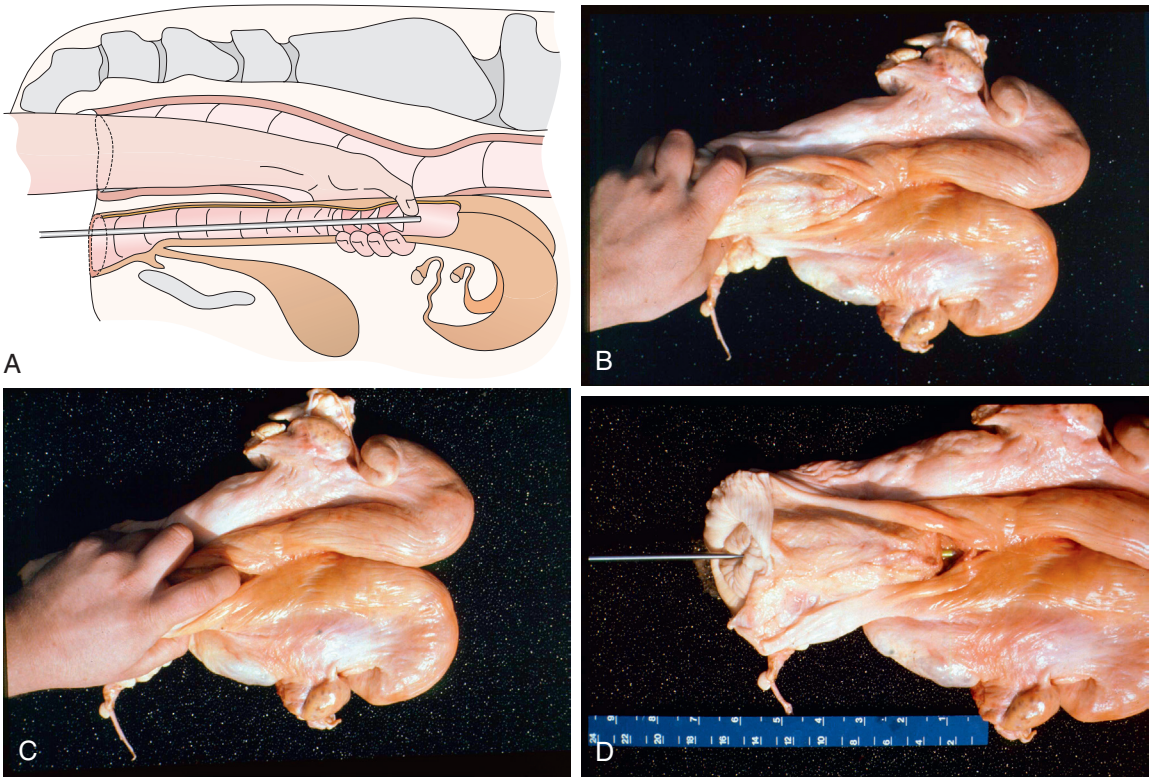
In fact the optimal timing of insemination is a compromise between many factors. Insemination early in oestrus is likely to achieve a low fertilisation rate because of limitations on spermatozoal viability, whereas oocytes that are successfully fertilised are likely to yield high quality embryos. Conversely, insemination late in oestrus is less likely to result in limitations on spermatozoa viability but is more likely to result in the fertilisation of an aged oocyte, resulting in impaired embryo development (Saacke et al. 2000). According to this proposal, the 'optimum' timing of insemination represents a compromise between the processes of aging of spermatozoon and oocyte (Fig. 43.4B). However, these processes are also affected by the duration of oestrus and the interval between the onset of oestrus and ovulation as well as the degree to which the spermatozoa have been affected by the preservation process. The latter can further involve both precapacitation changes and impairment of spermatozoa viability in the female tract.

Site

Standard Method of Insemination

Cows are inseminated at the internal cervical os or just inside the short uterine body. The standard technique of insemination is to grasp the cervix through the rectum with the left hand. A

VetBooks.ir



• **Fig. 43.5** Rectovaginal method of insemination. (A) General method. (B) Partially dissected bovine uterus showing grip on the cervix for the obliteration of the vaginal fornix to facilitate entry of the catheter into the external os of the cervix. (C) Second grip on the cervix to allow passage of the catheter through the tortuous cervical canal: the index finger is gently pressed over the internal os in order to feel the tip of the catheter as it emerges from the cervical canal. (D) Site of deposition of semen in the uterine body: the recommended site is no more than 0.5 cm deep to the internal cervical os.

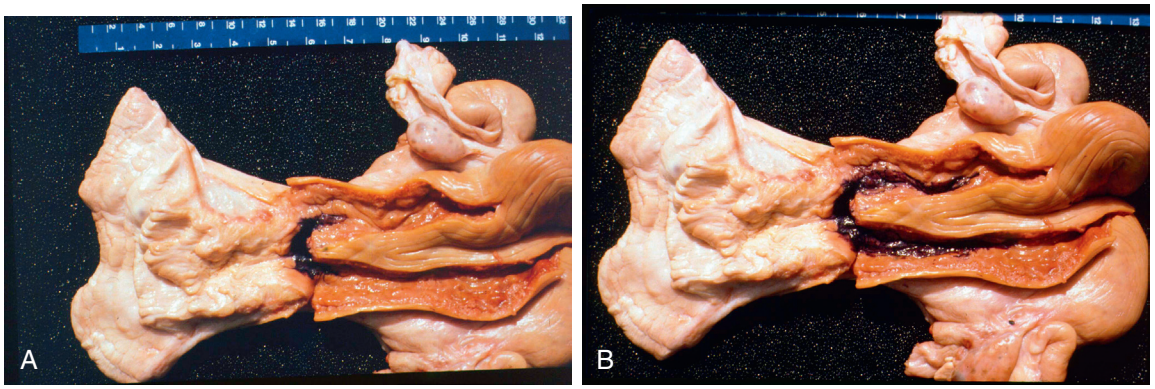
catheter, into which a paillette of semen has been inserted (Figs 43.3C, 43.5A) is then passed into the vagina and manipulated into and through the cervix by the right hand. This technique, the rectovaginal method of insemination, requires considerable practice for success. The vulval lips are opened by downwards pressure from the arm in the rectum, while the circular folds of vaginal mucosa are obliterated by pushing the cervix forward. The catheter is initially inserted pointing upwards at an angle of about 30° to avoid entering the urethral meatus or fossa and is then moved horizontally until it engages in the external os of the cervix. The left hand squeezes the anterior vagina on to the caudally projecting external os of the cervix, thereby obliterating the fornix of the vagina (Fig. 43.5B) and facilitating entry of the catheter into the cervix. Entry into the external os is accompanied by a characteristic 'gritty' sensation. The catheter is then introduced through the convoluted cervical canal by manipulation of the cervix through the rectal wall. One finger is placed over the internal os of the cervix so that the tip of the catheter can be palpated as it emerges from the cervical canal (Fig. 43.5C). As soon as the catheter has emerged, deposition of semen into the uterus begins and the catheter is not advanced any deeper into the uterus. In this way, semen should be equally distributed between the two uterine horns (Figs 43.5D and 43.6A, B). Insemination deeper into the uterus runs the risks of either inseminating into the uterine horn contralateral to the ovulation site or scoring the endometrium with the tip of the insemination catheter. Reduced fertility is the consequence of these errors.

No forward pressure should be exerted on the catheter with the right hand because the uterine wall is friable and easily penetrated if the catheter moves suddenly. The most common fault of insemination (Fig. 43.7A) is twisting the cervix in the left hand, so that one uterine horn is partly occluded. Alternatively, the catheter may be partly withdrawn during the deposition of semen, resulting in a partial intracervical insemination (Fig. 43.7B). Penetration of the cervical canal of maiden cattle is difficult at oestrus and virtually impossible at other stages of the oestrous cycle. Such animals are therefore often beyond the capabilities of inexperienced inseminators; it is common to find that semen is deposited into the caudal part of the cervix. However, the cervix of parous cattle can be traversed relatively easily at most stages of the oestrous cycle and early pregnancy. It is therefore imperative to know whether an animal is likely to be pregnant before insemination is attempted, for abortion can be induced if an insemination catheter penetrates the fetal membranes or if infection is introduced into a pregnant uterus by poor insemination hygiene.

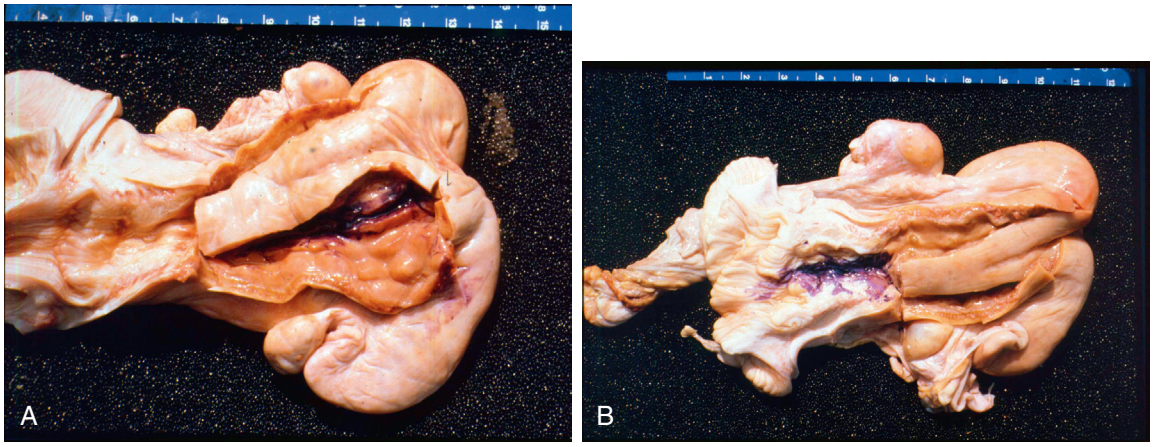
Alternative Sites for Insemination

Although traditional methods of insemination avoid deep uterine deposition of semen in cattle, this has been advocated as a means of improving conception rates (Senger et al. 1988, Dalton et al. 1999). However, this has not been achieved in all studies (e.g., McKenna et al. 1990) and has not been widely adopted in practice. Single horn insemination has also been advocated as a means of improving conception rates in cows. This technique requires

VetBooks.ir



• **Fig. 43.6** Distribution of semen in the cow after artificial insemination. A dark-coloured dye has been placed into the uterine body (A) and runs equally into both uterine horns (B). As inseminators are trained not to palpate the uterus or ovaries, they should be unaware of the side on which ovulation will occur, so semen must have access to both uterine horns.



• **Fig. 43.7** Distribution of dye in the reproductive tract of the cow after faulty insemination. (A) Uterus twisted during insemination, occluding one uterine horn. The dye is present in only one horn, typically the right. (B) Catheter withdrawn into the cervix during semen deposition. Some dye is present in the uterine body, but most is within the cervical canal.

palpation of the ovaries to determine the site of ovulation and a careful straightening of the ipsilateral horn to allow the insemination catheter to be inserted to within approximately 2 cm of the uterotubal junction. Again, some authors have found that this technique results in improved conception rates (Pallares et al. 1986, Lopez-Gatius & Camon-Urgel 1988), whereas others have not (Hawk & Tanabe 1986, Momont et al. 1989). Disadvantages include premature rupture of the follicle, perforation of the uterine wall, risk of polyspermic fertilisations (Hunter 2003), and possibly also an increase in the time required to perform the insemination.

Despite the equivocal results in field trials, some continue to advocate the use of deep intrauterine insemination, especially in situations in which semen may be compromised, as for example, in bulls whose semen does not respond well to preservation or when sexed semen is used (Hunter 2000, Lopez-Gatius 2000).

Management of Insemination

Inseminations may be performed by technicians employed by AI organisations but increasingly is being done by farm staff.

Fertility after AI is generally monitored by recording the proportion of cows that return to oestrus after the initial service. The proportion of females that do not return to oestrus is sufficiently closely related to the proportion that actually have become and remained pregnant to be a useful monitor of fertility (reviewed by Salisbury et al. 1978). The figure thus obtained, the non-return rate (NRR), which is an overestimate of calving rate, is generally in a fixed ratio to the calving rate depending on the interval after initial insemination at which it is calculated. The NRR is useful for observing trends in performance and for identifying below average performance. The NRR can be used by AI centres to monitor both the fertility of their bulls and the results obtained by their technicians. Technicians whose performance is below average are normally required to undergo a period of retraining and/or limited licensure until their results improve. Bulls that produce consistently low figures are removed from the AI service. Some centres make use of an 'adjusted NRR', whereby a number of factors that may affect fertility, such as cow or heifer, age of female, number of parities, location of farm, and identity of inseminator, are taken into account to create a 'fertility index score'. This score is believed to give a more accurate picture of a bull's fertility than using the unadjusted NRR.

Farm staff can be trained to inseminate cattle, with many countries allowing 'farmer-inseminators' to breed their own cattle. There are two potential advantages that persuade farmers to undertake

VetBooks.ir

their own inseminations: first, the avoidance of the costs associated with having an AI centre technician perform the insemination; and, second, the hope that improved timing of insemination to ovulation will raise conception rates. Morton (2000) undertook a widespread survey of the results achieved by farmer-inseminators in comparison to AI centre technicians. Overall, farmer-inseminators achieved a 3% lower conception rate than centre technicians (45% vs 48%). However, although 13% of farmer-inseminators achieved conception rates that were more than 5% higher than centre technicians, 45% had results that were more than 5% worse, and 12% had results that were more than 15% worse than centre technicians.

In practice, farmer-inseminators who are well trained, motivated, have enough time to perform inseminations, and have reasonably large herds tend to achieve good results, whereas those for whom it is 'another job' or who do not have the opportunity to develop a good insemination technique do not. Poor insemination technique can be associated with disastrously poor pregnancy rates.

Control of Infectious Diseases

Many diseases can be spread in bovine semen (Table 43.1); AI centre technicians, by travelling between farms, also pose a considerable risk as disease vectors. Consequently, there is legislative control over the health status of semen used in domestic trade, whereas international trade in bovine semen is subject to the requirements and recommendations of the OIE. There are also controls over the hygienic practices of inseminators. Diseases that are specifically regulated by the OIE are listed in Table 43.4.

Most of the serious viral diseases of cattle (particularly foot-and-mouth disease) can potentially be transmitted through AI. Legislative regulation of bovine AI has for many years been based upon the primary precept of preventing such transmission from occurring. Many other viral diseases, such as bovine herpesvirus-1, can also be transmitted in this manner (Chapman et al. 1979, Kahrs et al. 1980). Bovine viral diarrhoea (BVD) virus can be present in the semen of bulls (Barlow et al. 1986), potentially causing early embryonic death and abortions in inseminated cows (Grahn et al. 1984), as well as its better known ability to cause the birth of persistently infected progeny. Recently, it has become apparent that Schmallenberg virus can be transmitted in semen (Schulz et al. 2014). Other viral diseases that could be of potential concern to bovine AI include Akabane, ephemeral fever, and bovine immunodeficiency viruses. However, Thibier and Guerin (2000) reviewed literature suggesting that Akabane virus has not been detected in semen; moreover, although ephemeral fever and bovine immunodeficiency virus may be present in bull semen, transmission by AI has not been demonstrated. There is no evidence that the prion agent responsible for bovine spongiform encephalopathy (BSE) can be transmitted through semen (Wrathall 1997, Wrathall et al. 2008).

A number of bacterial diseases are transmissible in semen, including tuberculosis and brucellosis (Eaglesome & Garcia 1997). *Histophilus somni,* pathological species of *Mycoplasma* and *Ureaplasma diversum* may also be present in semen (Humphrey et al. 1982). Most importantly, the classic venereal pathogens of cattle, *T. foetus* and *C. fetus* subsp. *venerealis* are transmissible by AI, so control of these two organisms remains the second major precept upon which legislation governing cattle AI is based.

Three other conditions warrant specific mention. Firstly, although enzootic bovine leukosis (EBL) virus is considered not to be transmissible in semen (Radostits et al. 2007), infected bulls are excluded from AI studs. Secondly, bluetongue virus generally causes few or no clinical signs in infected cattle (Radostits et al. 2007), but cattle can act as sources of infection for other animals via arthropod hosts. Because the disease in sheep is severe, semen from potentially infected bulls (Bowen & Howard 1984) is carefully excluded from most countries in which sheep production is of economic importance. Finally, Johne's disease is also commonly regulated, as semen from clinical cases and subclinically infected animals is potentially contaminated with the organism.

In cattle, control of these diseases rests upon four major strategies:

i. Direct effects of freezing and thawing: *Leptospira* spp. may be killed by the freezing process.
ii. Antibiotics that are added to semen diluents in order to kill both pathogenical bacteria (including *C. fetus*) and the contaminant bacteria that originate from the penis and prepuce during semen. Antibiotics are also used to control mycoplasma and ureaplasma species.
iii. Serology: Diseases that can be detected by serology, such as brucellosis, IBR, EBL, Q fever, are controlled by exclusion of seropositive bulls from AI studs. Likewise, tuberculosis is controlled by exclusion of bulls that react to tuberculin testing. However, a negative serology test result only indicates that the animal has not reacted to an infection by producing antibodies; recent infections or congenital carriers may never exhibit an antibody response.
iv. Quarantine: The final and most potent means of control of disease is the quarantine of semen after its collection. After semen has been frozen, it is placed in a container where it remains untouched for 28 days. If, during that period, the donor bull develops any disease, the semen is destroyed. If not, it is released for use.

TABLE 43.4 World Organisation for Animal Health requirements for disease testing of sires use of semen in artificial insemination programmes

Cattle	Sheep and Goats	Pigs
Bluetongue	Bluetongue	African swine fever
Bovine herpesvirus-1	Brucellosis	Aujeszky's disease

Artificial Insemination of Sheep

Artificial insemination of sheep has been comprehensively reviewed by Evans and Maxwell (1987), Chemineau et al. (1991), and Kukovics et al. (2011). The sheep is less amenable to artificial insemination than is the cow because oestrus cannot be detected readily

VetBooks.ir

TABLE 43.5 Minimum numbers of motile spermatozoa for insemination of ewes at different sites

Route	Number of Motile Sperm (x 10^6)			Insemination Volume	Concentration of Inseminate (x 10^6/mL)
	Fresh	Liquid	Frozen		
Vaginal	300	400		0.3–0.5 mL	2000
Intracervical	100	150	180	0.05–0.2 mL	1000
Transcervical intrauterine		60		0.1–0.5 mL	200–400
Laparoscopic intrauterine	20	20	20	0.05–0.10 mL per horn	400–800

Derived from: Evans & Maxwell 1987, Usboko 1995, Shipley et al. 2007.

without the presence of rams, the technique of insemination is less straightforward than in cows, and ovine semen is less easy to freeze than bovine semen. In Eastern Europe, South America, and Australasia, AI is widely used in sheep breeding programmes, but its use is much less widespread in Western Europe and North America, mainly because of the high costs of handling and inseminating sheep compared with the costs of natural service. Fertility after AI depends on breed (whether dairy or meat breeds) and other factors such as parity, climate, farm, technique, and inseminator (Anel et al. 2005, Palacin et al. 2012).

In contrast to cows, ewes normally display oestrous behaviour only in the presence of a ram. In order to determine the time at which AI should be performed, either the timing of oestrus should be controlled or it should be detected with rams. In the former situation, pharmacological methods are used to induce and synchronise oestrus, so that the time of the fertile period is defined. In the latter situation, raddled, vasectomised rams are used to detect oestrus. The cost:benefit ratio for the use of AI in sheep has therefore to be considered carefully. When there are substantial costs associated with AI, such as either maintaining rams, or of buying and administering drugs for oestrus synchronisation, or of the procedures associated with insemination itself, these have to be set against the financial benefits gained from the superior carcass or wool characteristics of the progeny born to AI.

However, the most important limitation of the use of AI in sheep is in the method of insemination, as intrauterine insemination is difficult to achieve because the cervical canal of the ewe is so tortuous. Because intracervical AI results in both a lower conception rate and a lower number of lambs per litter than natural service, a number of methods of insemination have been devised that try to bypass the cervix. All of these methods have had varying success in achieving an economically viable compromise between fertility, technical difficulty, and numbers of spermatozoa needed for insemination. The methods currently in widespread use are via the intravaginal, intracervical, transcervical intrauterine, and laparoscopic intrauterine routes.

Collection and Storage of Semen

Semen is collected by an artificial vagina or by electroejaculation (see Chapter 35) and is subjected to routine examination for motility and spermatozoa concentration. Most inseminations of ewes are performed using semen that has been extended by the addition of simple extenders, because the small volume of the ovine ejaculate means that it is difficult to control spermatozoa numbers if used for direct insemination. Extender and the final number and concentrations of spermatozoa depend on the route of insemination, whether the insemination is undertaken during the natural breeding season or after induction of out-of-season breeding, and how the semen is to be stored between collection and insemination (i.e., direct insemination, cooled storage, cryopreservation). Recommendations for spermatozoa numbers and insemination volume are shown in Table 43.5.

TABLE 43.6 Diluents for ram semen for use at 5° to 15°C

Constituent (g/L)	Tris Diluent	Egg Yolk–Citrate	Skimmed Milk
Tris	36.3		
Fructose		5.0	
Glucose	5.0		10.0[a]
Citric acid	19.9		
Sodium citrate		23.7	
Skimmed milk powder			90.0
Egg yolk (mL/L)	140	150	50.0
Antibiotics	1000 IU penicillin and 1000 µg streptomycin/mL

Derived from: Evans & Maxwell 1987, Salamon & Maxwell 2000.

Liquid Semen

Extenders that are in routine use for unfrozen semen include buffers containing citrate or Tris, together with either egg yolk or cow's milk (Table 43.6). When milk is used, it should be heated first to destroy the spermicidal lactenin protein, so either skimmed or UHT-treated milk is used. After dilution, the semen is cooled and stored at either +15°C or +4°C until used. The semen should be used within 8 hours of collection, as fertility declines progressively after this time (Chemineau et al. 1991), with a 30% reduction in lambing rates after storage for 24 hours (Maxwell & Salamon 1993). More recently, Quan et al. (2016) suggested that the motility of spermatozoa was preserved for longer in Tris– or Tes–egg yolk extenders than in skimmed milk.

VetBooks.ir

Cryopreservation

Although simple extenders are capable of supporting spermatozoal viability for the relatively brief periods demanded for direct insemination, cryopreservation is required for long-term storage of semen. Unfortunately, cryopreservation of ovine semen is not particularly straightforward because the process itself causes a significant level of damage to ovine spermatozoa. In consequence, frozen semen is not recommended for intravaginal insemination, and although it can be used for intracervical insemination, fertility results are relatively poor.

There are also a number of difficulties encountered when semen is frozen for intracervical insemination. These arise as a relatively large number of spermatozoa ($150–200 \times 10^6$ total sperm; Salamon & Robinson 1962, Langford & Marcus 1982) have to be contained within the limited volume of inseminate that can be placed within the ovine cervix. Because the anatomy of the cervical canal limits the insemination volume to below about 0.25 mL (Evans & Maxwell 1987), the dilution rates are limited to between 1 : 1 and 1 : 4. In consequence, insufficient protection can be afforded to the spermatozoa by the diluent against cold shock and freezing damage (Miller 1986), generally resulting in mediocre postfreezing survival of functional sperm.

For intrauterine insemination, in which lower numbers of spermatozoa are required, far more satisfactory dilution rates of semen can be achieved, so cryopreservation is more successful. Furthermore, because the insemination site does not require spermatozoa to traverse the cervix, they do not have to survive in such a robust state as is needed for intracervical insemination. Hence the conception rates that are achieved with the use of cryopreserved semen for intrauterine insemination are commensurate with those of natural service after oestrus synchronisation (see, for example, Davis et al. 1984).

Extenders

Early extenders for cryopreservation of ram semen were based on citrate, egg yolk, a monosaccharide such as glucose or fructose, and/or milk. Other cryoextenders have been based on disaccharides (e.g., lactose), trisaccharides (e.g., raffinose), complex polysaccharides (e.g., gum arabic), or other complex molecules (e.g., polyvinylpyrrolidone). Optimal glycerol concentrations seem to be in the range of 4% to 6% (Salamon & Maxwell 2000), although this concentration is affected by other components of the extender, such as egg yolk and sugars. Although early studies suggested that there might be advantages to adding glycerol at 5°C, or to its stepwise addition, current practice is to add the glycerol at approximately 30°C. Two diluents that are currently widely recommended for ram semen are Tris–glucose–egg yolk (Salamon & Visser 1972) and Tris–citrate–fructose–egg yolk (Shipley et al. 2007) (Table 43.7), although there are many other diluents that are used successfully in commercial or research practice.

The problem of low dilution rates for semen that is to be used for intracervical insemination was addressed by Salamon (see Evans & Maxwell 1987) by preparing a range of different extenders for freezing semen at ratios of 1 : 1 to 1 : 4, in which the constituents were present in higher concentrations. In this way, compensation is achieved for the effects of the ratio between extender and seminal plasma. Chemineau et al. (1991) dealt with the same problem by using two different extenders (an egg yolk–lactose diluent and a glycerolised skimmed milk diluent) in varying proportions depending on the final dilution rate to be achieved.

One of the possibilities for improving the response to cryopreservation was the inclusion of seminal plasma in the extender.

TABLE 43.7 Diluents for the cryopreservation of ram semen

Constituent	Tris–Glucose	Tris–Citrate–Fructose
Basic Diluent		
Tris (g/L)	36.3	24.4
Fructose (g/L)		10.0
Glucose (g/L)	5.0	
Citric acid (g/L)	19.9	13.6
Glycerol (mL/L)	50.0	64.0
Preparation of Diluent		
Basic diluent	85%	80%
Egg yolk	15%	20%

Derived from: Evans & Maxwell 1987, Shipley et al. 2007.

Evidence reviewed by Maxwell et al. (2007) suggests that it is generally beneficial in terms of post-thaw membrane integrity and motility. Low molecular weight proteins (15–25 kDa) appear to be most associated with these benefits, and it has been postulated that a spermadhesin protein may be the critical component. As yet, however, the inclusion of seminal plasma has not been incorporated into field practice.

More recently, attention has focused on the inclusion of specific lipids such as oleic acid (Hashem et al. 2017) and palmitoleic acid (Eslami et al. 2017) into extenders. Bashawat et al. (2016) found that the low density of lipoprotein gave better overall outcomes after freezing than did egg yolk. Fish oil, as a source of docosahexaenoic acid, improved postfreezing recovery (Abdi-Benemar et al. 2015), whereas supplementing the diet with fish oil also improved post-thaw spermatozoal quality, pregnancy rate, and lambing rate (Masoudi et al. 2016a). Soybean lecithin as a source of phospholipid (Paz et al. 2010), specifically phosphatidylcholine (Masoudi et al. 2016b), has been successfully used to replace egg yolk in diluents. Finally, cholesterol, in the form of cholesterol-loaded cyclodextrin, has been used to improve the motility and proportion of intact acrosomes in a skimmed milk diluent (Salmon et al. 2017).

Addition of various antioxidants to semen extenders in an attempt to reduce lipid peroxidation has been increasing in popularity. Thus cysteine (Toker et al. 2016), green tea extract (Mehdipour et al. 2016), and taurine (Banday et al. 2017) were found to have a beneficial effect on post-thaw spermatozoal quality.

Freezing Protocols

After dilution, ram semen should be cooled slowly from 30°C to 5°C, as rapid cooling below 5°C is associated with poor spermatozoal survival (Fiser & Fairfull 1986). Hence cooling to 5°C should take place over 1.5 to 2 hours: Shipley et al (2007) recommend that this is best managed in a water bath. During this period of cooling, equilibration with glycerol takes place. Thereafter, semen can be successfully frozen in pellet form on the surface of blocks of solid carbon dioxide (Salamon 1971) or in paillettes in the vapour of liquid nitrogen (Fiser & Fairfull 1984). There is, however, much variation in the ability of the semen of individual rams to survive cryopreservation and the semen of a proportion of rams does not survive freezing successfully.

VetBooks.ir

Paillettes are thawed in water, typically at temperatures of 35° to 40°C. Pellets can be thawed in a dry tube in a water bath or can be placed in prewarmed thawing solution. It is suggested that pellets are thawed at 40°C, then maintained in a 30°C water bath until required for insemination (Shipley et al. 2007).

Insemination

Vaginal Route

Vaginal insemination deposits semen into the cranial part of the vagina without attempting to locate the cervix. The requirements of this method, in terms of both technical proficiency and handling facilities for the sheep, are minimal. However, the large numbers of spermatozoa that are required for each insemination means that the vaginal route is not really amenable for use with stored semen. Moreover, conception rates are also poor after pharmacological oestrus synchronisation, so intravaginal insemination is best suited to use after oestrus detection during the natural breeding season. The ideal timing of insemination is before ovulation, i.e., 12 to 18 hours after the onset of oestrus (Evans & Maxwell 1987). Highest conception rates are therefore achieved when the timing of insemination is optimised by drafting ewes for insemination twice per day.

Intracervical Route

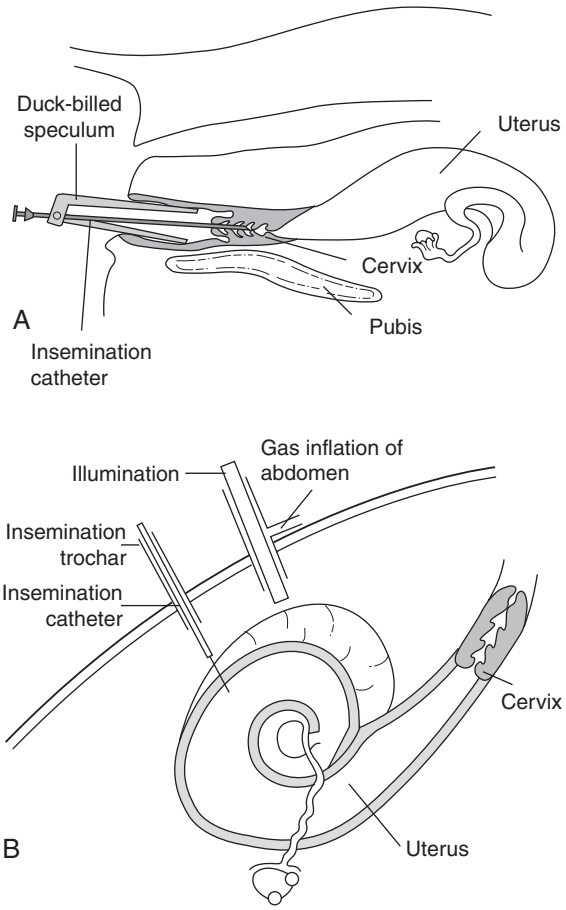
Intracervical insemination is best achieved with the hindquarters of the ewe elevated. After cleaning of the perineum, the vagina is opened with a duck-billed speculum, and the cervix is located (Fig. 43.8A). The insemination catheter is then inserted as far as possible into the cervix; penetration of the cervix is typically 0 to 2 cm.

The conception rate is highly correlated with the depth of penetration (Table 43.8) and hence the technical proficiency of the inseminator. Conception rates achieved with the use of unfrozen semen by this method are adequate after oestrus synchronisation (Chemineau et al. 1991). The ideal time for insemination is 55 ± 1 hours after removal of intravaginal progesterone inserts or 15 to 17 hours after the onset of detected oestrus. However, even when substantial numbers of cryopreserved spermatozoa are used for intracervical insemination, conception rates are below those of natural service or fresh semen insemination (Colas 1979). Conception rates of 65% to 80% are typical when this method is used in the ewe's breeding season, with a lower figure for out-of-season breeding regimens. According to Kukovics et al. (2011), pregnancy rates of 80% to 90% were achieved on Hungarian sheep farms using fresh semen inseminated via this route.

Laparoscopic Intrauterine Route

The method of direct intrauterine, laparoscopic insemination (Fig. 43.8B) was developed to overcome many of the difficulties of intravaginal and intracervical insemination. In this method, ewes are sedated and restrained in a cradle. Laparoscopy is performed close to the udder after administering local anaesthetic. The abdomen is insufflated with CO_2, the uterus is located and semen is injected into the uterine lumen via a small stab wound (Killeen & Caffery 1982). The semen can be introduced to the uterus via a simple pipette (Evans & Maxwell 1987) or by the use of specialised insemination equipment (Chemineau et al. 1991). With oestrus-synchronised ewes, the ideal timing of insemination is between 48 and 65 hours after withdrawal of progesterone sponges, with conception rates declining after 72 hours postwithdrawal (Salamon & Maxwell 2000). Conception rates to frozen semen inseminated by this method are higher than for intracervical insemination because of better cryopreservation of spermatozoa and a site of insemination that avoids spermatozoa having to traverse the cervix. Conversely, the laparoscopy is technically demanding, and there are far greater implications for the welfare of the ewes than with intracervical insemination.

The development of laparoscopic intrauterine insemination of ewes is undoubtedly the most significant development in sheep AI in recent years, for it circumvents many of the problems of traditional methods (Haresign et al. 1986). The number of spermatozoa required for each insemination is lower and the volume of inseminate is proportionally greater, allowing more appropriate



• **Fig. 43.8** Insemination of the ewe: (A) intracervical route. (B) Laparoscopic intrauterine insemination.

TABLE 43.8 Lambing rates (%) in relation to the depth of intracervical insemination

No. Spermatozoa Per Inseminate ($\times 10^6$)	Site of Insemination: On the Entrance Fold of the Cervix	Up to 1 cm into the Cervix	Deeper than 1 cm into the Cervix
400 (undiluted)	50	68.8	71.4
100 (diluted)	43.8	66.7	71.4
50 (diluted)	25.7	60.7	66.7

From: Evans & Maxwell 1987.

VetBooks.ir

dilution rates and therefore better preservation of sperm. Hence conception rates are similar to those achieved by natural service, and embryonic mortality is reduced to an acceptable level. The method also allows for the possibility of genuine progeny testing of rams, as semen from an individual sire can be used in many flocks over prolonged periods of time. Consequently, laparoscopic AI has been adopted in most of the major sheep producing countries (Haresign 1992). In Israel, a pregnancy rate of 71.4% was achieved with this method (Alfaris et al. 2012).

Transcervical Route

Transcervical insemination is a new method that attempts to achieve an intrauterine insemination via the cervical route. In this method the cervix is fixed by being grasped with forceps, and an insemination needle is introduced as far as possible through its lumen. Although better conception rates can be achieved by this method than by conventional intracervical insemination (Souza et al. 1994), both the retraction of the cervix and the penetration of the cervical lumen are associated with significant levels of trauma (Usboko 1995, Campbell et al. 1996). It is probable that, with the development of expertise in the method, its use will become more widespread, but at present, it seems to have little to commend it over laparoscopic insemination. In fact, pregnancy rates may be lower than those achieved with other methods even when no cervical trauma is evident (Wulster-Radcliffe et al. 2004).

Conception Rates to AI

Conception rates depend on the route and timing of insemination, whether ewes are being bred at synchronised or spontaneous oestrus, and whether fresh or frozen semen is used (Table 43.9). Equally importantly, it also depends on the management and condition of the ewes and the care with which the AI programme is managed. Results may also be difficult to interpret due to confusion in the terminology used, e.g., whether transcervical is really intracervical or not.

Control of Infectious Diseases

Diseases of sheep and goats that are transmissible in semen and that are regulated by OIE are listed in Table 43.4. *Brucella melitensis* and *B. abortus* can both be transmitted in semen, and of the organisms responsible for ovine epididymitis, *B. ovis* can be transmitted in semen; the pleomorphic Gram-negative organisms are also excreted in semen. Other significant diseases of sheep and goats that are controlled in AI donor sires include maedi-visna, caprine arthritis encephalitis virus, sheep pox, and goat pox, although there is no clear evidence for their transmission through semen (Thibier & Guerin 2000). It does not appear likely that the prion responsible for scrapie can be transmitted through this route (Wrathal 1997).

TABLE 43.9 Typical lambing rates achieved via different routes of insemination using fresh or frozen semen

Site of Insemination	Semen	Number of Motile Sperm	Lambing Rate (%)
Intravaginal	Fresh	400 x 10^6	20–60
	Frozen		5–20
Intracervical	Fresh	200 x 10^6	40–80
Synchronised oestrus	Frozen		25–40
Spontaneous oestrus	Frozen		30–60
Laparoscopic intrauterine	Fresh	20 x 10^6	70–95
	Frozen		40–80
Transcervical	Fresh	200 x 10^6	40–80
	Frozen		30–70

Artificial Insemination of Goats

Artificial insemination of goats is generally very similar to that of sheep; many of the factors affecting pregnancy rates in sheep are also relevant for goats (Abecia et al. 2016). However, it is much easier to achieve an intrauterine insemination via the cervix of the goat than that of the ewe. Second, although oestrus detection is more efficient in the presence of a buck (or after a synchronisation protocol), it is possible to detect it in the absence of a buck (Nuti 2007). Consequently, there has been a significant uptake of AI as a means of breeding goats in both the commercial and lifestyle sectors. In France, for example, the numbers of goat inseminations increased fourfold during the 1980s (Chemineau et al. 1991). On the other hand, there are difficulties in preserving buck semen, whether cooled or cryopreserved, because of toxic interactions between seminal plasma and milk/egg yolk-based extenders.

Collection and Storage of Semen

Semen is generally collected using an artificial vagina (AV). It can be collected by electroejaculation, but this is less well tolerated than in the ram. Because electroejaculation affects the composition of seminal plasma, it can reduce the ability of spermatozoa to survive preservation (Leboeuf et al. 2000). Bucks are seasonal breeders with a decrease in the quality and quantity of semen produced in the spring and summer. This decline can be mitigated if bucks continue to copulate regularly throughout the year (Corteel 1981).

Effects of Seminal Plasma upon Storage

The major problem with the preservation of goat semen is that there are components in seminal plasma that impair the viability of spermatozoa stored in media containing milk and egg yolk. The toxic interaction with egg yolk is due to an egg yolk–coagulating enzyme (EYCE) that is secreted by the bulbourethral gland. This enzyme coagulates egg yolk and hydrolyses lecithin to fatty acids and spermicidal lysolecithins (Iritani & Nishikawa 1964). It is considered that the primary activity of EYCE is via a phospholipase A, but it may also contain lipase (Leboeuf et al. 2000). Bulbourethral gland secretions also have a toxic interaction with milk. A 55 to 60 kDa glycoprotein lipase, originally named SBUIII (Nunes et al. 1982), now called BUSgp60 (Pellicer-Rubio et al. 1997), which is structurally related to pancreatic lipase PLRP2, releases oleic acid from milk triglyceride (Pellicer-Rubio & Combarnous 1998). Skimmed milk can therefore be used as a diluent, although its effectiveness depends on the extent to which it contains any residual fat.

As a consequence, extenders for goat semen have either been based on skimmed milk, in which spermatozoa survive adequately, or the seminal plasma has been removed before using egg yolk–based diluents (Corteel 1974). When yolk-based diluents are used, washing the spermatozoa is achieved by dilution in Krebs-Ringer phosphate solution and centrifugation (Corteel & Paquignon 1984). Spermatozoa survive for 12 to 24 h after semen collection.

VetBooks.ir

Liquid Semen

Two main strategies have developed for the use of liquid semen in goat AI.

Cooled Semen in Simple Diluents

- Removal of seminal plasma by washing in a simple buffer, followed by dilution in egg yolk–citrate or egg yolk–tris–fructose diluent and use at 5°C (Haibel 1986, Evans & Maxwell 1987, Chemineau et al. 1991).
- Because removal of seminal plasma is time-consuming and leads to loss of total numbers of spermatozoa, skimmed milk extenders can be used as an alternative for storage at 5°C. Such extenders are widely used (Leboeuf et al. 2003), although the effective lifespan of spermatozoa in skimmed milk extenders is relatively short (around 12 hours).
- Low levels of inclusion of egg yolk (~2.5%) do not result in the toxic effects of high inclusion rates; glucose citrate or Tris fructose plus a low concentration of egg yolk have also been used effectively (Shamsuddin et al. 2000, Bispo et al. 2012, Jiménez-Rabadán et al. 2012).
- Extenders that do not contain material of animal origin, e.g., soy lecithin (Roof et al. 2012), have been found to be as effective, if not more so, than egg yolk extenders.

Ambient Temperature Diluents

- If spermatozoa are not cooled below 15°C, egg yolk is not needed to prevent cold shock (Leboeuf et al. 2000). Skimmed milk and the commercial, soya–lipid-based diluent Biociphos Plus (IMV, L'Aigle, France) can maintain the viability of spermatozoa at 15° to 22°C for approximately 24 hours (Paulenz et al. 2005).
- Defined diluents, based on the antioxidant TEMPOL (4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl) (Mara et al. 2007) or phosphocaseinate (Leboeuf et al. 2003), have also proved effective.

Cryopreservation

For cryopreservation, egg yolk–based extenders are more widely used than skimmed milk–based ones, although acceptable results can be achieved with skimmed milk (Corteel 1974). The most widely used extenders (Leboeuf et al. 2000) are skimmed milk–glucose (Corteel 1974) and Tris–glucose–citric acid–egg yolk (Salamon & Ritar 1982), although soy lecithin extenders are gaining in popularity (Roof et al. 2012). When the final concentration of egg yolk is kept below 2.0% of the diluent (Ritar & Salamon 1982), egg yolk–based extenders can be used without removal of seminal plasma. Glycerol is the most effective cryoprotectant and can be added in one or two steps. For washed spermatozoa, Chemineau et al. (1991) recommend that primary dilution should be in glycerol-free, egg yolk–citrate diluent, followed by addition of extender containing 14% glycerol once the semen has reached 4°C. However, when unwashed spermatozoa are used, semen can be glycerolised in a single step at 30°C (Ritar & Salamon 1982, 1983).

For intracervical insemination, there are similar problems of numbers of spermatozoa in relation to the volume of inseminate to those that apply in the sheep. Hence, Salamon (Evans & Maxwell 1987) also suggested variable composition extenders (which also contain a final concentration of egg yolk of <2.0%) for one step dilution of goat semen for use in intracervical insemination at dilution rates of between 1 : 1 and 1 : 4.

Semen can be frozen either by the pellet method (i.e., on the surface of solid carbon dioxide) or in paillettes that are suspended over the vapour of liquid nitrogen or used in programmable freezers. Post-thaw recovery rates are better with pellet freezing than with other methods (Purdy 2006), but because acceptable recovery rates are also achieved with paillettes, the convenience of handling semen means that it is usually the preferred method of cryopreservation. Although much variation exists between individual animals, overall results with doses of 50×10^6 motile frozen–thawed spermatozoa inseminated into the uterus are comparable with those of natural service (Ritar & Salamon 1983). The relationship between numbers of spermatozoa and fertility is not known because few data from large scale surveys on the subject exist. Nevertheless, Haibel (1986) suggested that 100 to 125×10^6 spermatozoa are used per insemination, whereas Evans and Maxwell (1987) recommended similar numbers to those used in sheep. Semen is thawed using similar protocols to those for the ram.

Insemination

Similar routes of insemination can be used in the doe to those employed in the ewe. Intravaginal insemination is effective if fresh semen is directly inseminated (Nuti 2007) but gives poor results with extended or frozen semen. Hence the main means of insemination are intracervical insemination or laparoscopic intrauterine. Intracervical insemination is the most widely practised method, especially in 'lifestyle' herds. In a significant number of does, an intrauterine insemination can be achieved via the intracervical route (50%–60%; Cseh et al. 2012) because the caprine cervix is relatively easier to traverse than the ovine cervix. Interestingly, although intrauterine insemination can be achieved simply by direct pressure of the insemination catheter upon the cervix, many technicians prefer to deposit at least some of the semen into the cervical canal in case the intrauterine insemination had been entirely into a single uterine horn (Haibel 1986). Nuti (2007), however, suggested that the rates of insemination failure after intracervical insemination are relatively high, either because of failure to enter the cervix properly or because of damage to the cervix or uterus during the insemination process. Depth of insemination is related to pregnancy rate: intrauterine insemination results in the highest rate, with the chances of conception declining significantly as the site of deposition becomes further caudal in the cervix (Salvador et al. 2005). Operator proficiency is therefore a critical determinant of pregnancy success. Pregnancy rates as high as 80% are reported for fresh semen.

Laparoscopic intrauterine insemination is performed in the same way as in the ewe. It has the advantages of requiring a lower dose of spermatozoa (~20×10^6) and achieving a higher pregnancy rate than intracervical insemination but is more demanding to perform (Cseh et al. 2012). Sohnrey and Holtz (2005) suggested that deep corneal transcervical insemination produces results that are at least as good as that achieved by laparoscopy.

Artificial Insemination of Pigs

One of the main stimuli to the use of AI in pig breeding is the possibility it confers of maintaining a closed herd by obviating the necessity of introducing purchased boars. Furthermore, because the traits of economic importance in the pig (i.e., carcase conformation, growth rate, and feed conversion efficiency) have high heritability and can be evaluated in the sires themselves, genetic selection can be intense so that the potential value of AI boars in enhancing the genetic base of a breeding herd is considerable.

VetBooks.ir

Traditionally, the use of AI in pig breeding has been greatest in Eastern Europe and in countries such as Holland and Denmark with very high densities of pigs. However, there has been a marked increase in the use of pig AI in many other countries, in parallel with the improvements in AI technology and the demand for high genetic–merit sires (Johnson et al. 2000). In the UK, only about 9% of the national herd was bred by AI in the survey of Iritani (1980), whereas the figure in 2004 was 60% to 70% (Goss 2004). The United States has seen a similar growth of AI in pigs over the same period (Johnson et al. 2000). In Europe, more than 90% of sows have been bred by AI in the last two decades (Maes et al. 2011). Most inseminations in Europe are performed by farm staff as the costs of a technician service are too great to be economically viable, although technician services are available in some countries.

Two main difficulties exist in pig AI. First, the period of maximum fertility is not particularly easy to detect in sows (Evans & McKenna 1986) so that animals have traditionally had to be inseminated two (or even three) times during oestrus to maximise conception rate and litter size. Second, pregnancy rates and litter size are reported to be lower after AI with frozen semen than with fresh semen (Alm et al. 2006). Hence, insemination of sows has been based upon multiple inseminations of semen that has been extended and stored at 16° to 18°C containing large numbers of spermatozoa (~2.3×10^9). This has meant that each ejaculate produces enough doses to inseminate only 15 to 25 sows (Maes et al. 2011), a smaller number of doses per ejaculate than in other species such as bulls. Reducing the insemination dose to 1.8×10^9 causes a decrease in litter size of 0.07 piglets (Feitsma 2009), which has a marked effect on the economics of pig breeding.

Collection and Storage of Semen

Semen is manually collected from boars in the presence of a dummy sow (see Chapter 35). The frequency of collection depends on the semen characteristics of individual boars, but it is usually twice per week (Vyt et al. 2007). The pre-ejaculatory fluid is discarded, and the postsperm-rich fraction may not be included either, depending on individual practice or whether a sealed collection device is used. Between 100 and 150 mL of sperm-rich fraction is produced, which is filtered to remove gel, and is extended for insemination after evaluation for spermatozoa concentration, motility, and possibly spermatozoa morphology. Previously, when using the 'gloved hand' technique, it was possible to move the collecting vessel into position once it was apparent that the clear spermatozoa-free prostatic portion was changing to the coloured, sperm-rich fraction of the ejaculate, but the availability of sealed collection containers and automatic collection devices means that the whole ejaculate is collected instead. The sealed collection devices are believed to reduce the number of bacteria that contaminate the ejaculate during semen collection.

Liquid Semen

Approximately 99% of pig inseminations are undertaken using liquid semen (Johnson et al. 2000), and because pig spermatozoa are highly sensitive to cold shock, nearly all of these use ambient temperature extenders. When semen is to be stored at ambient temperatures, the activity of spermatozoa has to be inhibited to ensure an adequate period of viability.

Extenders designed to be used at ambient temperature were based upon the IVT extender throughout the 1960s and 1970s (Paquignon 1984). These have more recently been superseded by diluents such as the Guelph (= Kiev) diluent, BTS (Beltsville Thawing Solution) diluent, and Zorlesco diluent (Haeger & Mackle 1971, Pursel & Johnson 1975, Gottardi et al. 1980). The Guelph diluent is simpler than the IVT diluent to prepare but maintains the fertility of semen for a similar length of time. The more complicated Zorlesco diluent may maintain semen fertility for up to 12 days, although field trials indicated that the effective period is probably shorter than that. Newer diluents, such as the Zorpva (Cheng 1988), Reading (Revell & Glossop 1989), and Androhep (Weitze 1990) diluents, have reliably maintained the fertility of spermatozoa over longer periods of up to 5 days and are, consequently, in increasingly widespread use (Almond et al. 1998), although the most widely used diluent in the United States is the BTS (Johnson et al. 2000). Addition of antioxidants, buffering agents, and antibiotics extend the shelf life of the semen doses (Knox et al. 2016). Examples of short- and long-term diluents are given in Table 43.10.

Insemination doses are variously recommended to contain a minimum of 1×10^9 sperm, with increased numbers when semen is not used on the day of collection. Althouse (2007) suggests that, as a rule of thumb, spermatozoa numbers are increased by 1×10^9 for every day of delay between collection and insemination; hence a common dose rate for commercial boar AI services is 2.3×10^9 spermatozoa (Maes et al. 2011). If semen is collected in situations in which spermatozoa concentration cannot be determined accurately or if it is for local use within a breeding establishment, conservative dilution at 1:4-1:7 is recommended (Althouse 2007) to result in 2 to 4.5×10^9 spermatozoa per dose (Almond et al. 1998). The volume of material that is inseminated is important, because low volume insemination fails to achieve acceptable conception rates. Hence, a total insemination volume of 70 to 100 mL (typically 80 mL) is used. The necessity for using such a large volume is probably to stimulate uterine motility in the sow, thereby ensuring that adequate numbers of spermatozoa reach the site of fertilisation. Semen is typically packaged into plastic tubes, bags, flatpacks, or bottles and is maintained above 15°C before insemination.

For AI in commercial piggeries, it is common practice to mix the semen of different boars in insemination doses. This reduces the risk associated with the responses of an individual boar's semen to extension and dilution, making the outcomes of insemination more predictable (Godet et al. 1996). However, it does make the tracking of an individual boar's performance for the elimination of poor performers more difficult.

Cryopreservation

The semen of boars does not generally respond well to cryopreservation. Recovery after thawing is poor and highly variable between individual sires, and fertility of semen is invariably substantially lower than that of extended semen. Typical results for frozen semen are, at best, 70% of sows conceiving to a double insemination, compared with 80% to 90% for liquid semen insemination. Litter size is also lower after frozen than after liquid semen insemination (Roca et al. 2006b). Consequently, only approximately 1% of pig inseminations use frozen semen, which is largely limited to semen that has been traded internationally.

There are two major limitations to success in freezing boar semen. First, it is highly sensitive to cold shock, and neither egg yolk nor skimmed milk provides anything like the degree of protection against cold shock that it provides to the spermatozoa of most other species (Watson 1979). Second, although glycerol is probably the best cryoprotectant for the boar spermatozoa, its toxic effects are more pronounced in this species than in most others (Wilmut & Polge 1974). In consequence, the numbers of spermatozoa that are

VetBooks.ir

TABLE 43.10 Diluents for ambient temperature preservation of boar semen

	Short Term (Up to 3 Days)		Long Term (3–5 Days)		
Constituent (g/L)	Guelph (Kiev)	BTS	Zorlesco	Zorpva	Androhep
D glucose	60.0	37.0	11.5	11.5	26.0
Disodium EDTA	3.7	1.25	2.3	2.35	2.4
Sodium hydrogen carbonate	1.2	1.25	1.25	1.75	1.2
Trisodium citrate	3.7	6.0	11.7	11.65	8.0
Citric acid			4.1	4.1	
Tris			5.5	5.5	
Hepes					9.0
Polyvinyl alcohol (type II)				1.0	
Bovine serum albumin					2.5
Cysteine			0.1	0.07	
Antibiotics	Lincomycin, spectinomycin, gentamicin, neomycin, and/or benzyl penicillin plus streptomycin are commonly added to suppress mycoplasmas and *Leptospira* spp.				

Derived from: Haeger & Mackle 1971, Evans & McKenna 1986, Cheng 1988, Weitze 1990, Almond et al. 1998, Johnson et al. 2000.

required to obtain even the mediocre conception rates that follow the use of cryopreserved semen are very high indeed: typically 5 to 6×10^9 spermatozoa per insemination dose (Paquignon 1984). Hence, when frozen semen is used, only about five animals can be inseminated per ejaculate. This low extension rate effectively limits the use of frozen semen to international traffic in pig genetics and to the preservation of gene stocks for future use.

A great deal of work has been undertaken to improve the results of cryopreservation of porcine semen, which, despite the unpromising appearance of early studies, has resulted in better and more consistent survival of freezing. Progress has been made in a number of areas (reviewed by Johnson et al. 2000, Roca et al. 2006b).

Improvement in Extenders

The protective effect of egg yolk is greatly improved when detergent (OrvusEs Paste (OEP)) is added to the extender, probably as it breaks down the fat globules and allows better interaction of the egg phospholipids with the membranes.

Addition of antioxidants, such as vitamin E, glutathione, or superoxide dismutase, prevents lipid peroxidation during freezing and thawing. Addition of resveratrol from grapes or epigallocatechin-3-gallate from green tea to the extender had a beneficial effect on post-thaw penetration rates in IVF, even though no effect on spermatozoa viability or acrosome integrity was observed (Gadani et al. 2017). It has been suggested that adding seminal plasma to thawed boar spermatozoa may counteract lipid disorder arising during the cryopreservation process (Torres et al. 2016).

Improvement in Control of Freezing

Temperature control is a critical aspect of the success with which the spermatozoa of any species can be frozen. The large volume straws (5–6 mL) in which pig semen has traditionally been frozen do not provide good control of temperature, either during freezing or during thawing, especially in the centre of the straw. Much better responses are achieved when semen is packaged into 0.5 mL straws in aliquots of approximately 2×10^9 sperm, then diluted after thawing to an appropriate volume for insemination. Alternative 'flat pack' systems of freezing have also been developed, which package up to 5×10^9 spermatozoa in 5 mL of diluent but ensure even cooling throughout the pack. Saravia et al. (2010) reported good cryosurvival in a simplified procedure, freezing spermatozoa from only the first 10 mL of the sperm-rich fraction in 'mini flat-packs', with a considerable shortening of the procedure. As the authors indicate, the remainder of the ejaculate could be used for processing conventional semen doses (Saravia et al. 2010).

Selection of Sires

Boars can be selected for response to the freezing of their semen; selection for 'good' freezers results in more consistent quality of frozen–thawed semen and fewer ejaculates that fail to survive the freezing process. Roca et al. (2006a) even suggested that boar semen should be test frozen for identification of 'good' and 'bad' freezers. In this context, it is interesting to note that, in the early days of bovine AI, a similar selection process was practised, with an effective elimination of 'bad' freezers (at least of dairy breeds) from studs.

Management of Insemination

Spermatozoa that survive freezing have undergone significant capacitation-like changes that reduce the duration of their survival in the female tract. Re-examination of the insemination process with regard to the site of deposition of semen and the timing of insemination (see later in this chapter) is allowing significant improvements in pregnancy rates and litter sizes to cryopreserved semen.

Current Practice

Saravia et al. (2005) summarise the processing of semen for freezing, based on methods described by Eriksson and Rodriguez-Martinez (2000a, b). After holding at room temperature for approximately 1 hour, the semen is extended 1 : 1 in BTS. The extended semen is

VetBooks.ir

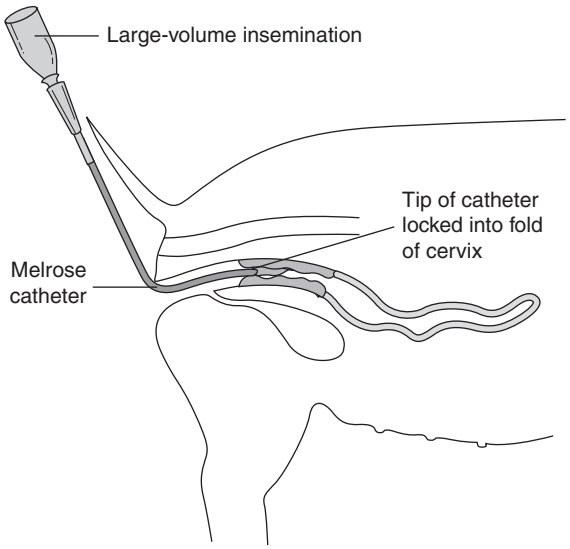
held at 16°C for 3 hours, after which it is centrifuged at 800 g for 10 minutes. After centrifugation, the supernatant is discarded, and the pellets are resuspended in a lactose–egg yolk diluent. The semen is then cooled to 5°C over 2 hours in the centrifuge. Thereafter, semen is mixed with a further lactose–egg yolk extender, which also contains OEP and glycerol (to give a final concentration of 3% glycerol).

After packaging into appropriate containers, the semen is frozen in static liquid nitrogen vapour or in a programmable freezer. The optimal cooling rate over the range 0° to 50°C is generally accepted as being −30°C/min (Johnson et al. 2000). This cooling rate has to be matched by a very rapid thawing rate.

Insemination

The optimum time for AI is during a 24-hour period in the middle of the 50 to 60 hours of oestrus, so that capacitated spermatozoa are present at the time of ovulation. The highest fertility results are achieved when insemination is undertaken 10 to 12 hours before ovulation (Evans & McKenna 1986). However, the interval between the onset of oestrus and ovulation is variable, and even twice daily oestrus detection may not accurately pinpoint the onset of oestrous behaviour. Hence it is recommended that optimal conception rates and litter sizes are achieved by delaying insemination until 12 to 18 hours after the first detection of oestrus, with a second insemination 12 hours (Evans & McKenna 1986) or 18 to 24 hours (Almond et al. 1998) later. The most widely used means of inseminating sows is the method developed by Melrose and O'Hagen (1959) and Rowson (1962), which involves passing a spiral rubber catheter into the cervix of the sow (Fig. 43.9). The catheter is rotated into the cervix until its spiral groove becomes locked into the cervical canal. The cervical lock prevents the catheter from becoming dislodged if the sow moves during insemination and prevents loss of the large volume of fluid that has to be inseminated.

However, there are very substantial losses of spermatozoa after insemination (reviewed by Roca et al. 2006a). Some 30% to 40% of the semen flows backwards out of the cervix, and of the spermatozoa that remain, many become trapped in the cervix or are eliminated by the immune system of the uterus. Hence, 90% of the spermatozoa are eliminated within 2 to 3 hours of insemination, and of the approximately 2.3×10^9 spermatozoa that are inseminated, only 1×10^5 become established at the uterotubal junction. This loss of spermatozoa is exacerbated when they are functionally impaired (e.g., when they have suffered damage through cryopreservation), with numbers at the uterotubal junction being tenfold lower than after insemination with liquid semen.



• **Fig. 43.9** Insemination of the sow, using a Melrose-type catheter.

In order to make the process of pig AI more efficient, two new approaches are being developed: more precise synchronisation of the timing of insemination with that of ovulations and deep intrauterine insemination.

Fertility is maximal when insemination is performed up to 12 to 18 hours before, or just after, ovulation (Nissen et al. 1997). Hence, if the timing of ovulation can be identified more accurately using signs other than those of behavioural oestrus, acceptable fertility might be achieved with a single insemination. Ultrasonography has been used, but scanning has to be undertaken frequently to give a useful prediction of the timing of ovulation (Bortolozzo et al. 2005, Sumransap et al. 2007). Hence ultrasound-based prediction of ovulation has yet to be refined to a point at which it is useful in commercial practice (Soede et al. 1998, Serret et al. 2005). Controlling the time of ovulation with gonadotrophins (GnRH, hCG, eCG) (de Rensis et al. 2003, Baer & Bilkei 2004, Kauffold et al. 2007), whether applied after the onset of observed oestrus or given at a fixed point after weaning, has been successfully used to allow adequate fertility to single inseminations. However, when single inseminations are used, the timing in relation to ovulation is critical (Garcia et al. 2007).

Intrauterine insemination has been performed in the caudal part of the uterus (postcervical insemination: PCI or deep within the uterine horns (deep uterine insemination; DUI)). Both are achieved by passing an insemination device through a conventional AI catheter; the device for PCI is rigid; that for DUI is longer, finer, and more flexible. PCI insemination requires more than 1×10^9 spermatozoa to obtain an acceptable litter size, although pregnancy rates are good even with lower numbers of sperm. In insemination trials with 1.5×10^9 spermatozoa in two doses, a farrowing rate of 84% with a litter size of 13.9 piglets was achieved (Hernández-Caravaca et al. 2012). However, success rates vary considerably with small numbers of spermatozoa (i.e., $0.5–1 \times 10^9$; Knox 2016). DUI with 600×10^6 spermatozoa is expected to give similar results in terms of pregnancy rate and litter size to conventional intracervical insemination with $2–3 \times 10^9$ spermatozoa (Roca et al. 2006b). Over 80% pregnancy rate has been achieved with 1×10^9 thawed spermatozoa deposited by DUI (Bathgate et al. 2008). Laparoscopic methods have been developed in which small numbers of spermatozoa are deposited into the ampullary part of the uterine tube very close to the time of ovulation (Vazquez et al. 2006). This has been used experimentally for sexed-semen inseminations, with good results (Roca et al. 2006b). However, the methods do not yet appear to be feasible for commercial use because they require general anaesthesia of the sow.

Insemination by Farm Staff

A semen delivery service was introduced into the UK in the mid-1960s (Melrose et al. 1968), and since then it has undergone steady expansion. Processed semen is dispatched from the processing centre to farms, where the farm staff, using conventional intracervical insemination catheters, inseminates the sows. This system allows double inseminations to be performed, and the risk of disease transmission is minimal. It requires some technical proficiency on the part of the farm staff in terms of oestrus detection as well as in the insemination procedure itself.

VetBooks.ir

The use of AI with delivered semen has also received considerable impetus from increased use of batch management of pig herds (see also Chapter 32). Thus, large groups of sows are weaned simultaneously in the knowledge that most of them will be in oestrus at a predictable interval after weaning. Standing or advance orders are placed for the semen to inseminate these sows, with small numbers of boars kept to mate the small proportion of sows that return to oestrus outside the predicted time period and to detect and mate animals that fail to conceive.

On-farm collection and insemination programmes can be used when large numbers of sows have to be inseminated as cheaply as possible. In this situation, inseminations are performed with raw or diluted semen immediately after collection. In a number of countries, AI centres have provided producers with semen extender for on-farm insemination programmes. This method minimises the risk of disease transmission but limits each farm to using the boars it has available. Access to performance/progeny-tested sires is therefore limited.

Inseminator Service

Technicians employed by AI centres transport the semen from the centre to the farm, where they inseminate the sows. This was the main form of insemination service in Western Europe when pig AI first started, but it has gradually lost favour, except in regions of exceptionally high pig density. Inseminator services generally provide only a single insemination of the sow in a given oestrus period, resulting in significantly lower conception rates and lower numbers of piglets per litter than are achieved by natural service (Reed 1982). Also, the cost of a technician service is high in relation to the value of the progeny, especially as litter sizes are lower than with natural service. Furthermore, itinerant inseminators are potential vectors for disease transmission between farms. Therefore the trends towards closed herds and 'minimal disease' precautions on most pig farms have mitigated against the use of such technicians.

Control of Infectious Diseases

A large number of pathogens can be transmitted through boar semen. The diseases that are specifically controlled by OIE are listed in Table 43.4.

Bacterial pathogens include *Brucella suis, Staphylococcus aureus, Streptococcus* spp., and *Mycoplasma* spp., which are transmitted by the venereal route and have significant effects upon sow fertility. *Leptospira* serovars and *Erysipelothrix rhusiopathiae,* although not directly spread through semen, are spread as urinary contaminants, so contamination of the semen through contact with urine or the presence of the organisms within the prepuce is likely (Cutler 1986).

More seriously, classical swine fever (hog cholera), African swine fever, and Aujeszky's disease can also be spread through semen, as can foot-and-mouth virus (Cutler 1986, Mengeling 1986, Almond et al. 1998). Porcine reproductive and respiratory syndrome (PPRS) virus can be shed in the semen and can be transmitted by insemination, although it is not specifically controlled by OIE (Yaeger et al. 1993). Likewise, parvovirus and Japanese encephalitis can also potentially be transmitted by semen (Thibier & Guerin 2000).

Routine serological testing of boars is undertaken by AI centres to ensure that they do not carry either venereally transmitted diseases or other conditions that might jeopardise the health status of the recipient herd. Antibiotics are added to semen to remove nonspecific and pathogenical bacteria. However, the most valuable means of controlling disease transmission is to quarantine incoming boars for a month, during which time observations for signs of clinical disease and/or further serological testing are undertaken.

Artificial Insemination of Horses

Artificial insemination of horses has been practised for many years. Initially, most of the breeding by AI took place in Eastern Europe, the former USSR (Tischner 1992), and China. Conversely, development of AI in horses in western countries was hampered for a long time by the refusal of key registration authorities to allow the registration of foals bred by AI. However, the recent acceptance of such registrations by the American Quarter Horse and American Paint Horse associations (Loomis 2001) has provided a significant impetus to the development of equine AI. Thus, although the Thoroughbred Breeders Association remains unwilling to allow registration of foals conceived by AI, most other breed societies allow restricted or unrestricted registrations of AI-bred foals. In most parts of Europe, up to 90% of Warmblood mares are now bred by AI.

There are a number of technical difficulties that have to be overcome in the development of AI programmes for horses:

- Semen collection: Coitus in horses is relatively protracted, which makes semen collection rather more difficult than in other large herbivores. In some countries, most of the seminal plasma is removed by centrifugation to enhance spermatozoa survival (Brinsko & Varner 1993).
- Storage of semen: Stallion semen is relatively susceptible to damage due to cold shock and cryopreservation (Amann 1984).
- Insemination: Synchronising insemination with ovulation has to be accurate. However, because of the variability and duration of oestrus in the mare, predicting the time of ovulation is difficult without regular and frequent examination. A commonly used practice is to inseminate every 48 hours once a dominant follicle has been detected until ovulation occurs. On the other hand, insemination of the mare is much easier than insemination of the cow because the equine cervix is soft and does not have a convoluted luminal canal.

Collection and Storage of Semen

Semen is normally collected by AV (see Chapter 35). Some people prefer to use an open-ended AV to allow collection of the separate fractions of the ejaculate. Alternatively, the gel fraction can be separated by use of a nylon mesh filter placed in the AV or semen bottle at the time of collection or by filtration through gauze after collection. The latter is associated with a greater loss of spermatozoa than other methods (Blanchard et al. 2003). In commercial AI programmes, it may be advantageous to train stallions to mount a 'breeding phantom' dummy-mounting device, in preference to the use of mares. Ground collection is also possible; this method is thought to place less strain on the back and hind legs than mounting a phantom.

Liquid Semen

After collection, equine semen requires careful temperature control to prevent damage to the spermatozoa by cold shock (Brinsko & Varner 1993). If the mares that are to be inseminated are close by, insemination can be performed directly using raw semen, but it is generally preferable to place the semen in an extender even if it is for direct insemination straight away. Simple extenders (Table 43.11), such as skimmed milk plus antibiotics used at a ratio of

VetBooks.ir

TABLE 43.11 Diluents for short-term storage of equine semen at 4°C

Component (g/L)	Skimmed Milk Diluent (Kenney)	Modified Kenney Extender	Egg Yolk–Glucose
Fat-free dried milk powder	24	24	
Glucose	49	26.5	70
Sucrose		40	
Sodium hydrogen carbonate	1.5		
Egg yolk			70 mL
Antibiotics	Penicillin G, streptomycin, gentamicin, polymyxin B, and/or amikacin are commonly added		

Derived from: Kenney et al. 1975, Tischner 1992, Brinsko & Varner 1993, Blanchard et al. 2003.

1:1 or 1:2, with semen maintained at ambient temperatures are adequate if the semen is to be used within 6 hours of collection (Samper 2007).

Equine semen can also be stored for longer periods of time before insemination if it is cooled. Most studies (see Batellier et al. 2001) have concluded that storage at 4° to 6°C is the ideal temperature (although there are some reports of better results at 15° or even 20°C). Extenders for cooled storage are mostly based upon milk, using either skimmed milk, cream-gel ('half-and-half' cream partially set with gelatin), or fat-free dried milk powder. Kenney's diluent (Kenney et al. 1975) and its very close derivative (Francl et al. 1987) EZ Mixin (Animal Reproduction Systems, Chino, CA) are probably the most widely used diluents in the United States because of their simplicity of use and the ease with which spermatozoa can be visualised after dilution (Blanchard et al. 2003) (Table 43.11).

Other extenders that are used for cooled storage of equine semen are based on milk plus egg yolk or are chemically defined (e.g., INRA-96; Batellier et al. 1998). Extenders based on egg yolk appear to provide best protection when seminal plasma is removed (Jasko et al. 1992), whereas milk-based diluents support cooled storage less well when seminal plasma is completely removed, the effect of which can be overcome if the extender is supplemented with salts such as Tyrode's (Rigby et al. 2001). However, milk-based diluents that are supplemented with Tyrode's salts require the removal of seminal plasma for maximal survival of spermatozoa (Katila et al. 2005). The defined diluent INRA-96, which is based on Hank's salts supplemented with 67 mmol/L glucose, 126 mmol/L lactose, and 27 g/L native phosphocaseinate (Batellier et al. 1998, Pagl et al. 2006), gives pregnancy rates that are better than simple skimmed milk diluents, especially for stallions whose semen does not respond well to simple extenders (Batellier et al. 2001). Webb and Humes (2006) showed that further improvements to the performance of semen in INRA-96 can be obtained by removal of the seminal plasma by centrifugation. However, although motility of spermatozoa may be improved by removal of most of the seminal plasma, there may be an increase in chromatin damage (Morrell et al. 2010). Masuda et al. (2004) suggested that an extender based on 2% milk casein plus 5% egg yolk also gave good results.

With these diluents, the rate of cooling from body temperature to 19°C is not critical, but between 19° and 8°C, slow cooling (ideally 0.1°–0.3°/min; no more than 0.5°C/minute) is necessary to avoid causing cold shock (Douglas-Hamilton et al. 1984, Katila 1997). Below 8°C, rate of cooling is not critical. Controlling the rate of cooling semen in the field has been greatly facilitated by cooled storage units such as the Equitainer (Hamilton Research, Inc., South Hamilton, MA). In this system, diluted semen is placed in an insulated container with prechilled cooling packs that reduce the temperature in the semen at an appropriate rate to prevent cold shock developing. Such devices can maintain semen fertility at acceptable levels for approximately 48 hours. Air should be excluded from storage vessels as the survival of spermatozoa is significantly greater when no air is present (Katila 1997, Batellier et al. 2001) because of the effects of aerobic respiration and lipid peroxidation. Addition of antioxidants, such as ascorbic acid, pyruvate, and, most recently, N-acetyl cysteine (Pagl et al. 2006), is therefore advocated as a means of increasing the longevity of spermatozoa in cooled storage.

Cryopreservation

Stallion semen has been successfully cryopreserved (Pickett & Amann 1993) using low concentrations of glycerol in diluents containing sugars, egg yolk, and/or skimmed milk. Before freezing, most of the seminal plasma is removed by centrifugation, usually after temporary extension of the semen in a diluent that will maintain its viability at ambient temperatures. Various diluents have been used for this step, including UHT skimmed milk, Kenney's diluent, lactose-EDTA, INRA-82 (glucose, lactose, rafinose, citrate, Hepes, plus egg yolk (Vidament 2005)), and EDTA–citrate. To minimise damage to spermatozoa during the centrifugation process, semen may be 'cushioned', by layering it on to a high viscosity solution before centrifugation. High concentrations of glucose or dense, inert, isotonic substances (e.g., Cushion-Fluid, Minitube; Landshut, Germany) (Sieme et al. 2006) have been used as the basis for cushioning media for centrifugation. After discarding the supernatant, the semen is resuspended in the freezing extender. It is then slowly cooled from ambient temperatures to 4°C because slow cooling over this phase is preferable to rapid cooling.

Freezing extenders are typically based on sugars, buffers, and egg yolk; many are available commercially and many others have been described in the literature. Among these, Kenney's plus 4% clarified egg yolk, INRA-82 plus 20% egg yolk, or lactose–EDTA plus 20% egg yolk (Pickett & Amman 1993, Loomis 2006) have been widely used as freezing media. Subsequent studies have suggested that defined media containing egg- or soy-derived phosphatidylcholine (Ricker et al. 2006) maintain spermatozoal survival during freezing at least as well as extenders containing whole egg yolk. Glycerol is the best tolerated cryoprotectant and is typically used at a final concentration of 2.5%, although some diluents use concentrations of up to 4% (Cochran et al. 1984, Heitland et al. 1996). More recently, there has been a move towards substituting methyl formamide and other amides for some of the glycerol in cryoextenders for stallion semen (Alvarenga et al. 2005). This substitution seems to aid cryosurvival for some individuals that display poor cryosurvival when only glycerol is used.

The use of 0.5 mL paillettes has superseded older, larger volume containers for freezing equine semen: little semen is now frozen in other containers. The insemination dose is commonly loaded into four to eight straws (Samper 2007). Freezing may be over the vapour of liquid nitrogen or as pellets on the surface of blocks of solid carbon dioxide. When programmable freezers are used,

VetBooks.ir

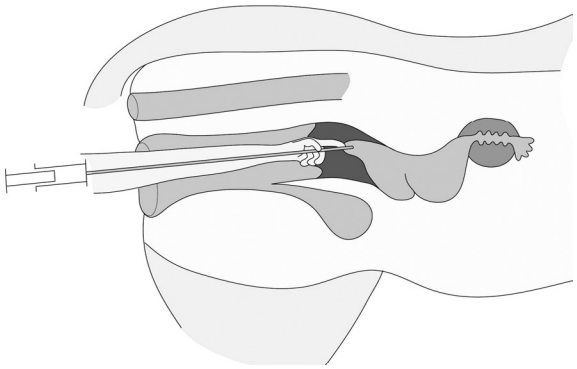
cooling rates of 40°C/min to −60°C then 60°C/min until −140°C is reached (thereafter plunged into liquid nitrogen) have given good results (Vidament 2005).

Thawing rates are more critical for cryopreserved equine sperm than for many other species. Loomis and Squires (2005) suggest that semen frozen in 0.5 mL straws should be thawed at 37°C for a minimum of 20 seconds. It is important that the temperature of the thawing water is accurately controlled because spermatozoa die rapidly if the temperature is raised to 39°C or 40°C. Higher thawing temperatures (e.g., 75°C for 7 seconds) give better post-thaw results, provided the straws are removed at the correct time; however, it is difficult to ensure that this occurs in field use. The contents of four to eight straws are pooled before insemination. When semen is supplied in 4 to 5 mL tubes, thawing should be at 50°C for 45 seconds.

Evaluating the fertility of cryopreserved equine semen is not a straightforward process. Post-thaw motility is a poor predictor of fertility in all species; it identifies the worst ejaculates but fails to discriminate between levels of fertility. In the stallion, it is particularly unreliable (Pickett & Amann 1993) given the minimal amount of reliable data on conception rates in mares. However, attempts have been made to find objective measurements that have high levels of correlation with fertility. Christensen et al. (1996) used *in vitro* induction of acrosome reactions as a predictor of fertility, whilst Samper (1992) and Hellander (1992) have used combinations of glass–wool/Sephadex filtration and motility estimates to predict fertility. Nevertheless, despite the progress that these methods represent, it remains difficult to predict the fertility of a stallion's semen after cryopreservation.

Insemination

The standard method of insemination with cooled or frozen semen is to deposit it into the caudal part of the uterine body via a catheter passed through the cervix (Fig. 43.10). Insemination is best performed with the mare restrained in stocks. After applying a tail bandage and cleaning the perineal area, a hand is inserted into the vagina and the cervix is located. The index finger is inserted into the cervix, and an insemination catheter is passed through the vagina, then alongside the index finger, and so into the uterus. A vaginal speculum can be used to aid locating the cervix. Semen is deposited slowly, in volumes ranging from 0.5 to 80 mL. Most inseminations use a low volume of fluid as there is little benefit from higher volumes upon uterine contractility, and there is a greater risk of retrograde flow from the cervix with larger volumes.



• **Fig. 43.10** Insemination of the mare.

Timing of Insemination

Insemination with cooled semen should take place somewhere between 48 hours before and approximately 6 hours after ovulation. Insemination later than 6 hours after ovulation may result in conception but is more likely to result in embryonic death. The optimal timing depends, however, upon the success with which the spermatozoa have survived the cooling process: the semen of some stallions needs to be inseminated within a few hours of ovulation if it is to achieve an acceptable result. Samper (2007) suggests that a fertile mare can be inseminated once or twice (12–24 hours apart) with good quality semen, but if the semen is of poorer quality or the fertility of the mare questionable, a single insemination as close as possible to the time of ovulation is preferable.

Insemination with frozen–thawed semen needs to be performed between 12 hours before and 6 hours after ovulation. Regular examination of the mare is required to ensure that this timing is achieved. In practice, most mares are inseminated once within 6 hours after ovulation or twice, once before and once after ovulation (Loomis & Squires 2005). Mares are often given human chorionic gonadotrophin (hCG) or a gonadotrophin-releasing hormone (GnRH) analogue to induce ovulation and thus control the timing of insemination more precisely. This has the added advantage of reducing the number of occasions on which the mare has to be examined. Samper (2001) suggested giving 2500 IU hCG once a follicle larger than 35 mm is present, then examining the mare's ovaries every 6 to 8 hours to pinpoint the time of ovulation, which will occur 36 ± 17 hours after treatment. The GnRH analogue deslorelin (Ovuplant) can be given as a short-term implant, resulting in a much closer regulation of the time of ovulation (Hemberg et al. 2006), with ovulation occurring at 38 ± 2 hours post-treatment, so that it is only necessary to examine mares at 36 and 41 hours post-implantation to determine the point of ovulation.

Spermatozoa Numbers and Conception Rates

Cooled Semen

Cooled semen inseminations are typically made with 250 to 500 × 10^9 progressively motile spermatozoa (Brinsko 2006), commonly doubled to 1 × 10^9 motile sperm when insemination is to be delayed by more than 24 hours. Conception rates of 73% to 75% have been recorded for this method. However, this number of spermatozoa almost certainly represents a wastage, at least in fertile stallions, as 100 × 10^6 motile spermatozoa have been used for insemination without any loss of fertility (Pace & Sullivan 1975, Pickett 1980), although lower numbers (e.g., 50 × 10^6) give more variable results (Householder et al. 1981). On the other hand, the use of higher numbers of spermatozoa is said to eliminate much of the variation between stallions.

There is, however, a great deal of variability in the quality of cooled semen that is supplied to horse breeders. Metcalf (1998) showed that semen rated as excellent or good on the basis of percentage of motile and morphologically normal sperm had higher (87% and 62%, respectively) pregnancy rates than semen rated as fair or poor (33% and 11%). Loomis (2001) reported a wide range of numbers of progressively motile sperm in cooled semen (mean: 598 × 10^6; SD: 604 × 10^6; range: 8–4257 × 10^6). Moreover, although controlled trials have shown that it is possible to reduce sperm numbers without loss of fertility, Brinsko (2006) showed evidence from use in the field that doses of less than 500 × 10^6 sperm are associated with much lower pregnancy rates (20%) than doses of more than 500 × 10^6 spermatozoa.

VetBooks.ir

Frozen Semen

Frozen semen inseminations typically contain between 150 and 600×10^6 motile sperm. With most stallions having post-thaw recovery rates of 40% to 70% (Vidament 2005), this necessitates a total insemination dose of around 800×10^6 spermatozoa. The fertility of frozen semen in commercial programmes has been reported to range between 32% and 73% per cycle and 56% to 89% over the breeding season (Loomis 2001). Various combinations of spermatozoal numbers and insemination timings have been reported: Vidament (2005) suggested that best results are achieved with up to two daily inseminations with 300 or 400×10^6 spermatozoa from the time of hCG administration or a single postovulation insemination, figures with which Newcombe et al. (2005) concurred.

New Insemination Methods for Compromised Spermatozoa

Losses of spermatozoa in traversing the uterus from the site of insemination to the uterotubal junction are high, especially when the functional integrity of the spermatozoa has been compromised by freezing or by sex sorting. Deep intrauterine insemination has been investigated as a means of reducing the numbers of spermatozoa and improving the pregnancy rates. In this method, a semirigid or flexible insemination catheter is guided to the cranial part of the uterine horn, and 20 to 200×10^6 spermatozoa are deposited. The catheter can be guided per rectum or using ultrasonography (Sieme et al. 2003). Early attempts at this method resulted in high embryonic loss rates due to traumatic injury to the uterus by the catheter (Morris 2006a), although this problem now appears to have been resolved (Sanchez et al. 2005). Whether an improvement in conception rates is achieved over conventional methods remains unclear: neither Squires et al. (2003) nor Sanchez et al. (2005) saw improved pregnancy rates, although sperm numbers to achieve conceptions were successfully reduced. A reduction in the incidence of postbreeding endometritis may be obtained if fewer spermatozoa are inseminated (Samper & Plough 2010).

Direct insemination on to the uterotubal junction has been investigated as an alternative to deep intrauterine insemination. Hysteroscopic insemination at the uterotubal junction allows reduction of sperm numbers to 10 to 25×10^6 (Sieme et al. 2004, Ball 2006) or even as low as 1 to 5×10^6 (Morris et al. 2003, Sieme et al. 2003, Morris 2006b), which allows acceptable pregnancy rates to be achieved even with sex-sorted sperm (Lindsey et al. 2001). Finally, direct insemination into the uterine tube has also been successfully used for insemination of compromised sperm (Lindsey et al. 2001, Morris 2004). Although these techniques have significant benefits in terms of improved usage of spermatozoa, especially when only small numbers are available (e.g., with sexed spermatozoa), the costs are substantial and training is required. Thus they are not in widespread use in the field.

Control of Infectious Diseases

A considerable number of pathogens are transmissible through equine semen (Table 43.1). Most importantly, this includes equine viral arteritis, which can be shed in the semen of stallions for long periods of time after infection. Because of the difficulties of identifying shedding stallions, the use of methods for processing semen that remove the virus has been recommended (Morrell & Geraghty 2006, Morrell et al. 2014). Many other viruses can be transmitted through semen, including EHV-III, equine infectious anaemia, and, possibly, EHV-II and vesicular stomatitis. The case with EHV-I is less clear-cut for, although its transmission through semen appears likely, no recorded cases have occurred (Klug & Sieme 1992). Many nonspecific bacterial contaminants of semen may cause infertility in inseminated mares. The presence of β-haemolytic streptococci in semen is associated with reduced fertility of mares (Klug & Sieme 1992), as are haemolytic *E. coli, Staphylococcus aureus,* and *Pseudomonas aeruginosa. Klebsiella* spp. are of more clear-cut significance as a cause of infertility, whereas *Taylorella equigenitalis,* the causal organism of contagious equine metritis, is an important venereal pathogen, although not controlled by OIE. Within its geographical area of distribution, *Trypanosoma equiperdum,* the protozoon responsible for dourine, is venereally transmitted. Legislative control exists in many countries to control the spread of equine viral arteritis, equine infectious anaemia, contagious equine metritis, and dourine, at least in the bloodstock industries, but control of venereal diseases in ponies and riding horses is often minimal. The simple precautions of serological examination of stallions for the presence of viral infection and serial bacteriological examination of their external genitalia before using the animals as AI (or, indeed, natural service) sires are all that is required to control most venereal pathogens, yet, all too often, this does not occur until after the onset of a disease outbreak. However, a negative serology result only indicates the absence of an antibody response to the virus, not the absence of infection.

Artificial Insemination of Dogs

It was upon the dog that the earliest recorded studies of AI were undertaken, by the Italian natural philosopher Spallanzani. Despite such an impeccable pedigree, demand for AI of dogs has been slow to develop, as there has historically been a significant degree of resistance to it by many breed societies. This position has changed in more recent years (UK Kennel Club 2017), so the use of AI in dogs has increased markedly. In parallel, methods have been developed for breeding nondomestic Canidae for conservation or commercial purposes.

Collection and Storage of Semen

Semen is usually collected from the dog by digital manipulation (see also Chapter 35). The use of electroejaculation under general anaesthesia has also been attempted (Kutzler 2005). The preejaculatory fluid, sperm-rich fraction and a little of the postejaculatory (prostatic) fluid are collected. The whole ejaculate may be immediately inseminated into the bitch's vagina, but it is more common to dilute the semen so that multiple inseminations can be performed. Where the whole ejaculate is used, only a few millilitres of prostatic fluid should be collected.

Liquid Semen

Dog semen can be stored in a cooled condition for 24 to 72 hours at 4°C, after dilution in simple diluents (e.g., skimmed milk) (Harrop 1962). This is generally long enough for at least two inseminations to be performed on the bitch, or for air freight transport to most international destinations. Hence, this method is very widely used in dog AI (Pena et al. 2006). Better longevity of semen can be achieved with the use of diluents such as Kenney's diluent for equine semen (Bouchard et al. 1990; Table 43.11) or Tris–glucose–egg yolk (Iguer-Ouada & Verstegen 2001; Table 43.12). Removal of the prostatic fluid by centrifugation improves

VetBooks.ir

TABLE 43.12 Diluents for cooled storage of canine semen

Component	Tris–Glucose/ Tris–Fructose	Skimmed Milk
Tris (g/L)	30.25	
Sodium citrate monohydrate (g/L)	17	
Glucose or fructose (g/L)	12.5	
Skimmed milk		80%
Buffer	80%	
Egg yolk	20%	20%
Antibiotics	Commonly penicillin, streptomycin	

Derived from: Iguer-Ouada & Verstegen 2001, Romagnoli 2002.

storage and viability, especially when samples are dilute (Romagnoli 2002), although semen can be preserved successfully without its removal (England & Ponzio 1996). Cooling from body temperature to 4°C should be slow to prevent cold shock: Bouchard et al. (1990) recommended cooling at 0.3° to 1.0°C/min. This rate can be achieved in practice by placing the diluted semen in a container filled with water at room temperature, which is then placed at 4°C overnight (Pena et al. 2006). The use of the Equitainer as a means of cooling/transporting canine semen has also been recommended. Dilution rates have to take into account the volume that can be inseminated into the bitch as well as the density of the semen but should aim to achieve at least 150×10^6 progressive motile sperm.

Cryopreservation

Cryopreservation of dog semen is more difficult than for many species, but success has been improving over recent years. Many different diluents have been tried, largely on an empirical basis or because they work for other species. Egg yolk appears to be an important component of most diluents. Likewise, many different glycerolisation regimens have been employed in an attempt to achieve a satisfactory compromise between its toxic effects upon sperm and the concentrations needed to give effective cryoprotection (England 1993). Although the optimal glycerol concentration appears to be about 6%, its addition in one or multiple steps does not have a major effect upon post-thaw survival (Silva et al. 2003).

Consequently, there are many regimens for freezing semen. Two methods are described as examples of those in current use. Thomassen et al. (2006) diluted semen in a Tris–fructose–citric acid extender, with 8% glycerol and 20% egg yolk, in a single step at 35°C. It was then cooled slowly to 5°C before packaging into 0.5 mL paillettes for freezing. Pena et al (2006) diluted semen 1:1 in a Tris–glucose extender before centrifugation to separate the seminal plasma. After that the spermatozoa were resuspended in further Tris–glucose–egg yolk diluent, with a two-step glycerolisation (3% at room temperature, followed by slow cooling to 5°C, then diluted further with a similar diluent with a higher content of glycerol, to provide a final glycerol concentration of 7%). Freezing is also in 0.5 mL paillettes.

Early methods for freezing relied on freezing in pellets on blocks of solid carbon dioxide or in paillettes suspended in the vapour of liquid nitrogen. The results achieved by these methods are remarkably similar: in 2001, Nianski et al. found no difference between the post-thaw recovery of semen frozen as pellets or in 0.25 or 0.5 mL paillettes. The use of programmable freezers has the potential to result in significant improvements in post-thaw recovery rates, although, as the optimal cooling rate is determined by the concentration of glycerol and the other components of the diluent, it is difficult to generalise about optimal cooling rates. Thus, Rota et al. (1998) found no difference in post-thaw recovery between cooling at 10°C/min and 50°C/min between −10°C and −40°C; however, a cooling rate of 30°C/min is commonly recommended over this period. Thawing at 70°C in water for 8 seconds provides good post-thaw recoveries, although 37°C for 30 seconds is also used (Thomassen et al. 2006).

Insemination

Liquid Semen

When the reason for AI is failure of copulation, semen is collected from the dog by digital manipulation, and the whole ejaculate may be inseminated into the vagina of the bitch immediately after collection. It may, however, be preferable to extend the semen, inseminating one portion immediately and the remainder 48 hours later.

Similarly, when cooled semen has been transported from the sire to the bitch, insemination may be performed upon receipt of the semen and repeated 48 hours later. It is therefore imperative to ensure that the recipient bitch is approaching the fertile period of oestrus before semen is collected.

When fresh or cooled semen is used, intravaginal insemination is undertaken, with the semen deposited as close as possible to the external os of the cervix (Burke 1986). The semen may be deposited through a shortened bovine insemination catheter, which may require the use of a speculum to be guided into the correct site. Some authors recommend inserting one or two fingers into the vulva after insemination, in order to promote the motility of the female genital tract that normally occurs during the copulatory tie. Alternatively, an Osiris catheter, which consists of an outer sheath with a Foley bulb and an inner catheter, can be used (Nianski 2006). The inflatable balloon is considered to both simulate the copulatory tie and prevent retrograde flow of semen. However, there is no unequivocal evidence that this type of catheter improves conception rates beyond those achieved with simple catheters. Whichever method is used, the hindquarters of the bitch should be raised for a few minutes after insemination to prevent retrograde loss of semen. Pregnancy rates of approximately 80% can be expected with fresh semen (England & Miller 2008).

Frozen Semen

Conception rates using frozen semen are poorer with intravaginal than intrauterine insemination. Hence direct intrauterine insemination, either via the cervix or directly via surgery or laparoscopy, is currently recommended. Linde-Forsberg et al. (1999) reported whelping rates of nearly 85% with intrauterine insemination compared with approximately 60% with the intravaginal route. However, higher pregnancy rates were achieved when multiple intravaginal inseminations were performed, although there was no benefit from multiple inseminations by the intrauterine route. The Osiris catheter has been used to try to improve conception rates to intravaginal insemination (Nianski 2006); however, whelping rates by this method were also approximately 60%.

Passing a catheter through the cervix is difficult because of the length of the vagina, the length of the cervix, and the site of its external os (England & Lofstedt 2000). However, the Norwegian

VetBooks.ir

catheter, which consists of a 2 mm catheter inside a Teflon sheath, has been used successfully, although considerable practice is required to master the technique (Romagnoli 2002). Thomassen et al. (2006) describe the method of intrauterine insemination as follows: Insemination is performed on standing bitches, which normally do not require sedation. The cervix is fixed through the abdominal wall with one hand as the steel catheter is manipulated through the cervix into the uterus with the other. After deposition of the semen, care is taken to avoid backflow by ensuring that the plastic sheath remains in close contact with the catheter and by elevating the hindquarters of the bitch (as described previously). As an alternative to transabdominal fixation of the cervix, an endoscope can be used to locate the cervical os. Insemination is easier in bitches of moderate size than in giant and miniature breeds, and is more difficult in animals that are excessively fat. However, pregnancy rates are reported to be similar to the Scandinavian method described previously (Payan-Carreira et al. 2011).

Insemination via a surgical laparotomy or via laparoscopy can also be used for insemination of frozen semen, especially when practitioners are not confident with the transcervical method.

Timing of Insemination

The bitch has a prolonged period of receptivity to the male but a relatively short fertilisation period (see Figs. 33.13–33.15). Thus the fertility achieved in canine AI primarily depends on achieving correct timing of insemination in relation to that of ovulation. When natural service is used, many breeders allow bitches only a single mating, which typically occurs 12 days after the onset of prooestral bleeding. For successful AI, much closer attention to the time of the fertilisation period is needed, especially when cryopreserved semen is used, although more latitude exists when cooled semen is used (Jeffcoate & Lindsay 1989, Linde-Forsberg & Forsberg 1989, 1993, Morton & Bruce 1989). The inherent fertility of the dog is also of importance, with the longevity of his spermatozoa in the female tract being a critical determinant of fertility. Dogs with long-lived spermatozoa can achieve pregnancies even if the timing of insemination is not optimal, whereas with dogs whose sperm have poor survival, sperm death is more likely to have occurred before ovulation under such circumstances (see Figs. 33.13–33.15).

The timing of ovulation can be predicted from the preovulatory rise in circulating progesterone concentrations or measurement of LH concentrations. Alternatively, the ovaries can be examined by ultrasonography. Vaginal cytology, although useful as an indicator of the approach of ovulation, is too imprecise for frozen semen inseminations. Measuring serum progesterone concentrations daily after the onset of oestrus (or after the appearance of a high percentage of cornified vaginal epithelial cells) provides a reasonably good predictor of the timing of ovulation. Progesterone concentrations rise from baseline values to 2.0 to 3.0 ng/mL on the day of the LH surge, thereafter increasing to 4.0 to 8.0 ng/mL on the day of ovulation, and 10 to 25 ng/mL during the 2 days after ovulation (Romagnoli 2002). Hence the first rise in progesterone concentrations can be taken as an indicator of the LH surge. Alternatively, LH can be measured directly using an 'animal-side' assay method (e.g., the semiquantitative Witness-LH, Zoetis, Parsippany, NJ); the assay is intended for use with serum, although it has also been used to detect LH in urine (Durrant et al. 2006). Insemination should ideally be performed 2 to 3 days after ovulation. Thomassen et al. (2006) showed that insemination at the optimal time results in a higher whelping rate and litter size (78% and 5.8 ± 0.2 pups, respectively) than late insemination (56% and 4.5 ± 0.5 pups). Another suggestion for fresh or cooled semen is to inseminate on the day of ovulation and again 2 days later, whereas with frozen semen, the first insemination is done 2 days after ovulation with the second 48 hours later (Payan-Carreira et al. 2011).

Artificial Insemination of Cats

Insemination of domestic cats is undertaken relatively rarely because of the small volumes of semen obtained (0.05–0.25 mL) and the need for anaesthesia for collection and insemination. However, it is used in conserving rare breeds or for international trade and especially for the conservation of wild Felidae, many of these species being endangered. Recent reviews of feline AI have been published by Rijsselaere and van Soom (2010) and England and Russo (2014).

Semen is collected by electroejaculation (Zambelli & Cunto 2006) under general anaesthesia or by urethral catherisation under sedation with medetomidine, which stimulates the α_2-adrenergic receptors (Rijsselaere & van Soom 2010). Semen can also be harvested postcastration from the epididymides, vasa deferentia, or even from minced testis tissue.

Cooled storage of semen requires prevention of cold shock. Egg yolk is less effective at protecting cat semen against cold shock than it is in most other domestic species and, although simple Test (Tes+Tris)-yolk will maintain sperm viability at 5°C, the low density lipoprotein fraction is far more effective than whole yolk (Glover & Watson 1987). Such diluents can maintain semen quality for approximately 24 hours, with occasional reports of longer periods of storage.

Similar extenders are used for freezing as those for cooled storage or with extenders based on Tris, citrate, glucose, fructose, or lactose plus egg yolk. Glycerol is the best cryoprotectant for cat semen, but because of sensitivity to its toxic effects, it is usually added at concentrations of up to 4%. Antioxidants, such as taurine, appear important in the maintenance of post-thaw viability. After loading into paillettes, semen can be frozen in liquid nitrogen vapour, in programmable freezers (at a cooling rate of 10°C/min between +5° and −80°C) or, less successfully, in pellets on dry ice.

Ovulation has to be induced before insemination. The most commonly used hormone for this purpose is hCG: one or two doses are given and insemination performed 15 to 30 hours later. Opinions vary concerning whether it is better to inseminate before or after ovulation has occurred because, with natural mating, ovulation would occur approximately 24 to 48 hours after coitus (England & Russo 2014). Intravaginal insemination has been reported, with pregnancy rates varying from 11% to 78% (reviewed by Rijsselaere & van Soom 2010). In domestic cats, intrauterine insemination via a laparotomy is more convenient, yielding pregnancy rates of 80% for fresh semen and 0% to 20% for frozen semen. However, in some countries this procedure is considered to be invasive and unethical and is prohibited for normal breeding. Sperm doses are 50 to 80 $\times 10^6$ for vaginal insemination and 20 to 50 $\times 10^6$ for intrauterine insemination (England & Russo 2014).

Embryo Transfer and Other Assisted Reproductive Technologies

HENRIK CALLESEN, INGRID BRÜCK BØGH AND TORBEN GREVE

Introduction

In animal husbandry, breeding and selection for special phenotypic characteristics or superior performance has been conducted by humans for thousands of years, but it was not until the last century that the first systematic assisted reproductive technology (ART) was developed and soon introduced in practical breeding. Initially, artificial insemination was the only one, but subsequently, a number of other ARTs have followed. Several of these ARTs, including artificial insemination, embryo transfer, and *in vitro* embryo production (IVP), were initially developed in farm animals for genetic progress or in research to establish animal models, but they have increasingly been modified and subsequently used in companion animals. Some of these techniques, such as intracytoplasmic sperm injection (ICSI), oocyte recovery, and gamete intrafallopian tube transfer (GIFT), were primarily developed in humans as part of a therapy for sub- or infertility. Subsequently, they have been adapted to different animal species either to circumvent specific causes of sub- or infertility or to facilitate basic and applied research. Within the context of this book, the present chapter will describe the basic principles of different ARTs, with emphasis on the large domestic animal species and with focus on the clinical aspects that are relevant to the veterinary practitioner, including obstetrics, pathology, and biosecurity.

Definition

Reproduction is basically the physiological process which guarantees the preservation of the species, and in nature, it requires mating. However, this physical encounter can be circumvented by different technical means that involve human intervention. ARTs that may have relevance for the veterinarian comprise: artificial insemination; embryo transfer, including superovulation and oestrous synchronisation; oocyte recovery for *in vitro* production; and manipulation of embryos, including production of embryos by means of somatic cell nuclear transfer (cloning), transgenic embryos as well as cryopreservation of oocytes and embryos.

Milestones in the Development of Assisted Reproductive Technologies

In 1890 Heape carried out the first successful embryo transfer in rabbits (Heape 1890) and the first calf after embryo transfer was born in 1951 (Willett et al. 1953). Research and development in ARTs have subsequently been substantial, especially in cattle. In the 1960s a technique for nonsurgical embryo transfer was introduced (Sugie 1965), and higher embryo yields from selected individuals were obtained by hormonal induction of multiple ovulations (superovulation). During the last 40 years hormonal regimens for superovulation in cattle have been refined and combined with subsequent transfer of fresh or cryopreserved embryos, a combination of techniques called multiple ovulation and embryo transfer (MOET). Today, this technique has become a routine procedure in many countries, and in 2015 more than 520,000 *in vivo* derived bovine embryos were transferred to recipients worldwide, mainly in North America and Europe (Perry 2016).

In the horse, increasing interest in maximising the reproductive potential of genetically valuable animals led to the first successful nonsurgical transfer of an equine embryo in the early 1970s (Oguri & Tsutsumi 1974, Allen & Rowson 1975, Vogelsand et al. 1947). Since then, the techniques have been improved so acceptable pregnancy rates can be achieved, and in 2015 at least 21,000 equine embryos were transferred to recipients (Perry 2016). Nevertheless, the two major limiting factors are still the lack of an efficient method for superovulation of mares and barriers with cryopreservation of horse embryos.

The first lambs were born after embryo transfer in 1949 (Warwick & Berry 1949). In sheep and goats, embryo transfer is used primarily to enable the importation of new breeds; however, the application is limited because of the high cost and low efficiency of the technology (Warwick & Berry 1949). At least 31,000 sheep and 11,000 goat embryos were transferred in 2015 (Perry 2016).

In the pig the use of embryo transfer for commercial breeding purposes has been and still is limited to a few hundreds (Perry 2016). On the other hand, the technology is widely used for research, but no systematic collection of data is available. In 2015, it can be roughly estimated that more than 15,000 porcine embryos have been transferred for research purposes, especially in relation to somatic cell nuclear transfer (cloning) and transgenesis. The majority of these embryos have been transferred fresh, even though vitrification of porcine embryos has become a possibility (Sanchez-Osorio et al. 2010).

In vitro embryo production has been developed in several species. The first child conceived by *in vitro* fertilisation (IVF) was born in 1978 (Steptoe & Edwards 1978), followed in 1981 by the first calf (Brackett et al. 1982). Since then the techniques for *in vitro*

VetBooks.ir

• **Fig. 44.1** Fifteen calves produced by nonsurgical embryo transfer after superovulation from one single donor. (Courtesy Søren Ernst Madsen, Trans Embryo, Denmark.)

production of bovine embryos improved rapidly, and soon it was possible to produce calves from oocytes, both matured and fertilised *in vitro* (Lu et al. 1988; Xu et al. 1988). Today, the complete *in vitro* technique with maturation, fertilisation, and culture has found a wide application both as a research tool and in veterinary practice (Blondin 2017). In 2015 the number of transfers of *in vitro* produced bovine embryos to recipients worldwide exceeded 400,000, mostly in South and North America (Perry 2016).

In 1991, two foals conceived by *in vitro* fertilisation of *in vivo* matured oocytes were born in France (Palmer et al. 1991, Bézard et al. 1992), but in spite of many attempts worldwide, this success has never been repeated. Instead, ICSI is a more reliable method for the *in vitro* production of equine embryos, and the first ICSI foal was born in 1998 after surgical transfer into the oviduct (Cochran et al. 1998). Subsequently, *in vitro* culture of the early embryo to the blastocyst stage has been developed, allowing for nonsurgical transfer (Carnevale et al. 2004). Since then the technique has been optimised and has found clinical use in cases in which natural breeding of genetically valuable mares or stallions is not possible, even allowing for foals being bred from mares immediately after their death (Carnevale et al. 2004, Hinrichs et al. 2012). The total number of ICSI-produced embryos transferred worldwide in 2015 is estimated to be fewer than 5000 (Hinrichs 2016).

The birth of the first mice and calf after cryopreservation was reported in the early 1970s (Whittingham et al. 1972, Wilmut & Rowson 1973), and this led to an entirely new situation for ARTs in domestic animals. Cryopreservation made it possible to store embryos for many years and transfer them independently of the date and site of recovery. This has been extremely important both for research purposes in rodents and many other species, but also for commercial embryo transfer in the domestic animal species.

Willadsen's original studies on embryo cloning in sheep (Willadsen 1986) initiated another important area for both research and commercial use of ARTs, and the birth of the sheep 'Dolly' (Wilmut et al. 1973), produced by somatic cell nuclear transfer (SCNT), was a great leap forward for production of not only cloned but also cloned and genetically modified animals. Transgenic animals of various species are today generated for production of essential pharmaceutical products, as animal models for the study of specific human diseases, or for research purposes.

Practical Uses of Assisted Reproductive Technologies

Breeding

One of the major advantages of using technologies such as artificial insemination, embryo transfer, superovulation, and cryopreservation is the breeding aspect, in which the technologies can be used to increase the number of offspring from males and females of high genetic value. In cattle a systematic use of superovulation, embryo collection, and embryo transfer has been used in the so-called MOET breeding programmes, in which young females produced by embryo transfer are used to create large full-sib or half-sib families, from which information is retrieved on a potential breeding bull's sisters rather than his daughters (Fig. 44.1). This will increase the selection intensity and reduce the generation interval and thus the genetic progress. The original MOET programme includes establishment of a central breeding herd, from which all genetic selection is based on records obtained within the herd. A variety of MOET programmes have been introduced from the mid-1980s and the genetic advantage has been demonstrated by this method in a large number of bulls (Callesen et al. 1996).

Horse owners may choose different methods of ARTs for various reasons: multiple offspring from dams and/or sires with high genetic value; offspring from mares that are in competition or terminally ill; or from subfertile mares in whom the cause is not related to problems in the genital tract. Although interest in commercial embryo transfer programmes is still limited, the recent improvements in superovulatory regimens are promising and may change the future demand for embryo transfer. Furthermore, advances in methods for embryo cryopreservation may lead to easier management because there will be no need for recipient synchronisation. Although the American Quarter Horse Association ruled in 2002 to allow registration of multiple foals per donor produced by embryo transfer, several breeding associations still impose limits on the number of such progeny or will not allow registration at all.

With the implementation of ultrasound-guided transvaginal oocyte recovery (ovum pick-up, OPU) and in conjunction with *in vitro* embryo production, it is now possible to use this technology as both a supplement to and a replacement for the traditional *in vivo* embryo production. In this way, embryos may be produced

VetBooks.ir

from animals with nonheritable infertility (for example, age, occluded oviducts, endometritis), from animals known to have a poor superovulatory response (individual cattle), from prepubertal or pregnant animals, and in the event of sudden unexpected death when ovaries may be recovered from the dead animal and oocytes subsequently processed *in vitro*.

Twinning

In certain beef cattle breeds, twinning may be an attractive prospect. With the transfer of two *in vivo* derived or *in vitro* produced embryos (IVP) to each recipient, it is possible to obtain a calving rate for each embryo that is greater than 100%. Embryos should be placed in both horns, as this will improve the number of fetuses that survive (Sreenan & Beehan 1976). It was speculated that the technology would gain a broader application with the use of IVP embryos, which can be produced at a lower price (Lu & Polge 1992), but it has not been used widely in practice, as it requires expensive equipment and advanced training; in some countries, it is even prohibited by law.

Export and Import

The potential risk of disease transmission with *in vivo* derived and *in vitro* produced embryos is described later in this chapter. It should be emphasised that movement of livestock as embryos is safer and preferable from an animal welfare perspective compared with transport of live animals, whether young or adult. Embryos have also been exported and imported throughout the world to improve the performance of indigenous cattle populations. In addition to a potential genetic gain, embryo transfer into local recipients will also allow the offspring to acquire immunity through colostrum. However, it should be emphasised that the training of people to ensure a high management level is important to achieve the anticipated production gains. In many countries or regions the price of embryos will prevent use of this technology, so artificial insemination using semen from sires of high genetic merit is probably a better and more realistic means of achieving genetic improvement.

Endangered Species

Several ARTs are used as part of the work with conservation of endangered species (Andrabi & Maxwell 2007). However, the number of animals produced is very much lower than for domestic species. This is partly due to scarce and costly animal resources, lack of economic demand, and inadequate research funding, resulting in insufficient knowledge of both the basic reproductive physiology and anatomy in many of the species, as well as the practical handling of the animals and the gametes involved.

Research

Apart from the previously mentioned applications, the development of ARTs has played an invaluable role in understanding basic cell biology events during normal and abnormal fertilisation and embryogenesis, e.g., placental development, ultrastructure, gene expression, chromosomal studies, epigenetics, and metabolism, in particular by comparing *in vivo*-derived embryos and embryos produced *in vitro* or by cloning. The experience obtained from domestic animal species may also be applied in human ART. For example, has the cloning era clearly shown the importance of epigenetic influences on the phenotype? The combination of transgenesis and cloning is now a possible tool for producing animal models for human diseases, thus developing better methods for the diagnosis and means of treatment.

Superovulation, Insemination and Recipient Synchronisation

Purpose

Superovulation, also called superstimulation, is a treatment intended to increase the ovulation rate and thus the number of available oocytes in the donor animal without disrupting the physiological and endocrinological processes associated with oocyte maturation, ovulation, and fertilisation, as well as subsequent embryonic and fetal development. Superovulation is a prerequisite for the successful application of embryo transfer in species with a physiologically low ovulation rate (cattle, sheep/goats, and horses), and the current description of superovulation will focus on these species. A close synchrony of oestrus between the donor and the recipient is crucial for obtaining optimal pregnancy rates and is an important part of the entire embryo transfer planning process.

Hormones

Follicular Stimulation

Two distinct groups of follicle-stimulating hormones have been used for superovulation. The first hormone used to superovulate ruminants was pregnant mare's serum gonadotrophin (PMSG), now designated equine chorionic gonadotrophin (eCG), which is a glycoprotein produced by the endometrial cups of pregnant mares. It is purified from pregnant mare's serum and has an effect that simulates both follicle-stimulating hormone (FSH) and luteinising hormone (LH). After injection in cattle, eCG has a half-life of approximately 5 days, and its use has both advantages and disadvantages. The advantage is that the drug is relatively cheap and is administered only once because of its long half-life. The disadvantages are: first, a variable and unpredictable FSH:LH effect ratio; and second, because of its long half-life, the residual amount of eCG can have a continuous stimulatory effect after ovulation, causing development of postovulatory, oestrogen-producing follicles. This prolonged and elevated oestrogen production may affect fertilisation and early embryonic development, and attempts have therefore been made to reduce the allegedly adverse effects of residual amounts of circulating eCG by injecting eCG antiserum around the time of oestrus. This was found to improve embryo number and quality in some (Dieleman & Bevers 1987) but not all studies (Callesen et al. 1992).

The second group of superovulatory hormones is FSH, a gonadotrophin extracted from the pituitary glands of pigs (pFSH), sheep (oFSH), or horses (eFSH). In contrast to eCG, pituitary gonadotrophin has a half-life of approximately 6 hours and therefore must be administered twice daily for 3 to 4 days in order to obtain the desired effect. Compared with eCG, it is expensive, but most FSH preparations have a more consistent FSH:LH effect ratio. Today, FSH preparations are the most widely used hormone for superovulation.

Induction of Oestrus

To achieve ovulation of the stimulated follicles, the donor must come into oestrus within a few days after the initiation of the eCG or FSH injections, and this requires induction of luteolysis, as the superovulatory treatment normally is initiated in the midluteal phase of the oestrous cycle. Induction of luteolysis is normally achieved with injections of prostaglandin ($PGF_{2\alpha}$) or its analogues, but insertion of vaginal or subcutaneous

VetBooks.ir

progesterone-releasing devices may also be used to suppress the LH surge until ovulation is desired.

Induction of Ovulation

Two hormones may be used, either human chorionic gonadotrophin (hCG) or gonadotrophin-releasing hormone (GnRH), either used alone or in combination with prostaglandin.

Recipient Synchronisation

Recipients are synchronised with prostaglandin or progesterone-releasing devices, and a close synchrony with the donor's oestrous cycle is always attempted (see Chapter 8).

Superovulation, Insemination, and Synchronisation Regimens in Cattle

A vast amount of data is available concerning superovulation in relation to embryo transfer in cattle (Mapletoft & Bo 2012), and in the following information, the practical importance of this is summarised.

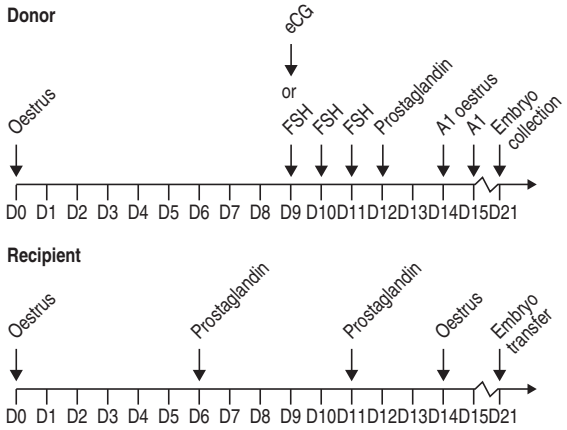
It must be stressed from the onset that superovulation of cattle is subject to a high degree of unpredictability and variability and may cause frustrations for the donor's owner and also for the veterinarian involved (Callesen & Greve 2002). Before entering into an embryo transfer programme, the owner should therefore receive detailed information and veterinary guidance about the shortcomings of superovulation and the procedure as a whole. However, there are a number of routine clinical and management procedures that may be undertaken to increase the likelihood of success.

Donor Selection

One of the routine measures is the careful assessment of potential donors. They should be in positive energy balance, and cows losing weight after calving are particularly poor candidates for induction of superovulation. In general, they should have had two regular oestrous cycles before commencement of the procedure and be otherwise gynaecologically normal. Age, parity, and season (except heat stress) have some influence on the subsequent outcome of superovulation, and there is also a certain breed effect. Ultrasonography may be used before superovulation to ensure that there is a degree of ovarian follicular activity (Singh et al. 2004), but the correlation between the ultrasonographically visualised number of small and medium-sized ovarian follicles at the time of initiation of hormone treatment and the subsequent number of ovulations is not high but may give some indication of the donor's subsequent response (Singh et al. 2004). The blood concentration of anti-Müllerian hormone (AMH) is an indicator of the active follicle population in the donors. It has some potential application as a method in assisting in the selection of donors for superovulation (Baruselli et al. 2015), but variation between breeds and different genetic lines requires further investigations.

Standard Superovulation Protocol

At the time of initiation of the gonadotrophin treatment, the veterinarian must ensure that there is an active CL. The standard superovulation protocol (Fig. 44.2) is as follows: around Day 9 to 11 after oestrus/ovulation, when the second follicular wave is emerging, the donor receives one injection of eCG or the first of FSH administered twice daily in decreasing doses for 3 to 4 days. At 48 to 72 hours after the initial injection of the superovulatory treatment, oestrus is induced by means of one or two injections of prostaglandin, and oestrus will normally occur around



• **Fig. 44.2** Hormonal regimen for superovulation and oestrus synchronisation in cattle.

48 hours afterwards. Because oestrus may occur earlier because of the increased oestrogen production from the growing follicles, it is advisable to observe the donor closely for oestrus signs from around 36 hours after prostagandin treatment. The LH surge coincides with the occurrence of oestrus, namely 42 to 45 hours after the prostaglandin injection (Callesen et al. 1986), and the donor will ovulate 24 to 30 hours later. Therefore insemination should be performed twice, at 12 and 24 hours after the onset of standing oestrus; it has been shown that more inseminations have no advantage (Callesen & Greve 2002).

It is important to use high quality semen (Stroud & Hasler 2006) from bulls of known fertility because semen transport in the superovulated female may be impaired; this is shown by the relatively high rate of unfertilised oocytes and the low number of supernumerary spermatozoa in the zona pellucida of embryos recovered from superovulated animals, compared with nonstimulated animals (Saacke et al. 1994). A certain bull effect has been seen (Callesen & Greve 2002), and there is also a farm-to-farm variation that is probably related to the farm management. When sex-sorted semen is used, factors such as inherent variation in the response of a particular bull's semen 'being sorted', the dose of sexed semen used for insemination, the insemination protocol, and the parity of the donor are also to be considered (Peippo et al. 2009).

Recipient Selection and Management

A close synchrony between donor and recipient oestrus is essential to achieve high pregnancy rates (Hasler 1998). To induce oestrus in the recipients, they are given two doses of prostaglandin 11 days apart (see Chapter 8). The last injection is given 24 hours before the donor's prostaglandin injection, as the recipient has a longer response time to oestrus in comparison to the donor. The reason for this is the earlier and increased rise in the donor's oestrogen (E2) concentrations that will trigger an earlier LH surge.

Measures to Improve the Superovulatory Response

Many attempts have been made to improve the superovulatory response after the conventional midcycle superovulatory regimen, and one focus area has been the follicular wave pattern through the oestrous cycle assessed by ultrasonography (Adams 1994, Ginther et al. 1996). This has helped in the design of new and more effective protocols for the manipulation and control of the follicular wave emergence (Mapletoft & Bo 2012).

Taking into account the pattern of follicular wave emergence, it is possible to design protocols in which the start of the FSH

VetBooks.ir

treatment coincides with the time of the wave emergence and when ovulation is timed so fixed-time AI can be performed (Callesen et al. 1992). This reduces the time spent by staff involved and also removes the need for oestrus detection; it furthermore optimises the number of fertilised eggs obtained (Bo et al. 2006). However, such protocols are not possible to use in several countries, particularly in the EU, where there are restrictions on the use of certain hormones in animals intended for human consumption.

Recombinant bovine somatotropin (rbST) has been shown to increase the number of growing follicles in cattle (Gong et al. 1993) and thus, theoretically, could be used to improve the superovulatory response. However, using repeated superovulations in a commercial organisation involving embryo transfer in dairy cattle (Hasler et al. 2003) failed to demonstrate a positive effect of this treatment in terms of total number of embryos and those of good quality.

Disadvantages and Variability of Superovulation Treatment

Superovulation has at least two major challenges: first, the efficacy of the gonadotrophins (purity, FSH:LH effect ratio) and the complex planning and management of the superovulatory protocol in relation to the emergence of the follicular wave; second, there exists an inherent between-animal variation in terms of the number and quality of both oocytes and embryos produced.

Superovulation always results in aberrant steroid hormonal profiles in both the follicular fluid and the peripheral circulation (FSH, LH, E2, and P4). Thus there are significantly elevated levels of E2 and P4 around the time of and after ovulations, and in most donors the LH surge is elicited sooner due to an earlier increase in E2. In some donors the LH peak is lower or absent. All or just some of these aberrations may lead to impaired oocyte maturation, reduced oocyte quality, lack of fertilisation, and an impaired embryo quality (Callesen et al. 1986). The only hormonal analysis that may be of practical relevance is the measurement of plasma P4 around the time of oestrus, as elevated levels are predictive of a poor response (Dieleman & Bevers 1987, Callesen et al. 1992, Callesen & Greve 2002).

The Donor After Superovulation and Flushing

Within approximately 30 days for heifers and 40 to 60 days for cows, the donors will return to normal cyclicity, and their fertility is generally normal. Nevertheless, through the profound alterations in the endocrine profiles, superovulation may obviously affect the subsequent fertility of the donor for a period of time, and it is important that the owner is made aware of this. Embryos may be left in the uterus after flushing, and to avoid spontaneous abortion around day 50 to 60 of multiple fetuses and to achieve a return to normal cyclical activity as soon as possible, prostaglandin should be given at the end of the collection procedure and eventually repeated some days later. Nevertheless, a certain proportion of animals will not return to normal cyclicity, as they may experience an anovulatory period or even develop cystic ovarian disease. These donors should be submitted for gynaecological examination, and treatment with progesterone may alleviate the problem.

Superovulation, Insemination, and Synchronisation Regimens in Horses

Superovulation

In the past, attempts to induce multiple ovulations in the mare have resulted in only marginal success. Paradoxically, eCG is ineffective in inducing a superovulatory response in the mare (Day 1940, Betteridge & Mitchell 1974), presumably because of insufficient binding to the FSH receptors in the mare's ovarian tissue (Stewart & Allen 1979). Different treatment regimens with pFSH have only resulted in an insignificant increase in the average ovulation rate of fewer than 2 ovulations, even when quite large doses were used (Irvine 1981, Squires et al. 1986, Fortune & Kimmich 1993). GnRH or GnRH-analogue treatment of mares during anoestrus has a moderate superovulatory effect (Johnson 1987, Ginther et al. 1990), whereas in cyclical mares, GnRH treatment has no effect and results in downregulation of the pituitary gland, with ovarian inactivity as a consequence (Montovan et al. 1990, Watson et al. 1992, Fitzgerald et al. 1993, Pedersen et al. 2002). Active immunisation against the α-subunit of inhibin has been used successfully to increase the ovulation rate, although passive immunisation only had a moderate effect. Immunoglobulins against inhibin neutralise the circulating inhibin and reduce the inhibitory effect on FSH from the pituitary. However, this method has not been used commercially because of variable results, the need for repeated injections, and several adverse reactions experienced after both active and passive immunisation (McCue et al. 1993, McKinnon et al. 1992).

It has been hypothesised that the relatively restricted area available in the ovulation fossa, combined with the large size of the preovulatory follicle in the mare, might be a limiting factor for superovulation (McCue 1996). Furthermore, if blood clotting in the ovulation fossa is increased when multiple ovulations occur on the same ovary, it may lead to lower embryo recovery rates when double ovulations occur on the same ovary as opposed to one follicle on each ovary (Squires et al. 1987, Riera et al. 2006). However, a report in which a mare spontaneously ovulated 12 follicles of diameters ranging between 18 and 22 mm within 2 days, followed by ultrasonographic identification of six embryonic vesicles on gestation Day 17 (Brück et al. 1997), shows that there is no intrinsic limitation preventing superovulation in this species. Although the mechanism for this spontaneous superovulation has never been determined, it clearly illustrates that the diameter of the preovulatory follicle is not necessarily a measure of follicular and oocyte maturity and that the normal mechanisms for selecting a dominant single follicle may sometimes be overridden.

Successful superovulation, with ovulation rates ranging from 1.7 to 4.6 ovulations/oestrus, has been achieved using equine pituitary extract (Squires et al. 1986, Douglas et al. 1974, Woods & Ginther 1984). Currently, the most effective protocol to induce multiple ovulations in the mare is a regimen with twice-daily injections of FSH (eFSH or recombinant FSH), initiated 5 to 8 days after ovulation when a CL is present and the largest follicle has reached 20 to 25 mm in diameter. On the second day of FSH treatment, prostaglandin is administered to induce luteolysis. The FSH treatment is continued for 3 to 5 days until the largest follicle(s) reaches 32 to 35 mm in diameter. After an interim period of 36 hours, the mare is treated with hCG to induce ovulation (Alvarenga et al. 2001, Scoggins et al. 2002, McCue et al. 2007, Meyers-Brown et al. 2011). This regimen has resulted in an average of approximately four ovulations and 1.5 embryos recovered per treated oestrous cycle (Niswender et al. 2003, Welch et al. 2006). The relatively intensive treatment regimen and the current price per dose render superovulation treatment in the mare an expensive and impractical procedure. As in cattle, there is variability in the superovulatory response, especially in older mares (Squires & McCue 2007), and so far, there is no information available on the effect of repeated superovulatory treatments on the mare's long-term fertility.

VetBooks.ir

Synchronisation and Insemination

For oocyte and embryo transfer, the time of ovulation has to be synchronised between donor and recipient mare. This is generally attempted by two separate injections of prostaglandin during dioestrus to induce luteolysis, followed by treatment with hCG or GnRH analogue during oestrus when the preovulatory follicle reaches 35 mm in diameter in order to induce ovulation. Nevertheless, the course of follicular development varies considerably between individual mares, and the onset of oestrus depends greatly on the size of the follicles present at the time of prostaglandin injection. Thus simple synchronisation with one prostaglandin injection during dioestrus is often suboptimal, and the administration of two prostaglandin injections approximately 10 days apart can improve the synchrony; alternatively, three recipients should be available per donor mare. Timed induction of luteolysis can also be combined with a previous prolonged treatment with allyltrenbolone (Loy et al. 1998), which has been shown to have the lowest incidence of adverse reaction compared with other forms of progestin treatments (Card et al. 2015). Fortunately, the degree of synchrony between the oestrous cycles of donor and recipient is less crucial in mares than in cattle. No significant difference in the pregnancy rates after transfer of embryos collected on Day 7 after ovulation was found if the recipient ovulated 1 day before or up to 5 days after the donor mare, although there was a trend for better pregnancy rates if the recipient ovulated 2 or 3 days after the donor (Squires et al. 1982, Jacob et al. 2012). Alternatively, pregnancies and foalings can be achieved after embryos are transferred to ovariectomised recipients that are kept under progesterone treatment for the first trimester of gestation (Hinrichs & Kenney 1987). This method has a major practical implication for commercial embryo transfer in mares because embryo transfer programmes are often hampered by the unreliability of recipient synchronisation and the unavailability of sufficient numbers of recipient mares.

The breeding technique (natural service or AI) is generally secondary, provided semen quality and the timing of breeding in relation to ovulation is optimal. If there is uncertainty concerning either the quality of frozen semen or the possibility of intensive monitoring necessary for AI with frozen semen, the use of fresh or chilled semen is preferred.

Superovulation, Insemination, and Synchronisation Regimens in Sheep and Goats

Superovulation

Techniques for superovulation are very similar for both species (Ishwar & Memon 1996), and the gonadotrophin preparations used are the same as those used in the cow, namely eCG or oFSH. Gonadotrophin treatment is usually initiated in mid- to late cycle, and prostaglandin is administered 24 to 72 hours later, inducing oestrus within 24 to 36 hours. Oestrus and ovulation can also be controlled by an intravaginal progesterone-releasing device; sheep are treated for 12 to 14 days and goats for 14 to 18 days using this method. Superovulation can also be induced outside the normal breeding season. The use of eCG antibodies has been attempted in sheep but without significant improvement of the superovulatory result.

Insemination

Insemination is usually achieved by natural service or AI using freshly collected semen every 12 hours from the time of oestrus. However, fertilisation failure occurs commonly in the ewe, particularly when the ovaries are overstimulated and response to gonadotrophin is high. This can be overcome by surgical insemination directly into the uterus, either by laparotomy or using laparoscopy. Synchronisation of donor and recipient oestrous cycles is normally achieved by progesterone-releasing intravaginal sponges, and an asynchrony of up to 2 days will still result in acceptable pregnancy rates (Ishwar & Memon 1996).

Superovulation, Insemination, and Synchronisation Regimens in Pigs

Superovulation and Insemination

Induction of superovulation of sows or of gilts involves the use of two very different regimens as described here.

In sows, hCG is administered 3 days after weaning to induce ovulation, and 15 days later luteolysis is induced by means of two prostaglandin injections given 12 hours apart (Hazeleger et al. 1999). To stimulate follicular growth, eCG (1000 or 1500 IU) is administered approximately 1 day after the last prostaglandin injection. Ovulation is induced 72 hours later with hCG (750 IU), and the sows are inseminated 36 and 42 hours after hCG injection. Recipients receive the same treatment apart from insemination.

In gilts, there are two possible methods: (1) insemination and induction of abortion with prostaglandin around Day 26, and subsequent superovulation with eCG; or (2) use of allyltrenbolone in combination with eCG and hCG (Cameron et al. 2004). In the latter method, after a natural oestrous cycle, the pigs are fed allyltrenbolone (20 g/day) for 18 days and, 24 hours after cessation of this treatment, they receive an injection of 1000 IU eCG followed by 750 IU hCG approximately 72 hours later. Mating (natural or artificial insemination) is then performed two or three times, starting approximately 24 hours after hCG. The latter method is preferred.

Embryo Collection and Transfer

Purpose/General Principles

After superovulation, the embryos are recovered from either the oviduct or the uterus. In all species, early attempts to recover embryos used surgical methods through a midventral laparotomy (Polge 1977) and flushing of the oviducts and uterus. This technique is still practised in species in which cervical catheterisation is difficult, and the procedure cannot be controlled by rectal palpation (sheep/goats and pigs). As a consequence, it is labour intensive, requires access to an operating theatre, is expensive, and poses a greater risk to the donor animal (anaesthesia, adhesions, and subsequent reduced fertility). A semisurgical technique involving endoscopy for the recovery of embryos from the oviduct has been developed both for pigs and cattle (Besenfelder 2006); its use is currently for more experimental purposes.

In cattle and horses, nonsurgical techniques were developed to collect embryos from the uterus of cattle (Drost et al. 1976, Elsden et al. 1976, Greve et al. 1977, Newcomb et al. 1978) and horses (Oguri & Tsutsumi 1974, Imel et al. 1981). This was a major advance in the application of commercial embryo transfer, especially in cattle.

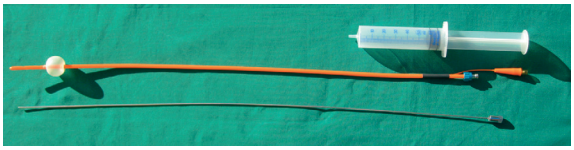
Embryo Collection and Transfer in Cattle

Embryo Collection

Bovine embryos enter the uterus around Day 4 and are collected 6 to 8 days after the onset of standing oestrus when the embryos

VetBooks.ir

• **Fig. 44.3** Cattle ovary with multiple corpora lutea after superovulation with eCG.

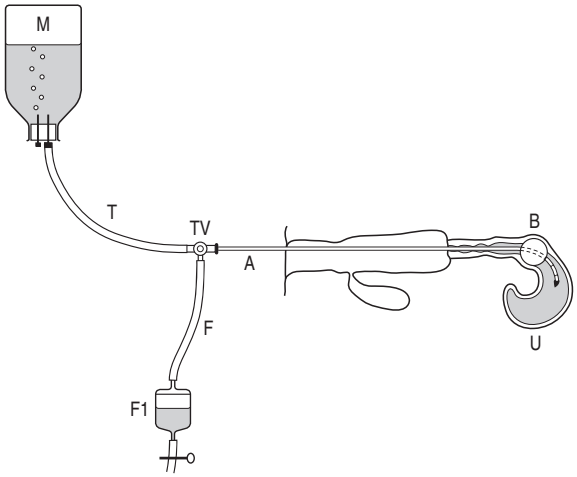


• **Fig. 44.4** Foley catheter used for nonsurgical embryo collection in cattle, balloon extended with air.

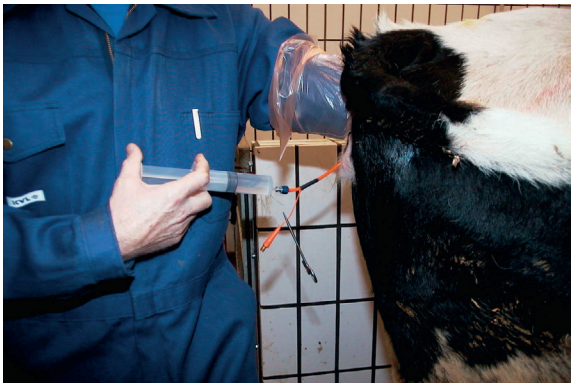
are at the morula and blastocyst stages and still surrounded by the zona pellucida (see Chapter 4).

Before embryo collection, the superovulatory response is assessed by rectal palpation (Fig. 44.3) and/or use of transrectal ultrasonography; the latter method gives a more accurate estimate of the number of CLs and anovulatory follicles. However, the exact number of CLs is difficult or even impossible to assess, particularly in donors with multiple CLs, and the veterinarian should avoid telling the owner about the expected number of embryos. If there are only one or two CLs or there are follicular cysts, it is advisable not to proceed with the collection procedure. Epidural anaesthesia is normally used to prevent straining and defecation. However, some animals may aspirate air into the rectum (ballooning) as a consequence of the epidural, and this makes the procedure more difficult. It is important to minimise contamination, so the perineal region is washed and disinfected carefully with a mild disinfectant, including the inside of the vulvar lips.

The embryo collection catheter most widely used is a Foley rubber catheter (Fig. 44.4) of different brands and sizes; a catheter 70 cm long and 14, 16, or 18G is most commonly used for cows and heifers, respectively. The catheter is guided through the cervix into the desired uterine horn under careful rectal control, and when the tip of the catheter is in the middle part of the horn, the balloon is inflated with air or saline. Care should be taken not to damage the endometrium during the passage of the catheter and during the inflation procedure, as this may lead to poor recovery of the flushing medium and/or bleeding with subsequent clotting, leading to difficulties in embryo identification. In heifers, it may be necessary to use a cervical dilator before introducing the catheter, but care must be taken not to penetrate the uterus just after passing through the last cervical ring.



• **Fig. 44.5** Schematic drawing of nonsurgical embryo collection in cattle using continuous flushing by the gravity flow.



• **Fig. 44.6** Embryo recovery in a heifer using the interrupted flow principle.

It is customary to flush each horn separately; flushing of the whole uterine body can be used but often requires more uterine manipulation than the separate horn flush. Modified Dulbecco's phosphate buffered saline (DPBS), supplemented with 1% to 2% bovine serum albumin (BSA) or fetal calf serum (FCS) and various antibiotics, were normally used for recovery (Greve et al. 1977); however, today, many companies sell ready-to-use media for this procedure. Protein supplementation of the flushing medium is important in order to prevent adhesion of the embryos to the plastic ware (filters, dishes, and tubing), but it is essential to assure that the protein source is not contaminated with virus (e.g., bovine viral diarrhoea (BVD)). Two different embryo collection (flushing) methods may be used: continuous flow (Fig. 44.5) or repeated interrupted collection using injection and evacuation of 30 to 50 mL medium (Fig. 44.6). The flushing volume varies between animals, but in general, approximately 0.5 litres is used per horn, with cows requiring more than heifers. Whatever method is used, it is of the utmost importance to recover all of the medium that has been infused, as the embryos may be present in the final residues.

The flushing medium is transferred to a specially designed filter with a pore size of 70 µm, allowing somatic cells (e.g., red blood cells) and certain debris to pass through but retaining the embryos (150–200 µm in diameter). The filter content is transferred to a dish marked with squares, and the filter bottom is washed several times with additional flushing medium. Sedimentation in a funnel

or glass cylinder can be used, but mucus and other debris may mask the embryos during the subsequent search in the dish. The search is performed under a stereomicroscope at ×50 to 100 magnification and, once the embryos are identified, they are transferred to a smaller dish containing the appropriate medium, e.g., DPBS medium supplemented with 5% to 10% FCS or another protein source.

Assessment of Embryo Quality

Embryo evaluation is performed in a dish that should contain no blood or other debris. The morphological evaluation of embryos includes assessment of stage and quality of the embryo and follows the guidelines from the International Embryo Technology Society (Stringfellow & Givens 2010). Among the fertilised eggs recovered on Day 6 to 7, most embryos are at the compact morula, early blastocyst, blastocyst, or expanded blastocyst stages (Fig. 44.7). Hatched blastocysts will rarely be present if collections are conducted before Day 8 after oestrus. A compact morula contains at least 16 cells, and the surface of individual blastomeres may be discerned. In the early blastocyst there is a small blastocoele cavity, so it is often possible to distinguish the inner cell mass and the trophectoderm. During the observation in the dish, the embryos may 'pump' and form a smaller or larger blastocoele cavity; it is believed that this is a sign of good health and quality. The embryo quality is scored as excellent, good, fair, or poor; additionally unfertilised oocytes have to be identified. It may be difficult to make a very clear distinction between excellent and good quality embryos, which are characterised by the embryo being spherical without signs of blastomere degeneration. In the fair category, some blastomeres may have degenerated and are lying outside the trophectoderm, so they are not participating in the embryo formation. In the poor category, very few blastomeres are normal. The unfertilised oocytes often assume different shapes and sometimes contain degenerated, unevenly distributed ooplasm.

In vivo-derived bovine morulae and blastocysts are quite robust and may be maintained in the appropriate medium in a small dish or in an AI straw at room temperature for up to 24 hours without losing their viability. If stored at 4°C, transfer will result in satisfactory pregnancy rates even after storage up to 48 hours after recovery (Lindner et al. 1983). Moreover, *in vivo*-derived embryos are quite tolerant to cryopreservation (see later in this chapter).

The results of embryo recoveries are subject to large variations (Stroud & Hasler 2006, Hasler 1998) as they depend on the response to superovulation. Nevertheless, in general, one may expect that:

- Five percent of the donors are not flushed because of a poor superovulatory response, i.e., 1 to 2 CLs.
- Nontransferable or nonviable embryos are recovered from 20% of the animals.
- The total number of embryos and unfertilised oocytes per donor is around 8 to 10, and of these, approximately 6 embryos are considered to be transferable (Stroud & Hasler 2006, Merton 2007, Mapletoft & Bo 2012).

Embryo Transfer

The embryo may either be transferred to the recipient immediately after recovery or be cryopreserved and transferred later. Data from the International Embryo Technology Society show that approximately 40% of the transferred embryos are fresh, whereas the other 60% are first cryopreserved (Perry 2016). Quite many of the cryopreserved embryos are not subsequently thawed and transferred, for example, because of lack of demand resulting from decreasing genetic value of these embryos after too long storage.

Until the mid-1970s, embryos were transferred surgically initially by midventral and later by flank approach into the tip of the uterine horn. These techniques – in particular the midventral approach – were tedious and involved a surgical risk to the animals. Since then, virtually all bovine embryos have been transferred by nonsurgical means through the cervix, yielding pregnancy rates similar to those obtained after surgical transfer, i.e., on average, 50% to 60% (Greve & Lehn-Jensen 1979, Wright 1981).

Before transfer, the embryos are washed 10 times according to the manual of the IETS (Stringfellow & Givens 2010), and each embryo is then loaded into a 0.25 mL sterile insemination straw. The straw is placed in an ordinary insemination pipette or a specially designed embryo transfer catheter, which is a thinner and longer version of the ordinary insemination pipette.

The oestrous cycle of the recipients must be synchronised with that of the donor, and before transfer, it must be ascertained that oestrus has occurred within ± 24 hours of the donor (Hasler 1998) and that a functional CL is present. The synchrony between recipient and embryo developmental stage may be a more reliable parameter than oestrous synchrony. Thus morulae should, for example, be transferred to recipients that are at Day 6 after oestrus, and blastocysts to recipients at Day 7.

It is advantageous to use epidural anaesthesia. However, this can be omitted, for example when the transfers are done by nonveterinarians who are not allowed to use anaesthetic drugs. As with the donors, the perineal region has to be cleaned carefully. In cattle, embryos must always be transferred to the uterine horn ipsilateral to the ovary bearing the CL in order to block the luteolytic mechanism. The embryo transfer catheter, fitted with a chemise, is passed through the cervix under rectal control and gently introduced into the midpart of the uterine horn, where the embryo is deposited (Fig. 44.8). The technique involves a combination of gently pushing the catheter into the uterine lumen and pulling the horn over the catheter. Any endometrial trauma with bleeding must be avoided. In terms of pregnancy rates (average 50%–60%), there are considerable variations from operator to operator and from farm to farm, and there is also a very significant effect of embryo quality, with excellent and good embryos giving the highest pregnancy rates.

After embryo transfer, pregnancy loss beyond gestation Day 45 is around 5% and thus very similar to that after artificial insemination, with cryopreserved poor quality embryos resulting in the highest loss (Callesen et al. 1996).

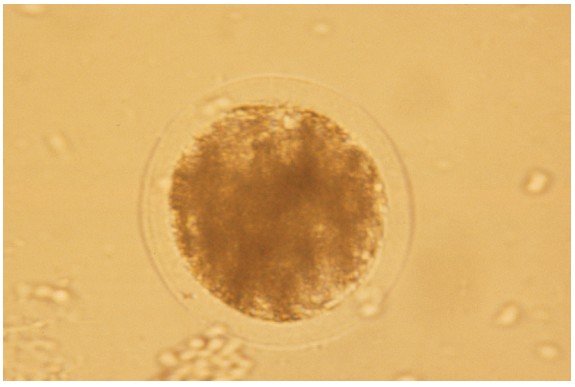
Embryo Collection and Transfer in Horses

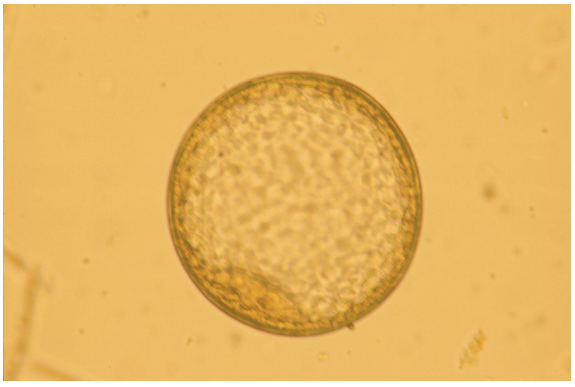
Embryo Collection

For comfortable working conditions, mares are restrained in a crush, and sedation is often unnecessary (Fig. 44.9). An initial thorough cleaning of the perineal area is essential. The tip of a Foley or silicone flushing catheter is inserted by digital manipulation through the cervix into the uterine body. The balloon of the catheter is inflated just cranial to the cervix, and the entire uterus is filled by gravity flow with Dulbecco's PBS supplemented with 1% FCS, which prevents especially the smaller embryos from adhering to the plastic ware. The volume of the flushing medium varies with the mare's age and parity, but in general, the uterus will accept 1 to 2 litres. It is important to install as much fluid as the uterus will accept, to ensure that all endometrial folds are distended before the flushing medium is collected through a 70 µm filter. Flushing is repeated three times, and oxytocin may be given before the last collection to enhance the recovery of the remaining fluid. Unlike cattle, the recovered flushing medium rarely contains red blood cells. Immediately after recovery, the donor can be treated with prostaglandin to induce oestrus and allow embryo recovery to be repeated with a 14- to 18-day interval.

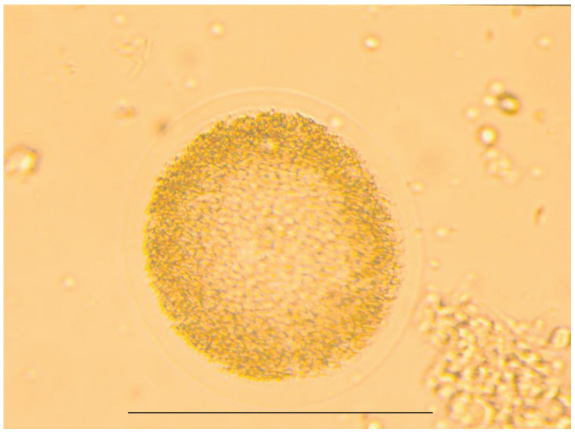
In mares, the embryo enters the uterus at the morula stage, approximately 5.5 days after ovulation (Betteridge et al. 1982), and



• **Fig. 44.10** Equine morula recovered *in vivo* on Day 7 after ovulation.



• **Fig. 44.11** Equine blastocyst recovered *in vivo* on Day 7 after ovulation.



• **Fig. 44.12** Unfertilised ovum recovered from a mare together with a fertilised egg.

in an embryo transfer programme, embryos are generally recovered 6 to 8 days after ovulation at the morula or blastocyst stage (Figs 44.10–44.12).

On Day 6, just upon entry into the uterus, the embryo has a similar size to unfertilised oocytes (approximately 150–250 µm in diameter (Betteridge et al. 1982)), but as the blastocoele forms, it expands rapidly to measure 200 to 600 µm in diameter on Day 7 and up to 600 to 1000 µm on Day 8 (Betteridge et al. 1982). This allows macroscopic identification of the embryo in the flushing medium from approximately Day 8. At this stage the zona pellucida has been shed, so the embryo is now surrounded by a capsule,

VetBooks.ir

which preserves its spherical shape until approximately gestation Day 17 (Fig. 44.13). Because the passage through the uterotubal junction requires a signal from the early embryo, most probably PGE2 (Weber et al. 1991), recovery of an unfertilised oocyte is always a sign that a fertilised ovum has also passed through the uterotubal junction.

Embryo recovery rates are correlated with embryonic age, with usually higher recovery on Day 8 than on Day 6 (Iuliano et al. 1985, Squires et al. 1985a, Squires et al. 1985b), most likely due to the larger size and better visibility of the embryo. In young fertile mares, embryo recovery rates of up to 70% to 80% can be achieved on Day 7, but lower recovery rates are usual when working with mares in practice. Thus pregnancy rates after transfer vary greatly, depending on the fertility of the donor, stallion, and recipient, as well as the operator's technical skills; also, the mare's age has a significant influence. Apart from an increased pregnancy loss (reviewed by Ball (1988)), the age-related decrease in mare fertility can be attributed to prolonged follicular development, decrease in oocyte quality, and endometrial alterations resulting in a decrease of the microcotyledon surface density (Brinsko et al. 1995, Carnevale & Ginther 1995, Wilsher & Allen 2003). Thus requirements for the donor are: optimal fertility, 3 to 10 years of age; first or second parity to assure optimal uterine capacity and function; adequate body size and nutritional status; and good temperament. Needless to say, embryo quality plays a major role, and morphological evaluation using light microscopy before transfer may provide an indication of the embryo's subsequent developmental competence. Nevertheless, morphological embryo quality will not always be accurately predictive and due to limited use of superovulation, often only one embryo will be available for transfer.

Embryo Transfer

As for the donor, there are preferable requirements for the recipient with respect to age, parity, fertility, and temperament. As mentioned before, synchrony between stages of the oestrous cycle of donor and recipient should be within + 1 and −5 days. Thus in countries with well-developed commercial horse breeding activities, large recipient stations have evolved. Alternatively, ovariectomised mares treated with progesterone during the first trimester of gestation have proved to be useful recipients (Hinrichs & Kenney 1987, Squires et al. 1989).

Equine embryos can either be transferred to a recipient immediately after recovery, after cooling to 5°C for 24 hours, or after cryopreservation (see later in this chapter). For nonsurgical transfer, the embryo is aspirated into an insemination straw, and for ease of identification, positioned between an air bubble and a second fluid column. The transfer instrument is introduced into the synchronised recipient in a way that in principle is similar to that used for AI but, to ensure extra sterility, thorough cleaning and disinfection of the recipient's perineal area and coverage of the transfer instrument with a sterile chemise (guarded method) are essential. As an additional measure to ensure sterility and avoid prostaglandin release, it has been suggested that the cervix is retracted caudally using cervical retraction forceps (Fig. 44.14) inserted into the vagina inside a Polansky speculum, before the tip of the insemination catheter is introduced through the cervix; this removes the need for manual intravaginal manipulation (Wilsher & Allen 2004). When the tip of the insemination catheter is positioned correctly in the uterine body, the embryo is gently released.

After nonsurgical transfer of Day 7 and 8 embryos, pregnancy rates of 50% to 75% can be achieved (Iuliano et al. 1985, Squires et al. 1999).

Embryo Collection and Transfer in Sheep and Goats

Embryo Collection

In the ewe and the doe goat, embryos are surgically collected 3 to 7 days after oestrus under general anaesthesia and through a midventral laparotomy (Moore 1982). The animals are placed in dorsal recumbency, preferably on a table that allows the hind part of the animals to be elevated (Fig. 44.15). After access to the abdominal cavity, the ovary, oviduct, and part of the uterine horn are exteriorised and the CL number determined in order to predict likely embryo recovery rates. Using a blunt needle fitted on a syringe, approximately 50 mL of, for example, modified DPBS saline containing 1% FCS is infused either into the tip of the horn or through the oviduct, and the medium is collected in dishes via a collection catheter placed in the distal part of the horn. Procedures for identification, isolation, and quality assessment are very similar to those previously described for cattle. The recovery rate is generally between 90% and 100%, and the number of collected embryos varies between and within breeds. Approximately 3 to 10 embryos per donor can be expected. Attempts to use semisurgical techniques (laparoscopy) for embryo recovery of tubal-stage embryos have been made, with similar recovery rates compared with surgical methods (Besenfelder 2006).

VetBooks.ir

• **Fig. 44.15** Laparoscopic collection of goat embryos.

Embryo Transfer

In goats and ewes, embryo transfer is performed under general anaesthesia using either a midventral laparotomy or laparoscopy. A short period of general anaesthesia is generally used without the need for endotracheal intubation, and it is important that the animal's rear end is elevated, particularly when using the laparoscopic approach. It seems that laparoscopy is as effective as laparotomy, but it requires considerably more experience to obtain good pregnancy rates.

Embryo Collection and Transfer in Pigs

Embryo Collection

Reviews of the principles for porcine embryo collection and transfer have been published by Polge (1982), and it is a technique that has not changed much over the years. Embryos are collected 3 to 7 days after oestrus under general anaesthesia through midventral laparotomy, and after having gained access to the abdominal cavity, the following procedure is performed bilaterally:

- The ovary, oviduct and uterine horn are exteriorised, and a specially designed curved glass tube or a collection catheter is inserted into the uterine lumen approximately 50 cm from the uterotubal junction.
- The medium, e.g., Dulbecco's PBS supplemented with 1% FCS or a commercial product, is flushed through the oviduct using a blunt needle inserted into the ampullar region.
- The fluid is gently massaged through the uterine horn and then collected into dishes via the glass tube or the collection catheter.
- Identification and isolation are very similar to the procedures described for cattle, but in terms of embryo quality, either good quality embryos or some unfertilised oocytes are found or only unfertilised oocytes.

Because of the higher lipid content in the cytoplasm, porcine embryos are darker than their bovine counterparts; moreover, a greater number of accessory sperm heads are found within the zona pellucida. The recovery rate is generally very high, and 25 to 30 embryos are normally harvested at each collection.

Embryo collection may also be performed using a laparoscopic technique (Besenfelder et al. 1997), essentially for experimental purposes. Transcervical embryo collection (nonsurgical) has also been described (Hazeleger 1999), but it requires prior resection of the major part of the uterus and results in low recovery rates. Therefore the only realistic approach for collection of embryos from donor sows is either by surgery or after slaughter (Martinez et al. 2017).

Embryo Transfer

Embryos are usually transferred surgically using a midventral laparotomy to exteriorise the tip of the uterine horn, into which 20 to 30 embryos are deposited. Because they will subsequently migrate into the contralateral horn, bilateral transfers are not necessary (Dzuik et al. 1964). The pregnancy rate is generally around 70% and embryo survival around 60% to 65%, yielding a litter size of five to seven piglets.

Embryos may also be transferred to the uterine tubes of gilts by means of laparoscopy (Besenfelder et al. 1997). The pregnancy rate after endoscopic transfer can be expected to be from 60% to 80%, with around five to six implantation sites.

A transcervical embryo transfer technique was developed for sows (Hazeleger & Kemp 1999) in which a specially designed embryo transfer catheter is placed deep into the uterine horn. The pregnancy rate depends on the stage of development at which the embryos are transferred, with morulae combined with blastocysts yielding a significantly higher rate (55%) than transfers of morulae (10%). The overall pregnancy rate is about 30%, with a litter size of around six to seven piglets. A further modification of this technique has been used in gilts and sows, in which the catheter can be inserted into the uterine horn in 70% to 80% of gilts or sows, resulting in farrowing rates around 80% and litter sizes around 9.5 after transfer of 25 to 30 fresh morulae and blastocysts (Martinez et al. 2013). The subsequent fertility of these recipients is not affected (Martinez et al. 2017).

Oocyte Collection by Use of Ultrasound

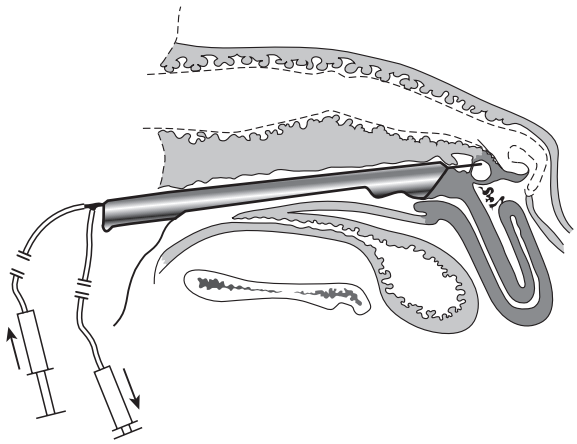
Purpose

If IVF is to be considered as a management tool in commercial livestock breeding programmes or as a routine treatment of sub- and infertility, it requires to be supplemented with a technique that allows repeated recovery of multiple oocytes from selected individuals without jeopardising their health and future fertility.

In the past, oocytes have been recovered from live cows and mares, primarily for basic research, using laparoscopy, laparotomy, colpotomy/ovariectomy, or blind needle penetration via the paralumbar fossa (Hinrichs & Kenney 1987, Lambert et al. 1986, McKinnon et al. 1986, Palmer et al. 1987). Obviously, a surgical approach can only be used on a limited number of occasions in each animal; however, the introduction of real time ultrasonography to the veterinary field in the late 1980s played an important role in enabling oocyte collection repeatedly from the same individual. Initially, transcutaneous ultrasound guidance was used to monitor paralumbar puncture (Callesen et al. 1987), but soon the technique of transvaginal ultrasound-guided follicular aspiration, which was first developed in humans, was modified and successfully applied to aspirate oocytes from cattle and mares (Pieterse et al. 1991, Brück et al. 1992, Cook et al. 1992).

Transvaginal ultrasound-guided oocyte aspiration (TVOR), transvaginal follicular aspiration (TVA), or ovum pick-up (OPU) is a rapid and minimally invasive technique for retrieving oocytes repeatedly from a donor animal. Thus it allows either the collection of oocytes for IVP (cattle) or oocyte transfer (mares) from genetically valuable animals and also if they would normally be considered infertile because of uterine diseases, oviductal occlusions, or a poor superovulatory response. Circumventing heritable infertility must obviously be avoided.

VetBooks.ir



• **Fig. 44.16** Schematic drawing of transvaginal–ultrasound-guided follicular aspiration in the mare.

Technique

OPU is generally performed in cattle under epidural anaesthesia (occasionally combined with sedation) and in mares after sedation and analgesia. Basically, the technique requires a 5 or 7.5 MHz transducer incorporated into a needle guide that can be inserted into the vagina of a cow or mare. Various models of needle guide and aspiration system have been developed, often based upon the different available ultrasound machines. The ovary is grasped transrectally by the hand and gently pulled caudally towards the transducer head (Fig. 44.16). When a suitable follicle is positioned correctly in relation to the monitor's puncture line, an aspiration needle is inserted into the follicular cavity. Its content is aspirated and the follicular cavity is curetted and/or flushed several times with modified PBS to create turbulence (Pieterse et al. 1991, Brück et al. 1992).

Within the follicular cavity, the oocyte is surrounded by many layers of cumulus cells, which together form the so-called cumulus oophorus. Once detached from the follicular wall, the oocyte surrounded by cumulus cells is termed the cumulus oocyte complex (COC). Flushing the follicular cavity requires that the follicle's diameter is at least 5 mm in order to avoid the COCs being flushed backwards and forwards within the dead space of the aspiration needle; this will result in a considerable decrease in the number of cumulus cells surrounding the oocyte (Brück et al. 1997). Alternatively, a double lumen needle may be used (Bracher et al. 1993, Cook et al. 1993, Duchamp et al. 1995). Oocyte recovery rates improve with increasing needle diameter, bevel length, and vacuum pressure, but the latter also increases the proportion of denuded oocytes (Bols et al. 1997, Fry et al. 1997). Because fertilisation rates and subsequent developmental competence of denuded oocytes are reduced (Tanghe et al. 2002), a compromise in the vacuum pressure must be sought.

Recovery rates vary with species, individual animals, follicular maturity, and experience of the person performing the aspiration (Merton et al. 2003). In cattle, twice-weekly follicular aspirations at 3- to 4-day intervals prevent a dominant follicle being selected, and this has proved to be an efficient regimen for repeated follicular aspirations with a yield of two to eight COCs from each aspiration session (Merton et al. 2003, Kruip et al. 1994, Broadbent et al. 1997, Garcia & Salaheddine 1998). In mares, oocyte recovery rates from subordinate follicles are approximately 30% to 50% and 70% to 80% from preovulatory follicles after hCG treatment (reviewed by Hinrichs 2016 and Bøgh 2003).

In the early OPU studies in cattle, no hormonal stimulation was used, but subsequent studies have shown that pretreatment with FSH over 2 to 3 days, followed by follicular aspiration 1.5 to 2 days after the last FSH treatment, the so-called 'coasting', may yield a larger number of oocytes with improved developmental competence (Blondin et al. 2012). Today, in some commercial settings, often depending on practical and economical considerations, hormonal pretreatment is routinely used.

Transvaginal oocyte recovery can be performed also on pregnant cows and mares as long as the ovaries are still accessible by rectal palpation, i.e., during the first trimester, with no effect on the ongoing pregnancy (Meintjes et al. 1995a, Meintjes et al. 1995b, Goudet et al. 1998, Cochran et al. 2000, Chastant-Maillard et al. 2003).

Consequences for the Donor

It has been documented that the procedure of transvaginal follicular aspiration conducted under controlled conditions is well tolerated by the cow and mare (Petyim et al. 2000, Bøgh et al. 2003). Occasionally, follicular evacuation may result in intrafollicular haemorrhages (Brück et al. 1997, Chastant-Maillard et al. 2003, Petyim et al. 2000, Gibbons et al. 1994, Gastal et al. 1997). In addition, prolongation of the luteal phase in both cattle and mares may occasionally occur, as some aspirated follicles luteinise, especially when preovulatory follicles are evacuated (Duchamp et al. 2003, Goudet et al. 1997, Amiridis et al. 2000). Progesterone production will be lower and the life span shorter of these CL-like structures when formed from subordinate rather than from dominant follicles (Petyim et al. 2000, McEvoy et al. 2002, Bøgh et al. 2003), but the animals usually continue to cycle normally and fertility is uncompromised with subsequent normal pregnancy rates obtained (Brück et al. 1997, Pieterse et al. 1991, Kruip et al. 1994, Broadbent et al. 1997, McEvoy et al. 2002, Bøgh et al. 2003, Kanitz et al. 1995). Repeated follicular aspiration can continue over several months, but in most donors a decrease occurs at some point in the number of follicles available and thus in the oocyte yield, both in cows and mares (Duchamp et al. 1995, Merton et al. 2003, Kruip et al. 1994, Boni et al. 1997, Kanitz et al. 2000). Finally, because each aspiration sessions includes one epidural anaesthesia, repeated sessions can result in formation of more connective tissue in the epidural canal (McEvoy et al. 2006). This does not cause lasting problems for the donors, and it can be minimised by use of smaller needles, careful injection technique, and by varying the injection site.

Additional Applications of Transvaginal Follicular Puncture

The development of this rapid and relatively simple technique has also provided opportunities for other procedures, such as oocyte transfer from donor to recipient (Carnevale et al. 2000), evacuation of anovulatory follicles and follicular ablation (Brück et al. 1995), as a research tool to study follicular development and to synchronise follicular growth (Garcia & Salaheddine 1998, Brück & Greve 1996, Bergfelt & Adams 2000, Brück et al. 2000, Shaw & Good 2000, Kim et al. 2001, Bøgh et al. 2002). It has also been used as an experimental tool to inject oocytes into follicles to obtain final maturation and subsequent ovulation, followed by fertilisation after insemination and then embryo collection at Day 7 in the horse (Hinrichs & DiGiorgio 1991, Deleuze et al. 2009) and in cattle (Kassens et al. 2015).

VetBooks.ir

Transvaginal ultrasound-guided follicular ablation can also be used in conjunction with superovulatory regimens. Aspiration of all follicles of more than 5 mm (Bergfelt et al. 1997), or only the dominant follicles (Merton et al. 2003), or a combination of follicular ablation with hormonal treatments with GnRH, E2 and/or progesterone (Bo et al. 2006, Martinez et al. 1999, Amiridis et al. 2006) will lead to the emergence of a new follicular wave approximately 3 days after aspiration; at this stage the superovulatory treatment may be initiated.

In addition, oocyte transfer, also called gamete intrafallopian transfer (GIFT), may be attempted as an alternative to *in vitro* embryo production in the mare. For this purpose, *in vivo* matured oocytes may be recovered 28 to 36 hours after hCG treatment of the donor mare, or immature oocytes may be recovered for *in vitro* maturation from mares after sudden death or euthanasia. The matured oocytes are then transferred surgically via a flank incision into the oviduct of either cyclical, inseminated recipients, whose oestrous cycle has been synchronised with that of the donor and whose preovulatory follicle has been previously aspirated to remove the oocyte so that it is not available for fertilisation. Alternatively, ovariectomised or nonovulating mares, pretreated for 3 days with oestrogen and inseminated, can be used (Hinrichs et al. 2000, Carnevale et al. 2003). Oocyte transfer via catheterisation of the oviduct with transabdominal laparoscopy has been performed successfully (Kollmann et al. 2011) but requires additional equipment and training.

In vitro Embryo Production

General Principles/Purpose

In vitro embryo production is normally designated IVF, even though in domestic animals it consists of three distinct *in vitro* phases: maturation of oocytes (IVM), fertilisation of oocytes with capacitated spermatozoa (IVF), and finally culture of the presumptive zygotes (IVC). Collectively, the whole procedure is designated *in vitro* embryo production (IVP) and results in IVP embryos. Chang (1959) published the first report of the birth of rabbits after IVF, and subsequently, live births after IVF were reported in the hamster and mouse (Iwamatsu & Chang 1969). In the domestic species, Brackett et al. (1982) were the first to report the live birth of a calf after IVF, using *in vivo* matured oocytes aspirated from follicles at laparotomy, with surgical transfer of the presumptive zygotes to the oviduct of synchronised heifers after 24 to 48 hours of *in vitro* culture. The first calves born after IVM and IVF were reported by Hanada et al. (1986), and almost simultaneously Xu et al. (1987) and Lu et al. (1987) reported pregnancies and birth of IVM-IVF calves. However, Xu et al. (1987) cultured the presumptive zygotes in the oviduct of heifers (intermediate recipients), flushed them from the uterus, and then transferred an embryo to the final recipient, yielding a normal calf. Live births were also reported after IVF from other species, including lambs by IVM/IVF (Cheng et al. 1986), piglets by IVF (Cheng et al. 1986), piglets by IVM/IVF (Mattioli et al. 1989), and foals by IVM/IVF (Palmer et al. 1991, Bézard et al. 1992).

Today, IVP is most widely used in cattle, but even after 30 years of research IVP-embryos are more 'fragile' than those which are *in vivo* derived. For a review and greater details on the development of bovine IVP, culture conditions, and other aspects, see Gordon (1994) and Avery (2006). Details of the merits of *in vivo*-derived versus *in vitro*-produced embryos are described later in this chapter.

Cumulus oocyte complexes (COC) from slaughterhouse-derived ovaries are generally aspirated from follicles more than 2 mm in diameter, as they have proved to contain developmentally competent oocytes (Fair et al. 1995). Other techniques, such as dissecting individual follicles or slicing the surface of the ovaries, have also been used, but for all practical purposes the aspiration technique is preferred for almost all species. After aspiration, the COCs are classified according to the number of layers of cumulus cells and the appearance of the ooplasm, although the latter may be difficult if the oocyte is surrounded by a tight layer of cumulus cells. Because the COCs originate from follicles at various sizes and developmental stages (nonatretic and atretic), their quality will vary. Irrespective of species, oocytes without a cumulus investment (denuded oocytes) and oocytes with signs of degeneration are normally discarded before IVM. The presence of at least two layers of cumulus cells is indispensable in order to allow the bidirectional communication required for adequate maturation and subsequent fertilisation and development (Gilrichst et al. 2004).

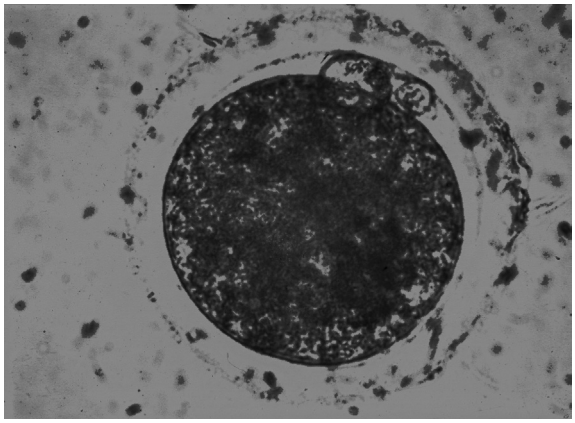
During IVM of the COCs, most oocytes resume meiosis and reach the metaphase II stage by end of the culture period. The cumulus investment surrounding the oocyte expands, and about 80% to 90% of the oocytes will extrude the first polar body, which is round and considerably smaller than the second polar body; the latter is extruded into the perivitelline space after fertilisation. The cytoplasmic and the nuclear maturations occur simultaneously. It is the intention to mimic *in vivo* maturation as close as possible, but it is clear that, although the nuclear kinetics of the *in vivo*- and *in vitro*-matured oocytes morphologically appears to be similar, the *in vivo*-matured COC is much 'stickier' than its *in vitro* counterpart. Hyttel et al. (1997) have described the details of the oocyte maturation process. When the oocyte reaches the MII stage, IVF is initiated. Therefore the duration of the IVM phase should be adjusted according to follicular maturity to the *in vivo*-maturation period for that particular species and to culture conditions.

The spermatozoa used for fertilisation must be capacitated *in vitro*, and various media and procedures have been used for this purpose. High ionic-strength medium was initially used by Brackett et al. (1982), but a major breakthrough for cattle IVF was achieved when Parrish et al. (1989) added heparin to the media and achieved *in vitro* capacitation. A motile fraction of spermatozoa may be obtained using a variety of different methods, such as simple washing and centrifugation, swim-up techniques, density gradient centrifugation, or filtration through glass wool; laboratories vary in their preferred choice (Avery 2006, Parrish & Foote 1987).

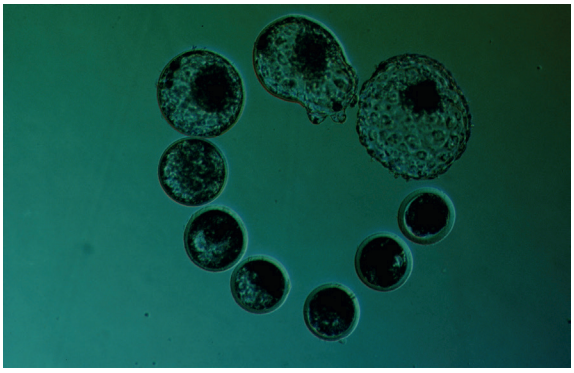
The COCs and spermatozoa are cocultured for 6 to 24 hours, and during the very early period most cumulus cells are shed. Upon contact between spermatozoa and zona pellucida, the acrosome reaction is initiated. Then the spermatozoa penetrate the zona pellucida and usually only one spermatozoon gains access to the perivitelline space, where it may move around before fusion with the oolemma. The most efficient ratio of spermatozoa to oocytes may vary from species to species but is generally much higher than during *in vivo* fertilisation. The cortical granule reaction is somewhat different for *in vitro* versus *in vivo* fertilisation (Hyttel et al. 1987), and for certain species, such as the pig, polyspermia is a serious obstacle to success.

The *in vitro* culture period will inevitably vary with species and the purpose of IVP, and within the first 24 hours the second polar body will be extruded (Fig. 44.17). In cattle, for example, the presumptive zygotes are normally cultured for 6 to 7 days before transfer, but in experimental studies, shorter and even longer *in vitro* periods have been used.

VetBooks.ir



• **Fig. 44.17** *In vitro*-fertilised cattle zygote showing both first and second polar body. Note the difference in size between the two.



• **Fig. 44.18** *In vitro*-produced cattle embryos on day 7 to 8 after fertilisation.

A fundamental element in the *in vitro* procedures is the media used. The first were based on different standard cell culture media with certain modifications believed to be suitable for the various steps of the development. Because it has been and still is a major area of research to optimise and improve them, a number of different media have been and still are used for the various species, e.g., Hams F-10, TALP, CR1, Menezo B2 and NCSU, M199/Hanks; in addition, a number of commercially produced media are also available today. The medium of choice varies from species to species, and in some coculture with cells is also used. Metabolic studies of oocytes and embryos have been useful, first of all to better understand their basic nutrient requirements at different developmental stages and thus to design more physiologically acceptable media for *in vitro* culture. In the early embryo, cell division is an exponential process that each time requires the duplication of the essential cell components. Thus an efficient and adequate supply of energy substrates, precursors is required for the DNA and RNA synthesis of DNA and electron carriers. The most important energy sources for early embryos of several mammalian species are carbohydrates (Rieger et al. 1989, Brück & Hyland 1991, Brück et al. 1997).

In vitro Embryo Production in Cattle

Over the last two decades, commercial *in vitro* production of cattle embryos has increased dramatically, with more than 400,000 embryos transferred worldwide in 2015 (Perry 2016). In addition, numerous IVP embryos have been produced for research purposes. Oocytes are obtained either from slaughterhouse-derived ovaries or after OPU. Using the first source, Lu and Polge (1992) created a bank of cheap embryos from animals of average genetic merit, and this approach is still used, for example, to export embryos to countries which need a rapid increase in a higher genetic-valued cattle population. Commercially, OPU is used to obtain oocytes from elite donor heifers or cows that are inseminated with semen from elite bulls. Over the last years, this breeding system has been further accelerated by use of genomic profiling of the IVP embryos based on a biopsy from the preimplantation embryos (Ponsart et al. 2014).

From slaughterhouse-derived ovaries, an average of eight to nine oocytes per ovary can be expected, and after OPU around 15 per animal. For example, the number is dependent on the breed as several beef cattle breeds may give much higher numbers. The selected COCs are placed in groups in culture medium, and one might expect that 80% of the oocytes reach the MII stage, 80% cleave, and after IVC, 40% reach the blastocyst stage. The speed of development is different among the zygotes, which explains why different developmental stages are seen on Day 7 (Fig. 44.18). It should be emphasised that there is a very great animal-to-animal variation, not only in the number but also in the quality of the aspirated oocytes (Tamassia et al. 2003).

Sex-sorted spermatozoa have been used to produce IVP embryos and calves since the 1990s (Cran et al. 1993, Lu et al. 1999), and today it is used routinely in several commercial operations. In general, cleavage and blastocyst rates are lower than after the use of unsorted spermatozoa (Hayakawa 2012) with a considerable variation between bulls (Blondin et al. 2009).

Pregnancy rates after transfer of IVP embryos are generally 10% to 20% lower than their *in vivo* counterparts (Hasler 1998, Hasler 2006, Pontes et al. 2009). As mentioned previously for *in vivo* transfer, factors such as embryo quality and recipient management influence these rates.

ICSI has not been widely used in cattle, but embryo development (Zhang et al. 2003) and birth of live offspring has been reported (Horiuchi et al. 2002). Freezing of blastocysts after ICSI is also possible (Keskintepe & Brackett 2000).

In vitro Embryo Production in Horses

In vitro production of equine embryos was initially considered to be a promising alternative to superovulation and embryo transfer, and in 1990 two foals conceived after IVF of *in vivo*-matured oocytes were born (Palmer et al. 1991, Bézard et al. 1992). In spite of worldwide attempts, this has never been repeated, and no live foals have been produced by IVF since. Refinement of the IVF technique for the horse has progressed only slowly, which appears to be related to the inability of the sperm to penetrate the zona *in vitro*. Attempts have been made to solve this challenge, and acceptable *in vitro* fertilisation rates have been obtained by breaching the zona pellucida through partial dissection or dissolution (Choi et al. 1994, Li et al. 1995) or by pretreatment of sperm with calcium ionophore (Zhang et al. 1990, Dell'Aquilla et al. 1996, Alm et al. 2001, Hinrichs et al. 2002). The low IVF rates can be circumvented by ICSI, allowing the establishment of pregnancies and birth of live foals after transfer of early stage embryos into the oviduct of recipients (Cochran et al. 1998, Meintjes et al. 1996, Squires et al. 1996, McKinnon et al. 2000, Hinrichs et al. 2007). Extension of the postfertilisation culture period has provided the possibility of nonsurgical intrauterine transfer of blastocysts produced from

VetBooks.ir

in vitro-matured oocytes fertilised by ICSI (Li et al. 2001, Galli et al. 2002, Choi et al. 2003).

The first prerequisite for successful IVP is access to meiotically competent oocytes, optimisation of oocyte retrieval, and adjustment of IVM conditions to the different maturity stages of recovered COCs. *In vivo*-matured oocytes can only be recovered from preovulatory follicles by OPU, and because of the lack of an efficient superovulation treatment for mares, the availability of these oocytes is limited to one or two per oestrous cycle. Oocytes recovered from subordinate follicles are generally immature and have to be matured *in vitro*. Thus in an equine IVP programme, oocytes recovered *in vivo* 24 to 36 hours after hCG treatment will still have to undergo partial IVM to metaphase II, whereas immature oocytes recovered from subordinate follicles (e.g., from the ovaries of a mare after sudden death) are generally immature and will have to be matured *in vitro* for 24 to 36 hours.

Many investigations have been undertaken to improve IVM conditions, and IVM success evaluated as nuclear maturation rates varies considerably among laboratories. There is ample evidence that these variations are due to biological and methodological factors such as age of mare, follicular size and atresia, time of ovary transport, method of oocyte recovery, culture media, and culture time; generally, a 50% to 80% MII rate may be expected (reviewed by Hinrichs (2016) and Bøgh (2003)).

Because IVF as practised in cattle is not a feasible method, ICSI is currently the method of choice. Choi, Hinrichs, and their colleagues have contributed significantly to the development of ICSI in the horse. Approximately 20% to 35% of the injected oocytes develop into blastocysts, both after *in vitro* embryo culture and *in vivo* after transfer into the oviduct of a recipient mare (Choi et al. 2004, Choi et al. 2003, Hinrichs et al. 2005, Hinrichs 2016). Importantly, these rather high developmental rates were achieved with immature oocytes. ICSI with frozen–thawed sperm has been performed without jeopardising the developmental rate (Choi et al. 2006), so ICSI is a potential method for foal production from stallions with acquired subfertility or with limited reserves of frozen semen.

IVP requires optimisation of each of the individual technical steps: retrieval of oocytes and sperm, oocyte maturation, sperm capacitation, fertilisation, embryo culture, and embryo transfer. In horses the actual IVP is generally the prerogative of an experienced research team and a well-equipped research laboratory, although the veterinary practitioner participates with donor and recipient management, supply of high quality semen, and the actual embryo transfer. The clinical use of ICSI using oocytes recovered postmortem from mares of high economical value has become a speciality in which the veterinary practitioner may provide a service to the horse owner with relatively limited means. Ovaries should be excised from the mare as soon as possible after death, preferably before euthanasia but under general anaesthesia. If transport time to the laboratory performing ICSI is less than 2 hours, ovaries can be transported at body temperature (37°C); otherwise, they should be cooled down to 15° to 20°C during the transport. Oocytes derived from ovaries recovered from mares immediately before euthanasia as well as up to 5 hours postmortem have been associated with production of foals (Carnevale et al. 2003, Ribeiro et al. 2008, Hinrichs 2016).

In vitro Embryo Production in Sheep and Goats

IVP of sheep and goat embryos follows the basic principles mentioned for cattle and has been reviewed in detail by Cognié et al. (2003); minor differences are related to the method of oocyte retrieval and the IVM procedure. Obviously, conventional cattle OPU cannot be performed in small ruminants, but COCs can be obtained by laparotomy or laparoscopy-guided ovum pick-up, yielding about six COCs and one to two blastocysts per session (Tervit 1996, Kühholzer et al. 1997). Regarding IVM, addition of cysteamine to the IVM medium will increase the blastocyst yield in goats (10% vs 50%). After surgical transfer of two IVP embryos per recipient, kidding percentage and percentage of kids born per transferred embryo of approximately 60% and 50%, respectively, may be expected. ICSI has also been successfully accomplished in sheep, with birth of a male lamb (Catt et al. 1996, Gomez et al. 1998), but, as in cattle, this method has not gained widespread use.

In vitro Embryo Production in Pigs

IVP of porcine embryos has not gained widespread commercial use, and it is still primarily used for experimental purposes. After IVM, IVF, and IVC, several authors have reported birth of piglets; for review on IVP of porcine embryos, see Grupen (2014).

In comparison to IVP methods in cattle and horses, the IVM period for pigs is 40 to 45 hours. In addition, in the start of the 2000s the use of North Carolina State University (NCSU) medium supplemented with porcine follicular fluid or bovine fetal calf serum resulted in considerable higher blastocyst recovery rates than was seen with other media (Peters et al. 2001). Today, other media, such as PZM-3 (Yoshioka et al. 2002) and commercially available media, are routinely used for porcine IVP.

The selected COCs are placed in groups in culture medium, and the nuclear maturation rate reaches the same level as in cattle (80%–90%), whereas the cleavage rate approaches 40% to 50%, and approximately 20% of the fertilised oocytes can reach the blastocyst stage. These figures illustrate that one major problem is still encountered in porcine IVP, namely a high incidence of polyspermic fertilisation, which is at least 30% (Nagai et al. 2006); in addition, several chromosomal abnormalities have been documented (McCauly et al. 2003). The fertilisation process is the principal cause that is illustrated by the quite successful use of the IVM and IVC procedures, as key parts of somatic cell nuclear transfer (SCNT).

Reports on ICSI in pigs are scarce, although this technique has the advantage of avoiding the problem with polyspermia. Kolbe and Holtz (2000) achieved a cleavage rate around 25% and obtained one pregnancy after surgical transfer of two- to four-cell stage embryos, and even sex-sorted sperm may be used for this purpose (Probst & Rath 2003).

In vivo-derived versus *In vitro*-produced Embryos and Advanced Quality Measurements

General Comments

It has become increasingly clear that *in vivo*-derived and *in vitro*-produced embryos are substantially different both morphologically and functionally.

Morphologically, Avery and Greve (1995) and Van Soom (1996) have described some of the features and differences between *in vivo* and *in vitro* embryos. Compared with their *in vivo* counterparts, IVP embryos: are darker, probably because of their higher lipid content; are less compacted; the total cell number is lower; the

VetBooks.ir

zona pellucida is more fragile; the ratio between inner cell mass and trophectoderm (ICM:TE ratio) is lower; and the density is lower due to the higher lipid content. At the ultrastructural level, several differences are obvious regarding organelle distribution of for example mitochondria and cortical granules (Maddox-Hyttel et al. 2003) and certain biochemical features such as fat content and protein composition (Farin et al. 2001).

Functionally, *in vivo*-derived embryos are quite robust in response to different environmental conditions, such as temperature and light, whereas IVP embryos are more fragile and less tolerant. One very important feature is their increased sensitivity to chilling and to cryopreservation (Greve et al. 1992, Leibo & Loskutoff 1993). In contrast to *in vivo*-produced embryos, male IVP embryos develop faster than female embryos (Avery et al. 1992, Peippo et al. 2001) in some IVP systems but not in others (Holm et al. 1998, Pontes et al. 2011); therefore this characteristic cannot be used to guarantee that embryos selected at a later stage (Day 7) for transfer will result in a higher proportion of a specific sex.

All of these features are clearly a consequence of the artificial conditions under which the process is performed; thus improvement of the culture conditions (temperature, atmosphere, media) may reduce these differences. It has been unclear which one of the three steps in the *in vitro* production system may have the most significant effect on embryo quality, but IVC appeared to be the most sensitive part (Lonergan et al. 2003). Currently, the focus is mainly on the competence of the immature oocytes used at the very start of the *in vitro* process (Blondin 2017).

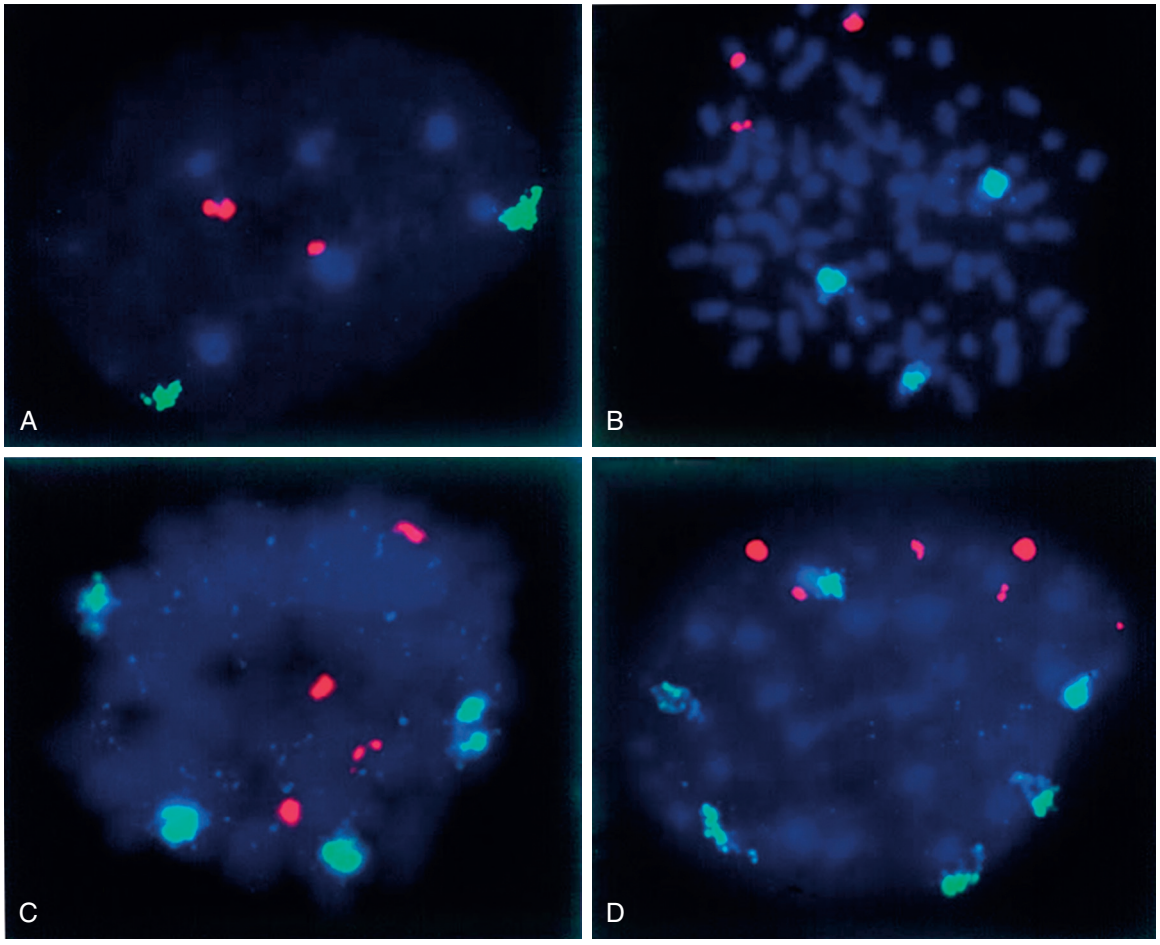
Different Measures of Embryo Quality

As a measure of embryo quality, the classical morphological method described earlier has been used because it is simple to perform and thus useful under practical conditions. However, with the differences experienced between *in vivo* and *in vitro* embryos, it has become even more important to find other and additional quality measures, as the use of morphology has proved to be of limited value in explaining and understanding how to evaluate *in vitro* embryos. Together with rapid appearance of various new technical possibilities, a range of more or less sophisticated methods for evaluating embryo quality have been tested and will be described.

When considering the methods of evaluation, it is important that the method used does not itself adversely affect embryo quality. Thus there are clear limitations on the thoroughness of the evaluation method, and hence the only realistic method for embryo evaluation in veterinary practice is by means of light stereomicroscopy.

Fluorescence In situ *Hybridisation*

Fluorescence *in situ* hybridisation studies (FISH) allow localisation of specific DNA and RNA sequences and are suitable for chromosome analysis in cells from embryos. Viuff et al. (1999) demonstrated that around 75% of Day 7 to 8 IVP bovine embryos were mixoploid, compared with only 25% of their *in vivo* counterparts (Fig. 44.19). Chromosomal anomalies may reduce the viability of IVP embryos, and chromosome analysis of a biopsy from an embryo may thus be used to assess viability. Another important difference between



• **Fig. 44.19** Fluorescence in situ hybridisation of cattle embryos indicating normal diploidy (A), triploidy (B), and other types of polyploidy (C, D). (Courtesy Dorthe Viuff, Denmark.)

VetBooks.ir

in vivo and IVP embryos is the incidence of apoptosis measured by TUNEL, in which IVP embryos have a higher apoptosis index than in vivo-derived embryos (Maddox-Hyttel et al. 2003, Gjørret et al. 2003), and it is anticipated that a higher index is inversely related to viability. The culture medium, duration of culture, and oxygen tension seems to influence the degree of apoptosis.

Frequent Microscopical Observations

Frequent stereo- and light-microscopical observations (time lapse) of oocytes and embryos can be used to assess the developmental pattern of oocytes and embryos without interfering with their normal development, and the time intervals to first and subsequent cleavages seem particularly important (Van Soom et al. 1997, Holm et al. 2002, Lonergan et al. 1999). Studies of this type are obviously tedious and time consuming, but semiautomatic time-lapse recording systems are easier to use and may be used to estimate embryonic developmental kinetics (Peippo et al. 2001, Holm et al. 2002). In the latter study, clear kinetic differences were observed between *in vivo*-derived and *in vitro*-produced embryos cultured *in vitro*, as the second, third, and fourth postfertilisation cell cycles were shorter for *in vivo*-derived embryos. The initial cleavage time is known to be correlated with embryo quality, as measured by pregnancy rate and cryotolerance of IVP embryos (Lonergan et al. 2003), and therefore kinetic studies may be useful to predict embryo viability. This knowledge is utilised in several commercial products, in which semiautomatic time-lapse recordings are an integrated part of the embryo culture system used for the selection process of the most viable embryos for subsequent transfer. Such equipment is mostly used for experimental purposes in farm animals, whereas it is more or less routine in human fertility clinics.

The development of multiphoton laser scanning microscopy, combined with specific intravital fluorophores, has been used to visualise particular structural or molecular features during *in vitro* development of mammalian oocytes and embryos (Squirrel et al. 1999, Petersen et al. 2008). It appears that these techniques may be optimised to such an extent that subsequent developmental competence may be predicted, for example, as part of the time-lapse systems.

PCR Techniques

The rapid advances in polymer chain reaction (PCR) techniques (e.g., RT-PCR and DD-RT-PCR) have had a major influence on understanding normal embryo development, e.g., activation of the embryonic genome (Viuff et al. 1998, Watson et al. 1999). Many studies have clearly shown that genes of developmental importance are expressed differently when embryos are produced *in vitro* and that these deviations may be used to evaluate the quality of a given culture system (Bertolini et al. 2002, Niemann et al. 2002, Rizos et al. 2002). It has also been documented that embryos with deviant gene expression patterns have increased sensitivity to cryopreservation as an indication of poorer quality (Lonergan et al. 2003). Chromosomal anomalies are also more pronounced in *in vitro*- than *in vivo*-developed embryos (Viuff et al. 2002).

Metabolic Studies

Metabolic studies of oocytes and embryos were developed in an attempt to evaluate embryo quality and viability (see review by Donnay (2002)), but it is also very useful as a way to monitor the development and thus can be used as an additional quality measurement (Rødgaard et al. 2015). Practically, this can be performed by sampling the culture media after their use ('spent culture medium') in order to analyse for various substances that may reflect the normality of the individual embryo's development. In some semiautomated culture systems, its use is becoming a realistic possibility, together with the use of time-lapse observations.

In 1996, Thompson et al. (1996) developed a noninvasive microfluorescent technique to measure the rate of oxygen uptake, and Overström (1996) reviewed work on studies using specific gas-sensing microoxygen electrodes for evaluating the quality of *in vivo* cattle embryos subsequently measured by pregnancy rates. Using a similar approach on single bovine embryos, Shiku et al. (2001) found a strong correlation between the embryo's quality and oxygen consumption. In the same period a microsensor technique was developed to measure partial oxygen pressure in the surrounding culture medium of individual IVP bovine embryo (Lopes et al. 2007a). Oxygen tension varied considerably among and between *in vivo*-derived and *in vitro*-produced embryos (Lopes et al. 2007b), and there was a significant correlation between oxygen tension and expression of certain developmentally important genes (Lopes et al. 2007c). There was no effect of the measurements per se on the survival rate of *in vivo*-derived embryos after nonsurgical transfer (Lopes et al. 2007b), which may render this technique a useful noninvasive tool for quality assessment.

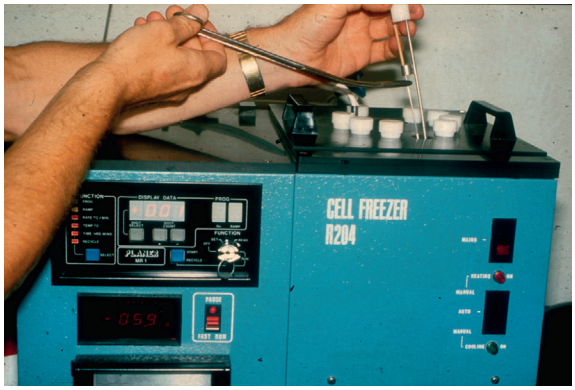
The culture systems are extremely important for the development of IVP embryos, and domestic animal embryos seem to reach a higher developmental rate when given the possibility to grow in groups of approximately 10 to 20 (Gil et al. 2003). According to some views, it is a more natural situation to culture embryos individually compared with group cultures, and in certain cases it is necessary to culture the embryos individually in special microenvironments. This is already a routine in human IVF, and with the use of embryo biopsy for use in genomic selection, it is also needed in cattle to keep the embryos individually. For this purpose, several systems have been developed that allow for paracrine interactions between the individual embryos, such as small dents made in a four-well dish, the so-called well-of-the-well system (WOW; Vajta et al. 2000), the glass–oviduct system (GO; Thouas et al. 2003), agar compartments (Peura 2003), or a polyester mesh system (Matoba et al. 2010). The WOW system results in a consistent and high level of development into blastocysts of bovine IVP embryos (Vajta et al. 2000) and has also been successfully applied to produce cloned, zona-free embryos (Booth et al. 2001, Vajta et al. 2003). Another approach to this small-size culture system is based on microfluid technology. Beebe et al. (2002) obtained higher blastocyst development rates of murine embryos with such equipment, and the technique has also proved to be effective for porcine embryos (Clark et al. 2003, Walters et al. 2003). It may ultimately not only lead to an easier IVP method but also facilitate studies on, for instance, substrate requirements. In addition, this approach could become the basis for a more or less automated system for future *in vitro* embryo production (Le Gac & Nordhoff 2017).

Cryopreservation of Oocytes and Embryos

Purpose/General Principles

The overall purpose of cryopreservation is to ascertain that the cells can be stored for an unlimited time, at least in theory, and only if the storage temperature is sufficiently low, e.g., by using liquid nitrogen. Having accomplished this, the cryopreserved oocytes or embryos can be stored for many different purposes, e.g., embryo banking and transportation. The general cryopreservation principles are similar for all mammalian cells. Nevertheless, as embryos contain

VetBooks.ir



• **Fig. 44.20** Freezing of cattle embryos in an automatic cell freezer; induction of crystallisation (seeding).

a fluid blastocoele and as both oocytes and embryos are surrounded by a zona pellucida and contain considerably more cytoplasm than spermatozoa, the loading of cryoprotectants and the intracellular dehydration and rehydration processes are different compared with other cell types (Leibo 1977, Lehn-Jensen & Rall 1983).

The first successful freezing of cattle embryos was reported by Wilmut and Rowson (1973), applying the principles developed in mice by Whittingham et al. (1972). It led to the birth of the calf 'Frosty 2', but the overall success rate of the technique was low. Subsequently, the technique was refined for sheep and cattle (Willadsen 1977, Willadsen et al. 1978), and this procedure has now been applied to most other domestic species. The studies have shown that Day 6 to 7 sheep and cattle embryos at the morula, early blastocyst, or blastocyst stage are more tolerant to low temperature preservation than earlier and later developmental stages.

The main principle in this 'slow rate freezing–thawing procedure' is to use low concentrations of the intracellular cryoprotective agent, normally 1.5 mol/L glycerol or 1.5 mol/L ethylene glycol in Dulbecco's PBS supplemented with 20% FCS, or using a commercially available medium. The embryos are equilibrated for 10 to 15 minutes, then loaded into a straw and placed in the chamber of a manual or automatic freezer at −6°C. After approximately 5 minutes, ice crystal formation ('seeding') is induced with supercooled forceps (Fig. 44.20), and a slow freezing rate is used until −35°C, at which stage the embryos are plunged directly into liquid nitrogen at −196°C.

A good selection of simple freezing equipment is now available at relatively low cost and this, together with the high survival rate at least of ruminant embryos after freezing and thawing, has resulted in cryopreservation becoming a routine procedure in practice.

Exposing the straw for a short period of time to air and then submerging it in a water bath at 25° to 30°C for a few minutes is the best method of thawing, irrespective of species. When embryos are frozen/thawed in ethylene glycol, they can be transferred directly (Voekel & Hu 1992), whereas embryos frozen/thawed in glycerol must be submitted to a procedure in which the cryoprotectant is removed stepwise before transfer. Sucrose, a nonpermeating cryoprotectant, may be used to dilute the glycerol, and this seems to improve the embryo survival rates.

Obviously, injuries may occur during freezing and thawing, and these include osmotic shock, intracellular ice crystal formation, fracture damage, and chilling injuries; detailed descriptions of these have been presented by Leibo (1977) and Lehn-Jensen and Rall (1983).

An alternative to slow freezing is an 'ultrarapid freezing and warming procedure', the vitrification method that is defined as a glass-like solidification of solutions at low temperature without ice formation (Vajta et al. 1997a). Rall and Fahy (1985) and Massip et al. (1986) were the first to use this method successfully in mice and cattle embryos, respectively. It has subsequently been used to cryopreserve oocytes and embryos of most other domestic animal species, in particular porcine embryos, as well as IVP and cloned embryos, which are more sensitive to freezing than their *in vivo* counterparts (Du et al. 2007, Van Wagtendonk-de Leeuw et al. 1997).

Vitrification requires addition of high concentrations of the cryoprotectant followed by ultrarapid freezing and warming, with an inherent risk of osmotic and toxic injuries. In contrast to the slow rate of freezing/thawing, injuries by ice crystal formation and chilling are virtually nonexistent (Vajta et al. 1997a, Vajta et al. 1997b). In an improved modification of the vitrification method, Vajta et al. developed the so-called open pulled straw (OPS) vitrification method, which basically reduces the fluid volume surrounding the embryo during vitrification to a minimum (Vajta et al. 1997a).

The vitrification procedure may vary from laboratory to laboratory and from species to species, but common to all is that the vitrification protocol, in particular the equilibration time, must be followed very carefully in order to obtain satisfactory survival rates. High concentrations of cryoprotectant, as with vitrification, may result in irreversible depolymerisation of the microfilaments and microtubules (Overström et al. 1993). To use the method commercially, each embryo must be handled and the straws marked individually, so the time required for vitrification is likely to be at least as long as when using slow rate freezing. The previously mentioned vitrification methods may also pose certain biosecurity challenges as the straws are unsealed, and for most practical purposes, slow freezing is still the preferred method for preserving embryos under practical conditions. However, several methods other than the OPS are available – for example. the microdroplet (Yang & Leibo 1999), the cryoloop (Lane et al. 1999), the Cryotop method (Kuwayama 2007), or various modifications of these, whereby disease transmission in the liquid nitrogen may be prevented.

Efforts have also been directed towards oocyte cryopreservation, and it has been shown that both immature and mature equine and bovine oocytes can be vitrified in an OPS system without affecting their competence to reach metaphase II (Hurtt et al. 2000), and bovine oocytes can even tolerate a second vitrification after IVF and IVC, resulting in birth of calves (Vajta et al. 1998). Although cryopreserved and thawed *in vivo*-matured oocytes, after transfer to an inseminated recipient, can lead to the establishment of a normal pregnancy and birth of healthy offspring (Maclellan et al. 2002, Squires et al. 2003), cryopreservation of immature oocytes is less successful. Transmission electron microscopy and confocal laser scanning microscopy show that cryopreservation of immature oocytes results in cellular injury near the sites of the gap junctions between cumulus cells and the oocyte (Hochi 2003) and reduced meiotic spindle quality (Tharasanit et al. 2006). Different aspects of oocyte cryostorage have been reviewed (Ledda et al. 2007).

Cryopreservation of Cattle Embryos

Approximately 60% of all transferred *in vivo*-derived cattle embryos have been frozen (Perry 2016), mostly using the slow rate freezing method, although vitrification is also used. Extensive data are available on pregnancy rates after transfer of frozen–thawed embryos; for example, Hasler et al. (1995) showed that it is possible

VetBooks.ir

to obtain a pregnancy rate of 64% with grade 1, Day 7 embryos. Embryonic loss after transfer of frozen–thawed embryos is slightly higher than that reported for fresh embryos, and poor quality frozen–thawed embryos will even experience a slightly increased gestation length (Callesen et al. 1996).

IVP cattle embryos are, as mentioned earlier, less tolerant of chilling and cryopreservation than their *in vivo* counterparts (Greve et al. 1992, Leibo & Loskutoff 1993), and several studies have clearly shown that the pregnancy rate after transfer of IVP embryos is lower than that after the transfer of *in vivo*-derived embryos (Hasler et al. 1995). Possibly, a more fragile cytoskeleton and/or the higher lipid concentration in IVP embryos contribute to the reduced survival.

Vitrification seems to be a promising alternative to preserve IVP embryos (Donnay et al. 1998). The method was successfully applied to cattle embryos already in 1986 (Massip et al. 1986), and in a comparative study, it was found that conventional slow freezing and vitrification of *in vivo*-derived embryos yielded similar pregnancy rates (Van Wagtendonk-de Leeuw et al. 1997). For IVP embryos, Vajta et al. (1998) achieved high hatching rates when culturing 6- to 7-day-old blastocyst *in vitro*, and nonsurgical transfer of warmed OPS vitrified embryos has given pregnancy rates of about 50% to 60% (Jacobsen et al. 2003).

Cryopreservation of Horse Embryos

The first birth of a foal from a frozen embryo was reported by Yamamoto et al. (1982), followed by several others (Slade et al. 1985, Czlonkowska et al. 1985). In principle, it is possible to combine the different ARTs with cryopreservation of embryos. Pregnancies can be obtained from *in vivo*-collected, *in vitro*-matured oocytes after ICSI with frozen–thawed semen, and subsequent IVC to the blastocyst stage, which are then conventionally frozen and transferred after thawing (Hinrichs 2016). Nevertheless, developmental competence is often reduced with increasing amount of *in vitro* interference, and cryopreservation may contribute to this after exposure to cryoprotectants that alter the embryonic metabolism (Rieger et al. 1991).

Although freezing of bovine embryos has found routine application in commercial embryo transfer programmes, the cryopreservation of equine embryos has been more complex and less successful. The survival of equine blastocysts after cryopreservation is complicated by the development of the capsule, which apparently hinders the permeability and equilibration of cryoprotectants (Legrand et al. 2000). There is a clear correlation of embryonic size and survival after cryopreservation, with more than 300 µm having higher survival rates (Squires et al. 1989, Boyle et al. 1985, Hochi et al. 1995, Caracciolo di Brienza et al. 2004). Partial removal of the capsule with trypsin treatment has led to a decreased percentage of necrotic cells after cryopreservation, although there was no clear advantage in the term of pregnancy rates (Legrand et al. 2000, Legrand et al. 2002, Maclellan et al. 2002). Puncturing, followed by partial removal of the blastocoele before vitrification using micromanipulation equipment or manually with a 25-gauge needle, has been used with good results in embryos larger than 300 and up to 650 µm in diameter, even though pregnancy and foaling rates are still lower than for embryos smaller than 300 µm (Ferris et al. 2016, Choi & Hinrichs 2017).

Several cryoprotectants, including glycerol, ethylene glycol, DMSO, methanol, and 1,2-propanediol, have been tested on equine embryos (Landim-Alvarenga et al. 1993, Bruyas et al. 1997, Young et al. 1997, Bass et al. 2004), and glycerol and ethylene glycol are generally used, having resulted in birth of live foals when the conventional slow freezing procedure has been employed (Slade et al. 1985, Seidel et al. 1989, Hochi et al. 1996). Equine blastocysts exhibit a higher permeability to ethylene glycol than to glycerol (Pfaff et al. 1993), and ethylene glycol or a combination of glycerol and increasing concentrations of ethylene glycol combined with vitrification resulted in acceptable pregnancy rates (Hochi et al. 1995, Caracciolo di Brienza et al. 2004, Hochi et al. 1994, Eldridge-Panuska et al. 2005).

Thus currently, the most practical commercial approach in veterinary practice without the availability of micromanipulation equipment is to collect embryos for cryopreservation just when they enter the uterus 5.5 to 6 days after ovulation. This is before capsule development and with a maximum diameter of less than 300 µm, even though the embryo recovery rate for Day 6 embryos is significantly lower than for later stages (Squires 2016). For the slow freezing approach, the embryos are exposed at room temperature to increasing concentrations of cryoprotectant in two steps (5% v:v glycerol in DPBS for 10 minutes, 10% for 20 minutes), then loaded into 0.25 mL straws, sealed, cooled from room temperature to −6°C at 1°C/min and held at −6°C for 5 more minutes. The straws are seeded, held at −6°C for another 5 minutes, and subsequently cooled to −32°C at 0.3°C/min, then to −35°C at 0.1°C/min before being plunged into liquid nitrogen (Lascombes & Pashen 2000). This is a time consuming procedure and requires a programmable freezer. Alternatively, the embryos may be vitrified, which involves stepwise equilibration in a medium containing increasing concentrations of ethylene glycol of up to 40%, or glycerol plus ethylene glycol, loaded into 0.25 mL straws or low volume micropipette tips that allow for vitrification by direct plunging into liquid nitrogen. Pregnancy rates of up to 45% to 67% can be achieved this way (Hochi et al. 1995, Eldridge-Panuska et al. 2005, Hinrichs & Choi 2016).

The thawing procedure for equine embryos follows closely the general principles of thawing embryos described previously (Squires et al. 1989, Seidel 1996). With the previously described methods, embryos smaller than 300 µm in diameter can be frozen with reasonable success leading to pregnancy rates of 50% to 75% (Squires et al. 1989, Jacob et al. 2012, Slade et al. 1985, Choi & Hinrichs 2017, Lascombes & Pashen 2000).

Cryopreservation of Sheep and Goat Embryos

Slow rate freezing of small ruminant embryos follows the principles outlined for cattle and has been used extensively (Tervit et al. 1986). Several vitrification studies have shown that it is possible to achieve pregnancy rates of 50% to 60% after direct transfer (Baril et al. 2001, Hong et al. 2007), whereas direct laparoscopic transfer of vitrified sheep embryos (Okado et al. 2002, Isachenko et al. 2003) yields lower rates (20%).

Cryopreservation of Pig Embryos

Pig embryos at most stages of development are sensitive to cooling and freezing (Polge 1977), probably because of their high lipid content. Nevertheless, it was possible to produce offspring from slow freezing of expanded blastocysts (Hayashi et al. 1989). It seems advantageous to use perihatching stages (Kuwayama et al. 1997), and removal of the lipid droplets seems to improve the survival rates considerably (Nagashima et al. 1995, Dobrinsky et al. 1998).

However, vitrification has resulted in high *in vitro* survival rates (Kobayashi et al. 1998, Holm et al. 1999, Berthelot et al. 2000),

VetBooks.ir

and many studies have subsequently shown that vitrification is the preferred method for both *in vivo*-derived (Cameron et al. 2004, Ushijima et al. 2004), *in vitro*-produced embryos (Hiruma et al. 2006), and even cloned porcine embryos (Li et al. 2006).

Additional Embryo Manipulations

ARTs include many, often unphysiological, manipulations of the gametes, e.g., moving them from one dish or tube to another as well as placing them under quite different conditions (temperature, light, media, atmosphere). Furthermore, some procedures are considered to be a routine part of today's set of ART, such as cryopreservation. Several other manipulations are also available, but they are far more sophisticated and are primarily for experimental purposes. These manipulations are of a physical, chemical, or biological nature and will be discussed briefly here.

Bisection

In the late 1970s, Willadsen made great advances in developing techniques for micromanipulation and bisection of embryos in domestic animal species. In 1979 he produced identical (monozygotic) twins by microsurgical bisection of two-cell stage sheep embryos (Willadsen 1979). The technique involved embedding the zygotes in agar before culture in ligated sheep oviducts and subsequent surgical transfer to synchronised ewes. A few years later, the birth of twin lambs and monozygotic quadruplets, monozygotic triplets and monozygotic twin calves after microsurgical separation of four- and eight-cell stage embryos was reported (Willadsen 1981, Willadsen & Polge 1981). Willadsen et al. (1981) produced monozygotic cattle twins from embryos collected nonsurgically. In both sheep and cattle, the success rate is inversely proportional to the stage of embryo development. Thus, if 16-cell stages are used, development to the blastocyst stage is very low, and the cell number is too low to allow establishment of pregnancy.

A simpler technique to produce identical twins in cattle from morula and blastocyst stages was described later (Ozil 1983, Williams et al. 1984, Picard et al. 1986). The method involves opening the zona pellucida and cutting the embryo in two parts either: (1) inside the zona pellucida, leaving one half within the original zona and transferring the other half into a surrogate zona obtained from another oocyte; or (2) removing the embryo proper and bisecting it on the bottom of the dish outside the zona, before transferring the two halves into the original and a surrogate zona. Initially, agar embedding before transfer was used, but pregnancy rates after direct transfer without the agar procedure seem to be virtually identical (Warfield et al. 1987). Comparable pregnancy rates may be expected as for whole embryos (Bredbacka et al. 1992).

Despite an increased calving rate after transfer of bisected embryos (approximately 120%) and its possible use as a research tool whereby genetically identical individuals can be placed in different treatment groups (e.g., nutrition and environment), this technology has never been widely used. Zona pellucida is an effective barrier against infection, and opening it by microsurgery has reported to cause infection with BVD virus; this risk must be taken into consideration.

Chimerism

Experiments on interspecies sheep and goat chimerism showed that mixing blastomeres from 4- and 8-cell stage sheep and goat embryos can result in the formation of viable blastocysts that, after transfer, can give rise to viable sheep–goat chimeras (Fehilly et al. 1984). After these initial studies, several other groups have successfully produced chimeras from sheep–goat (Polzin et al. 1987), ovine (Butler et al. 1987), and cattle (Brem et al. 1984). Attempts to produce live offspring of horse–donkey chimeras have not been successful, although pregnancies were established (Pashen et al. 1987). Chimera production has no direct practical applications, but the technology may constitute an important experimental tool for studies of fetal–maternal interaction.

Biopsy

From the developing embryo, a biopsy with one or more cells can be taken for various purposes (Mullaart 2002). This can be done by using a micromanipulator with which the maximal precision can be obtained so only one blastomere can be isolated if required, but it can also be done by hand if more cells are needed and if loss of more cells can be tolerated by the embryo. This biopsy can be used for different molecular studies, either to determine the embryo's sex or to describe the complete genomic profile (Hinrichs 2016, Ponsart et al. 2014). Both applications are discussed further in a later paragraph.

Cloning

Willadsen (1981) observed that separation and culture of blastomeres from 16-cell stages could not give rise to live offspring. These findings led him to follow alternative means of producing identical individuals, and in 1986 he published his initial results with cloning of sheep embryos (Willadsen 1986). Ten years later, Campbell et al. (1996) produced live sheep offspring using a differentiated cell population of embryonic cells. Cloning with cultured cells from fetal and adult tissues, the so-called somatic cell nuclear transfer (SCNT), resulted in the birth of the sheep 'Dolly' in 1996 (Wilmut et al. 1997). The donor cell source was the mammary gland, and since then, cells from many other tissues have been used successfully, e.g., oviductal epithelial cells (Goto et al. 1999), fetal fibroblasts (Zakhartchenko et al. 1999), granulosa cells (Wells et al. 1999), and skin fibroblasts (Hill et al. 2000). Also since then, this technology has been applied successfully with reports in scientific journals of the birth of viable offspring from a large range of species representing both ruminants and many monogastric species; so far no primate offspring has been reported.

There are two major components to cloning, namely the oocyte and the donor cell. In cattle and sheep, IVM oocytes are routinely used in many laboratories. The genetic material (MII plate and the first polar body) of the mature oocyte is first removed to avoid ploidy abnormalities and arrested development (Willadsen 1986). As the MII is not readily visible using light microscopy, the polar body and part of the ooplasm anticipated to contain the metaphase plate are removed either by micromanipulation using a suction pipette or by manual bisection with a scalpel blade. The enucleated oocyte is then called a cytoplast. Alternatively, removal of the chromatin (enucleation) may take place after having stained the DNA, with subsequent confirmation of complete enucleation using a fluorescence microscope.

With traditional cloning, a so-called 'karyoplast', meaning a somatic cell derived from either early stage embryos (A), embryonic stem cell-like cells (B), cultured somatic cells from a fetus (C), or an organ (e.g., skin or udder (D)) is injected under the zona of the cytoplast, i.e., the enucleated matured oocyte (Fig. 44.21). The cell membranes are subsequently fused using a direct current

electric pulse, and the resulting zygote is activated by means of, for example, 6-DMAP or calcium ionophore. It is important that the oocyte and the donor cells are in the relevant stage of their cell cycle (G0 or G1), to achieve optimal reprogramming of the donor cell genome, i.e., that the adult cell is able to be programmed as a newly fertilised egg. In the initial experiments, the reconstituted embryo was cultured in ligated sheep oviducts, but, with the rapid advancement of IVC, this *in vitro* method is now the most commonly used when the cloned embryo is cultured; often the embryo is transferred rapidly after completion of cloning to avoid a subsequent culture step. The WOW system is very useful when culture of individual reconstituted embryos is desired, as it creates a suitable microenvironment and prevents the zona-free zygotes and embryos from disintegrating, which they might otherwise do in a normal-sized medium droplet. Comprehensive reviews of the number of offspring after different activation protocols and *in vitro* culture in different media are available (Niemann et al. 2011, Cibelli et al. 2016).

Most of the aforementioned results are based on the use of micromanipulatory equipment, but the so-called 'handmade cloning' (HMC) was subsequently developed (Booth et al. 2001, Peura et al. 1998, Vajta et al. 2001, Oback et al. 2003). No micromanipulatory equipment is needed, and the procedure differs from the classical method in two ways: (1) At 21 hours after the start of maturation (Day 0), cumulus cells and zona pellucidae are removed and oocytes randomly bisected by hand in a dish; (2) After a repeated fusion step with two fibroblasts, reconstructed embryos are activated with calcium ionophore and dimethyl aminopurine before they are cultured for 5 to 6 days (Holm et al. 1999) using the WOW system (Vajta et al. 2000). Using the HMC technique, it is possible to bisect 95% of the oocytes, to fuse 85% successfully and obtain a blastocyst rate of about 50%. In our initial studies, when Day 7 HMC cattle embryos were transferred nonsurgically, we obtained a pregnancy rate of 48%, but by the end of the third semester, only 8% were pregnant (Pedersen et al. 2004). The first HMC piglets were born in 2006 (Du et al. 2007) (see Figs 44.22 and 44.23), and since then, a rather robust system has been developed (Callesen et al. 2014) with high pregnancy rates (approximately 90% over a 4-year period) and an abortion rate around 10%.

It must be emphasised that the success rate of cloning generally is still very low and rarely exceeds a blastocyst production rate of 2% to 5% (Liu et al. 2015) and a rate of 15% piglets born per cloned embryos transferred (Callesen et al. 2014). This is due to a number of factors, such as improper epigenetic reprogramming (methylation pattern; for reviews see Farin et al. (2006) and Campbell et al. (2007)) of the somatic cell nuclei resulting in aberrant expression of developmentally important genes (Niemann et al. 2002, Wrenzycki et al. 2004) and a high incidence of chromosomal abnormalities (Slimane-Bureau & King 2002), including entirely polyploid embryos (Booth et al. 2003). Collectively, these abnormalities will not only cause poor embryonic development but can also have effects on the course of pregnancies (conceptus loss) and later also the offspring (see discussion later in this chapter). Nevertheless, the efficiency of the cloning of horses is surprisingly high, with a report of a pregnancy rate of 25% after transfer of eight cloned horse embryos (Hinrichs et al. 2006).

SCNT per se is not routinely used in livestock production due to low efficiency and high costs, but it may be used for certain very valuable animals, e.g., elite breeding bulls or show jumping horses. In several countries the technology has also been used in pets and endangered species. However, there are ethical concerns regarding these applications, and in some countries, particularly in the EU, cloning of pet animals, cattle, and horses is not allowed for production purposes. It should be added that the legislation in most countries prohibits human consumption of cloned animals, although there are no reports indicating that meat or milk from cattle, swine, or goat clones or their progeny should present a risk for human health (Kochhar & Rudenko 2010).

VetBooks.ir

Transgenesis

In 1985 the first transgenic pigs were produced by injecting copies of human growth hormone genes into the pronuclei of newly fertilised eggs (Hammer et al. 1985). The technique was subsequently used in several studies (Pursel et al. 1990), and comprehensive reviews are available (Cibelli et al. 2016, Wall 1996, Niemann & Kues 2000). However, as a consequence of the random insertion of the injected transgene, a number of problems were encountered with the offspring. Furthermore, it was not known if and how the transgene was positioned before the birth of the animal, so today this approach is not used in larger animals.

With the emergence of SCNT, it became possible to produce transgenic embryos by genetic modifications of the donor cells before fusion with the cytoplasts. One great advantage was that the successful positioning of the transgene at the anticipated place could be tested on the cells before they were used for cloning, so the animal born was known to carry the transgene as planned. This procedure was published for the first time in pigs (Lai et al. (2002), sheep (Schnieke et al. 1997), goats (Reggio et al. 2001), and cattle (Cibelli et al. 1998). Since then, many different types of such genetically modified animals have been born for a number of purposes such as: (i) for basic research; (ii) as disease models for certain important human diseases; (iii) as bioreactors, in which pharmaceuticals for treatment of human diseases may be extracted from blood, urine, or milk; and (iv) for organ transplantation from pigs to humans (xenotransplantation). Among these, the most promising seem to be the production of model animals that may develop important human diseases such as atherosclerosis (al-Mashhadi et al. 2013) or Alzheimer's (Jakobsen et al. 2016), and a recent report illustrates that the xenotransplantation aspect is still under development (Fischer et al. 2016). The bioreactor area is still being investigated, with one example being antithrombin III produced from goat's milk to be used to treat patients with inheritable antithrombin deficiencies. However, at present only a very few drugs have been licensed for clinical practice.

It should be stressed that use of transgenic animals for specific agricultural purposes such as increased disease resistance, e.g., against bacteria causing mastitis (Hyvönen et al. 2006), has yet to be implemented, as it most likely will be far too expensive and may not effectively protect animals against the specific disease. A comprehensive review of cloning and transgenic animal production has been published by Cibelli et al. (1998).

It should finally be mentioned that transgenic offspring may also be produced by artificial insemination with spermatozoa carrying the desired construct. However, the method, designated sperm-mediated gene transfer, has so far only been successfully applied in mice and pigs (Lavitrano et al. 2006).

Consequences of *In vitro* Handling of Gametes

Manipulations of the living cells that are fundamental in the creation of a new individual may obviously have inherent negative consequences. This has been the situation ever since the first experiments were made using either sperm, oocytes, or embryos. However, it caused much attention in 1991 when Willadsen presented data from a large cloning experiment in which blastomeres from non-surgically collected embryos were used as donor cells (Willadsen et al. 1991). The overall pregnancy rate was satisfactory, but late gestational losses, very large calves, and congenital malformations were seen much more frequently than after transfer of *in vivo*-derived embryos. Furthermore, in 1996 Walker reported on the birth of lambs with unusually high birth weights after IVP (Walker et al. 1996). This was considered to be a consequence, first described the so-called 'large offspring syndrome' (LOS), later expanded to 'abnormal offspring syndrome' (AOS; Farin et al. 2010). This opened up a new research area to identify and explain problems related to the handling of gametes under artificial and unphysiological conditions.

Direct Consequences

Some of the procedures have direct effects on the gametes, either resulting in their immediate death or causing damage resulting in subsequent impaired development. Examples are numerous, e.g., sperm after the sexing procedure, oocytes after exposing ovaries to suboptimal temperatures when being transporting from slaughterhouse to laboratory before IVM, or embryos after suboptimal incubator conditions related to a failure in the gas supply or temperature. Often these adverse conditions might have a cumulative effect and thus cause different forms of damage.

The consequences, although often problematic, have the advantage of being visible soon after they have occurred. Therefore immediate action can be taken and subsequent damage prevented.

Indirect Consequences

Some other forms of gamete damage are not apparent immediately, but their effects are observed later during the subsequent embryo and conceptus development. These consequences are much more problematic because their effects are first seen sometimes a long time after the damage has occurred, and it can have a cumulative effect. With the complex technical and chemical systems in use for the ARTs, this is really a serious part of the work; the LOS/AOS mentioned previously was one such very visible consequence, but there are many others.

On Embryos

Very well-known consequences of previous damages are problems with the preimplantation development – for example, low cleavage rates, delayed or arrested embryonic development, low blastocyst rates, lower cell number of blastocysts, deviating morphological features (fragmentations, dark colours), and increasing chromosome problems. Sometimes the problems are first revealed when the embryos are used for another ART, e.g., cryopreservation, when a low survival rate after thawing can be a clear sign of previous damages. Another typical time to discover the presence of damage can be after transfer of the embryos, when low pregnancy rates or a higher rate of early abortions can be a sign.

On Fetuses

The developing fetus may experience slower development or early or late abortion, perhaps resulting from suboptimal placental formation due to chromosomal abnormalities in the trophectodermal cells. Some of these features have been revealed in cloned pregnancies resulting in retarded growth rates and enlarged placentomes (Pedersen et al. 2004, Chavatte-Palmer et al. 2006, Bertolini et al. 2002; Fig. 44.24). In polytocous species such as the pig, the problems may appear as variations in litter size and in disparity in size of different fetuses, sometimes first identified at birth.

VetBooks.ir

• **Fig. 44.24** Large placentomes in a cloned pregnancy on gestation Day 252.

On the Newborn

Emphasis on the LOS was probably because it was so apparent because of the extreme sizes of the offspring. However, Farin et al. (2010) later described the phenomenon as 'abnormal offspring syndrome' (AOS), making it clear that several other abnormalities were identified in these offspring, particularly in calves and lambs. LOS/AOS has seldom been observed in pigs and goats and has not been reported in cloned horses, although the total number of cloned foals is so low that it is difficult to assess whether and to what extent these phenomena occur in this species. The problems were considered to be associated with the high concentration of serum used in the media, and because new media preparations with much lower serum concentrations began to be used, the frequency of this problem occurring has gradually diminished.

However, some problems still exist and present clinical challenges for both the recipient and the offspring. For the recipient this can be: prolonged gestation (Van Wagtendonk-de Leeuw 2006), weak labour and stillbirth (Schmidt et al. 1996), dystocia, and need for an obstetrical intervention (Hill et al. 1999). For the calf itself, problems other than increased fetal body mass (Bertolini et al. 2002, Walker et al. 1996, Schmidt et al. 1996, Jacobsen et al. 2000) are enlarged umbilicus, hydrallantois (Hasler 1998, Wells et al. 1999, Hill et al. 1999, Pace et al. 2002), lethargy and acidosis, poor suckling reflex (Hill et al. 1999, Pace et al. 2002, Garry et al. 1996), congenital malformations (Van Soom 1996, Pedersen et al. 2004, Vajta et al. 1998, Hill et al. 1999), biochemical abnormalities, immune dysfunction, and anaemia (Sangild et al. 2000, Chavatte-Palmer et al. 2013). Many of these abnormalities will be apparent to the practitioner such as the need for assistance (close observation of recipients at parturition and possible Caesarean operation) and neonatal care of the offspring such as fluid replacement therapy.

In pigs, several reports have been made in relation to piglets born after cloning (Chavatte-Palmer et al. 2013). The general picture is similar to that described for cattle, with an additional feature that there is often a significant variation between the sizes of piglets in a litter; not all piglets are affected the same way or to the same extent. Systematic autopsies on a larger material (Schmidt et al. 2015) have revealed that all the abnormalities can occur after natural breeding but at a higher frequency and with varying occurrences between piglets of the same litter.

After the Perinatal Period

It is important to emphasise that the problems identified affect only a proportion of all offspring; most calves and piglets are born without AOS (Chavatte-Palmer et al. 2013). Those appearing normal, or surviving a problematic perinatal period, survive without further problems, and when they reproduce, their offspring are normal and are not different from their noncloned progeny. There have been some reports of sudden deaths among cloned calves at 1 year old, but the specific cause has not been determined. Other observations regarding production and reproductive characteristics of cloned versus noncloned offspring have identified differences in the timing of the onset of puberty, which according to some studies may be delayed in IVP and cloned animals (Pace et al. 2002, Jacobsen et al. 2003). In addition, follicular development may be altered, with more small follicles and fewer medium-sized and large follicles present in cloned heifers (Pace et al. 2002). For pigs born after cloning, similar types of abnormalities have been reported after several generations in individuals that have been born from the cloned founder animals.

Sex Determination and Genotyping of Embryos

In animal breeding, there is a strong wish to plan the timing of the birth of offspring to best match the breeding plan. In addition, planning also includes two other activities before mating: one is planned matings with selection of both maternal and paternal genes, and the other is use of sexed semen.

Sex Determination

Sex determination of embryos before transfer can have several advantages in cattle. Using the bisection technique, in which one demi-embryo (morula or blastocyst) is sexed and the other transferred to heifers, it was possible to obtain satisfactory pregnancy rates, even after transfer of frozen–thawed demi-embryos (Picard et al. 1985). Other groups have attempted to sex embryos by means of determining H-Y antigens, but this method has not been applied in practical breeding programmes. Determination of an embryo's sex, using PCR of Y-specific sequences, has been used in practice for a number of years, based on an embryo biopsy taken either by 'hand-cutting' or by using micromanipulation at the morula stage (e.g., Hinrichs 2016, Herr & Reed 1991, Bredbacka et al. 1995, Thibier & Nibart 1995, Hasler et al. 2002).

The use of sex-sorted sperm may replace the need for PCR sexing of embryos but, with the current low pregnancy rate using sexed sperm (see Chapter 43), particularly in cows, there is still a need for sexing of embryos (Lacaze et al. 1997).

After transfer, sexing of 2-week-old bovine embryos is possible by means of cytogenetic analysis of an embryo biopsy (Hare et al. 1976). Later in pregnancy, ultrasound scanning of the sex of the fetus is a routine in many commercial operations; it is typically made from Day 60 to 90 of gestation and with a very high accuracy (> 95%; Stroud 2005).

Genotyping

In animal breeding and production, there is great interest in using information about single genes for specific heritable diseases but also more and more for multiple genes coding for various production and health traits (Ponsart et al. 2014). Mapping of the cattle and

VetBooks.ir

pig genome has made it possible to use genotyping for certain traits in both cattle and pig production. This is done routinely on the offspring, but especially in cattle, it is now also done on embryo biopsies (Ponsart et al. 2014). Such an activity requires advanced facilities, a strong logistical set-up, and considerable experience to perform the embryo biopsies with sufficient accuracy and efficiency first to obtain a biopsy size with sufficient DNA to identify all the genes of interest, and second not to compromise subsequent embryonic development (Blondin 2017). However, this has become an integrated part of more and more breeding companies, in which OPU and IVP is being performed.

Biosecurity Precautions

Many studies have clearly shown that the risk of disease transmission by embryos is lower than with live animals, providing the embryos are treated according to guidelines set by IETS (Stringfellow & Givens 2010) and as recommended by the Office International des Epizooties (OIE) in Paris (Appendix 3.3.1 of Terrestrial Animal Health code, available online at www.oie.int).

Comprehensive reviews (Stringfellow et al. 2004, Bielanski 2007, Givens et al. 2007) have summarised the essential precautions needed to avoid transmission of important diseases, including both *in vivo*-derived, and *in vitro*-produced embryos. Most studies involving *in vitro*-produced embryos (with the inherent risk of contamination with infectious agents and subsequent washing, and transfer) and *in vivo*-derived embryos (with the inherent risk of recovering embryos from infected animals, washing, and transfer) have shown that, with proper washing (10 times) including trypsin treatment, certain infectious agents such as infectious bovine rhinotracheitis and Aujeszky's disease viruses can be removed. Embryos collected from a persistently infected animal are shown to carry a large amount of BVD virus particles attached to the zona. Transfer of these embryos after washing according to IETS standards resulted in BVD free calves (Bak et al. 1992).

With IVP embryos, the situation is different. Many oocytes are obtained from slaughterhouse ovaries and could be contaminated with various infectious agents. In addition, the zona pellucida of *in vitro*-produced embryos allows more intimate contact with the infectious agents and thus makes it more difficult to remove the microorganism from the embryo. Furthermore, there are risks of contamination during the different IVP procedures. Therefore it is necessary not only to wash the embryos 10 times but also to set biosecurity standards for the abattoir and the laboratories, including the media used for culture. Addition of certain antimicrobial agents may also be advisable.

Obviously there will always be a risk of disease transmission with embryo transfer, and thus it is mandatory that *in vitro* and *in vivo* experiments are conducted to ascertain that a particular disease cannot be transmitted using this technique. Using the IETS and OIE standards, the impression is that movement of livestock at the 'embryo stage' is preferable to doing so in the 'free living' stage not only for economic and biosecurity reasons but certainly also for the benefit of animal welfare.

Abdominal ballottement, in cow, 93
Abdominal contractions (straining)
  as cause of uterine rupture, 338–339
  epidural anaesthesia abolishing, 253
Abdominal incisions
  caesarean operation
    in calf, 299
    in horse, 311
  closure, 302*f*
Abdominal palpation
  for cystic endometrial hyperplasia, 601–603
  for pregnancy diagnosis, 105–106, 105*f*
Abdominal wall, ventral hernia, 245
Abnormal offspring syndrome (AOS), 225
Abnormal parturition, and reproductive health, of pig, 322–324
Abortion, 192–193, 705
  bovine
    in bovine herpesvirus 1, 458
    Mycoplasma, Ureaplasma, Acholeplasma, and Chlamydia infections and, 446–449
    pyrexia and, 444
    storm, 444, 453
    viral agents, 454–461
  in buffalo, 689–690
  in caesarean surgery, 294
  in camels, 679
  in cats and dogs, prostaglandins for, 614
  in deer, 699
  in equine, 551–555, 551*f*
    infectious causes of, 552–555
    noninfectious causes of, 551–552, 551*f*–552*f*
  habitual
    in bitch, 598–599
    in cats and dogs, 615
    in queen cat, 609–610
  in herd fertility, 476
  porcine reproductive respiratory syndrome and, 588
  retained fetus and, 236–237
  in South American camelids, 673–674
Abortus material, campylobacteriosis, 437
Abscess
  periovarian, 369
  peripenile, in bulls, 638, 639*f*
Abscessation, ovarian, in equine infertility, 575–576
Accessory glands
  lesions of, 665–666
  male, 38, 47
  sex, physical examination of, in breeding soundness examination, 625
Accessory tails, 661
Acepromazine, 252
  in persistent breeding-induced endometritis, 560–561
Acetylcysteine (ACE), in chronic infectious endometritis, 559
Acholeplasma spp., 447
Achondroplastic calves (bulldog calf deformity)
  caesarean operation and, 293
  inheritance, 747
Acidosis, in newborn, 142
Acquired rectovaginal fistula, 337*f*
Acrosome, 38, 46
  abnormalities in, 660
  defects in, 630–631, 632*t*
  detached and swollen, 660
  development of, 45
  reaction, 38
Actinobacillus actinoides, 665
Actinobacillus seminis, 663–664, 664*f*
Actinobaculum suis, 591
Actinomycosis, of the prepuce, 648
Activin, in female reproduction, 4
Activity monitors, oestrus detection in cows, 386–387
Acute phase protein, increase in, postpartum, 149–150
Acyclin, 613
  for pyometra, 615
Adaptive immunity, 417
Adenitis, vesicular, 665
Adenocarcinoma
  in cervix, 371
  malignant endometrial, in queen cat, 607–608
  in uterus, 370
Adhesions
  after caesarean operation, 306–307
  ovarian bursal, 368–369, 368*f*
  peripenile, 638–639
  preputial, 644–645, 645*f*, 648
  uterine, 370, 371*f*
    in equine infertility, 569, 569*f*
Adrenal disease, in ferrets and rabbits, 706–708
Adrenals, fetal, initiation of parturition, 116, 119
b-adrenergic agents, in delaying parturition, 125
Adrenocorticotrophic hormone (ACTH), initiation of parturition, 116
Aerobic bacteria, in vagina of normal bitch, 599
Aeromonas spp., 446
African pygmy hedgehog
  anatomy of, 702
  neoplasms of reproductive tract in, 707*t*
  sexing, 701–702
Agalactia, 586
  of sows, 346
Age
  of bitch, 593, 594*f*
  cystic ovarian disease and, 377
  at first breeding, 589
  of male
    in breeding soundness examination, 620
    degeneration of the vertebral column, 637, 637*f*
  testicular degeneration and, 657–658
  uterine involution and, 152
Ageing, ovarian, 8
Aglepristone, 613–614
  for cystic endometrial hyperplasia, 611
  for pyometra, 615
  for termination of pregnancy, 710
Aino virus, 187
Akabane virus, 187, 293
  in cattle, 460–461
Albumen, quality of, of backyard chicken, 539
Albumin, 399*t*
Allantoamnion, 65
Allantochorion (chorioallantois), 65
  in horse, 67–68
  palpation of, for pregnancy diagnosis, 95
  pig, 73
  in ruminants, 65, 71
Allantochorionic sac, 65
  rupture of, in second stage of labour, 130
Allantoic fluid, 71–72
Allantois, 65, 65*f*
Alpaca, 670
  Huacaya, 670, 671*f*
  Suri, 670
Altrenogest
  for embryonic death, 550
  for seasonal cyclicity, of equine infertility, 543
  for subfertile/infertile gilt/sow, 590–591
Ambient temperature preservation, for semen, for artificial insemination (AI), 751–752
Amnion, 64–65, 64*f*, 71
Amniotic fluid, 71–72
Amniotic plaques, 73
Amniotic vesicle, palpation of, in pregnant cow, 95
Amorphous globosus, 189, 190*f*
Amoxicillin, for listeriosis, 518
Ampulla, 38*t*, 47
  lesions of, 666
Anaemia, after caesarean operation, 310
Anaerobic bacteria, in vagina of normal bitch, 599

VetBooks.ir

Anaesthesia
  caesarean operation and, 295–297
    farm animals, 308
    horses, 309
    mare, 312
  epidural
    for caesarean operation, 296
    for cattle, 253, 253*f*
    for dystocia, 205–206
    for embryo collection, 784
    for embryo transfer, 785
    fetotomy and, 281
    for horse, 254, 254*f*
    in OPU, 789
    for pig, 254
    for vaginal delivery, 253–254
  general, for vaginal delivery, 252
Anasarca, fetal, 288–289, 293
Androgen
  in developing male, 40
  tumours secreting, 364–365
Androgenized steers/cows, oestrus detection, 388
Anencephaly, fetal, 293
Aneuploidy, 179
Angiotension-tension converting enzyme inhibitors, developmental abnormalities and, 185
Angora goat
  abortion in, 522–523
  cryptorchidism in, 655
Animals, developmental disorders in, 169
Ankylosed calves, 274
Ankylosed fetuses, 288–289
Anoestrus, 2
  in buffalo, 689
  in cat, 31
  in cow, 372–381
    anovulatory, 372–375
    causes of, 372
    cystic ovarian disease, 375–381
    expression of oestrus, 381–382, 381*f*
    follicular or luteal dysfunction, 382
    hormone combinations for, oestrous cycle and, 164–165
    pregnancy, 372
    progesterone devices for, 160
  in dog, 27
  in horse, 10
  prolonged
    in bitch, 596–597
    in queen cat, 608
  in sheep, 23–24, 510
  in sows, 586
Anogenital distance, in rodents, 701
Anorchidism, 617
Anovulatory anoestrus
  cow, 372–375
    clinical findings of, 374
    hormonal treatment of, 374–375, 375*f*
    management of, 374
    pathogenesis of, 372–374, 373*f*
    prevalence of, 372
  in pastoral dairy herds, 487–489
Anovulatory follicles, in equine infertility, 573–575, 574*f*
Anterior longitudinal presentation
  subcutaneous fetotomy, 279–280
  total fetotomy, 282–285, 282*f*
Anterior pituitary, oestrous cycle regulation, 3–5
Anterior presentation
  calf in, 298–299, 298*f*
  dystocia and, 254–262
  positional defects, 264–265
  postural defects of, 260–262
    in cattle, 255–257
    in horse, 257–260
Antiandrostenedione, 165
Antibiotic therapy
  for chronic infectious endometritis, 558
  for persistent breeding-induced endometritis, 561–562
Antibiotic treatment
  for *Histophilus somni*, 445
  for venereal campylobacteriosis, 438
Antibiotics
  caesarean operation of, 296, 311–312
  for endometritis, 427
  for enzootic abortion of ewes, 514–515
  fetotomy and, 290
  in semen diluents, 748
Antimicrobial
  activity, in semen for AI, 748
  treatments, for uterine infections in pigs, 591
Anti-Müllerian hormone, 40
Antioxidants, 397, 398*t*
Antisocial behaviour, in cats and dogs, 616–617
Antler cycle, 696
AOS. *see* Abnormal offspring syndrome
Arginine vasopressin (AVP), initiation of parturition, 116
Arhinencephaly, 189–190
Arthrogryposis, 316
  caesarean operation and, 293, 294*f*
Arthrogryposis multiplex, 176, 176*f*
Artificial insemination (AI), 746–777
  advantages and disadvantages of, 746–747
  of beef suckler herds, 498
  of buffalo, 689
  of cats, 773
  of cattle, 754–759
    alternative sites for, 757–758
    collection and storage of semen in, 754–759, 755*t*
    infectious diseases in, control of, 759, 759*t*
    insemination, 755–756, 756*f*
    management of, 758–759
    site of, 756–758
    standard method of, 756–757, 757*f*–758*f*
    timing of, 756, 756*f*
  colloid-selected spermatozoa for, 752
  for deer, 697
  of dogs, 771–773
    collection and storage of semen for, 771–772
    cryopreservation for, 772
    frozen semen for, 772–773
    intravaginal, 772
    liquid semen for, 771–772, 772*t*
    timing of, 773
  of elephants, 741–742
Artificial insemination (AI) *(Continued)*
  of goats, 523, 763–764
    collection and storage of semen for, 763–764
    cryopreservation for, 764
    intracervical, 764
    intrauterine, 764
    laparoscopic intrauterine, 764
    liquid semen for, 764
    seminal plasma in, 763
  of horses, 768–771
    cervical, 770, 770*f*
    collection and storage of semen for, 768–770
    cooled semen for, 770
    cryopreservation for, 769–770
    frozen semen for, 771
    infectious diseases, control of, 771
    liquid semen for, 768–769, 769*t*
    new methods, for compromised spermatozoa, 771
    timing of, 770
  of pigs, 764–768
    collection and storage of semen for, 765–767
    cryopreservation for, 765–767
    deep uterine, 767
    by farm staff, 767–768
    infectious diseases, control of, 768
    inseminator service for, 768
    intrauterine, 767
    laparoscopic, 767
    liquid semen for, 765, 766*t*
    management of, 766
    postcervical, 767
    sow, 767, 767*f*
  semen for
    ambient temperature preservation for, 751–752
    cryopreservation and cryoprotectants of, 749–751, 750*f*
    diseases transmissible in, 754, 754*t*
    extending life span of, 748–749
    extension of, 747–748
    microencapsulation of, 752
    preparation of, 747–752
    sexed, 753–754, 753*f*
  of sheep, 512, 759–763
    collection and storage of semen for, 760–762, 760*t*
    conception rates to, 763, 763*t*
    cryopreservation for, 761–762, 761*t*
    infectious diseases, control of, 763
    intracervical route of, 762, 762*f*, 762*t*
    laparoscopic intrauterine route of, 762–763, 762*f*
    liquid semen for, 760, 760*t*
    transcervical route of, 763
    vaginal route of, 762
  spermatozoa selection for, 752–754
  timing of, 590
Artificial vagina (AV)
  for boars, 628
  for buffalo, 688–689
  for bull, 625–626, 626*f*

  for porcine parvovirus, 587, 587*f*
  status of, in breeding soundness examination, 622
  for toxoplasmosis, 516–517
  for venereal campylobacteriosis, 438
Vacuoles, nuclear, 660
Vagina
  of backyard chicken, 528
  of bitch
    congenital anomalies in, 594
    digital stimulation in uterine inertia, 247
    hyperplasia of, 595, 595*f*
    normal bacterial flora of, 599
    prolapse of, 595
    tumour of, 595, 596*f*
  of buffalo, 685, 685*f*
  of cow
    bovine venereal campylobacteriosis in, 435–436
    cyclic changes in, 16–17
    obstetrical damage to, 371
    tumours of, 372
  of dog, changes in, 28
  equine infertility in, 566
  of horse, during pregnancy, 82
Vagina rupture, postpartum haemorrhage of, 338–339
Vaginal aplasia, in queen cat, 607
Vaginal cystocele, 238
Vaginal cytology
  of bitch, 605, 606*f*
  in small pet mammals, 703
Vaginal delivery
  farm animals and horses, sedation and anaesthesia, 252–254
  faulty fetal position, 264–265
  sedation and anaesthesia for, 252–254
Vaginal disease, infertility and, in South American camelids, 674–675
Vaginal epithelium, in dog, 28
Vaginal examination
  for cattle, pregnancy diagnosis for, 96
  for dystocia, 206
  for horse, pregnancy diagnosis for, 83
  for pig, 318

  in cattle, 257
  digital manipulation, 327*f*
Vertical presentations, 265
Vesicovaginal reflux, 566
Vesicular adenitis, 665
Vesicular glands, 47
  lesions of, 665
Vesiculitis, seminal, 653, 665, 665*f*
Veterinary examination, in dairy herd, 470*t*
Veterinary herd fertility control programmes, 591
Vicugna vicugna (Vicuna), 670
Video monitoring, in oestrus detection, 388
Vink calving jack, 208, 209*f*
VIP. *see* Vasoactive intestinal peptide
Viral agents, in cattle, causing infertility/subfertility, 454–461
Viral infections, pigs and, 587–588
Viral infectious disease
  equine, 563, 563*f*
  in small pet mammals, 709
Vitamin A
  antioxidant activity, 397, 398*t*
  deficiency, 397
Vitamin A deficiency, developmental abnormalities and, 181
Vitamin B deficiency, development and, 181–182
Vitamin B_{12}
  deficiency in, development and, 181–182
  in sheep, 511
  synthesis, 394
Vitamin C deficiency, development and, 182
Vitamin D deficiency, development and, 182
Vitamin E, 396–397
  deficiency, development and, 182, 182*f*
  excess, development and, 182
Vitamin imbalance, on shell quality, of backyard chicken, 539
Vitamin K, deficiency in, development and, 182
Vitrification, 751
  in embryo cryopreservation, 795
Volume, addition of, of semen for AI, 748
Voluntary wait period (VWP), in herd fertility, 467, 474
Vulva
  equine infertility in, 563–565, 564*f*
  haematoma of, 334, 335*f*
  incomplete relaxation of caudal vagina and, 238
  tumours of, 372
Vulval discharge, cow, bovine venereal campylobacteriosis in, 435
Vulval disease, infertility and, in South American camelids, 674–675
Vulval hypoplasia, infertility and, in South American camelids, 674–675
Vulvar atresia, 368
Vulvar discharge
  in bitch
    differential diagnosis of, 602*t*
    mucohaemorrhagic, 598
Vulvar discharge *(Continued)*
  in queen cat, 611
  in sow, infertility and, 584
Vulvar discharge syndrome, 585
Vulvar hypoplasia, in bitch, 594
Vulvar softening, in bitch, 607
Vulvar swelling, in queen cat, 611–612
Vulvovaginitis, 445
  granular, 445
VWP. *see* Voluntary wait period
